A critical issue is positioning of an obese individual for laryngoscopy and endotracheal intubation. These procedures are often considered to be much more difficult to perform in obese patients than in patients with a normal BMI. Difficulty with laryngoscopy and intubation is usually thought to result from the obese patient having a short, thick neck, large tongue, and significant redundant pharyngeal soft tissue. However, the correlation between morbid obesity and difficult laryngoscopy and intubation is not universally observed in clinical practice. It is possible that no difference exists between laryngoscopy and intubation in thin and obese patients if one follows the simple, but important, approach to clinical care of paying careful attention to patient positioning before induction of general anesthesia. Appropriate positioning plays an important role in providing optimal conditions for successful placement of the endotracheal tube under direct vision.

A number of studies have been conducted to determine the incidence of difficult laryngoscopy or intubation in the obese

population, with mixed findings. One study found an association between oropharyngeal Mallampati classification and BMI as a predictor of difficult laryngoscopy.[75] During laryngoscopy, patients' heads were placed in the optimum sniffing position, regardless of BMI. In a study conducted exclusively with obese patients, BMI was not found to be associated with intubation difficulties.[24] A high Mallampati score was identified as a predictor of "potential intubation problems," but intubation by direct laryngoscopy was successful in 99 of 100 patients studied. All patients were positioned with pillows or towels under their shoulders, the head elevated, and the neck extended. Another group studied both lean and obese patients and found a Mallampati score of III or IV to be the only independent risk factor for difficult intubation in the obese group.[76] The authors demonstrated that the Mallampati score had low specificity and low positive predictive value (62% and 29%, respectively) for difficult intubation. They concluded that intubation was more difficult in obese patients. During intubation, patients were placed in a semirecumbent position (30-degree elevation) with the head in the sniffing position. In another study, ultrasound was used to quantify the amount of soft tissue between the skin and the anterior aspect of the trachea at the level of the vocal cords.[77] The authors also assessed the airway by measurement of the thyromental distance, mouth opening, degree of neck mobility, Mallampati score, neck circumference, and the presence of OSA. Only an abundance of pretracheal soft tissue measured ultrasonically and neck circumferences were found to be positive predictors of difficult intubation with laryngoscopy performed with patients in the sniffing position. A meta-analysis of 35 studies was conducted to determine the diagnostic accuracy of preinduction tests for predicting difficult intubation in patients with no airway pathology.[78] The incidence of difficult intubation in obese patients was three times the incidence in the nonobese population. This may have resulted from suboptimal patient positioning, which was not clearly described in any of the preceding studies, including ramped positioning or elevating the upper body and head of morbidly obese patients to align the ear with the sternum horizontally, as has been shown to improve the laryngoscopic view.[79] Collins and colleagues studied morbidly obese patients who were assigned to be placed in a sniffing position or in a ramped position for airway management. The study demonstrated a statistically significant difference in laryngeal view, with the ramped position providing the superior view.

Based on the evidence from randomized controlled trials and other literature on the airway management of obese patients, patients should be readily intubated by direct laryngoscopy if placed carefully in the ramped position. Obese patients must be examined for the common objective signs of potential difficult intubation, which include small mouth opening, large protuberant teeth, limited neck mobility, and retrognathia. Alternative airway management techniques such as awake, topicalized direct laryngoscopy with modest sedation can be used to assess the laryngoscopic view when deciding whether to proceed with induction of general anesthesia or awake, sedated fiberoptic intubation. Of course, the equipment for emergency airway management, including laryngeal masks and a fiberoptic bronchoscope, should be immediately available.

Another area that requires specific attention during the perioperative period is the obese patient's pulmonary physiology. It is especially important to appreciate techniques to maintain oxygenation and lung volume when caring for an obese patient. First, obese patients have multiple pulmonary abnormalities, including decreased vital capacity, inspiratory capacity, expiratory reserve volume, and functional residual capacity. Second, closing capacity in obese individuals is close to or may fall within tidal breathing, particularly in the supine or recumbent position. As a result of the underlying physiology, an obese patient is likely to undergo rapid oxygen desaturation, especially during periods of apnea such as occurs during induction of general anesthesia. Patients may also continue to derecruit gas exchange units throughout the anesthetic course.[80] A variety of maneuvers have been studied in an attempt to preserve oxygenation and maintain lung volume specifically in the obese population.

In one study of the rate of development of hypoxemia in patients during apnea, patients received 100% oxygen by facemask to achieve denitrogenation before induction of general anesthesia.[80] The apneic period was continued after induction until Spo_2 fell to 90%. Obese patients reached the end point in less than 3 minutes, whereas it took 6 minutes in patients with a normal BMI. Efforts to prevent the formation of atelectasis and desaturation during induction of general anesthesia in obese individuals include application of CPAP during preoxygenation[81-83] and mask application of positive end-expiratory pressure (PEEP) and mechanical ventilation after induction.[83] Use of 10 cm H_2O CPAP during preoxygenation in the supine position resulted in a higher Pao_2 after intubation and decreased the amount of atelectasis that developed.[81] The combination of CPAP during preoxygenation and PEEP/mechanical ventilation after induction significantly increased the duration of nonhypoxemic apnea from 2 minutes, found in controls not receiving CPAP or PEEP, to 3 minutes. Use of 7.5 cm H_2O CPAP during 3 minutes of preoxygenation while supine, however, did not change the time required for obese patients to desaturate to an Spo_2 of 90%.[82] Preoxygenation using 25-degree head-up (back inclined) as opposed to supine positioning without positive airway pressure did increase the time needed for anesthetized, apneic obese individuals to desaturate to an Spo_2 of 92%.[84] Patients in the head-up position had a significantly higher Pao_2 after preoxygenation, just before induction. The obesity-associated gas exchange defect depended on the waist-to-hip ratio, an index of the distribution of adipose tissue surrounding the thorax.[85] This study further demonstrated that morbidly obese men are more likely than morbidly obese women to have poorer pulmonary gas exchange. In a study conducted to assess the relationship between patient positioning and the development of hypoxemia in obese patients during apnea after induction of anesthesia and intubation, patients were ventilated with a 50% oxygen/50% air mixture for 5 minutes before the ventilator circuit was disconnected.[86] Apnea was continued until the Spo_2 fell to 92%, at which time ventilation was resumed. Patients in the supine position reached the end point in 2 minutes, but it took 30 seconds longer if the supine position with the back elevated 30 degrees was used and 1 minute longer if the 30-degree reverse Trendelenburg position was used. Use of the 30-degree reverse Trendelenburg position in obese patients undergoing bariatric surgery was also shown to reduce the alveolar-to-arterial oxygen difference, as well as to increase total ventilatory compliance and reduce peak and plateau airway pressure when compared with the supine position.[87] Vital capacity has also been shown to decrease to a greater extent under general anesthesia in obese patients than in normal-weight patients.[88]

A variety of intraoperative maneuvers to maintain lung volume and oxygenation have also been studied. Increasing tidal

volume incrementally from 13 to 22 mL/kg in obese patients ventilated under general anesthesia did not improve the gas exchange defect but did increase airway pressure.[89] Use of 10 cm H_2O PEEP has been demonstrated to have a greater effect in obese patients than in normal subjects on improving ventilatory mechanics, increasing Pao_2, and decreasing the alveolar-to-arterial oxygen difference during general anesthesia with neuromuscular blockade.[90] Pneumoperitoneum during laparoscopic procedures increases pulmonary resistance and decreases dynamic lung compliance.[91] During pneumoperitoneum, alterations in body position, tidal volume and respiratory rate had no effect on the alveolar-to-arterial oxygen difference in obese patients.[92] During pneumoperitoneum for laparoscopic bariatric surgery, alveolar recruitment by repeated sustained lung inflation to 50 cm H_2O followed by mechanical ventilation with 12 cm H_2O PEEP has been shown to increase Pao_2 intraoperatively, but at the expense of causing hypotension that required the use of vasopressors.[93] In an attempt to optimize PEEP in obese patients undergoing LGB surgery, a normal functional residual capacity was maintained with 15 ± 1 cm H_2O PEEP. Infusion of intravascular volume expanders was required to prevent PEEP-induced hemodynamic compromise.[94]

In summary, the most favorable patient position or optimal amount of PEEP during preoxygenation, induction of anesthesia, or intraoperatively has not been clearly established for obese patients. Furthermore, the application of noninvasive modes of ventilation, including pressure support and bilevel support delivered by mask for preoxygenation, induction, and maintenance of anesthesia to maintain oxygenation and ventilatory mechanics in obese patients, has not been sufficiently studied. The ideal patient positioning, use of PEEP, and special modes of ventilation just before emergence and extubation to maintain pulmonary function and gas exchange after extubation have not been identified. Currently, there are no published guidelines to address the issues of maintenance of oxygenation and ventilatory mechanics in obese patients undergoing general anesthesia. Accordingly, in view of the airway management issues detailed previously, as well as the oxygenation, lung volume, and ventilatory mechanics issues just described for obese individuals, anesthesia care providers should position patients to achieve the combined goals of providing a superior laryngoscopic view for ease of endotracheal intubation while establishing optimal conditions for oxygenation and preservation of pulmonary mechanical function.

It is the practice at our institution that obese patients initially be placed in a ramped position and then in the reverse Trendelenburg position, if needed, to achieve a 25- to 30-degree incline of the thorax before preoxygenation. Patients are then preoxygenated for 3 to 5 minutes with 100% oxygen delivered under positive pressure. For patients receiving CPAP at home for OSA, we use CPAP or pressure-support ventilation by facemask at a pressure level identical to the patient's home CPAP setting. Otherwise, CPAP of 8 to 10 cm H_2O is appropriate. After induction, it is reasonable to maintain 10 to 12 cm H_2O PEEP intraoperatively, but care must be taken to treat any hypotension that may occur. Finally, if the patient's position must be changed intraoperatively, one must return the patient to the head-up position before emergence and extubation.

In preparation for emergence from anesthesia, the neuromuscular blockade must be fully reversed before the patient is extubated. Given the advent of a pressure-support ventilation mode on many newer models of anesthesia machines, a bariatric patient can be maintained on pressure support during emergence as soon as spontaneous ventilation has resumed. When adequate muscle strength has returned, as demonstrated by sustained tetanus with the nerve stimulator and performance of a 5-second head lift, an awake patient who is following commands can be safely extubated. Pressure support or CPAP can be delivered immediately by mask applied to the face as is done during preoxygenation before induction of anesthesia. A variety of devices are available to provide CPAP during transport of the patient from the operating room. We use CPAP during recovery, especially in patients who are already prescribed CPAP for their OSA.

Anesthetic Drugs and Dosing

Anesthetic drugs such as opioids, propofol, and benzodiazepines are all well known to have exaggerated responses in patients with OSA. They may decrease pharyngeal musculature tone, which is essential in maintaining airway patency.[95,96] Volatile agents are known to diminish the ventilatory response to carbon dioxide in the setting of OSA, at least in children with tonsillar hypertrophy. Another pediatric study showed that spontaneously breathing, intubated children with a history of OSA have depressed ventilation and half have apnea with 0.5 μg/kg of intravenous fentanyl. Although these data are from the pediatric literature, it would be prudent to apply these same principles to obese adult patients until proved otherwise. It therefore becomes attractive to use short-acting drugs and nondepressors of ventilation such as the α_2-agonist dexmedetomidine. This should, at least in theory, speed up the return to baseline respiratory function.[73]

Commonly used anesthetic drugs can be dosed according to total-body weight (TBW) or IBW based on lipid solubility. In the past, IBW was interpreted to mean fat-free weight, thus implying that it could be used as a substitute for lean body weight or more correctly, lean body mass, usually approximated as 120% of IBW. Lean body mass is a good weight approximation to use when dosing hydrophilic medications. As expected, the volume of distribution is changed in obese patients with regard to lipophilic drugs. This is especially true of benzodiazepines and barbiturates, among the commonly used anesthetic drugs. Three exceptions to this rule are digoxin,[97] procainamide,[98] and remifentanil,[99] which even though highly lipophilic, have no relationship between properties of the drug and their volume of distribution.[100] Consequently, dosing of commonly used anesthetic drugs such as propofol, vecuronium, rocuronium, and remifentanil is based on IBW. In contrast, thiopental, midazolam, succinylcholine, atracurium, cisatracurium, fentanyl, and sufentanil should be dosed on the basis of TBW. Another caveat to this recommendation is that maintenance doses of propofol should be based on TBW and, conversely, on IBW for sufentanil.[100] This implies that one can use, based on patient weight, larger amounts of benzodiazepines, fentanyl, or sufentanil, although these drugs are best titrated to the desired clinical effect. Conversely, based on real body weight, smaller amounts of propofol are needed to anesthetize the patient.

With vecuronium or rocuronium, the initial dose should be based on IBW and redoses based on the closely followed state of neuromuscular blockade. Complete blockade in the morbidly obese is necessary not just for surgeons' convenience but also to facilitate mechanical ventilation. The drug chosen is not as important as the state of paralysis.

The choice of volatile agents is based on the physical characteristics of tissue solubility, expressed as blood-gas partition coefficients and fat-blood partition coefficients. Some evidence suggests that desflurane may be the anesthetic of choice because of a more consistent and rapid recovery profile than is seen with sevoflurane and propofol.[101,102] However, a more recent study has suggested that the difference in immediate recovery between sevoflurane and desflurane is not clinically significant.[103]

Even though nitrous oxide provides some analgesic effect and is eliminated rapidly, we prefer to avoid it because of the high oxygen demand in the obese. Its entry into air spaces during short intra-abdominal surgery may not be a significant factor, but in bariatric surgery, especially when done laparoscopically, any increase in bowel gas volume could make a challenging surgical procedure even more difficult for the surgeon.

Induction of Anesthesia

There has been considerable debate regarding obesity, the risk for aspiration of gastric contents, and the need to provide prophylaxis for aspiration.[104] Abdominal bloating or fullness and female sex are associated with delayed gastric emptying of solids and liquids in diabetic patients.[105] Although many obese patients have type 2 diabetes, separate studies of gastroesophageal reflux during anesthesia have not demonstrated body habitus to be a predictor of reflux rates.[106] Gastric fluid volume and pH have been shown to be the same in obese patients who are fasting and in those who have oral intake of up to 300 mL of clear liquid 2 hours before being anesthetized.[107] Obesity itself does not increase the risk for aspiration. However, acid aspiration prophylaxis, including H_2 receptor agonists or proton pump inhibitors, must be considered in patients with identifiable risk for aspiration. Awake fiberoptic intubation may also be considered in such patients.[23]

Based on experience from obstetric practice, there is a body of evidence showing that regional anesthesia, especially epidural and spinal, is safe and feasible in patients with large body habitus.[73] However, regional anesthesia is technically more difficult because of the physical challenge of placing the catheters and the tendency of these catheters to migrate out of the epidural space. Special equipment, in terms of longer needles or special ultrasound probes, may be needed for correct placement of catheters in these patients. Care should be exercised in dosing these catheters because of the increased cephalad spread of the drug and the block as a result of a smaller epidural space than in normal-weight patients.[108,109] The degree of respiratory compromise suffered by obese patients will also be of a larger magnitude than that of normal-weight patients with a high regional block.

There is little evidence suggesting that epidural pain management improves overall outcomes. Because the trend of laparoscopic surgery is increasing at the expense of open laparotomy, this becomes less of an issue. In the morbidly obese who undergo open laparotomy, use of epidural catheters to control pain via a thoracic epidural has the most important benefit of reducing the attenuation in vital capacity postoperatively.[110]

Obesity per se does not require invasive monitoring, so GPB surgery can be performed safely with routine monitoring. Indications for invasive monitoring stem from the comorbid conditions noted in these patients. Because such conditions tend to be present in obese patients needing surgery, the incidence of invasive monitoring in these patients thereby increases.[111] The morbidly obese with serious comorbid diseases such as obesity-hypoventilation syndrome with pulmonary hypertension and cor pulmonale may require a pulmonary artery catheter or intraoperative use of transesophageal echocardiography. The rationale for central venous access may stem from difficulties in peripheral access rather than any other indication. Access should probably be achieved under ultrasound guidance to decrease complications, as well as to increase ease of placement. Similarly, difficulty in noninvasive blood pressure measurements because of body habitus–related difficulty in appropriate cuff placement may be an indication for placement of an arterial catheter. Arterial blood gas analysis may help guide intraoperative ventilation and extubation.

Postoperative pain management in weight loss surgery patients can involve intravenous analgesia via patient-controlled analgesia (PCA) or thoracic epidural analgesia. There are no clear data proving the superiority of one technique over the other, so in many instances, surgical technique, open versus laparoscopic, may help guide that decision. In our practice we tend to reserve epidural analgesia for patients undergoing open GBP. Even with these drawbacks, we have approximately an 80% success rate in supermorbidly obese patients.

Opioid-based PCA with local anesthetic infiltration of the wound and adjunctive non-narcotic medication is a reasonable approach for most patients. Injection of local anesthetic into the incision site before making the incision may result in preemptive analgesia. Adjunctive analgesia with non-narcotic medications, unless contraindicated, will decrease opioid requirements and thereby opioid-induced side effects as well.

Intraoperatively, using the appropriate table for the patient's weight is critical inasmuch as the consequences of having a table not rated for the patient's weight can have serious consequences for the patient and the operating room personnel. It may be useful to keep the patient strapped throughout the period of sedation and sleep. Along with a safety strap, it might also be helpful to apply a bean bag under the patient to keep the patient from sliding off the operating room table.

Thermal management in the operating room is best accomplished with forced-air warmers. Armboards may need extra padding to keep the patient from having the arm and shoulder out of an anatomic position. If the arms are to be tucked by the side of the patient, a wide, well-padded sled may be useful.

Fluid requirements may be greater than predicted, and in even a relatively short, 2- to 3-hour case, 4 to 5 L of crystalloid fluid may be needed to prevent acute tubular necrosis in the kidneys. Hypovolemia, which can cause a protracted prerenal state, can be prevented by appropriate hydration. Retrospective data from the University of Pittsburgh Medical Center suggest that primary acute renal failure after weight loss surgery occurs on the order of 2%. Other predisposing factors are BMI greater than 50 kg/m^2, prolonged surgical time, previous history of renal disease, and intraoperative hypotension.[112]

Postoperative Management

In our practice, we prefer to have bariatric patients stay at the same location consistently after surgery. This practice allows skilled nursing and ancillary care to be provided to patients on a consistent basis. These patients are maintained on their CPAP or

biphasic positive airway pressure machines as much as possible, with monitoring of Spo_2 by pulse oximetry recommended.

If and when patients are found to have a difficult airway, they are labeled at the Hospital of the University of Pennsylvania with an armband for the remainder of their hospital stay. A note by the attending anesthesiologist explaining the difficulty in intubation, as well as the means used to secure the airway in the operating room, is available in the room. In case of an unexpected emergency intubation, for whatever reason, we believe that this extra information is extremely useful to the resuscitation team.

Management of Complications

Bariatric surgery is considered to be very safe, but not without potential complications. In-hospital mortality rates for LGB and open GBP surgery are 0.27% and 0.81%, respectively, a statistically significant difference.[113] Mortality is associated with a need for reoperation during the same hospitalization,[114] with intestinal leakage being a serious complication accounting for a large number of patient deaths.[115] Risk factors also include the comorbid conditions of congestive heart failure and renal failure.

Morbidity occurring during the immediate postoperative in-hospital period typically falls into one of four categories: wound, gastrointestinal, pulmonary, and cardiovascular complications. Complication rates are significantly lower in each category for patients undergoing laparoscopic rather than open procedures and range from 1.35% (wound complications) to 4.52% (gastrointestinal complications) after LGB and from 1.98% (wound complications) to 5.33% (gastrointestinal complications) after open GBP.[113]

The most common complications requiring reoperation include postoperative intra-abdominal bleeding, anastomotic leakage, suture line dehiscence, small bowel obstruction, and deep wound infection (Table 64-5),[115-120] all of which may require a general anesthetic for repeat laparotomy. Despite prophylaxis therapy, deep vein thrombosis or pulmonary embolism can also develop and require an anesthetic for placement of an inferior vena cava filter device.

Table 64-5 Specific and Nonspecific Complications

	All Surgeries	Gastric Banding	Roux-en-Y
Early	Bleeding Infection Dehydration Peritonitis Bowel obstruction Perforation Pneumonia DVT/PE Death	Band slippage Band malfunction Infection at band site	Leak from anastomotic site
Late	Cholelithiasis Cholecystitis Pouch dilation GERD/dysphagia Herniation at the surgical site Nutritional issues Fat-soluble vitamin deficiencies, especially vitamin B_{12}	Anorexia Band slippage Band malfunction Infection at the band site	Small bowel obstruction Marginal ulcers Pancreatitis Stricture

DVT, deep venous thrombosis; GERD, gastroesophageal reflux disease; PE, pulmonary embolism.

In all cases requiring reoperation shortly after the original bariatric procedure, it is prudent to review the anesthesia record. Specific attention should be paid to documentation of the patient's position and the technique used for airway management during the previous anesthesia. Patients may be hypovolemic from blood loss, inadequate hydration, vasodilatation, and insensitive fluid losses associated with fever and infection. It is especially important to consider additional or new risks for aspiration of gastric contents. Aspiration may be due to the presence of postoperative ileus, small bowel obstruction, and surgical creation of a Roux-en-Y gastric bypass limb that excludes the pylorus as an element of protection from reflux of intestinal contents. Decompression of the gastric pouch in patients undergoing surgery to relieve a small bowel obstruction can be achieved with careful introduction of a nasogastric or orogastric tube placed in the OR just before induction of general anesthesia. Since this may increase the risk of violating a fresh, competent anastomotic suture line, communication between the anesthesiologist and surgeon can be pursued to determine the risks/benefits of this maneuver. During laparotomy, any perforation resulting from the attempt to decompress the gastrointestinal tract can be repaired and the nasogastric or orogastric tube can be left in place for continued postoperative drainage.

Depending on the extent of the reoperation, requirement for volume resuscitation or blood transfusion, the degree of peritonitis with an anastomotic leak, and the presence of sepsis or other significant continued risks to health, patients undergoing a reoperation may require prolonged postoperative ventilation. Requirements for postoperative pain management may also be considerably different from those associated with the initial bariatric procedure. In patients who are sufficiently hemodynamically stable immediately before reoperation, an epidural catheter can be placed before induction for pain management as part of the postoperative care. This is especially valuable in obese patients undergoing laparotomy as described elsewhere in this chapter.

A number of potential major complications can also occur and require surgical intervention weeks, months, or even years after a bariatric surgical operation has been performed. Anastomotic strictures or ulcers, ventral hernias, gastrogastric fistulas, and severe reflux disorders requiring additional surgery may develop.[60] Small bowel obstruction may appear weeks after surgery.[119] Patients may desire cosmetic operations to remove excess skin or liposuction procedures to sculpt dysmorphic body areas after significant weight loss. Patients may also require adjustment of a gastric band or pursue band removal. Anesthetic considerations for such patients should include a review of the previous anesthetic record to glean information regarding airway and pain management. The degree of weight loss achieved and the resolution of comorbid diseases, including diabetes, hypertension, and OSA, may significantly alter the approach used in the bariatric operation.

Significant neurologic complications develop in a fraction of patients after GBP surgery,[121-123] including polyneuropathy, polyradiculoneuropathy, myelopathy, encephalopathy, and optic neuropathy. Myelopathy occurs most frequently but is not manifested until about 10 years after surgery.[121] These patients have demonstrable nutritional deficiencies, but except for the vitamin B_{12} and copper deficiencies found in patients with myelopathy, no

specific nutritional profile has been found to correlate with neurologic complications. Although the neurologic symptoms accompanying weight loss surgery are not likely to result in additional surgery, they represent new or additional comorbid conditions that should be fully considered by the anesthesiologist caring for patients who have previously undergone bariatric surgery.

The nutritional and metabolic complications of bariatric surgery also include protein and protein-calorie malnutrition. Patients may have excessive weight loss occurring either too rapidly or beyond the predetermined goals, steatorrhea or severe diarrhea, hypoalbuminemia, marasmus, edema, and hyperphagia.[60,124-126] In cases of severe malnutrition, patients may require enteral or parenteral nutrition therapy. Surgical revision may be required to correct the excessive weight loss and hypoalbuminemia. Under such circumstances, an anesthetic regimen accounting for the decreased drug-binding effects of a low serum albumin level must be considered.

Considerations for Management of Obese Patients Undergoing Nonbariatric Surgery

Few studies have evaluated the importance of morbidity when performing common surgical procedures. A study by Dindo and coworkers[127] evaluated 6336 patients and did not find any difference in the incidence or severity of complications after elective general surgery, except for surgical site infections. Other studies have assessed the effect of obesity on wound infections and have shown that they are increased.[128,129]

Multiple studies had demonstrated that obese patients are at higher risk after gynecologic, orthopedic, cardiovascular, urologic, and transplantation surgery, whereas other studies have not.[130,131]

From the data of Dindo and associates[127] regarding complications and the type of surgical procedure, operative severity and open laparoscopic surgery were independent risk factors for postoperative complications. They found no differences in the type of postoperative complications in obese and nonobese groups. This study provides data to decrease the prejudice that patients with obesity are implied to have a higher incidence of postoperative complications. This preconception may pertain more to the perception of the medical team as a result of technical difficulties on the anesthetic and surgical end. Surgeries may last longer, about 25% more time for laparoscopic than for open cholecystectomy in the morbidly obese. Significantly, the wound infection rate was much better after laparoscopic than after open surgery, which supports the practice of performing laparoscopic surgery in obese patients rather than the alternative.

65 Anesthesia and the Renal and Genitourinary Systems

Key Points

1. Innervation of the intra-abdominal components of the genitourinary system—the kidney and the ureter—is primarily thoracolumbar (T8-L2). The nerve supply of the pelvic organs—the bladder, the prostate, the seminal vesicles, and the urethra—is primarily lumbosacral with some lower thoracic input.
2. The spinal level of pain conduction for the external genitourinary organs is S2-4 except for the testes (T10-L1).
3. The kidneys receive 15% to 25% of the total cardiac output, with most of this blood directed to the renal cortex. Renal medullary papillae are more vulnerable to ischemic insults. Kidneys successfully autoregulate their blood flow between 60 mm Hg and 160 mm Hg mean arterial pressures.
4. The glomerular filtration rate (GFR) is the best measure of glomerular function. Creatinine clearance is a good measure of the GFR; urine output is not.
5. Hypervolemia, acidemia, hyperkalemia, cardiorespiratory dysfunction, anemia, and bleeding disturbances are manifestations of chronic renal failure.
6. Although renal transplantation reverses most of the abnormalities in end-stage renal disease, dialysis improves only some, and introduces additional complications of its own.
7. Newer techniques, such as laser prostatectomy, are making transurethral resection of the prostate (TURP) syndrome a rare event. TURP syndrome is a constellation of symptoms caused by the absorption of hypotonic bladder irrigants. Cardiovascular and neurologic changes are due to hypo-osmolality, hyponatremia, hyperglycinemia, hyperammonemia, and hypervolemia.
8. Regional anesthesia offers several advantages over general anesthesia for standard, but not laser, TURP, although 30-day mortality rates remain unchanged at 0.2% to 0.8%.
9. Laparoscopic surgery in urology frequently requires insufflation of carbon dioxide into the retroperitoneal space. In lengthy procedures, pneumomediastinum and subcutaneous emphysema of the head and neck may occur.
10. Extracorporeal shock wave lithotripsy (ESWL) is associated with significant physiologic changes related to immersion if a water bath is used. Shock waves can cause arrhythmias and injury to the lungs. Pregnancy and untreated bleeding disorders are contraindications to ESWL.
11. Of renal tumors, 5% to 10% extend into the renal vein, inferior vena cava, and right atrium. Complications ranging from circulatory failure to embolization of tumor during surgery may occur. Cardiopulmonary bypass may be necessary for surgery.
12. Radical prostatectomy is accompanied by significant blood loss. Intraoperative venous air embolism has been reported. Regional anesthesia with spontaneous ventilation is associated with less blood loss than general anesthesia and intermittent positive-pressure ventilation. Other advantages of epidural anesthesia include decreased deep vein thrombosis and preemptive analgesia. Although some studies report better outcomes with epidural anesthesia, others do not.
13. Robotic radical prostatectomy is associated with reduced blood loss and postoperative pain compared with open radical prostatectomy. Anesthetic concerns are related to steep head-down tilt and pneumoperitoneum and include hypercarbia, hypoxemia, increased intraocular and intracranial pressures, decreased perfusion pressure to lower extremity, and positional injuries.

Table 65-1 Pain Conduction Pathways and Spinal Segment Projection of Pain of the Genitourinary System

Organ	Sympathetics, Spinal Segments	Parasympathetics	Spinal Levels of Pain Conduction
Kidney	T8-L1	CN X (vagus)	T10-L1
Ureter	T10-L2	S2-4	T10-L2
Bladder	T11-L2	S2-4	T11-L2 (dome), S2-4 (neck)
Prostate	T11-L2	S2-4	T11-L2, S2-4
Penis	L1 and L2	S2-4	S2-4
Scrotum	NS	NS	S2-4
Testes	T10-L2	NS	T10-L1

NS, not significant for nociceptive function.

Patients requiring anesthesia for renal and genitourinary surgery are frequently at the extremes of age. In addition to the physiologic changes of aging in elderly patients, concomitant cardiovascular and respiratory comorbidity is common. A medical history, physical examination, and appropriate laboratory tests are necessary to evaluate concomitant disease. In pediatric urologic patients, a careful history should exclude other nonurologic congenital lesions.

Urologic procedures are performed mostly on the kidneys, adrenals, ureters, urinary bladder, prostate, urethra, penis, scrotum, testis, and spermatic cord. Because their sensory nerve supply is primarily thoracolumbar and sacral outflow (Table 65-1), these structures are well adapted for regional anesthesia.

Innervation of the Genitourinary System

The parts of the genitourinary system that are in the abdomen receive their nerve supply from the autonomic nervous system by means of sympathetic and parasympathetic pathways. The pelvic urinary organs and genitalia are supplied by somatic and autonomic nerves. Table 65-1 summarizes the pain conduction pathways and spinal levels of the genitourinary system.

Kidney and Abdominal Ureter

Sympathetic nerves to the kidney originate as preganglionic fibers from the eighth thoracic through the first lumbar segments and converge at the celiac plexus and aorticorenal ganglia (Fig. 65-1). Postganglionic fibers to the kidney arise mainly from the celiac and aorticorenal ganglia. Some sympathetic fibers may reach the kidney via the splanchnic nerves. Parasympathetic input is from the vagus nerve.[1] Sympathetic fibers to the ureter originate from the 10th thoracic through the 2nd lumbar segments and synapse with postganglionic fibers in the aorticorenal and superior and inferior hypogastric plexuses. Parasympathetic input is from the second through fourth sacral spinal segments.[1] Nociceptive fibers travel along the sympathetics to the same spinal segments. Pain from the kidney and ureter is referred mainly to the somatic

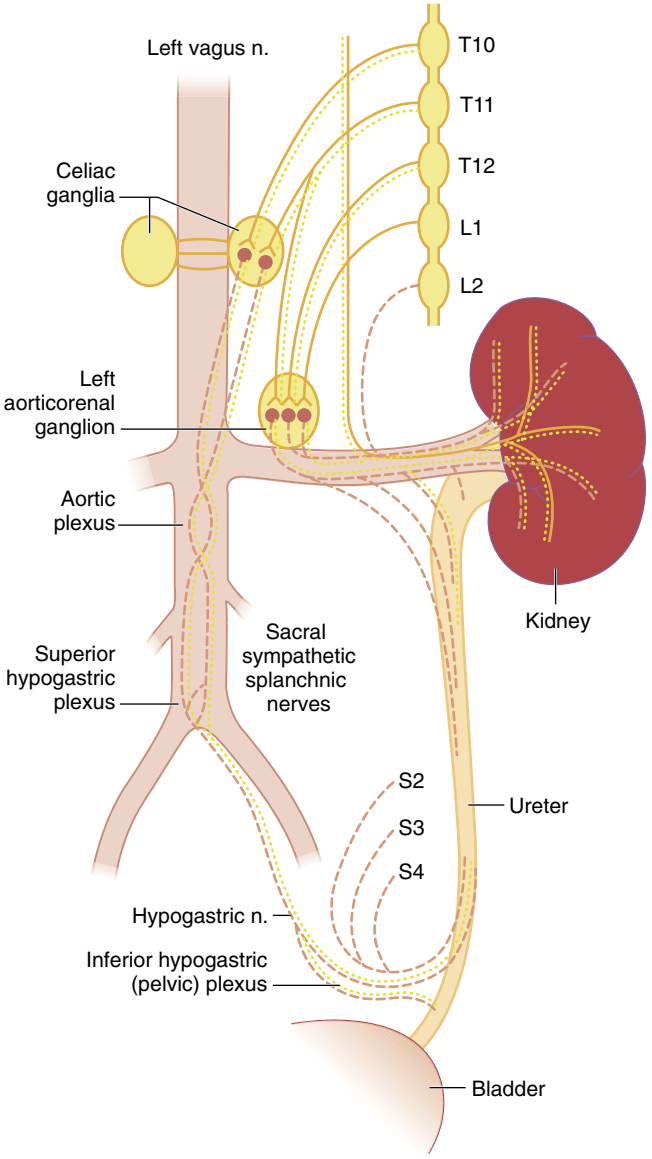

Figure 65-1 Autonomic and sensory innervation of the kidney and ureters. *Solid line* indicates preganglionic fibers; *dashed line* indicates postganglionic fibers; and *dotted line* indicates sensory fibers. *(From Gee WF, Ansell JF: Pelvic and perineal pain of urologic origin.* In *Bonica JJ [ed]: The Management of Pain, 2nd ed. Philadelphia, Lea & Febiger, 1990, pp 1368-1378.)*

distribution of the 10th thoracic through the 2nd lumbar segments—the lower part of the back, flank, ilioinguinal region, and scrotum or labia. Effective neural block of these segments is necessary to provide adequate analgesia or anesthesia.

Bladder and Urethra

Sympathetic nerves to the bladder and urethra originate from the 11th thoracic to the 2nd lumbar segments, travel through the superior hypogastric plexus, and supply the bladder through the right and the left hypogastric nerves.[2] Parasympathetic nerves arise from the second through the fourth sacral segments and form the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. Vesical branches proceed toward the bladder base, where they provide the nerve supply to the bladder and proximal part of the urethra (Fig. 65-2). Parasympathetic fibers are the main motor supply to the bladder (with the exception of the trigone) and far outnumber sympathetic fibers in the bladder.[2]

The afferents carrying sensations of stretch and fullness of the bladder are parasympathetic, whereas pain, touch, and temperature sensations are carried by sympathetic nerves. Sympathetic fibers are predominantly α-adrenergic in the bladder base and urethra, and β-adrenergic in the bladder dome and lateral wall. Knowledge of these aspects of neuroanatomy is important to appreciate the pharmacologic effects on the urologic system of neural ablation or regional block and drugs with adrenergic or cholinergic effects.[2]

Prostate and Prostatic Urethra

The prostate and prostatic urethra receive sympathetic and parasympathetic supply from the prostatic plexus arising from the pelvic parasympathetic plexus, which is joined by the hypogastric plexus. The spinal origin of the nerve supply is primarily lumbosacral (see Fig. 65-2).[2]

Penis and Scrotum

The autonomic supply to the penile urethra and the cavernous tissue comes from the prostatic plexus. Somatic fibers from the pudendal nerve (S2-4) supply the external sphincter. The dorsal nerve of the penis, the first branch of the pudendal

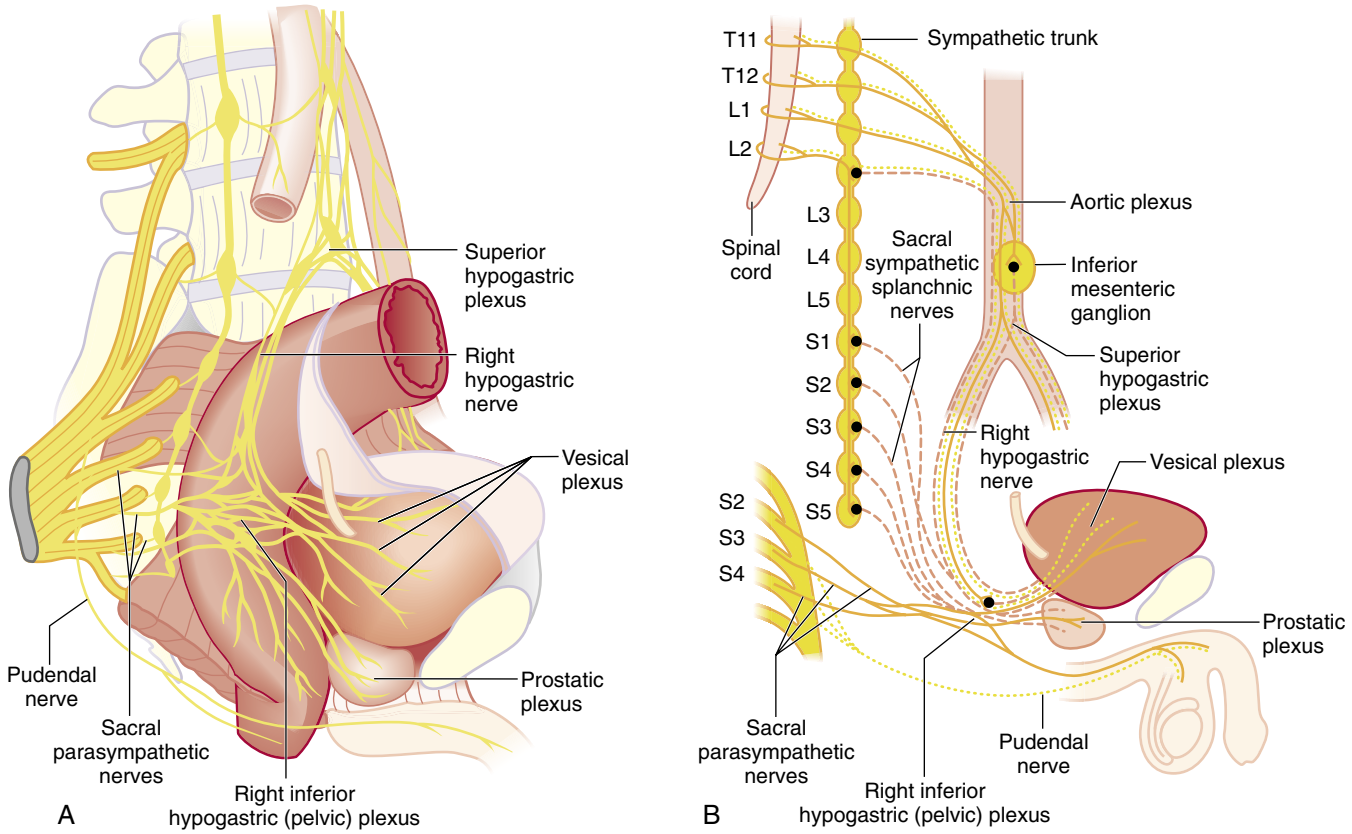

Figure 65-2 **A,** Nerve supply of the urinary bladder and prostate showing the relationship of the various nerve structures to the large intestine and their distribution in the bladder and prostate. **B,** Schematic illustration showing the segmental nerve supply to the bladder, penis, and scrotum. *Solid lines* indicate preganglionic fibers; *dashed lines* indicate postganglionic fibers; and *dotted lines* indicate sensory fibers. *(From Gee WF, Ansell JF: Pelvic and perineal pain of urologic origin.* In *Bonica JJ [ed]: The Management of Pain, 2nd ed. Philadelphia, Lea & Febiger, 1990, pp 1368-1378.)*

nerve, is its main sensory supply. The scrotum is innervated anteriorly by the ilioinguinal and genitofemoral nerves (L1 and L2) and posteriorly by perineal branches of the pudendal nerve (S2 and S4).[2]

Testes

The testes descend from their intra-abdominal location to the scrotum during fetal development. Because they share their embryologic origin with the kidney, their nerve supply is similar to that of the kidney and upper part of the ureter and extends up to the T10 spinal segment.[2]

Renal Blood Flow

The kidneys receive approximately 15% to 25% of total cardiac output, or 1 to 1.25 L of blood per minute through the renal arteries, depending on the state of the body. Most of the blood is received by the renal cortex, with only 5% of cardiac output flowing through the renal medulla, which makes the renal papillae vulnerable to ischemic insults. Renal blood flow is regulated by various mechanisms that control the activity of vascular smooth muscle and alter vascular resistance. Sympathetic tone of renal vessels increases during exercise to shunt renal blood flow to exercising skeletal muscle; similarly, renal blood vessels relax during the resting condition of the body. Sympathetic stimulation as a result of surgery can increase vascular resistance and reduce renal blood flow, whereas anesthetics may reduce renal blood flow by decreasing cardiac output.

Glomerular capillaries separate afferent arterioles from efferent arterioles. Glomerular capillaries are high-pressure systems, whereas peritubular capillaries are low-pressure systems. Consequently, the glomerular capillaries are a fluid-filtering system, whereas the peritubular capillaries are a fluid-absorbing system. The vasa recta, a specialized portion of peritubular capillaries formed from efferent arterioles, are important in the formation of concentrated urine by a countercurrent mechanism. An intrinsic mechanism that causes vasodilation and vasoconstriction of renal afferent arterioles regulates the autoregulation of renal blood flow. A decrease in mean arterial pressure also decreases renal blood flow and eventually affects the glomerular filtration rate (GFR) when the pressure decreases to less than 60 mm Hg. A persistently low mean arterial pressure greater than 60 mm Hg affects renal blood flow, but does not affect the GFR because of the intrinsic mechanism of autoregulation (Fig. 65-3). Autoregulation maintains mean arterial pressure between 60 mm Hg and 160 mm Hg in intact and denervated kidneys.[3]

Although knowledge of neuroanatomy and renal blood flow is essential to provide adequate anesthesia, a thorough understanding of renal physiology and pharmacology is equally important. Genitourinary surgical patients frequently have mechanical or functional renal disease. Anesthetics and surgery can significantly alter renal function. Conversely, renal dysfunction significantly affects the pharmacokinetics and pharmacodynamics of anesthetics and adjuvant drugs. Evaluation of a patient with renal disease is discussed later.

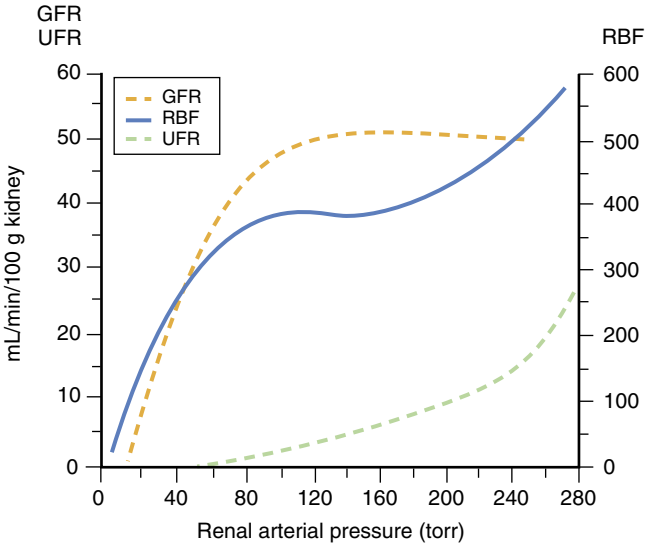

Figure 65-3 Autoregulation of renal blood flow (RBF) and the glomerular filtration rate (GFR). The relationships between RBF, GFR, and urine flow rate (UFR) and mean renal arterial pressure in dogs are shown as renal arterial pressure is varied from 20 to 280 mm Hg. Autoregulation of RBF and GFR is observed between about 80 mm Hg and 180 mm Hg. *(Redrawn from Hemmings HC: Anesthetics, adjuvants and drugs and the kidney.* In *Malhotra V [ed]: Anesthesia for Renal and Genitourinary Surgery. New York, McGraw-Hill, 1996, p 18.)*

Anesthesia for Patients with Renal Disease

Evaluation of Renal Function

Renal disease may be discovered incidentally during a routine medical evaluation, or patients may present with evidence of renal dysfunction, such as hypertension, edema, nausea, and hematuria (see Chapter 18). The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases, this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the GFR. The history and physical examination, although equally important, are variable among renal syndromes; specific symptoms and signs are discussed in sections on each disease entity. Further diagnostic categorization is according to anatomic distribution: prerenal disease, postrenal disease, and intrinsic renal disease. Intrinsic renal disease can be divided further into glomerular, tubular, interstitial, and vascular abnormalities. Laboratory tests useful in evaluating renal function are described next (Table 65-2).

Glomerular Function

Glomerular Filtration Rate

The GFR is the best measure of glomerular function. Normal GFR is approximately 125 mL/min. Manifestations of reduced GFR are not seen, however, until the GFR has decreased to 50% of normal.

Table 65-2 Commonly Ordered Renal Function Tests

Test Name	Reference Range	Units
Urea nitrogen	5-25	mg/dL
Creatinine	0.5-1.5	mg/dL
Sodium	133-147	mmol/L
Potassium	3.2-5.2	mmol/L
Chloride	94-110	mmol/L
CO_2	22-32	mmol/L
Uric acid	2.5-7.5	mg/dL
Calcium	8.5-10.5	mg/dL
Phosphorus	2.2-4.2	mg/dL
Urinalysis, routine		
Color	Straw-amber	
Appearance	Clear-hazy	
Protein	0	mg/dL
Blood	Negative	
Glucose	0	mg/dL
Ketones	0	mg/dL
pH	4.5-8.0	
Specific gravity	1.002-1.030	
Bilirubin	Negative	
Urinalysis, microscopic		
Red blood cells	0-3	per high-power field
White blood cells	0-5	per high-power field
Casts	0-2	per low-power field

From Miller ED Jr: Understanding renal function and its preoperative evaluation. *In* Malhotra V (ed): Anesthesia for Renal and Genitourinary Surgery. New York, McGraw-Hill, 1996, p 9.

When GFR decreases to 30% of normal, a stage of moderate renal insufficiency sets in. Patients remain asymptomatic with only biochemical evidence of a decline in GFR (i.e., an increase in serum concentrations of urea and creatinine). Further workup usually reveals other abnormalities, such as nocturia, anemia, loss of energy, decreasing appetite, and abnormalities in calcium and phosphorus metabolism.

As the GFR decreases further, a stage of severe renal insufficiency begins. This stage is characterized by profound clinical manifestations of uremia and biochemical abnormalities, such as acidemia; volume overload; and neurologic, cardiac, and respiratory manifestations. At the stages of mild and moderate renal insufficiency, intercurrent clinical stress may compromise renal function further and induce signs and symptoms of overt uremia. When the GFR is 5% to 10% of normal, it is called end-stage renal disease (ESRD), and continued survival without renal replacement therapy becomes impossible. Although most clinical abnormalities of corticotropin-releasing factor (CRF) are reversed by renal transplantation, the response to dialysis is quite variable (Table 65-3).

Blood Urea Nitrogen

The blood urea nitrogen (BUN) concentration is not a direct correlate of reduced GFR. BUN is influenced by nonrenal variables, such as exercise, bleeding, steroids, and massive tissue breakdown. The more important factor is that BUN is not elevated in kidney disease until the GFR is reduced to almost 75% of normal.[4]

Creatinine and Creatinine Clearance

Measurements of creatinine provide valuable information regarding general kidney function. Creatinine in serum results from turnover of muscle tissue and depends on daily dietary intake of protein. Normal values are 0.5 to 1.5 mg/100 mL; values of 0.5 to 1 mg/100 mL are present during pregnancy. Creatinine is freely filtered at the glomerulus, and apart from an almost negligible increase in content because of secretion in the distal nephron, it is neither reabsorbed nor secreted. Serum creatinine measurements reflect glomerular function (Fig. 65-4),[4] and creatinine clearance is a specific measure of GFR. Creatinine clearance can be calculated by the following formula derived by Cockcroft-Gault that accounts for age-related decreases in GFR, body weight, and sex:

$$\text{Creatinine clearance}\left(\text{mL/min}\right) = \frac{\left(140-\text{age}\right)\times\text{lean body weight}\left(\text{kg}\right)}{\text{plasma creatinine}\left(\text{mg/dL}\right)\times 72}$$

This value should be multiplied by 0.85 for women because a lower fraction of body weight is composed of muscle.

Because there is such a wide range in normal values, a 50% increase in serum creatinine concentration, indicative of a 50% reduction in GFR, may go undetected unless baseline values are known. Also, excretion of drugs dependent on glomerular filtration may be significantly decreased despite what might seem to be only slightly elevated serum creatinine values (1.5 to

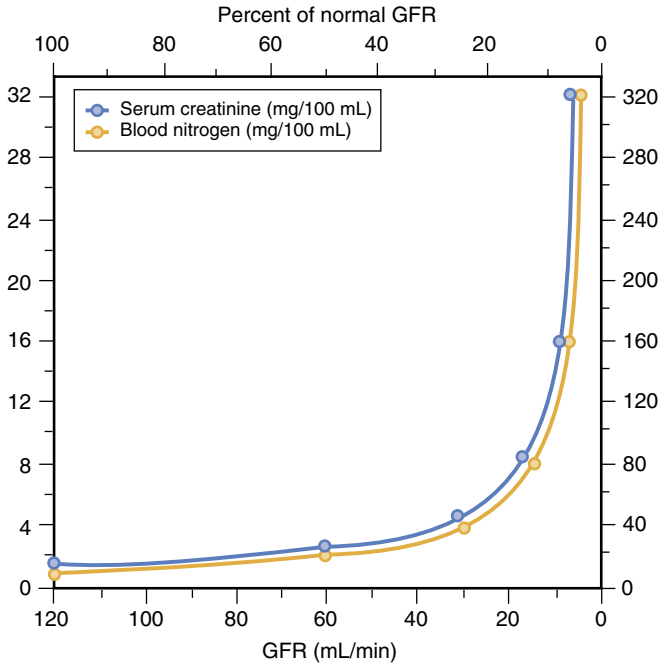

Figure 65-4 Theoretical relationship between blood urea nitrogen and creatinine versus glomerular filtration rate (GFR). *(Redrawn from Kassirer JP: Clinical evaluation of kidney function-glomerular function. N Engl J Med 285:385, 1971.)*

Table 65-3 Clinical Abnormalities in Chronic Renal Failure and Their Response to Dialysis and Erythropoietin Treatment

Improved by Dialysis	Improved by Adding Erythropoietin	Variable Response	Not Improved	Develop after Dialysis Therapy
Volume expansion and contraction	Fatigue Impaired mentation	Secondary hyperparathyroidism	Increased lipoprotein level	Adynamic osteomalacia β_2-Microglobulinemia
Hypernatremia and hyponatremia	Lethargy Pallor	Hyperuricemia Hypertriglyceridemia	Decreased high-density lipoprotein level	Muscle cramps Dialysis dysequilibrium syndrome
Hyperkalemia and hypokalemia	Anemia Bleeding diathesis	Protein-calorie malnutrition	Impaired growth and development	Hypotension and arrhythmias
Metabolic acidosis Hyperphosphatemia Hypocalcemia		Headache Peripheral neuropathy Restless legs syndrome	Infertility and sexual dysfunction	Hepatitis Idiopathic ascites
Vitamin D–deficient osteomalacia		Paralysis Seizures	Amenorrhea Amenorrhea	Peritonitis Leukopenia
Carbohydrate intolerance		Myopathy	Sleep disorders	Hypocomplementemia
Hypothermia		Arterial hypertension	Pruritus	
Asterixis		Cardiomyopathy	Lymphocytopenia	
Muscular irritability Myoclonus		Accelerated atherosclerosis	Splenomegaly and hypersplenism	
Coma		Vascular calcification		
Congestive heart failure or pulmonary edema		Hyperpigmentation Peptic ulcer		
Pericarditis		Gastrointestinal bleeding		
Uremic lung		Increased susceptibility to infection

Uremic fetor				
Gastroenteritis				

2.5 mg/100 mL). The serum creatinine concentration and clearance are better indicators of general kidney function and GFR than similar measurements of urea nitrogen (Table 65-4). There are disease states, however, in which even the serum creatinine may be affected independent of the GFR (Table 65-5).

Table 65-4 Conditions Affecting Blood Urea Nitrogen (BUN) Independently of Glomerular Filtration Rate

Increased BUN
Reduced effective circulating blood volume (prerenal azotemia)
Catabolic states (gastrointestinal bleeding, corticosteroid use)
High-protein diets
Tetracycline
Decreased BUN
Liver disease
Malnutrition
Sickle cell anemia
SIADH

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Tubular Function

Concentration

Urinary specific gravity is an index of the kidney's concentrating ability, specifically, renal tubular function. Determination of urinary osmolality (i.e., measurement of the number of moles of solute [osmoles] per kilogram of solvent) is a similar, more specific test. Excretion of concentrated urine (specific gravity 1.030; 1050 mOsm/kg) is indicative of excellent tubular function, whereas a urinary osmolality fixed at that of plasma (specific gravity 1.010; 290 mOsm/kg) indicates renal disease. The urinary dilution mechanism persists after concentrating defects are present, so a urinary osmolality of 50 to 100 mOsm/kg still may be consistent with advanced renal disease.

Protein

Patients without renal disease may excrete 150 mg of protein per day; greater amounts may be present after strenuous exercise or after standing for several hours. Massive proteinuria (i.e.,

Table 65-5 Conditions Affecting Serum Creatinine Independently of Glomerular Filtration Rate

Condition	Mechanism
Conditions Causing Elevation	
Ketoacidosis	Noncreatinine chromogen
Cephalothin, cefoxitin	Noncreatinine chromogen
Flucytosine	Noncreatinine chromogen
Other drugs—aspirin, cimetidine, probenecid, trimethoprim	Inhibition of tubular creatinine secretion
Conditions Causing Decrease	
Advanced age	Physiologic decrease in muscle mass
Cachexia	Pathologic decrease in muscle mass
Liver disease	Decreased hepatic creatine synthesis and cachexia

>750 mg/day) is always abnormal and usually indicates severe glomerular damage.

Glucose

Glucose is freely filtered at the glomerulus and is subsequently reabsorbed in the proximal tubule. Glycosuria signifies that the ability of the renal tubules to reabsorb glucose has been exceeded by an abnormally heavy glucose load and is usually indicative of diabetes mellitus. Glycosuria also may be present in hospitalized patients without diabetes who are receiving intravenous glucose infusions.

Additional Diagnostic Tests

Urinalysis and Appearance

Gross and microscopic observation of urine and its sediment, along with determination of urinary pH, specific gravity, protein content, and glucose content, is one of the most readily available, inexpensive, and informative laboratory tests. The gross appearance of urine may indicate the presence of bleeding or infection in the genitourinary tract. Microscopic examination of urinary sediment may reveal casts, bacteria, and various cell forms, supplying diagnostic information in patients with renal disease.

Serum and Urine Electrolytes

pH and Blood Gases. Sodium, potassium, chloride, and bicarbonate concentrations should be determined if impairment in renal function is suspected. The results of these tests usually remain normal until frank renal failure is present, however, and hyperkalemia does not occur until patients are uremic.[5] Measuring urinary sodium or chloride excretion is especially useful when attempting to differentiate between causes of hyponatremia, as seen in volume contraction (whether a decrease in total circulatory volume or a decrease in effective arterial blood volume), versus conditions associated with increased salt loss, such as the syndrome of inappropriate secretion of antidiuretic hormone, salt-losing nephropathy, or adrenal insufficiency.[6] If significant renal disease is present, patients consuming a diet high in animal protein may have metabolic acidosis.

Electrocardiogram. The electrocardiogram (see Chapter 34) reflects the toxic effects of potassium excess more closely than determination of the serum potassium concentration.

Imaging Studies

Computed Tomography Scan of Kidneys. A stone protocol computed tomography (CT) scan of the kidneys, ureter, and bladder has become the study of choice for the detection of kidney stones because of its ability to detect stones of all kinds, including uric acid stones and nonobstructing stones in the ureter. Masses in the kidney can be evaluated using either contrast-enhanced CT or renal ultrasound.[6]

Computed Tomography Angiography. CT angiography is used for the evaluation of renal artery stenosis and is emerging rapidly as a useful study. Although it is comparable to magnetic resonance angiography as a noninvasive tool, it requires the use of iodinated contrast material, which may cause renal dysfunction in patients with chronic kidney disease.[7]

Magnetic Resonance Imaging with Magnetic Resonance Angiography The use of magnetic resonance imaging (MRI) with magnetic resonance angiography has revolutionized the evaluation of renovascular disease. The test is highly sensitive, but tends to overestimate the degree of stenosis. Its accuracy in detecting fibromuscular dysplasia causing renal artery stenosis has not been well validated. MRI also can be used to evaluate renal masses. Its main advantages of MRI are that it is a noninvasive test and does not require iodinated contrast material.

Important Pathophysiologic Manifestations of Chronic Renal Failure (see also Chapter 96)

Hypervolemia

Total-body contents of Na^{++} and H_2O are increased in chronic renal failure (CRF),[4] although this increase may not be clinically apparent until the GFR is reduced to very low levels. Weight gain is usually associated with volume expansion and is offset by the concomitant loss of lean body mass. The combination of loop diuretics with metolazone, which acts by inhibiting the Na-Cl cotransporter of the distal convoluted tubule, can overcome diuretic resistance.

Acidemia

Although urine can be acidified normally in most patients with CRF, these patients have a reduced ability to produce ammonia. In the early stages, the accompanying organic anions are excreted in urine, and the metabolic acidosis is of the non–anion gap variety. With advanced renal failure, a fairly large "anion gap" may develop (to approximately 20 mmol/L), however, with a reciprocal decrease in plasma HCO_3^- concentration. This acidemia is usually corrected by hemodialysis. Although acidemia is well compensated in moderate CRF, patients can become acidemic and hyperkalemic[8] in the postoperative period (Table 65-6).

Table 65-6 Metabolic Acidosis in Chronic Renal Failure

	$Paco_2$ (mm Hg)	pH	HCO_3^- (mEq/L)	K^+ (mEq/L)
Preoperative	32	7.32	17	5
Intraoperative	40	7.25	18	5.3
Postoperative	44	7.21	19	5.6
	48	7.18	19	5.9

The patient is a 36-year-old man with severe diabetic nephropathy and end-stage renal failure undergoing cadaver renal transplantation. Preoperatively, the patient has a chronic metabolic acidosis (HCO_3^- 17 mEq/L) with partial respiratory compensation ($Paco_2$ 32 mm Hg; pH 7.32). Potassium is high normal at 5 mEq/L. Intraoperatively, he is given "standard" mechanical minute ventilation, and with "normal" $Paco_2$ (40 mm Hg), the metabolic acidosis is unmasked (pH 7.25), and potassium increases to 5.3 mEq/L. His trachea is extubated at the end of the procedure, but graft function is sluggish, and the metabolic acidosis remains unchanged. With residual opioid-induced narcosis, moderate CO_2 retention occurs ($Paco_2$ 44 mm Hg and 48 mm Hg), pH decreases further to 7.18, and a dangerous degree of hyperkalemia develops (K^+ 5.9 mEq/L).

Hyperkalemia

The approximate daily filtered load of K^+ is 700 mmol. Most of this filtered load is reabsorbed in tubule segments, and most of the K^+ excreted in the final urine reflects events governing K^+ handling at the level of the cortical collecting tubule and beyond. K^+ excretion in the gastrointestinal tract is augmented in patients with CRF. Hyperkalemia may be precipitated, however, in numerous clinical situations, including protein catabolism, hemolysis, hemorrhage, transfusion of stored red blood cells, metabolic acidosis, and exposure to various medications that inhibit K^+ entry into cells or K^+ secretion in the distal nephron.

Cardiac and Pulmonary Manifestations

Hypertension is a common complication of CRF and ESRD. Because hypervolemia is the major cause of hypertension in uremia, normotension is usually restored by the use of diuretics in predialysis patients or by dialysis in ESRD patients. Despite therapy, patients continue to be hypertensive because of the vasodilators required for the management of overwhelming hyperreninemia. Patients generally have left ventricular hypertrophy and accelerated atherosclerosis (disordered glucose and fat metabolism). Pericarditis can be observed in underdialyzed patients versus patients with CRF who undergo regular dialysis.

A unique form of pulmonary congestion and edema may occur even in the absence of volume overload and is associated with normal or mildly elevated intracardiac and pulmonary capillary wedge pressure. This entity, characterized radiologically by peripheral vascular congestion giving rise to a "butterfly wing" distribution, is due to increased permeability of alveolar capillary membranes. This "low-pressure" pulmonary edema and the cardiopulmonary abnormalities associated with circulatory overload usually respond promptly to vigorous dialysis.[9]

Hematologic Manifestations

CRF usually causes a normochromic, normocytic anemia. Anemia is generally observed when the GFR decreases to less than 30 mL/min and is due to insufficient production of erythropoietin by the diseased kidneys. Other factors are iron deficiency, either related to or independent of blood loss from repeated laboratory testing, blood retention in the dialyzer, or gastrointestinal bleeding.[10] Treatment of anemia with iron, darbepoetin alfa, and human recombinant erythropoietin (Table 65-7) normalizes the hematocrit, avoids repetitive red blood cell transfusion, reduces the requirement for hospitalization, and decreases cardiovascular mortality by about 30%.[11]

Prolongation of the bleeding time because of decreased activity of platelet factor 3, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption contributes to the clotting defects. The abnormality in platelet factor 3 correlates can be corrected by dialysis, although prolongation of the bleeding time can be observed in well-dialyzed patients. Abnormal bleeding times and coagulopathy in patients with renal failure may be managed with desmopressin, cryoprecipitate, conjugated estrogens, blood transfusions, and erythropoietin use.[10]

Effects of Drugs in Patients with Reduced Renal Function

Most anesthetic drugs are weak electrolytes and are lipid soluble in the un-ionized state; they are extensively reabsorbed by renal tubular cells (see Chapters 26 and 29). Termination of their action does not depend on renal excretion; redistribution and metabolism produce this effect. After biotransformation, these drugs are excreted in urine as water-soluble, polar forms of the parent compound. They are usually pharmacologically inactive, and their retention is harmless.[10] Most drugs with prominent central and peripheral nervous system activity fall into this category, including most narcotics, barbiturates, phenothiazines, butyrophenone derivatives, benzodiazepines, ketamine, and local anesthetics.[12] Several drugs are lipid insoluble or are highly ionized in the

Table 65-7 Management Guidelines for Correction of Anemia of Chronic Renal Disease

Erythropoietin	
Starting dosage	50-150 U/kg/wk IV or SC (once, twice, or three times per week)
Target hemoglobin	11-12 g/dL
Optimal rate of correction	Increase hemoglobin by 1-2 g/dL over 4 wk
Darbepoetin alfa	
Starting dosage	0.45 μg/kg administered as single IV or SC injection once weekly 0.75 μg/kg administered as a single IV or SC injection once every 2 wk
Target hemoglobin	12 g/dL
Optimal rate of correction	Increase hemoglobin by 1-2 g/dL over 4-wk period
Iron	
Monitor iron stores by TSat and serum ferritin	
If patient is iron-deficient (TSat <20%; serum ferritin <100 g/L), administer iron, 50-100 mg IV twice per week for 5 wk; if iron indices are still low, repeat the same course	
If iron indices are normal but hemoglobin is still inadequate, administer IV iron as outlined above; monitor hemoglobin, TSat, and ferritin.	
Withhold iron therapy when TSat >50% or ferritin >800 ng/mL (>800 g/L)	

IV, intravenously; SC, subcutaneously; TSat, percent transferrin saturation.

physiologic pH range, however, and are eliminated unchanged in urine. Their duration of action may be extended in patients with impaired renal function. Drugs in this category include muscle relaxants, cholinesterase inhibitors, thiazide diuretics, digoxin, and many antibiotics (Table 65-8).[13]

Opioids

Renal failure has implications of major clinical importance with respect to morphine and meperidine (see Chapter 27). For the fentanyl congeners, the clinical importance of renal failure is less marked.[14]

Morphine is an opioid with active metabolites that depend on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver, and the water-soluble glucuronides (morphine-3-glucuronide and morphine-6-glucuronide) are excreted via the kidney. The kidney also plays a role in the conjugation of morphine, accounting for nearly 40% of its metabolism.[15] Patients with renal failure can develop very high levels of morphine-6-glucuronide and life-threatening respiratory depression.[14] In view of these changes induced by renal failure, morphine may not be a good choice in patients with severely altered renal clearance mechanisms.

The clinical pharmacology of meperidine also is significantly altered by renal failure. Normeperidine, the chief metabolite, has analgesic and central nervous system (CNS) excitatory effects.[16] Because the active metabolites are subject to renal excretion, this potential CNS toxicity secondary to normeperidine accumulation is especially a concern in patients in renal failure.

The clinical pharmacology of the fentanyl congeners is not grossly altered by renal failure, although a decrease in plasma protein binding potentially may alter the free fraction of the fentanyl class of opioids.[14] Fentanyl clearance is not altered by renal failure. As with fentanyl, sufentanil pharmacokinetics are not altered in any consistent fashion by renal disease, although greater variability exists in the clearance and elimination half-life of sufentanil when patients have impaired renal function.[17] An increased clinical effect is likely with alfentanil in renal failure because of a decreased initial volume of distribution and an increased free fraction of alfentanil.[18] No delay in recovery after alfentanil administration should be expected, however. Neither the pharmacokinetics nor the pharmacodynamics of remifentanil are altered by impaired renal function.[18]

Hydromorphone,[19] as the parent drug, does not substantially accumulate in hemodialysis patients. Conversely, an active metabolite, hydromorphone-3-glucuronide, quickly accumulates between dialysis treatments, but seems to be effectively removed during hemodialysis. With careful monitoring, hydromorphone may be used safely in dialysis patients. It should be used with caution, however, in patients with a GFR less than 30 mL/min who have yet to start dialysis or who have withdrawn from dialysis.

Table 65-8 Drugs Used or Encountered in Anesthesia Practice That Significantly Depend on Renal Elimination

Completely Dependent	Partially Dependent
Digoxin, inotropes (used frequently; monitoring of blood levels indicated in chronic renal failure)	IV anesthetics—barbiturates
Others—aminoglycosides, vancomycin, cephalosporins, and penicillins	Muscle relaxants—pancuronium
	Anticholinergics—atropine, glycopyrrolate
	Cholinesterase inhibitors—neostigmine, edrophonium
	Others—milrinone, hydralazine, cycloserine, sulfonamides, and chlorpropamide

Inhaled Anesthetics

All inhaled anesthetics (see Chapters 20, 21, and 24) are biotransformed to some extent, with the nonvolatile products of metabolism eliminated almost entirely by the kidney.[20] Reversal of the CNS effects of inhaled anesthetics depends on pulmonary excretion, however, so impaired kidney function would not alter the response to these anesthetics. From the viewpoint of selecting an anesthetic that would not be harmful to patients with mild or moderate impairment of renal function, all the modern potent anesthetics are suitable. Enflurane is biotransformed to inorganic fluoride, but levels after 2 to 4 hours of anesthesia average only 19 μM in patients with mild to moderate kidney disease, significantly lower than the nephrotoxic threshold of 50 μM, which is frequently reported after the administration of methoxyflurane.[21,22] This level of fluoride should not cause further renal impairment. Fluoride levels after isoflurane increase by only 3 to 5 μM,[23] and by only 1 to 2 μM after halothane,[22] so these anesthetics have no nephrotoxic potential.

Desflurane and sevoflurane, two newer inhaled anesthetics, are remarkably different in their molecular stability and biotransformation. Desflurane is highly stable and resists degradation by soda lime[24] and the liver. The mean inorganic fluoride concentration after 1 minimum alveolar concentration (MAC)–hour exposure to desflurane was less than 1 μmol/L.[25] The safety of desflurane in renal failure patients has been confirmed.[26] In addition, more sensitive indices of renal function—urine retinol-binding protein and β-*N*-acetylglucosaminidase—showed no evidence of renal damage. Prolonged exposure to desflurane (7 MAC-hours) has been associated with normal renal function.[26]

Sevoflurane is not very stable. Soda lime causes it to decompose,[27] and it is biotransformed by the liver. Plasma inorganic fluoride concentrations approaching nephrotoxic levels (50 μmol/L)[28] have been reported after prolonged inhalation of sevoflurane. No evidence of gross changes in renal function was found in humans, however.[29] In one study, sevoflurane was used at low flow (1 L/min), and there was no relationship to compound A and renal function.

Inhaled anesthetics cause a transient reversible depression in renal function. GFR, renal blood flow, urine output, and urinary excretion of sodium are decreased (Table 65-9). Probable mechanisms include reduced renal blood flow, loss of renal autoregulation, neurohumoral factors (e.g., antidiuretic hormone, vasopressin, renin), and neuroendocrine responses. Although most inhaled anesthetics have been shown to reduce GFR and urinary excretion of sodium, their effects on renal blood flow have yielded conflicting results, which can be explained by differences in experimental methodology. Data suggest that renal blood flow is maintained with halothane, isoflurane, and desflurane,[30,31] but it is decreased with enflurane and sevoflurane.[32,33]

Table 65-9 Effects of Various Anesthetics on Renal Function

	RBF	GFR	Urine Output	Urine Solutes
General anesthesia	↓	↓	↓	↓
Intravenous anesthetics				
Thiopental	↔	↓	↓	↓
Midazolam	↔	↔	↓	↔
Fentanyl/droperidol	↔	↔	↓	↓
Fentanyl (high dose)	↔	↔	↔	↔
Inhaled anesthetics				
Halothane	↔	↓	↓	↓
Enflurane	↓	↓	↓	↓
Isoflurane	↔	↓	↓	↓

Intravenous Anesthetics

Reversal of CNS effects after the administration of ultrashort-acting barbiturates such as thiopental and methohexital occurs as a result of redistribution, and hepatic metabolism is the sole route of elimination of these drugs (see Chapter 26). Thiopental is 75% to 85% bound to albumin,[34] the concentration of which may be markedly reduced in uremia. Because it is a highly bound drug, reduced binding permits a greater proportion of an administered dose of thiopental to reach receptor sites. In addition, thiopental is a weak acid, with its pK_a in the physiologic range; acidosis results in more un-ionized, nonbound, active thiopental. In combination, these changes produce an increase in the free fraction of thiopental from 15% in normal patients to 28% in patients with CRF.[35] With thiopental metabolism essentially unchanged in renal disease, the dose to produce and maintain anesthesia should be reduced.[35] The same considerations are true for methohexital, although metabolism plays a slightly greater part in termination of its therapeutic effect.[36]

Propofol does not adversely affect renal function as reflected by measurements of creatinine concentration. Prolonged infusions of propofol may result in the excretion of green urine because of the presence of phenols in the urine. This discoloration does not affect renal function. Urate excretion is increased after the administration of propofol and is usually manifested as cloudy urine when urate crystallizes under conditions of low pH and temperature.[37]

There are no reports of the disposition of narcotics and tranquilizers when used in large dosage for anesthesia in uremic patients. These drugs are extensively metabolized before excretion, so when combined with 30% to 50% nitrous oxide, they should not have a particularly prolonged effect. The benzodiazepines, especially diazepam,[13] have a long half-life, so they tend to accumulate in any case. Because of the greater ease of reversibility of the potent inhaled anesthetics versus intravenous drugs, inhaled anesthetics may offer some advantages for the induction of general anesthesia in uremic patients.

Muscle Relaxants and Their Antagonists

Succinylcholine has been used without difficulty in patients with decreased or absent renal function (see Chapter 29). Its metabolism is catalyzed by pseudocholinesterase to yield the nontoxic end products succinic acid and choline. The metabolic precursor of these two compounds, succinylmonocholine, is excreted by the kidney. Large doses of succinylcholine, which might result from prolonged infusion, should be avoided in patients with renal failure. Although pseudocholinesterase levels are reduced in uremia,[38] these reductions are insufficient and they cause a prolonged block. Hemodialysis has been reported to have no effect on cholinesterase levels.[39]

Administration of succinylcholine causes a rapid, transient increase of 0.5 mEq/L in the serum potassium concentration. In traumatized, burned, or neurologically injured patients, the increase may be 5 to 7 mEq/L, probably as a consequence of denervation supersensitivity of the muscle membrane to succinylcholine and to acetylcholine,[40] which can result in cardiovascular collapse. An exaggerated increase in serum potassium could be particularly dangerous in uremic patients with hyperkalemia, so the use of succinylcholine is inadvisable, unless the patient has undergone dialysis within 24 hours before surgery. If the patient has recently undergone dialysis or has normal serum potassium, the use of succinylcholine is reportedly safe.

The disposition of nondepolarizing muscle relaxants has been well studied. Renal failure influences the pharmacology of nondepolarizing muscle relaxants by producing either decreased elimination of the drug or its metabolites by the kidney or decreased activity of enzymes that metabolize the drug, such as in the case of mivacurium (see Table 65-12). Consequently, the duration of action of muscle relaxants may be prolonged in patients with renal failure.

As can be appreciated from examination of the pharmacokinetics data in Table 65-10, excretion of tubocurarine is delayed in patients with renal failure.[41] Although tubocurarine is no longer used, studies with this drug served as a standard for the current drugs. Clearance is reduced, and the volume of distribution is unchanged—hence an increase in the terminal elimination half-life. With protein binding sensitivity of the neuromuscular junction to tubocurarine unchanged in patients with renal failure, the consequence of delayed excretion would be a prolonged duration of action. This would not be apparent after the administration of a single small dose because redistribution, rather than excretion, is responsible for termination of action.[42] Recovery after a single large dose or several small doses of tubocurarine is directly related to the terminal elimination half-life. Maintenance doses for patients with decreased renal function should be smaller than for patients with normal renal function, the interval between doses should be increased,[43] and administration should be monitored with a nerve stimulator.

Approximately 40% to 50% of pancuronium is excreted in urine. A portion of this excretion occurs after biotransformation to the less active metabolite 3-hydroxypancuronium.[43] Pancuronium has a prolonged terminal elimination half-life in patients

Table 65-10 Pharmacokinetics Data for Nondepolarizing Muscle Relaxants in Normal and Anephric Patients

Drug	Patients Studied	Elimination Half-Life (hr)	Clearance (mL/kg/min)	Volume of Distribution (L/kg)
Vecuronium	Normal	0.9	5.3	0.20
	Anephric	1.4	3.1	0.24
Atracurium	Normal	0.3	6.1	0.18
	Anephric	0.4	6.7	0.22
Tubocurarine	Normal	1.4	2.4	0.25
	Anephric	2.2	1.5	0.25
Pancuronium	Normal	1.7	1	0.14
	Anephric	8.2	0.3	0.14
Metocurine	Normal	6	1.2	0.57
	Anephric	11.4	0.4	0.48
Rocuronium	Normal	0.71	2.9	0.207
	Anephric	0.97	2.9	0.264
Cisatracurium	Normal	—	5.2	0.031
	Anephric	—	—	—
Mivacurium	Normal	0.03	106	0.278
	Anephric	0.06	80	0.475

with reduced renal function (see Table 65-10),[44] so it should be administered cautiously, particularly when several doses are required.

Two nondepolarizing muscle relaxants, atracurium and vecuronium, were introduced into clinical practice during the early 1980s. Atracurium is degradated by enzymatic ester hydrolysis and nonenzymatic alkaline degradation (Hofmann elimination) to inactive products that are not dependent on renal excretion for termination of action.[45] Predictably, their terminal elimination half-life and indices of neuromuscular blockade (onset, duration, and recovery) are the same in patients with normal and absent renal function.[46]

About 30% of a dose of vecuronium is eliminated by the kidneys. Lynam and colleagues[47] found that the duration of neuromuscular blockade after the administration of vecuronium was longer in patients with renal failure than in patients with normal renal function (99 minutes versus 54 minutes) because of a longer elimination half-life (83 minutes versus 52 minutes) and lower plasma clearance (3.1 mL/kg/min versus 5.3 mL/kg/min). In a related area, an interaction between the solvent of cyclosporine (Cremophor) with atracurium and vecuronium has been reported, with the action of these muscle relaxants potentiated in cats,[48] but it is unknown whether such potentiation also occurs in human renal transplant recipients.

Cisatracurium is the single *cis* isomer of atracurium. Organ-independent mechanisms (Hofmann elimination) account for 77% of the total clearance of cisatracurium. Because renal excretion accounts for only 16% of the elimination of cisatracurium, renal failure should have little impact on its duration of action.[46]

The short-acting drug mivacurium is metabolized by plasma pseudocholinesterase. Its effect has been shown to be lengthened by 10 to 15 minutes in patients with ESRD, most likely because of a decrease in plasma cholinesterase activity in these patients associated with uremia or hemodialysis,[49,50] and a decrease in the mivacurium requirement by infusion in anephric patients.[50]

The elimination half-life of rocuronium is increased in renal failure because of an increase in the volume of distribution with no change in clearance. This explanation may account for a longer duration of action in anephric patients, although its clinical significance is uncertain.[51]

Pharmacokinetics data for the cholinesterase inhibitors neostigmine, pyridostigmine, and edrophonium for normal, anephric, and renal transplant patients are presented in Table 65-11; there are no major differences among the three drugs.[52-54] Renal excretion is of major importance for the elimination of all three agents, with approximately 50% of neostigmine and 70% of pyridostigmine and edrophonium excreted in urine. Excretion of all the cholinesterase inhibitors is delayed in patients with impaired renal function to the same or perhaps to a slightly greater extent than is elimination of muscle relaxants. "Recurarization" after reversal of neuromuscular blockade in a patient with renal failure is, in most cases, due to some other cause, such as an interaction of the residual muscle relaxant with an antibiotic or a diuretic. Table 65-11 contains data indicating that the pharmacokinetics of all the cholinesterase inhibitors is similar in normal patients and patients with well-functioning newly transplanted kidneys.

Comparable findings have been reported for tubocurarine pharmacokinetics, and they probably hold for the disposition of pancuronium. As a category, transplant recipients with well-functioning kidneys can be considered normal in the way that they eliminate renally excreted drugs. There is sufficient interindividual variability in these data, however, to indicate that treatment with muscle relaxants and their antagonists should be individualized, as determined by clinical signs and the results of tests with a nerve stimulator.

Table 65-11 Pharmacokinetics Data for Cholinesterase Inhibitors in Normal, Anephric, and Renal Transplant Patients

Drug	Patients Studied	Elimination Half-Life (hr)	Clearance (mL/kg/min)	Volume of Distribution (L/kg)
Neostigmine	Normal	1.3	8.4	0.7
	Anephric	3*	3.9*	0.8
	Renal transplant	1.7	9.4	1.1
Pyridostigmine	Normal	1.9	8.6	1.1
	Anephric	6.3*	2.1*	1
	Renal transplant	1.4	10.8	1
Edrophonium	Normal	1.9	8.2	0.9
	Anephric	3.6*	2.7*	0.7
	Renal transplant	1.4	9.9	0.9

Vasopressors and Antihypertensive Drugs

Patients with severe renal disease are frequently given antihypertensive and other cardiovascular medications (see Chapter 12). More than 90% of the thiazides[55] and 70% of furosemide[56] are excreted by the kidney and have prolonged durations of action in patients with abnormal or absent renal function. Propranolol is almost completely metabolized in the liver, and esmolol is biodegraded by esterases in the cytosol of red blood cells, so their effects are not prolonged in patients with abnormal or absent renal function.[57] The calcium channel–blocking agents nifedipine, verapamil, and diltiazem are extensively metabolized in the liver to pharmacologically inert products; they may be administered in usual doses to patients with renal insufficiency.[58] Nitroglycerin is useful because it is metabolized rapidly, with less than 1% excreted unchanged in urine.[59]

Sodium nitroprusside has had a resurgence in use since its initial introduction as a hypotensive drug in the 1920s. Cyanide is an intermediate in the metabolism of sodium nitroprusside, with thiocyanate being the final metabolic product. Although cyanide toxicity as a complication of sodium nitroprusside therapy is well described,[60] it is less well appreciated that thiocyanate is also potentially toxic. The half-life of thiocyanate is normally more than 4 days, and it is prolonged in patients with renal failure.[60] Hypoxia, nausea, tinnitus, muscle spasm, disorientation, and psychosis have been reported when thiocyanate levels are greater than 10 mg/100 mL. Sodium nitroprusside is less desirable for prolonged administration than either trimethaphan or nitroglycerin.

Hydralazine is slower acting than the other three drugs discussed previously. Its action is terminated by hydroxylation and subsequent glucuronidation in the liver, with approximately 15% excreted unchanged in urine.[61] The elimination half-life of hydralazine is prolonged in uremic patients, so caution is required when it is administered.[62] After a single intravenous dose of 0.5 mg/kg of labetalol, the volume of distribution, clearance, and elimination half-life were similar in patients with ESRD and normal volunteers.[63] Esmolol is independent of renal function because it is metabolized by red blood cell cytosol esterases.[64]

If administration of a vasopressor is necessary, a direct α-adrenergic-stimulating drug such as phenylephrine would be effective. This type of vasopressor causes the greatest interference with renal circulation. Although β-adrenergic-stimulating drugs such as isoproterenol maintain heart and brain perfusion without renal vasoconstriction, they also increase myocardial irritability. When possible, it is best to substitute simple measures such as blood volume expansion for drug therapy. If these measures are inadequate, β-adrenergic-stimulating drugs or dopamine should be used.

Acute Renal Failure and Hemodialysis

Acute Renal Failure

Acute renal failure (ARF) is defined as the sudden inability of the kidneys to vary urine volume and content appropriately in response to homeostatic needs. Synonymous terms are *acute tubular necrosis* and *lower nephron nephrosis*. The three major types of ARF when classified according to their predominant etiologic antecedents are prerenal (caused by acute circulatory problems that impair renal perfusion), renal (caused by primary or secondary renal disease, toxins, and pigments), and postrenal (caused by obstruction of the urinary tract).[65] Table 65-12 lists common prerenal, renal, and postrenal causes of perioperative oliguria. Prerenal failure is usually reversible if the circulatory status is promptly improved; postrenal failure is reversible when the obstruction is removed. ARF secondary to primary renal disease is the most serious of the three types and most often requires hemodialysis.

Renal failure also is classified according to urine flow rates, so the terms *oliguric, nonoliguric,* and *polyuric renal failure* are often encountered. The diagnosis of acute oliguric renal failure is made when creatinine and BUN concentrations progressively increase while urine flow remains less than 20 mL/hr in an adequately hydrated patient who has stable blood pressure and a patent urinary outflow tract. Urine chemistry values are as indicated in Table 65-13. In some cases, patients with ARF may have normal or high (>2.5 L/day) urine flow rates, but they have biochemical abnormalities that are similar to the abnormalities occurring in patients with low urine output. Their management is less complex than that of oliguric patients because adequate drug therapy and proper nutrition are easier to maintain, given the less stringent limitations on daily fluid intake.

The major problem arising from ARF is an inability to maintain dynamic balance between dietary intake of essential substances and production of waste products. This imbalance results in a progressive increase in serum urea, creatinine, uric acid, magnesium, sulfate, phosphate, some amino and organic acids, and polypeptides; a daily increase in serum potassium of 0.3 to 3 mEq/L except when there is concomitant potassium loss from diarrhea or vomiting (greater increases may occur in trau-

matized or postsurgical patients); a decrease in serum sodium and calcium; a decrease in serum proteins, particularly albumin; a consistent increase in total reducing substance in serum, frequently occurring with true hyperglycemia, which may be either sensitive or resistant to insulin; elevation of total lipids, cholesterol, phosphorus, and neutral fats; and metabolic acidosis.[65,66] The kidney functions as an endocrine and as an excretory organ. Disorders of renin-angiotensin and aldosterone secretion occur and contribute to the hypertension that develops in patients with severe renal disease. Reduced erythropoietin production leads to anemia. Heart failure and abnormalities in liver function and blood coagulation also may occur in patients with renal shutdown. Infection is common and difficult to treat because the altered excretion of antibiotics leads to the rapid development of toxic levels of these drugs.

When established, oliguria is usually present for 10 to 18 days, but may persist for 30 to 45 days. During this period, hemodialysis is required every 2 to 4 days. When diuresis occurs, the beginning of the recovery phase is signaled. During the diuretic phase, urine volume gradually increases until 5 to 6 L of urine is produced daily. Management of the patient is directed at maintaining fluid and electrolyte balance in the face of these large losses. Finally, concentrating ability gradually returns toward normal. Complete return of all measurable parameters of renal function occurs in approximately two thirds of patients who survive. Fifty percent to 60% of patients with ARF do not survive long enough for recovery or the development of CRF, however.[67] Arrhythmias, bleeding, and infection are the most frequent causes of death.

Outcome analysis indicates that the overall mortality rate from ARF has not been significantly reduced in recent years despite earlier and more frequent dialysis. It is likely that there has been an increase in the survival rate of some categories of patients without any change in the overall rate because of an increase in the proportion of seriously ill patients who are now treated in dialysis units. This conclusion is suggested by the steady improvement in mortality data of obstetric patients with renal failure. The low (15%) mortality rate for this group emphasizes that the most significant feature determining survival is the physical status of the patient before the onset of renal failure.

As noted earlier, many patients with ARF have normal or high urinary flow rates. In these patients, the antecedent cause of renal failure may be the same as that in patients with classic oliguric renal failure, but an oliguric or anuric phase is not identifiable. Patients are unable to alter urinary volume and content appropriately, with an average daily output often greater than 2.5 L/day. The more frequent incidence of nonoliguric and polyuric renal failure in recent years compared with the 1940s and 1950s is thought to be due, in part, to more vigorous early treatment of patients with incipient oliguric renal failure.

Hemodialysis

The steady improvement in hemodialysis techniques (see Chapter 67) from the first artificial kidney developed in 1944 by Kolf and Berk[68] to the current practice of home dialysis has resulted in additional years of productive life for patients with CRF. This improvement, coupled with the 1976 federal legislation extending Medicare coverage to renal failure patients, has resulted in a large increase in the number of hemodialysis patients. Dialysis improves most of the signs and symptoms of uremia (e.g., volume overload, acid-base and electrolyte imbalance, abnormal mental function, peripheral neuropathy, muscle weakness, and defective coagulation). Hypertension is improved except in patients with high renin levels. Some patients have been undergoing hemodialysis for more than 10 years. The 3-year survival rate for U.S. patients 20 to 25 years old treated by hemodialysis is 85%; for patients 60 to 65 years old, 3-year survival is 60%.

Presently, two basic dialysis techniques are used: peritoneal dialysis and hemodialysis. Peritoneal dialysis can be either

Table 65-13 Urinary Composition of Oliguria

	Physiologic Oliguria	Prerenal Failure	Acute Tubular Necrosis
Urinary sodium	<10 mEq/L	<25 mEq/L	>35 mEq/L
Urinary specific gravity	>1.024	>1.015	1.010-1.015
Urinary osmolality	>700 mOsm/kg	>500 mOsm/kg	<350 mOsm/kg
Urinary/plasma osmolality	>2.5:1	>1.8:1	≤1.1:1
Urinary/plasma urea	>100:1	>20:1	3:1, rarely >10:1
Urinary/plasma creatinine	>60:1	>30:1, rarely <10:1	<10:1
Fractional sodium excretion	<1	>1	>0.5

long-term intermittent or continuous ambulatory; both are performed at home dialysis centers. In most circumstances, hemodialysis is used, and it is generally the method of choice. Peritoneal dialysis is preferred for patients who have had (1) recent cerebral surgery, a cerebrovascular accident, or trauma because the risk of fluid shifts or bleeding after heparinization is greater with hemodialysis; (2) recent cardiac surgery or a myocardial infarction because the risk of hypotension and arrhythmias is greater with hemodialysis; (3) a recent acute hemorrhage; or (4) a severe coagulopathy. Peritoneal dialysis also is frequently used in children.

The dialysis principle involves equilibration of waste products in the patient's blood across a semipermeable membrane to the dialysis bath. Peritoneal dialysis relies on the patient's peritoneum as the exchange membrane, avoiding the need for vascular cannulas and expensive equipment. Exchange volume rates during peritoneal dialysis are 1 to 3 L/hr. Clearance of small molecules is less than with hemodialysis (e.g., urea, 25 versus 150 mL/min), but clearance of large molecules is greater. The ionic content of the dialysate may be altered to suit the patient's needs, and the fluid may be made hypertonic or hypotonic to plasma to remove or add fluid to the patient's extracellular fluid volume. Peritoneal dialysis is less efficient than hemodialysis, so dialysis times are longer. In addition, peritonitis is a danger, and pain during dialysis may be severe.

Hemodialysis is the most commonly used dialysis technique today. Originally, polytetrafluoroethylene (Teflon) shunts were inserted between the radial artery and a forearm vein with a connector between them to allow access to the circulation. Today, vascular access is usually obtained by the creation of an end-to-side arteriovenous fistula in the forearm or by insertion of a prosthetic arteriovenous graft when the vessels are inadequate. During hemodialysis, which is performed two or three times weekly, the patient and the external circuit are heparinized to prevent clotting. Flow rates are usually 500 mL/min, so the patient's blood is exposed to 120 L of fluid during a standard 4-hour dialysis. Variation in ionic content and osmolarity of the dialysate permit correction of abnormalities in fluid and electrolyte balance. If fluid and electrolyte shifts are too rapid, dialysis dysequilibrium may occur. This syndrome is characterized by weakness, nausea, and vomiting, and occasionally convulsions and coma. In the interval between treatments, clotting does not occur because the shunted circuit is short, and blood flow is rapid (150 to 300 mL/min).

Local infiltration, axillary block, and general anesthesia have been used successfully for creation of arteriovenous fistulas (see Chapters 52 and 53). Several anesthetic precautions are appropriate. Uremic patients may be debilitated, in which case smaller doses of all drugs, including local anesthetics, should be administered. Hyperkalemia, acidosis, and overhydration can combine to cause myocardial irritability; local anesthetic solutions that contain epinephrine should be used with caution. If epinephrine is used, concentrations greater than 1:200,000 are not necessary, and solutions as dilute as 1:400,000 are probably adequate. Brachial plexus block may facilitate greatly the introduction of cannulas by producing analgesia combined with peripheral vasodilation. Bromage and Gertel[68a] reported that brachial plexus block had a 38% shorter duration in renal failure patients than in patients with normal renal function. This finding could not be confirmed, however, in a subsequent study of renal failure patients.[68b]

Preservation of Renal Function

Conducting renal preservation therapy studies is difficult because ARF has multiple etiologies, occurs in multiple clinical settings, affects patients with normal versus preexisting renal disease, and has therapy initiation before onset or after newly diagnosed renal insufficiency (see Chapter 96). It is estimated that 5% of hospitalized patients experience renal failure, resulting in greater than 50% mortality. Optimizing patients with renal insufficiency and perioperative renal preservation remain important goals. It is crucial to renal preservation strategies to maintain adequate renal oxygen delivery by maintaining circulating blood volume and oxygen carrying capacity.

Dopamine has been used for decades to prevent or ameliorate renal insufficiency. Use of dopamine is criticized because of the lack of prospective, large, randomized clinical trials revealing a permanent, positive outcome. An adequately powered study of septic patients in critical care revealed that dopamine at 2 μg/kg/min for nearly 4 days failed to protect from renal dysfunction.[69] A large dopamine meta-analysis by Friedrich and colleagues[70] involved 3359 patients in 61 trials using dopamine at 5 μg/kg/min or less. Analysis revealed a significant increase in urine output of 24% on day 1, but improved serum creatinine and creatinine clearance observed on day 1 were clinically insignificant. Overall, dopamine therapy had no effect on mortality, need for renal replacement therapy, or incidence of adverse events. Off-label use of the dopamine-1 receptor agonist fenoldopam has generated interest in renal preservation. A meta-analysis involving 1290 patients in 16 randomized controlled trials by Landoni and coworkers,[71] including critical care unit patients and patients undergoing major surgery, suggested that fenoldopam reduced the need for renal replacement therapy and mortality during episodes of acute renal injury. The authors cautioned that a large, multicenter, adequately powered trial is needed to confirm these results.

Mannitol has been described to have a protective renal effect if administrated in the setting of a preischemic renal insult therapy. This benefit is postulated to occur by renal vasodilation via prostaglandin effect, from free radical scavenging to reduce the effects of hydroxyl-type free radical injury, and by maintaining or improving urine production as an osmotic diuretic to diminish tubular obstruction. Loop diuretics continue to be administered in the clinical setting without reproducible evidence of a renoprotective perioperative benefit. A meta-analysis by Ho and Sheridan[72] analyzing 849 patients in 23 randomized controlled trials evaluated the need for renal placement therapy and mortality. The findings revealed a lack of support for any significant clinical benefit using furosemide. The antioxidant *N*-acetyl cysteine and intravenous $NaHCO_3$ therapy have been used and evaluated mainly in the setting of contrast-induced nephropathy with inconsistent conclusions regarding revealing a renal preservation benefit. In analysis of 12 meta-analyses evaluating *N*-acetyl cysteine during intravenous contrast dye exposure, 9 suggested improved renal outcomes.[73] Significant study heterogenicity was cited as the primary reason by this review to prevent a conclusion regarding a positive benefit of *N*-acetyl cysteine therapy.

Several additional renal preservation therapy studies, including the use of atrial natriuretic peptide, theophylline, dopexamine (β_2-agonist), calcium channel blockers, prostaglan-

din E_1, growth factors, hemodialysis, and hemofiltration, have been published. Results from these clinical trials are often inconsistent across similar studies and cannot yet be recommended as standard therapy for clinical use as part of a standard renal preservation strategy.

Renal and Genitourinary Procedures

Transurethral Resection of the Prostate

Pathophysiology of Prostate Hypertrophy

The prostatic gland consists of four closely integrated zones—the anterior, peripheral, central, and preprostatic zones. Each zone consists of secretory, smooth muscle, and fibrotic tissue. All four zones are enclosed in one capsule. The gland is rich in blood supply. Arteries and veins penetrate the prostatic capsule and branch inside the gland. The venous sinuses adjacent to the capsule are particularly large. Nodules begin to develop by the fourth decade of life in the preprostatic zone and form middle, lateral, and posterior lobes. The middle and posterior lobes are most often associated with symptoms of urinary tract obstruction.[74]

Surgical Procedures

Transurethral resection of the prostate (TURP) is performed by inserting a resectoscope through the urethra and resecting prostatic tissue with an electrically powered cutting-coagulating metal loop. As much prostatic tissue as possible is resected, but the prostatic capsule is usually preserved. If the capsule is violated, large amounts of irrigation solution are absorbed into the circulation and the periprostatic and retroperitoneal spaces.

Bleeding during TURP is common, but usually controllable; however, when large venous sinuses are opened, hemostasis becomes difficult. If bleeding becomes uncontrollable, the procedure should be terminated as quickly as possible, and a Foley catheter should be passed into the bladder and traction applied to it. The catheter's inflated balloon exerts lateral pressure on the prostatic bed and reduces bleeding. Bleeding requiring transfusion occurs in about 2.5% of TURP procedures.[75]

Irrigation Solutions

Ideally, an irrigation solution for TURP should be isotonic, electrically inert, nontoxic, transparent, easy to sterilize, and inexpensive. Such a solution does not exist. Distilled water is electrically inert and inexpensive and has excellent optical properties, but it is extremely hypotonic. When absorbed into the circulation in large amounts, plain water causes hemolysis, shock, and renal failure.

Numerous nearly isotonic irrigation solutions are available. Commonly used solutions are glycine 1.2% and 1.5%, mannitol 3% to 5%, glucose 2.5% to 4%, sorbitol 3.5%, Cytal (a mixture of sorbitol 2.7%, and mannitol 0.54%), and urea 1% (Table 65-14). These solutions are purposely moderately hypotonic to preserve their transparency.

Although they cause no significant hemolysis, excessive absorption of these irrigation solutions might lead to other complications, such as pulmonary edema and hyponatremia. In addition, the solutes may have adverse effects. Glycine may cause cardiac and retinal toxic effects, mannitol rapidly expands the blood volume and might cause pulmonary edema in cardiac patients, and glucose might cause severe hyperglycemia in diabetic patients. These complications are discussed in detail later.

Table 65-14 Osmolality of Irrigation Solutions Used for Transurethral Resection of the Prostate

Solution	Osmolality (mOsm/kg)
Glycine, 1.2%	175
Glycine, 1.5%	220
Sorbitol, 3.5%	165
Mannitol, 5%	275
Cytal (see text)	178
Glucose, 2.5%	139
Urea, 1%	167

Replacement of distilled water with nearly isosmotic solutions has eliminated hemolysis and its sequelae as a complication of TURP. The incidence of severe CNS problems associated with extreme hyponatremia, such as convulsions and coma, has been reduced. The other major problem associated with the absorption of large volumes of irrigating solution, overhydration, still remains, however.

Anesthetic Techniques

Spinal anesthesia is the most frequently used anesthetic for TURP in the United States and is believed to be the technique of choice by many anesthesiologists. A spinal anesthetic provides adequate anesthesia for the patient and good relaxation of the pelvic floor and the perineum for the surgeon. The signs and symptoms of water intoxication and fluid overload can be recognized early because the patient is awake. Accidental bladder perforation also is recognized easily if the spinal level is limited to T10 because the patient would experience abdominal or shoulder pain. Satisfactory regional anesthesia for TURP involves achieving an anesthetic block level that interrupts sensory transmission from the prostate and bladder neck. In addition, the uncomfortable sensation of bladder distention must be considered.[76,77]

As explained earlier, the visceral pain sensation from the prostate and bladder neck is transmitted by afferent parasympathetic nerve fibers derived mostly from the second and third sacral roots traveling with the pelvic splanchnic nerves. Bladder sensation is supplied by sympathetic nerves of the hypogastric plexus, derived from nerve roots extending inferiorly from T11 to L2. Regional anesthesia resulting in a sensory level to T10 is required to eliminate the discomfort caused by bladder distention and other aspects of this procedure; however, slightly lower sensory levels often suffice for smaller lesions. In one study in which bladder pressure was monitored and kept low, anesthetic levels to T12 or L1 were adequate, but midlumbar blocks to L3 were not.[78] Sensory levels above T9 should not be sought because the capsular sign (i.e., pain on perforation of the prostatic capsule) would not be present should perforation occur.

Subarachnoid anesthesia is generally preferred over continuous epidural anesthesia for the following reasons. It is technically easier to perform in elderly patients, and the duration of surgery is generally not very long. The incomplete block of sacral nerve roots that occasionally occurs with the extradural technique is usually avoided with subarachnoid anesthesia.

Caudal and sacral blockade also has been used effectively for prostate surgery, and bladder distention is avoided with the use of continuous irrigation. Caudal anesthesia has been used effectively in high-risk patients undergoing laser prostatectomy.[79] Hemodynamic stability is the main advantage with this technique. Local infiltration of the perineum and the prostatic fossa also has been advocated by some anesthesiologists for limited TURP procedures, although the operative analgesia afforded by local infiltration is not comparable in quality to spinal anesthesia. General anesthesia may be necessary in patients who require ventilatory or hemodynamic support, have a contraindication to regional anesthesia, or refuse regional anesthesia.

Advantages of Regional Anesthesia over General Anesthesia

Regional anesthesia offers several advantages over general anesthesia for TURP (see Chapter 51). The incidence of deep vein thrombosis is decreased, and the amount of operative blood loss is reduced with regional anesthesia compared with general anesthesia. The reduction in operative blood loss when regional rather than general anesthesia is used has been shown to be the case in other pelvic procedures in addition to TURP, such as cystectomy and major vaginal surgery.[80] The decrease in systemic blood pressure secondary to the sympathetic blockade produced by the regional technique was determined not to be the only factor in reducing blood loss. Good evidence indicates that peripheral venous pressure and central venous pressure decrease during regional anesthesia and spontaneous ventilation. It is postulated that this decrease in peripheral venous pressure might result in reduced blood loss during prostatic and other surgery.

Additional factors influencing blood loss during TURP are the vascularity and size of the gland and the duration of surgery. An increase in fibrinolysis during prostate resection as a result of the release of urokinase from prostate tissue also factors into the blood loss that occurs. Other factors that affect blood loss during TURP include the size of the gland, the duration of the procedure, the number of sinuses opened during resection, the presence of infection, and prostate inflammation from repeated or recent catheterizations. These factors make it quite difficult to compare studies evaluating blood loss during TURP or to arrive at conclusive findings based on meta-analysis.[75,77]

Patients undergoing prostatectomy are prone to deep vein thrombosis for many reasons, including advanced age and the presence of malignancy, cardiac disease, varicose veins, and obesity. In this case, the increased blood flow resulting from the sympathetic blockade of regional anesthesia may play a role in reducing deep vein thrombosis formation.[81] More recent data also confirm the earlier belief that regional anesthesia decreases the hypercoagulable tendency in the postoperative period and helps maintain normal coagulation and platelet function; these benefits are believed to be due to modulation of the neuroendocrine response to tissue injury. There is evidence that homeostasis of the neuroendocrine system and the immune response are better preserved after regional anesthesia than after general anesthesia.[81]

TURP is associated with a particular set of complications with anesthetic implications. These problems must be considered, along with the usual considerations, such as the general health of the patient, the length of the procedure, and patient and surgeon preferences, when choosing an anesthetic technique.

The use of regional anesthesia for TURP can allow the anesthesiologist the advantage of monitoring the patient's mental status intraoperatively. Excessive absorption of irrigating fluid during the procedure produces numerous problems with cardiovascular and neurologic implications. A change in the patient's mental status provides an early indication that excessive absorption of irrigating fluid has occurred. These changes are described more fully in the next section.

Visual disturbances, such as blurred vision and transient blindness, have been reported in association with TURP (see Chapter 90). The biotransformation of absorbed glycine to ammonia has been implicated in these and other CNS abnormalities. Another potential complication during TURP is bladder perforation secondary to overdistention with irrigation fluid or contact of the bladder wall with the surgeon's resectoscope. Conscious patients may experience symptoms related to perforation well before it becomes apparent to the surgeon, alerting the operating team early on. Signs and symptoms of bladder perforation include bradycardia, hypotension, restlessness, diaphoresis, nausea, abdominal pain, dyspnea, shoulder pain, and hiccups. Extraperitoneal perforation may be manifested as pain in the periumbilical, inguinal, or suprapubic area. Intraperitoneal bladder perforation, a less frequent event, may cause symptoms related to diaphragmatic irritation (i.e., pain referred to the upper part of the abdomen, precordial area, shoulder region, or neck).[81]

Regional anesthesia for TURP offers some advantages over general anesthesia. Although laboratory monitoring of electrolytes is useful intraoperatively, a change in mental status in a conscious patient provides an early indication of electrolyte disturbances. Bladder perforation is recognized earlier in a conscious or lightly sedated patient, as noted previously.

Sensory levels above T9 are undesirable because pain caused by perforation of the prostatic capsule (capsular sign) would not be apparent to the patient if this complication occurs. Another benefit of regional anesthesia for TURP is a decreased requirement for analgesics in the immediate postoperative period compared with general anesthesia.[82]

Morbidity and Mortality after Transurethral Resection of the Prostate

Although spinal anesthesia offers certain distinct advantages over general anesthesia for TURP surgery, mortality and many markers of patient outcome have been similar for both groups. What constitutes the safest anesthetic for prostatectomies was debated in 1924, with proponents of regional anesthesia gaining ground quickly thereafter.[83] Currently, the 30-day mortality rate associated with TURP is 0.2% to 0.8%.[77] Mortality rates are similar in patients receiving regional anesthesia or general anesthesia.[84] With mortality rates as low as 0.2%, however, many more patients need to be studied than previously examined in any of the studies to draw a meaningful and statistically significant conclusion.[76] The postoperative morbidity rate in one study was 18%.[77] Increased morbidity was found in patients with resections exceeding 90 minutes, gland size larger than 45 g, acute urinary retention, and age older than 80 years.[77] Ashton and coworkers[85]

studied 250 men undergoing TURP and observed one postoperative myocardial infarction (0.4%) resulting in one death. The incidence of postoperative complications, including myocardial infarction, pulmonary embolism, cerebrovascular accidents, transient ischemic attacks, renal failure, hepatic insufficiency, and the need for prolonged ventilation, is similar when comparing patients receiving regional anesthesia with patients receiving general anesthesia.[75,77]

Many investigators have studied postoperative cognitive function after TURP performed under general versus regional anesthesia. Most studies have failed to show any significant difference in cognitive function in patients receiving regional anesthesia and patients receiving general anesthesia.[86] Postoperative behavioral changes in TURP patients are believed to be related to fluid absorption and increased cerebral fluid; cerebral oximetry studies have confirmed this relationship.[87] Preoperative mental impairment in elderly patients also influences postoperative mental function, which makes another case against the use of heavy sedation in these patients.

Complications of Transurethral Resection of the Prostate

Absorption of Irrigating Solution

Because the prostate gland contains large venous sinuses, it is inevitable that irrigating solution would be absorbed. Simple principles govern the amount of absorption: (1) The height of the container of irrigating solution above the surgical table determines the hydrostatic pressure driving fluid into prostatic veins and sinuses, and (2) the time of resection is proportional to the quantity of fluid that is absorbed. On average, 10 to 30 mL of fluid is absorbed per minute of resection time, with 6 to 8 L absorbed in some procedures lasting up to 2 hours. Whether patients experience complications as a consequence of the absorption of irrigating fluid depends on the amount and type of fluid absorbed.[88,89]

Excessive Circulatory Volume, Hyponatremia, and Hypo-osmolality

Solutions such as normal saline and lactated Ringer's solution would be well tolerated when absorbed intravascularly, but these electrolyte solutions are highly ionized and facilitate the dispersion of high-frequency current from a monopolar resectoscope. Solutions of nonelectrolytes, such as glucose, urea, glycine, mannitol, sorbitol, or Cytal, have replaced distilled water. Of all the irrigating solutions available today (see Table 65-14), glycine and Cytal are the two most commonly used.[88]

Replacement of distilled water with nearly isosmotic solutions has eliminated hemolysis and its sequelae as a complication of TURP. The incidence of severe CNS problems associated with extreme hyponatremia, such as convulsions and coma, has been reduced[89]; however, the other major problem associated with the absorption of large volumes of irrigating solution, overhydration, remains. Under usual conditions, only 20% to 30% of a load of crystalloid solution remains in the intravascular space; the remainder enters the interstitial space. When intravascular pressure is increased, movement of fluid into the interstitial space and the development of pulmonary edema are favored. Whether symptoms of circulatory overload develop in a given patient depends on the patient's cardiovascular status, the amount and rapidity of absorption of irrigating fluid, and the extent of surgical blood loss.[89]

The situation is dynamic, and patients must be monitored carefully. In this regard, spinal or epidural anesthesia, supplemented with only light intravenous sedation, has the advantage of allowing the patient's subjective judgment to contribute to assessment of his or her condition during surgery. In addition, the cardiovascular depression associated with the administration of potent inhaled anesthetics is avoided. Another advantage of regional anesthesia is that the sympathetic block that it produces increases venous capacitance and tends to mitigate intraoperative fluid overload. When the block dissipates, venous capacity acutely decreases, and circulatory overload can occur.

Concomitant with the circulatory overload caused by significant absorption of irrigating fluid are usually hyponatremia and hypo-osmolality. TURP syndrome has been typically described as being caused by hyponatremia and subsequent water intoxication. It is now recognized that the classic CNS signs of TURP are not caused by hyponatremia per se, but are due to the accompanying acute serum hypo-osmolality that allows movement of water into cells and causes cerebral edema.[88,89]

The use of nonelectrolyte isosmotic irrigating solutions has reduced the incidence of severe CNS complications because extreme extracellular fluid hypo-osmolality does not occur, and the subsequent development of cerebral edema is avoided.[88,89] That CNS symptoms occur at all is probably due to the fact that the incidence and extent of hyponatremia are unchanged. The concentration of extracellular sodium must be in the physiologic range for depolarization of excitable cells and production of the action potential. CNS symptoms, which include irritability, apprehension, confusion, and headache, provide early warning signs of rapidly developing hyponatremia. Further progression of hyponatremia (sodium ≤102 mEq/L) and decreased serum osmolality lead to the development of seizures and coma. The CNS effects become apparent at sodium levels less than 120 mEq/L. The cardiovascular effects of severe hyponatremia include negative inotropy, hypotension, and dysrhythmias. At sodium levels less than 115 mEq/L, electrocardiogram changes are made manifest by QRS widening and ST-segment elevation.[81]

When extracellular sodium levels are less than 100 mEq/L, consciousness is lost, and convulsions may ensue.[89] Signs and symptoms of cardiovascular dysfunction secondary to hyponatremia also may occur, including arrhythmias, hypotension, and pulmonary edema.[90] It is often impossible, however, to separate the latter events from events attributable to fluid overload.

Glycine Toxicity

Since the early 1980s, attention has turned to the absorption of glycine (HO_2—CCH_2—NH_2), a nonessential amino acid, as a possible cause of some CNS symptoms associated with TURP. In one publication, five cases of transient blindness were attributed to glycine toxicity.[91] Glycine has a distribution similar to that of aminobutyric acid, the latter being an inhibitory transmitter in the brain; it has been suggested that glycine is a major inhibitory transmitter acting in the spinal cord and brainstem.[91] Normal plasma glycine levels are 13 to 17 mg/L, whereas levels of 1029 mg/L were measured during one episode of blindness. Twelve hours later, the glycine level in this case had declined to 143 mg/L, by

which time vision had returned; however, an overall correlation between plasma glycine levels and CNS toxicity has not been established, so the relationship, although interesting, still must be considered speculative. Glycine also has been implicated in the myocardial depression and hemodynamic changes associated with TURP syndrome.[92]

Ammonia Toxicity

Absorption of glycine may result in CNS toxicity as a result of oxidative biotransformation of glycine to ammonia.[93,94] In a report of delayed awakening after TURP in three patients,[93] an association with elevated blood ammonia concentrations was noted. Blood ammonia levels of 500 M were noted in this and another case report.[94] Deterioration of CNS function is said to occur when ammonia levels are greater than 150 M. In a prospective study examining glycine metabolism, blood ammonia levels were increased postoperatively in 12 of 26 patients in whom 1.5% glycine was used as the irrigating solution for TURP.[93] Blood glycine levels also were measured. Glycine and ammonia levels did not correlate; the opposite relationship was prevalent. High ammonia levels were not associated with CNS symptoms of toxicity. Although the investigators postulated that delayed awakening and other CNS symptoms were due to ammonia toxicity, it is unclear whether this hypothesis is correct.

Perforation

Another common complication of TURP is perforation of the bladder.[95] Perforations usually occur during difficult resections and are most often made by the cutting loop or knife electrode. Some are made by the tip of the resectoscope, whereas others may result from overdistention of the bladder with irrigation fluid. Most perforations are extraperitoneal, and in a conscious patient they result in pain in the periumbilical, inguinal, or suprapubic regions; additionally, the urologist may note the irregular return of irrigating fluid. Less often, the perforation is through the wall of the bladder and is intraperitoneal, or a large extraperitoneal perforation may extend into the peritoneum. In such cases, pain may be generalized in the upper part of the abdomen or be referred from the diaphragm to the precordial region or the shoulder. Other signs and symptoms, such as pallor, sweating, abdominal rigidity, nausea, vomiting, and hypotension, have been reported; the number and severity depend on the location and size of the perforation and the type of irrigating fluid. In an early series of 2015 cases in which the incidence of complications of TURP was examined, perforation occurred in 25 patients (1.2%).[96] Four deaths and five additional major complications occurred in 12 patients in whom suprapubic cystostomy was delayed more than 2 hours after perforation. Distilled water was the bladder irrigant in most of these cases, so it is unclear whether these morbidity and mortality data are still relevant.

Transient Bacteremia and Septicemia

The prostate harbors many bacteria, which can be a source of intraoperative and postoperative bacteremia through the prostatic venous sinuses. This risk is increased further by the presence of an indwelling urinary catheter. Bacteremia is usually asymptomatic and easily treated with commonly used antibiotic combinations that are effective against gram-positive and gram-negative bacteria. In 6% to 7% of patients, septicemia may occur, however.[77] Common manifestations include chills, fever, and tachycardia. In severe cases, bradycardia, hypotension, and cardiovascular collapse may occur, with mortality rates of 25% to 75%. Aggressive treatment with antibiotics and cardiovascular support is warranted.

Hypothermia

Irrigating fluids stored at room temperature are frequently used during TURP. Heat loss as a result of irrigation and significant absorption of this fluid may lead to a decrease in the patient's body temperature and cause shivering. The use of warmed irrigating solutions has been shown to be efficacious in reducing heat loss and the resultant shivering.[97] Although one may believe that warming of fluids might cause increased bleeding because of vasodilation, such is not the case, as shown by the study of Heathcote and Dyer.[98] The use of systemic and intrathecal opioids decreases postoperative shivering from cold.[99]

Bleeding and Coagulopathy

A hypertrophied prostate is highly vascular, and operative bleeding can be significant. The blood is washed into the draining bucket and mixed with ample quantities of irrigant fluid. Estimation of blood loss is inaccurate and extremely difficult. Efforts have been made to quantify blood loss based on resection time (2 to 5 mL/min of resection time) and size of the prostate in grams (20 to 50 mL/g); however, these guidelines are rough estimates at best, and the patient's vital signs and serial hematocrit values should be monitored to assess better the blood loss and need for transfusion. Because adrenergic receptors are abundant in prostate tissue, the use of adrenergic agonists would cause vasoconstriction of prostatic blood vessels and a decrease in blood loss.

Abnormal bleeding after TURP occurs in less than 1% of cases; it is believed by some clinicians to be due to systemic fibrinolysis secondary to plasmin. The prostate releases plasminogen activator, which converts plasminogen to plasmin. Other clinicians believe that the fibrinolysis is secondary to disseminated intravascular coagulation triggered by the systemic absorption of resected prostate tissue, which is rich in thromboplastin.[75] If primary fibrinolysis is suspected, aminocaproic acid may be effective when given intravenously in a dose of 4 to 5 g during the first hour, followed by 1 g/hr.[75]

Treatment of Transurethral Resection of the Prostate Syndrome

Treatment of TURP syndrome (Table 65-15) consists of fluid restriction and a loop diuretic such as furosemide. Hypertonic saline (3% sodium chloride) is rarely, if ever, necessary and should be considered only in patients with severe hyponatremia. CNS complications of hypertonic saline include cerebral edema and pontine myelinolysis.[76,89] Cardiovascular support should be provided as necessary.

Anesthetic considerations for TURP should include positioning. TURP is usually performed in the lithotomy position with a slight Trendelenburg tilt. This positioning results in changes in pulmonary blood volume; a decrease in pulmonary compliance; a cephalad shift of the diaphragm; and a decrease in lung volume parameters such as residual volume, functional residual volume, tidal volume, and vital capacity. Cardiac preload may increase. Nerve injuries to the common peroneal, sciatic, and femoral nerves are likely.[76]

Table 65-15 Signs and Symptoms of Transurethral Resection of the Prostate Syndrome

Cardiovascular and Respiratory	Central Nervous System	Metabolic	Other
Hypertension	Agitation/confusion	Hyponatremia	Hypo-osmolality
Bradyarrhythmias/tachyarrhythmias	Seizures	Hyperglycinemia	Hemolysis
Congestive heart failure	Coma	Hyperammonemia	
Pulmonary edema and hypoxemia	Visual disturbances (blindness)		
Myocardial infarction			
Hypertension			

Laser Prostatectomy, Cryosurgery, and Microwave Ablation

Laser prostatectomy has found renewed interest among urologists and is being conducted in several centers. Based on initial experience, it promises to replace conventional TURP in the near future. The neodymium: yttrium-aluminum-garnet (Nd-YAG) laser has been replaced by holmium and potassium-titanyl-phosphate (KTP) lasers. These lasers produce varying degrees of coagulation and vaporization of prostate tissue. The main advantages over conventional TURP include minimal blood loss (50 to 70 mL) and minimal fluid absorption, which should nearly eliminate these two major complications of TURP; however, other potential complications are introduced, including coagulation through the prostatic fossa and sloughing of prostatic debris in the postoperative period, with subsequent urinary obstruction and urinary retention.[100-104] Protective eyewear and a means to evacuate the smoke plume are needed.[105] In critically ill patients, caudal anesthesia has been successfully used for laser prostatectomy because the use of continuous irrigation combined with minimal bleeding obviates the need for copious irrigation and minimizes bladder distention.[79]

In a systematic review of randomized, controlled trials evaluating the efficacy and safety of laser prostatectomy techniques versus TURP for symptomatic benign prostatic obstruction, the authors observed that TURP provided slightly greater improvement in urinary symptoms and flow. Laser procedures resulted in fewer transfusions and strictures and shorter hospitalizations. Reoperation was required more often after laser procedures.[106]

Cryosurgery has proved to be technically complex and has not attained much popularity. Microwave ablation of the prostate is another promising technique that can be performed on an outpatient basis under local or sacral block.

New Therapies for Transurethral Resection of the Prostate

Traditional monopolar electrode and previously described laser TURP therapies are currently being challenged with new urethral prostate resection techniques. Bipolar electrode resection and next-generation prostate lasers are proving to be alternative surgical therapies for benign prostatic hyperplasia resection. An advantage of bipolar electrode resection is that normal saline can be used to avoid morbidity associated with hypo-osmolar bladder irrigants such as glycine. Laser therapy delivers vaporization energy creating a thin resecting coagulation treatment zone that also can be created using normal saline bladder irrigation. Both treatments are promoted to prevent excessive prostatic bleeding, extend rather than limit resection time, and reduce hospital stay. Hanson and associates[107] reviewed the anesthetic implications of the newer prostate laser resection therapies. The described advantages included minimal bladder irrigating fluid absorption, a minimized risk of TURP syndrome, potential to perform the procedure on anticoagulated patients, delivery in an outpatient setting, and less emphasis on describing regional as the preferred anesthetic technique.

Laser Lithotripsy

Laser lithotripsy is used for ureteral stones that are low in the ureter and not amenable to extracorporeal shock wave lithotripsy (ESWL). A pulsed dye laser is generated with a laser beam of 504-nm wavelength passing through an organic green dye.[108] This laser beam is easily absorbed by the stones, and pulsatile energy is released that causes disintegration of the stones. The beam is carried over a bare wire passed through a rigid ureteroscope, which is longer and more pointed than a cystoscope, so the risk of ureteral perforation exists. Ideally, general anesthesia with paralysis should be maintained to avoid patient movement. If regional anesthesia is chosen, a spinal level of T8 to T10 is required. The bare laser wire is sharp and can cause mucosal injury to the ureter. These lasers are not well absorbed by red blood cells or other tissues, however, which provides safety against tissue coagulation or thermal injury. Because the laser beam is reflective, the user, other personnel, and the patient should wear protective eyeglasses. Some hematuria always occurs; good intravenous hydration is recommended.[108]

Laparoscopic Surgery in Urology

Urologic laparoscopic surgery continues to pioneer new surgical approaches for treatment of diseases previously performed by an open surgery. Advances in this area now routinely include laparoscopic varicocelectomy, hernia repair, adrenalectomy, partial adrenalectomy, renal pelvis or ureter percutaneous stone retrieval, nephrectomy, radical prostatectomy, extra-adrenal pheochromocytoma, nephropexy, pyeloplasty, nephrectomy, partial nephrectomy, and cystectomy. Many of these surgeries are robot assisted for tumor resection and reconstruction. During robotic laparoscopic surgery, the surgeon is stationed in the operating room away from the operating room table while working at a computer

console with a three-dimensional view of the operating field and manual controls at the console for robotic instruments placed in the abdomen via laparoscopy trocars.

For radical prostatectomy, the objectives of laparoscopic surgery are to reduce perioperative morbidity compared with conventional surgery and allow a more precise operative procedure. The quality of surgery can be improved by better visualization of the operative site as a result of optical magnification and the maneuverability of the laparoscope, which provides a hitherto unobtainable anatomic view. The laparoscopic approach not only improves the postoperative course, but also allows better preservation of periprostatic vascular, muscular, and neurovascular structures.[109]

A unique challenge in nephron-sparing laparoscopic surgery is achieving successful renal hypothermia for renal preservation during renal artery occlusion. Techniques described for renal hypothermia include laparoscopic deployed ice slush kidney surface cooling (preferred option), endoscopic retrograde cold saline infusion, and transarterial renal hypothermia via femoral artery catheter approach.

Although all the conventional complications and concerns associated with laparoscopy are applicable to urologic procedures (see Chapter 68), two unique problems also are identified. First, because the urogenital system is mainly retroperitoneal, the large retroperitoneal space and its communications with the thorax and subcutaneous tissue are exposed to the insufflated carbon dioxide. Subcutaneous emphysema occurs frequently in these patients and may extend all the way up to the head and neck.[110] The upper airway is at risk for compromise in the most severe cases because of pharyngeal swelling secondary to submucous carbon dioxide. This complication should be kept in mind before extubation of these patients. Second, the procedures tend to be lengthy, allowing for sufficient absorption of carbon dioxide to result in acidemia and marked acidosis.[110] Because of significant increases in intra-abdominal and intrathoracic pressure as a result of insufflated carbon dioxide, a steep Trendelenburg position, and lengthy procedures, general anesthesia with controlled ventilation is the method of choice. Despite adequate hydration, intraoperative oliguria may occur and be followed by diuresis in the immediate postoperative period. Although the exact mechanism is unclear, it is believed to be due to increased perirenal pressure exerted by the insufflated gas in the retroperitoneal space.

Extracorporeal Shock Wave Lithotripsy

ESWL has become the treatment of choice for disintegration of urinary stones in the kidney and upper part of the ureter. The first clinical model of the lithotripter introduced into common practice (Dornier HM-3) used a water bath in a steel tub and a metal gantry chair to support the patient suspended in a sitting position. This first-generation lithotripter is still used in some institutions and presents complex challenges of immersion physiology and monitoring difficulties. Second-generation and third-generation lithotripters (e.g., Siemens, Lithostar, Wolf Piezolith, Dornier HM-4, MFL 5000, MPL 9000) have evolved mainly in the direction of multipurpose use, eliminating the water bath and producing a pain-free lithotripter. All lithotripters share similar technologic principles in having three main components: (1) an energy source, most commonly a spark plug (alternatively, an electromagnetic membrane or piezoelectric elements); (2) a system to focus the shock wave, such as ellipsoid or reflecting mirrors; and (3) fluoroscopy or ultrasound to visualize and localize the stone in focus.[111]

Technical Aspects

The patient is immersed in water up to the clavicles (see Chapter 100). An electrode (or spark plug) is placed in the water at the base of the tub in an ellipse and is connected to a generator that supplies 16 to 24 kV of electricity. The electric energy creates a spark across the gap in the electrode with the generation of a loud noise, intense heat, and explosive vaporization of water. The sudden expansion of air bubbles created sets up a pressure wave (shock wave) with distinct mechanical and acoustic properties. The shock wave is focused by the ellipse to a focal point called the F2 focus (the tip of the electrode is the first focus). The shock wave travels through water and body tissues without significant localized dissipation of energy because the acoustic impedance of the two media is similar. When the shock wave arrives at the entry surface of the stone, however, it encounters a sudden change in impedance that causes it to release compressive energy on the magnitude of several atmospheres. Similarly, when the wave exits on the opposite surface of the stone, an interface is encountered again, and shock wave energy is released in a blast. Repeat applications cause the stone to disintegrate. Shock wave energy is most concentrated in the F2 focal zone and rapidly decreases beyond it.[112]

Biomechanical Effects of Shock Wave Therapy

For shock waves to be most effective, the stone should remain in the F2 focus during treatment.[79] Pressure energy measurements show an exponential decrease beyond this small focal zone. The kidneys and the kidney stone follow the up-and-down movements of the diaphragm during respiration. The stone is likely to move in and out of focus during respiration. This issue has been studied, and ventilatory techniques such as decreased tidal volumes with increased respiratory rates and high-frequency jet ventilation have been used to increase the efficacy of the treatment.[113] Other data[114] and wide clinical experience with success rates of lithotripsy do not support or justify the routine use of these techniques, which add their own complexity and complications to the procedure.[115] Regional anesthesia and analgesia-sedation are frequently used for lithotripsy, in which case spontaneous ventilation is the only option. Studies in sedated patients with intercostal blocks and local infiltration anesthesia have documented that stone movement with spontaneous respiration is mainly restricted to the F2 focal zone during ESWL.[116]

Conventional ventilation during general anesthesia or spontaneous respiration during regional anesthesia is generally acceptable for lithotripsy. Occasionally in an awake patient, one may have to titrate sedation carefully, or if the patient is under general anesthesia, one may need to manipulate respiratory parameters to decrease abnormally large stone movement.

For effective stone disintegration, shock waves should reach the stone unimpeded. The flank area should be kept free of any medium that would provide an interface for the dissipation of shock wave energy. Nephrostomy dressings should be removed, and the nephrostomy catheter should be taped clear of the blast path. Similarly, epidural catheters and dressings should be taped well clear of the blast path. Pandit and associates[117] noted an unusually high rate of failure of lithotripsy in their patients receiving epidural fentanyl analgesia. They discovered that the

foam tape placed to secure the epidural catheter was frequently in the blast path of the shock waves and could absorb 80% of the shock wave energy.

Except when piezoelectric lithotripters or lithotripters with very low shock wave energy are used, the procedure is painful and requires some form of anesthesia. Shock waves produce sharp stinging pain at the entry site in the flank along with a sensation of deep visceral pressure discomfort.

Although shock waves pass through most tissues relatively unimpeded, they do cause tissue injury, the extent of which depends on the tissue exposed and the shock wave energy at the tissue level. Skin bruising and flank ecchymoses are common at the entry site. Painful hematoma in the flank muscles may occur. Hematuria is almost always present at the end of the procedure and results from shock wave–induced endothelial injury to the kidney and ureter. Adequate hydration is necessary to prevent clot retention. A decrease in postoperative hematocrit should arouse suspicion of a large perinephric hematoma. Punctate hemorrhages have been observed in the stomach and bowel, and this injury might be responsible for abdominal distention, nausea, and vomiting in some patients.

Lung tissue is especially susceptible to injury by shock waves. Air trapped in alveoli presents the classic water (tissue)-air interface to the shock wave and causes dissipation of energy with alveolar rupture and hemoptysis. Massive hemoptysis and death from pulmonary damage have been reported in laboratory animals after a single exposure of the thorax to a shock wave.[118] Shock wave–induced hemoptysis in a child and a pulmonary contusion with life-threatening hypoxemia in an adult have been reported.[119,120] Children are more likely to sustain pulmonary damage from shock waves because of the shorter distance of the lung bases from the kidneys than in adults. It is recommended that a Styrofoam sheet or Styrofoam board be placed under the back in children to shield the lung bases from shock waves during ESWL.[119,120]

Shock wave–induced cardiac arrhythmias previously reported in 10% to 14% of patients undergoing lithotripsy are extremely rare nowadays.[121,122] These arrhythmias are believed to be due to mechanical stress on the conduction system exerted by the shock waves. The intricate grounding system of the lithotripter ensures that any current-induced arrhythmias are unlikely. Atrial and ventricular premature complexes, atrial fibrillation, and supraventricular and ventricular tachycardia have been reported.[121,122] Artifacts on electrocardiogram also are common. Artifacts and arrhythmias usually disappear when the lithotripsy is stopped. Arrhythmias occasionally may persist and require treatment, however.

Physiologic Changes During Immersion Lithotripsy

Water immersion with the Dornier HM-3 lithotripter produces significant changes in the cardiovascular and respiratory systems (Table 65-16). Cardiovascular changes include an increase in central blood volume with an increase in central venous and pulmonary artery pressure.[123,124] Weber and colleagues[123] observed that increases in central venous pressure and pulmonary arterial pressure were directly correlated with the depth of immersion. The sitting position, together with general or epidural anesthesia, would tend to cause peripheral pooling and decreased venous return. A decrease in cardiac output and an increase in systemic vascular resistance during immersion lithotripsy under general anesthesia has been documented.[124] Respiratory changes with immersion up to the clavicles are significant; functional residual capacity and vital capacity are reduced by 20% to 30%, pulmonary blood flow has been shown to increase,[125,126] and tight abdominal straps and the hydrostatic pressure of water on the thorax impart a characteristic shallow, rapid breathing pattern.[126] Ventilation-perfusion mismatch and hypoxemia are more likely. The renal effects of immersion include diuresis, natriuresis, and kaliuresis. A decrease in antidiuretic hormone and renal prostaglandins occurs. The temperature of the bath water can cause profound changes in the patient's temperature. This heat transfer is augmented further by the vasodilation produced by general or epidural anesthesia. Hypothermia and hyperthermia have been reported.[127]

Table 65-16 Changes on Immersion during Lithotripsy

Cardiovascular	Increased	Central blood volume
	Increased	Central venous pressure
	Increased	Pulmonary artery pressure
Respiratory	Increased	Pulmonary blood flow
	Decreased	Vital capacity
	Decreased	Functional residual capacity
	Decreased	Tidal volume
	Increased	Respiratory rate

Anesthetic Choices for Lithotripsy

Anesthetic regimens used successfully for lithotripsy include general anesthesia, epidural anesthesia, spinal anesthesia, flank infiltration with or without intercostal blocks, and analgesia-sedation, including patient-controlled analgesia.[128-136] General anesthesia offers the advantages of rapid onset and control of patient movement. Ventilatory parameters can be controlled to decrease stone movement with respiration. Disadvantages include a likelihood of positional injury and difficulty in transporting an anesthetized patient to other locations if adjunctive procedures become necessary.

Epidural anesthesia offers the advantage that an awake patient can help with transfers, reducing the likelihood of injury. With epidural anesthesia using loss of resistance to air to identify the epidural space, only the smallest amount of air necessary should be injected. Air in the epidural space provides an interface and causes dissipation of shock wave energy and local tissue injury. Korbon and associates[137] found a decrease in epidural compliance and pain on injection with repeat epidurals for subsequent lithotripsies in their patients. In animal experiments, they were able to show epidural tissue damage after injection of air and exposure to shock waves.[138] It is reassuring, however, that in most lithotripsies performed under epidural anesthesia worldwide, neurologic injury has not been a problem.[139]

The main disadvantage of epidural anesthesia is its slow onset. Spinal anesthesia offers a reasonable alternative with its rapid onset. The incidence of hypotension (the patient is in a sitting position for treatment) is higher, however. In one series, the incidence of hypotension with general, epidural, and spinal anesthesia was 13%, 18%, and 27%.[140] Local anesthetic infiltration of the flank with or without intercostal blocks provides adequate anesthesia when combined with intravenous sedation and avoids hypotension.[128] Intravenous analgesia-sedation in various combinations has been used successfully by many anesthesiologists.[130,131]

Newer Lithotripters

Newer lithotripters have no water bath, and they tend to use multifunctional tables that allow other procedures, such as cystoscopy and stent placement, to be accomplished without moving the patient off the table. The shock waves are tightly focused, so they cause less pain at the entry site, and intravenous analgesia-sedation is the mainstay of anesthesia with these newer lithotripters. Other incidental interventions, such as cystoscopy, stone manipulation, or stent placement, alter anesthetic requirements. Many of these newer lithotripters have a much smaller focal zone for the shock waves. It is even more imperative that adequate analgesia and sedation be provided, so that stone excursion with respiration is limited to the focal zone. Most analgesia-sedation combinations are adequate. Even patient-controlled analgesia with alfentanil and a combination of propofol and alfentanil has been used.[141,142] Many centers routinely use general anesthesia with short-acting inhaled or intravenous anesthetics and employ laryngeal mask airway for ventilation.

Contraindications

Pregnancy and untreated bleeding disorders are the only contraindications to lithotripsy. Women of childbearing age must have a pregnancy test that is documented to be negative before lithotripsy. Standard tests of coagulation, such as the platelet count, prothrombin time, and partial thromboplastin time, should be obtained. Pacemakers, automatic implanted cardioverter-defibrillators (AICDs), abdominal aortic aneurysm, orthopedic prostheses, and obesity are no longer considered contraindications.

Patients with pacemakers can be treated safely if the pacemaker is pectorally placed and the following precautions are observed (see Chapter 43).[143-145] Pacemaker programmability should be established before the treatment, and the pacemaker should be switched to a nondemand mode in case the shock waves interfere with pacemaker function. Alternative means of pacing should be available. Although most pacemakers located pectorally are at a safe distance from the blast path, some may be damaged. Weber and coworkers[143] examined 43 different pacemakers and found that 3 were affected. Dual-chamber pacemakers tend to be more sensitive to interference. Treatment must be started at a low energy level and gradually increased while observing pacemaker function.

Manufacturers of AICDs and lithotripters generally consider an AICD a contraindication for lithotripsy. Patients with AICDs have been treated successfully with lithotripsy, however.[144] Transvenous AICDs are less of a concern than the older abdominally implanted defibrillators. AICD devices should be shut off immediately before lithotripsy and then reactivated immediately after treatment.[146]

Patients with small aortic aneurysms have been treated safely, provided that the stone is not close to the aneurysm. Orthopedic prostheses, such as hip prostheses and even Harrington rods, are not a problem if they are not in the blast path, which is usually the case. Positioning of obese patients may be problematic at times. Not only do extremely obese patients present anesthetic challenges related to obesity, but also focusing of the stone may be extremely difficult in the very obese, and it is common for the procedure to be abandoned in these patients because of an inability to bring the kidney stone into the F2 focal zone. It is prudent for focusing of the stone to be attempted before administering any anesthetic in this high-risk population. With the newer lithotripters, some of these patients may have to be placed prone, a position that they may not be able to tolerate safely.

Radical Surgery in Urology

Radical surgery is becoming common in the urologic suite with the introduction of radical nephrectomy, radical cystectomy, and radical retropubic prostatectomy. Common features include lengthy procedures, associated sudden and significant blood loss, and attention to renal function preservation. With radical nephrectomy, significant cardiorespiratory changes attendant to the flank position are a concern. Respiratory changes include decreases in thoracic compliance, tidal volume, vital capacity, and functional residual capacity. Dependent atelectasis is common and may lead to hypoxemia. Pneumothorax may occur and can have significant respiratory and hemodynamic consequences intraoperatively. It is common to see a decrease in blood pressure when the kidney rest is raised. This decrease is usually due to compression of the inferior vena cava. In addition, hepatic encroachment on the vena cava and mediastinal shift may reduce venous return and stroke volume further. Cervical plexus, brachial plexus, and common peroneal neuropathies may occur as a result of stretch or compression of nerves in the lateral position.

Radical Nephrectomy for Renal Cell Carcinoma

The most common malignancy of the kidney is renal cell carcinoma; 85% to 90% of all solid renal masses are renal cell carcinoma.[147] Because renal cell carcinoma is refractory to chemotherapy and radiation therapy, surgical resection or ablation can offer curative treatment of localized disease (Table 65-17). More recently, resection of the ipsilateral adrenal gland has been reserved for patients with large upper pole lesions or when the adrenal gland is enlarged or appears abnormal.[148] Partial nephrectomy (nephron-sparing surgery) is considered for patients with small lesions or bilateral tumors or for patients at risk because of other diseases, such as diabetes or hypertension.[147-150]

In 5% to 10% of patients, the tumor extends into the renal vein and the inferior vena cava and right atrium. Tumor extension into the inferior vena cava and atrium occurs more frequently with right-sided renal cell carcinoma. Several problems can occur

Table 65-17 Anesthetic Implications of Radical Nephrectomy for Tumors

85%-90% are for renal cell cancer
5%-10% extension to the IVC and right atrium
Large-bore IV access, A-line, IJV line (preferably on left side if IVC is involved)
Paraneoplastic syndrome
Hypercalcemia, eosinophilia; increased prolactin, erythropoietin, and glucocorticoids
Men > women
Chronic smoking history usually associated
CAD, COPD
Renal failure

CAD, coronary artery disease; COPD, chronic obstructive pulmonary disease; IJV, internal jugular vein; IVC, inferior vena cava.

in these patients, ranging from circulatory failure as a result of complete occlusion of the vena cava by tumor to acute pulmonary embolization of tumor fragments during surgery. To operate on these patients safely, the extent of the lesion must be defined preoperatively. Cardiopulmonary bypass is often required in these cases to prevent tumor embolization, and necessary with tumor thrombus extension into the upper portion of the hepatic vena cava or when venous return is significantly compromised. Right heart catheterization is potentially hazardous because of the danger that a part of the tumor may be dislodged and embolize. Some anesthesiologists use a central venous pressure catheter inserted through left internal jugular or external jugular vein so as not to place it beyond the superior vena cava. Central venous pressure in such cases may not reflect intravascular volume accurately because venous return through the inferior vena cava is impaired by the thrombus, and transesophageal echocardiography may be of value.[151] This decrease in venous return also predisposes the patient to hypotension during induction of anesthesia. Venous obstruction leads to dilation of the epidural veins and the development of abdominal wall and retroperitoneal collaterals. The emphasis is on appropriate preoperative preparation, which is possible only when the full extent of the lesion has been defined.[150]

Radical Prostatectomy

Localized prostate cancer is treated by either radiation therapy or radical prostatectomy (Table 65-18). Radical prostatectomy has become more commonly performed because of routine prostate-specific antigen testing in men older than 50 years and popularization of the nerve-sparing surgery to reduce the risk of impotence. Although originally described in 1905 via the transperineal approach, the retropubic approach is mostly used now. The prostate, the ejaculatory ducts, the seminal vesicles, and part of the bladder neck are removed along with the pelvic lymph nodes.

Generally, the procedure is performed by open laparotomy, but laparoscopic and robotic surgery are being used more frequently. The most common intraoperative problem is hemorrhage and massive blood loss requiring blood transfusion. Autologous predonation, preoperative recombinant erythropoietin therapy, intraoperative isovolemic hemodilution, and cell salvage are commonly practiced to reduce the patient's exposure to allogeneic blood. The routine use of these practices, their indications, and the need for transfusion in these patients have been questioned by some. Early postoperative complications, including deep vein thrombosis, pulmonary embolism, hematoma, seroma, and wound infection, occur in 0.5% to 2% of cases.[152] Death within 30 days has been reported by several centers to occur in approximately 0.2%.[152] Late complications include incontinence, impotence, and bladder neck contracture.[153] Patients undergoing radical prostatectomy are placed supine in the Trendelenburg position with the back extended, which places the pubis above the head. Air embolism from the prostatic fossa as a result of a gravitational gradient between the prostatic veins and the heart has been reported.[154]

Table 65-18 Anesthetic Implications of Radical Prostatectomy

Disease of the elderly
CAD, COPD, and renal dysfunction
Significant blood loss
Wide-bore IV access and invasive monitoring
Acute normovolemic hemodilution versus autologous blood donation
Hyperextended position
Nerve injuries, soft tissue injury, joint dislocations
Venous air embolism
Anesthesia
Benefits of regional anesthesia versus general anesthesia debated
Not known to influence mortality
Epidural anesthesia with spontaneous ventilation decreases blood loss
General or combined anesthesia with IPPV increases blood loss

CAD, coronary artery disease; COPD, chronic obstructive pulmonary disease; IPPV, intermittent positive-pressure ventilation.

Comparison of Anesthetic Techniques for Radical Prostatectomy

Epidural anesthesia, spinal anesthesia, general anesthesia, and combined epidural and general anesthesia have been used for this surgery. For the epidural component of combined techniques, a thoracic or a lumbar approach to anesthesia or analgesia has been used, and spontaneous ventilation or intermittent positive-pressure ventilation (IPPV) has been used for the general anesthesia component. Many investigators have reported their findings in comparing the three anesthetic techniques for radical retropubic prostatectomy,[155-158] and certain trends emerge.

Intraoperative blood loss is significantly less if epidural anesthesia or a combined epidural and general anesthetic with spontaneous ventilation is used. In one study, blood loss in the general anesthesia and the combined anesthesia group with IPPV was significantly more than in the epidural anesthesia group despite little difference in arterial pressure among the three groups.[155] It was postulated that the increased venous pressure as a result of IPPV was the most likely cause of increased bleeding in the general and the combined anesthesia groups during radical prostatectomy. Previous studies had shown that central and peripheral venous pressure was lower in patients during spontaneous ventilation under epidural anesthesia or combined epidural-general anesthesia than in patients receiving IPPV during general anesthesia.[159] Epidural anesthesia alone or when added to a general anesthetic decreases postoperative hypercoagulability, decreasing the risk of thromboembolism.[160] The preemptive analgesia provided by the epidural block decreases postoperative pain and analgesic requirements.[161] Homeostasis of neuroendocrine responses may be better maintained with regional block than with general anesthesia. Recovery of bowel function occurs faster with epidural anesthesia than with general anesthesia, although it does not result in earlier hospital discharge of the patient.[162]

The length of stay and the cost of hospitalization can be decreased with the judicial use of epidural anesthesia and established clinical pathways.[163,164] In one study, 80% of patients were satisfactorily discharged after 1 day, and the mean length of stay was 1.34 days.[165]

Although some studies report better outcomes with epidural anesthesia than with general anesthesia, others fail to support such results. The divergent findings in these studies com-

paring three anesthetic techniques may be a consequence of small numbers of subjects in many studies, difference in design (e.g., retrospective, prospective, controlled, randomized), the use of different techniques (e.g., thoracic versus lumbar epidural block), the use of spontaneous ventilation versus IPPV, and the use of local anesthetics with or without opiates. Local practices are based on the preferences of the urologist, the anesthesiologist, and the patient, and these preferences assume precedence over almost everything else.

Robotic Assisted Radical Prostatectomy

Many surgical advantages of robotic assisted radical prostatectomy (RARP) are described, including better visualization, more controlled finer movements of robotic arms allowing better dissection, decreased blood loss, less scarring and pain, shorter recovery time, faster return to daily activity, and possibly improved continence and potency rates (although these last outcomes have been suggested only given the short-term follow-up at this time). Anesthetic concerns are primarily related to steep head down tilt and pneumoperitoneum required for surgery.

Ventilatory and respiratory changes resulting from pneumoperitoneum include decreased compliance, increased airway pressures, increased ventilation-perfusion mismatch. Application of positive end-expiratory pressure improves oxygenation in these patients.[166] Hypercapnia develops within 15 to 30 minutes of carbon dioxide insufflation with resultant hypercarbia, acidosis, tachycardia, arrhythmias, and other deleterious hemodynamic and CNS effects.[167] Increase in mechanical ventilation can obviate these changes in most patients, and most healthy patients tolerate the changes even though they are clinically significant. Extraperitoneal insufflation of carbon dioxide is associated with larger increases in arterial P_{CO_2} than intraperitoneal insufflation.[168] Hemodynamic changes include decreased venous return with decreased cardiac output despite an increase in filling pressures indicative of increased intrathoracic pressures.

Physiologic changes resulting from steep head down tilt include hemodynamic effects such as decreased perfusion pressure of lower extremities, increased mean arterial pressure at the circle of Willis, increased central blood volume, decreased cardiac output, and a decreased perfusion of vital organs in a normovolemic patient. Increased myocardial oxygen consumption, ischemia, arrhythmias, and decreased oxygen delivery are potential risks in patients with cardiac disease. Respiratory effects of steep head down tilt—decreased compliance, reduced vital capacity and functional residual capacity, 20% decrease in lung volumes, and ventilation-perfusion mismatch—compound the effects of pneumoperitoneum. Pulmonary congestion and edema have been reported in susceptible patients.

Other significant effects of steep head down tilt include increased intracranial pressure and increased intraocular pressure, venous air embolism, brachial plexopathy, arthralgias, and finger injuries. Regurgitation in this position in patients with history of reflux increases their risk of aspiration. Maintaining normothermia may be a problem in some cases because of prolonged pneumoperitoneum with dry cold gases.

Compared with retropubic radical prostatectomy, robotic assisted radical prostatectomy is associated with much less blood loss, although in one study transfusion rate was not much different despite this finding.[169] Mild to moderate pain is expected postoperatively, and low pain scores of 0 to 4 have been reported after retropubic radical prostatectomy and robotic assisted radical prostatectomy using preemptive analgesia with ketorolac given intraoperatively combined with rescue opiate or nonopiate analgesia.[170] Most patients are discharged home the day after surgery. Use of robots in urologic surgery has been extended to include radical cystectomy, pyeloplasty, and renal and adrenal surgery in adults and children, and newer indications are developing.

Urogenital Pain Syndromes

Pain syndromes of the urogenital system result from inflammatory disease, anatomic anomalies, obstructive uropathy, and malignancies (see Chapter 58). The visceral type of renal pain is frequently caused by pyelonephritis or ischemic events secondary to an embolus or a thrombus. The hematuria in sickle cell disease or sickle cell trait is typically painless. The site of pain, the characteristics of referred pain, and the quality of pain help the clinician identify the source of pain.

Benign Renal Neoplasms

Flank pain is a common symptom in adults with angiomyolipoma (more common in women than in men) and in children with mesoblastic nephroma and Wilms' tumor or nephroblastoma. Nephroblastomas may be combined with several congenital malformations, such as sporadic anhidrosis (lack of sweating), microcephaly, mental retardation, and spina bifida. Treatment consists of surgical resection of the tumor supplemented by chemotherapy and adequate pain management. Opiates are the mainstay of pain management.

Renal Cell Carcinoma

Renal cell carcinoma, also known as hypernephroma, is characterized by the classic triad of hematuria, flank pain, and a renal mass. The development of pain may be a warning sign for metastatic disease. Pain control becomes an important issue with metastatic disease, and an intrathecal implantable pump or permanent placement of an epidural catheter for continuous delivery of pain medications may be indicated. Less than 5% of tumors of renal origin are sarcomas; most are leiomyosarcomas. The peak age is the fourth and fifth decades of life. Flank pain is usually the initial symptom, and this pain is mainly due to stretching of Gerota's fascia or compression and invasion of intercostal nerves, or both.

Inflammatory Renal Diseases

Inflammatory renal diseases commonly producing flank pain include acute pyelonephritis, pyelitis, renal carbuncle, and perinephritic abscess. Spiking fever is an important associated finding that suggests the presence of infection. The most prominent sign is tenderness in the flank. Because the kidneys are retroperitoneal organs, peritoneal signs develop very late. The differential diagnosis must include pneumonitis, pancreatitis, appendicitis, and cholecystitis. Oral or parenteral narcotics are very effective for pain control. Systemic antibiotics and fluid resuscitation are important for the management of renal infections.

Perinephritic fasciitis is an inflammation of the renal capsule and fascia of Gerota, and it may follow a perinephritic abscess. Depression of the immune system (e.g., owing to human immunodeficiency virus infection, chemotherapy, radiotherapy) and sickle cell disease are the major risk factors. Perinephritic abscesses need to be drained. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in treating the associated reflex skeletal muscle spasm.

Idiopathic nephralgia is a rare condition that mimics renal pain and other urologic symptoms. The pain is thought to originate from uncoordinated hyperactivity and spasms of calyces and the renal pelvis. A comprehensive psychological evaluation may be required to eliminate psychological factors as a source of pain. Diagnostic and therapeutic paravertebral blocks may help diagnose and treat this disabling pain condition.

Pseudorenal pain syndromes are caused by genital nerve entrapment and ilioinguinal neuropathy after inguinal surgery, and they may mimic renal pain. Referred pain in the dermatomal distribution is characteristic of these conditions. Diagnostic and therapeutic ilioinguinal or genitofemoral nerve blocks help establish the diagnosis and treat this pain. In congenital polycystic kidney disease, renal pain is caused by distention of the cysts and stretching of Gerota's fascia. Hemorrhage in the cysts, rupture of the cysts, or infection produces exacerbation of pain. Surgical intervention, including percutaneous drainage of solitary renal cysts, may relieve the symptoms. Renal vein thrombosis and renal infarctions cause acute or acute-on-chronic pain syndromes. Along with treatment of shock and embolectomy, narcotics are used to control pain.

Obstructive Uropathy

Obstruction of the urinary tract causes severe pain in the flank. Chronic conditions cause a constant dull ache, in contrast to the spasmodic episodic pain with acute obstruction. Surgery may be indicated. Generally, pain from the upper third of the ureter is referred to the loin, pain from the middle third is referred to the iliac fossa, and pain from the lower third is referred to the suprapubic and groin area. The pain caused by ureteric calculi is often felt in the upper inner aspect of the thigh and the ipsilateral testicle in males and the labia majora in females. NSAIDs are helpful in relieving pain, an effect believed to be due to the antiprostaglandin action of NSAIDs. Ketorolac is the only NSAID available in injectable form and is a drug of choice for renal colic. Calcium channel blockers (verapamil, diltiazem, and nifedipine) have been effective in treating ureteric colic. Although it is believed by some clinicians that morphine and meperidine may have a spasmogenic effect on the ureter, opiates remain the mainstay of treatment of ureteric colic.

Bladder Pain

Bladder pain is mostly a dull ache and is usually localized to the suprapubic region. The most common causes of pain are bladder distention by obstruction and cystitis. Bladder distention accompanied by acute or chronic inflammation is manifested as severe suprapubic spasmodic pain, urinary frequency, and dysuria. Treatment of the cause of inflammation (e.g., obstruction, stone, enlarged prostate, vesicoureteral reflux) is the treatment of choice for pain. Untreated cystitis may result in upper urinary tract infection. Pregnancy, diabetes mellitus, and immunodeficiency are additional risk factors.

Interstitial cystitis is a condition with unknown cause that frequently poses a challenge to physicians. The pathologic features of interstitial cystitis are nonspecific chronic inflammatory infiltrates, edema, and vasodilation. Suprapubic pain is due to bladder spasm or uncoordinated detrusor muscle contraction. Suprapubic pain and the frequency of micturition may become so incapacitating that cystectomy may be required in extreme cases. Options for pain control include bladder denervation (rhizotomy), transurethral electrocautery, cystolysis, presacral nerve blocks, and neurolytic blocks. Medical management includes antihistamines, corticosteroids, anticholinergics, and calcium channel blockers.[171]

Urothelial Tumors

The most common urothelial tumor is transitional cell carcinoma of the urinary bladder. Painless hematuria is the most common manifestation. Thirty percent of patients initially may complain of bladder irritability, which is thought to be due to muscular involvement. Surgical treatment includes fulguration, transurethral resection, or more extensive radical cystectomy with urinary diversion. Pain control is an integral part of treatment in metastatic disease of the bladder.

Testicular Pain

The most common testicular congenital anomaly producing pain is cryptorchidism. Pain in an undescended testis without trauma usually indicates infection or torsion. Emergency surgical exploration is the treatment of choice. The incidence of malignancy is 20 times higher in an undescended testis than in a descended testis. Bacterial or viral orchitis or epididymo-orchitis is a painful condition that needs urgent attention.

Tumors of the testis are generally malignant; however, extratesticular tumors within the scrotum are usually benign. The earliest sign of the tumor is a painless testicular mass. Pain is a late sign and is usually described as a dull ache, testicular heaviness, or dragging. Treatment of testicular tumor depends on the cell type and disease stage. Seminoma is generally radiosensitive.

Prostatic Pain

Acute or chronic prostatitis is very painful. Acute prostatitis is usually caused by a bacterial infection and responds to antibiotic therapy. Chronic prostatitis is due to inadequate treatment of acute infection, recurrent infection, or prostatic uroliths. Treatment includes prostatic massage, NSAIDs, antibiotics, and surgical drainage.

Adenocarcinoma of the prostate is the most common male cancer and is usually painless. Rectal or sacral pain with prostatic cancer may be a sign of metastatic disease. Patients with sacral or pelvic pain should be investigated for bone metastasis. Oral or parenteral high-dose opiates are the mainstay of treatment initially. Permanent placement of an epidural catheter or intrathecal

implantable pump for continuous delivery of medications and radiation therapy should be considered for metastatic disease.

Priapism

Priapism is a prolonged pathologic and painful erection caused by engorgement and thrombosis of the pelvic veins. It is seen in patients with metastatic malignant diseases such as pancreatic cancer and leukemia, pelvic trauma, sickle cell disease, or spinal trauma. Pathology of the corpora and local neurovascular abnormality also can cause priapism. Prompt therapy should be instituted to control pain and prevent subsequent impotence from fibrosis of the corpora cavernosa. The cause of priapism may be important in defining the treatment. Sickle cell priapism is treated with hydration, alkalinization, and blood transfusion to increase hemoglobin to more than 10 mg/dL. The priapism associated with leukemia responds to radiation therapy. Intracorporeal injection of phenylephrine is recommended for selected cases of priapism. Stepwise institution of pain medications from NSAIDs to opiates is recommended. Severe pain warrants parenteral administration of morphine or hydromorphone.

Peyronie's disease is a sexually crippling condition that causes severe penile pain during sexual intercourse because of curvature. The treatment of choice is surgery and NSAIDs for pain.

Female Genital Pain

Vulvodynia is a chronic pain condition of unknown cause that is associated with sexual inactivity or dysfunction, depression, anxiety, and obsessive behavior. Vestibulitis is characterized by painful penetration during coitus. It is more common in white women and is resistant to most medical treatment. Some success with tricyclic antidepressants and antihistamines has been reported. Heat treatment (sitz bath) also is helpful.

Chronic dysmenorrhea is a severe pain-producing condition caused by the hypercontractility of uterine muscles during menstruation. Ovulation suppression and the use of NSAIDs are effective because of the antiprostaglandin effect. Presacral neurectomy can be considered as a last resort after other options have been tried and failed.

Uncoordinated contraction of the muscles of the pelvic floor (levator ani, pubococcygeus, and deep transverse perineal) causes vaginismus. It produces extreme spasms and painful sexual dysfunction. Psychological factors, such as rigid sexual upbringing and traumatic sexual experience, inadvertently reinforce the vaginal spasm. Treatment involves correction of any physical conditions and then behavior modification that includes desensitization techniques.

Dyspareunia is defined as recurrent and persistent genital pain before or after intercourse; it may be due to infection, trauma, or lack of lubrication. Treatment includes psychotherapy and systemic desensitization.

Chronic pelvic pain also is known as pelvic congestion, pelvic fibrosis, pelvic neurodynia, and pelvic sympathetic syndrome. The pain is often multifactorial and requires multidisciplinary pain management involving psychotherapy, medications, and trigger point injections. In selected cases, nerve root blocks and neuraxial opioid therapy are promising. Metastatic disease of the cervix and uterus can cause severe vulvovaginal pain syndrome and requires aggressive opioids and adjuvant pain treatment.[172]

Role of Sympathetic Blocks

The pelvic viscera in men and women—the urogenital organs, the colon, and the rectum—are supplied by afferent fibers from the lumbar sympathetic chain. The pelvic pain caused by either inflammatory diseases or cancer can be relieved by interruption of bilateral sympathetic pathways,[173,174] which can be achieved with a superior hypogastric plexus block (see Chapter 58). The superior hypogastric plexus is a retroperitoneal structure that is formed by confluence of the bilateral lumbar sympathetic chains; it is situated between the body of the L5 and S1 vertebrae. Interruption of the ganglion impar is targeted to mixed somatic and sympathetic pain arising from the distal end of the urethra, the vulva, the perineum, and the distal third of the vagina.

General Considerations

General considerations for genitourinary pain management follow the same principles of pain management elsewhere. For nonmalignant acute pain, medical management is the first choice. Narcotics and non-narcotic medications, such as acetaminophen, aspirin, and NSAIDs, are indicated for the control of acute pain. Tricyclic antidepressants (amitriptyline and nortriptyline) are often the first choice for neuropathic pain. Difficult neuropathic pain may respond well to the combination of tricyclic antidepressants and anticonvulsant agents (gabapentin and pregabalin). When oral administration is not feasible, parenteral administration of narcotics should be used. Patient-controlled epidural analgesia or continuous epidural infusion produces segmental dose-related analgesia and prevents atelectasis. The use of lipophilic versus hydrophilic narcotics depends on the segmental level of epidural catheter placement. Intravenous patient-controlled analgesia should be the next option. Meperidine and morphine should be avoided in patients with compromised renal function because of the long half-life of metabolites. Normeperidine, a metabolite of meperidine that lowers the seizure threshold and induces CNS excitability, and morphine-6-glucuronide and morphine-3-glucuronide metabolites of morphine may accumulate and enhance sedation and respiratory depression in patients with renal failure. Hydromorphone, a semisynthetic opioid, is recommended for patients with renal failure because of the lack of identifiable metabolites. The antiprostaglandin effect of NSAIDs affects the regulation of renal blood flow in susceptible patients. Patients requiring long-term NSAIDs should be appropriately monitored for renal function.

A pain management algorithm based on a World Health Organization–recommended stepladder approach to management of malignant pain syndromes is shown in Figure 65-5. Interventional techniques are an integral part of pain control in chronic nonmalignant and malignant pain syndromes. Continuous epidural infusion of opioids causes minimal fluctuation of drug levels in cerebrospinal fluid. Before consideration of a tunneled epidural catheter, pain should be treated aggressively with sustained-release morphine preparations, methadone, and fentanyl transdermal patches to optimize the medication requirement. If

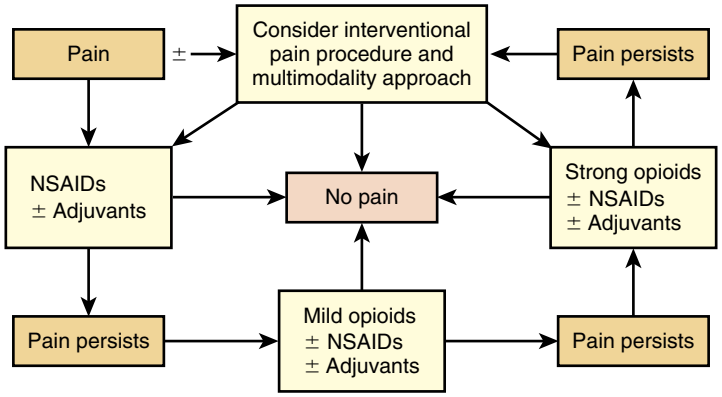

Figure 65-5 Cancer pain management algorithm based on World Health Organization stepladder approach to pain management. NSAIDs, nonsteroidal anti-inflammatory drugs.

intractable pain persists despite aggressive systemic opioids and adjuvant drug therapy, treatment with an implantable drug delivery system should be considered. Methadone is often an alternative to opioid-tolerant patients with neuropathic pain owing to its mu receptor agonistic and *N*-methyl-D-aspartate receptor antagonistic effect. Because of the safety, efficacy, and relative ease of intraspinal administration of opioids for the control of intractable pain resulting from metastatic disease, implantable intrathecal and epidural drug administration systems are being used increasingly.

Acknowledgment

The authors acknowledge the invaluable contribution and expertise of Dan Paloski, editorial assistant in the Department of General Anesthesiology at the Cleveland Clinic, in preparation of this manuscript.

66 Anesthesia and the Hepatobiliary System

Key Points

1. All volatile anesthetics decrease hepatic blood flow, but desflurane and sevoflurane have the least significant effect on total hepatic blood flow and hepatic oxygen delivery, whereas halothane induces the most profound reductions in hepatic blood flow.
2. Advanced liver disease may impair the elimination, prolong the half-life, and potentiate the clinical effects of several drugs, including morphine, meperidine, alfentanil, vecuronium, rocuronium, mivacurium, benzodiazepines, and dexmedetomidine. These drugs should be used cautiously in patients with cirrhosis or end-stage liver disease from any cause and their dosage and administration should be adjusted accordingly.
3. Abnormal liver enzyme test results may be seen in up to 4% of normal individuals and up to 36% of psychiatric patients, although the prevalence of clinically significant hepatic dysfunction in these individuals is less than 1%, thus suggesting that further costly preoperative testing is unnecessary in asymptomatic patients.
4. Patients with asymptomatic elevations in serum transaminase levels (less than two times normal values) may undergo surgery with minimal impact on perioperative outcome.
5. Retrospective data suggest that patients with acute hepatitis from any cause are at increased risk for hepatic failure and death after elective surgery. Thus, elective surgery should be delayed in these individuals until resolution of acute hepatocellular dysfunction can be confirmed.
6. Asymptomatic patients with any form of chronic hepatitis should be carefully assessed before elective surgery and meticulous care should be taken to maintain hepatic perfusion in the perioperative period and to avoid any hepatotoxic drugs or significant hypotension that might precipitate liver failure or hepatic encephalopathy.
7. Based on large retrospective studies, patients with cirrhosis who are undergoing abdominal surgery, especially those in CPT class C, appear to have an increased risk of perioperative death. Elective surgery in these individuals should be avoided, if possible, in favor of less invasive procedures.
8. Postoperative jaundice may occur as a result of intraoperative hepatobiliary injury, anesthetic-induced hepatotoxicity, severe hepatic hypoperfusion (e.g., cardiogenic or hypovolemic shock), and a variety of medications.
9. Patients with the most advanced forms of liver disease (e.g., CPT class B or C cirrhosis) should receive management designed to maximize hepatic perfusion and hepatic oxygen delivery and to prevent and treat the complications of hepatic encephalopathy, cerebral edema, coagulopathy, hemorrhage, and portal hypertension.

The liver is the largest internal organ in the body and it plays a critical role in the homeostasis of many physiologic systems, including nutrient and drug metabolism, synthesis of plasma proteins and critical hemostatic factors, and detoxification and elimination of many endogenous and exogenous substances.[1] Acute or chronic liver dysfunction can impair the response to anesthesia and surgery in several critical ways, whereas certain anesthetics and hemodynamic disturbances can induce unique and serious alterations in postoperative hepatic function.

In this chapter we will review the anesthetic implications of acute and chronic liver disease, discuss the impact of anesthetics on hepatic function, evaluate perioperative changes in liver function test results and hepatobiliary function, and provide periprocedural considerations for some selected surgical procedures involving the liver and gallbladder.

Effect of Anesthetics on Hepatic Function

This section will focus on the impact of volatile and intravenous anesthetics on liver blood flow and hepatic function. Halothane

hepatitis and related volatile anesthetic-induced hepatotoxicity are discussed in Chapter 24.

Volatile Anesthetics

Volatile anesthetics variably affect blood flow to the liver, whereas intravenous anesthetics and opioids have a less significant impact, although their propensity to alter hepatic blood flow has been less extensively investigated than that of volatile agents. Interpretation of clinical and experimental results is further limited by numerous potential confounding variables that may influence hepatic blood flow and liver function, including the animal species studied, subject age, intravascular volume status, type of mechanical ventilation used, body position at the time of physiologic measurements, simultaneous surgical procedures, changes in blood pressure, concomitant use of vasopressor drugs and local anesthetics, and alterations in hemoglobin and arterial oxygen concentrations. Despite these variables, reasonably firm conclusions can be reached regarding the impact and probable clinical significance of anesthetic agents on hepatic function in normal and cirrhotic patients.

The impact of volatile anesthetics on hepatic blood flow (including hepatic arterial and portal venous blood flow), oxygen delivery, and hepatic oxygen supply-demand ratios has been extensively evaluated for all the major volatile anesthetics, primarily in rat and pig experimental models. Available data from human studies also support the findings of these early experimental investigations.[2,3] A variety of measurement techniques have been used to assess hepatic and portal venous blood flow, but plasma clearance of indocyanine green is most commonly used to assess hepatic blood flow. Transesophageal echocardiography is a new investigative tool that has been used to evaluate hepatic vein flow, but it can be considered only an indirect measurement of hepatic perfusion and oxygenation. A novel technique involving pulsed Doppler probes implanted in animals and in humans undergoing cholecystectomy has allowed accurate measurement of hepatic arterial and portal vein blood flow.[4] Most anesthetics decrease portal blood flow (PBF) because of decreased cardiac output; however, hepatic arterial blood flow (HABF) may increase, although often not sufficiently to restore total hepatic blood flow (THBF) to normal values.[5] THBF is equal to the sum of PBF and HABF. A consistent finding from most studies has been a reduction in mean arterial pressure (MAP) and a modest decrease in cardiac output with all volatile anesthetics but a more pronounced reduction in PBF, HABF, and THBF with halothane and enflurane than with isoflurane and sevoflurane (Fig. 66-1).[2-4,6-10] These changes generally apply across a range of minimum alveolar concentrations (MACs). Volatile anesthetics also alter portal venous and hepatic arterial vascular resistance to variable degrees, which in conjunction with decreases in cardiac output, MAP, and mesenteric sympathetic activity modifies hepatic vascular supply.[11]

Although all current volatile anesthetics decrease MAP and PBF, halothane has a more consistently dramatic impact on HABF. Halothane appears to cause vasoconstriction in the hepatic arterial vascular bed, as reflected by an increase in hepatic arterial resistance.[4,12] In vivo videomicroscopy after halothane exposure in rats has demonstrated reduced sinusoidal blood flow as a result of decreased sinusoidal diameter, thus providing direct evidence of vasoconstriction at the microvascular level.[12] In contrast, isoflurane increased flow velocity in hepatic sinusoids and in this way preserved microvascular blood flow more than halothane or enflurane.[12] Interestingly, Benumof and colleagues[13] demonstrated markedly reduced HABF after halothane administration in two patients during hepatic arteriography; hepatic blood flow returned to normal 20 minutes after discontinuation of halothane anesthesia.

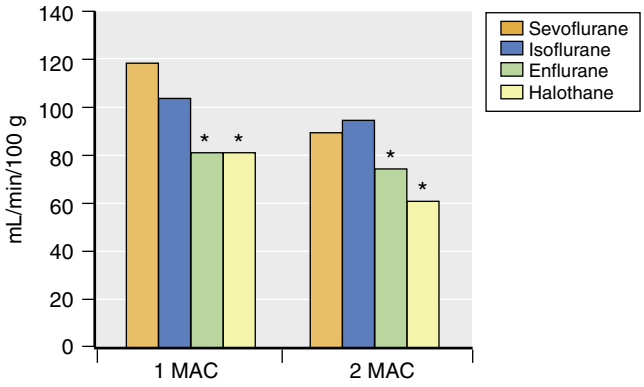

Figure 66-1 Impact of halothane, enflurane, isoflurane, and sevoflurane at 1.0 and 2.0 minimum alveolar concentration (MAC) on total hepatic blood flow (THBF) in dogs. THBF decreased with increasing anesthetic concentrations of each volatile agent. Sevoflurane and isoflurane were similar in their modest effect on THBF, whereas halothane caused a dramatic decrease in THBF, especially at 2-MAC exposure. *Differs from sevoflurane and isoflurane at comparable MAC values ($P < .05$). (*Data from Frink EJ, Morgan SE, Coetzee A, et al: The effects of sevoflurane, halothane, enflurane, and isoflurane on hepatic blood flow and oxygenation in chronically instrumented greyhound dogs. Anesthesiology 76:85-90, 1992.*)

Halothane also reduces hepatic oxygen delivery and hepatic venous oxygen saturation (Fig. 66-2).[14] These changes are related to decreased MAP and more dramatic reductions in cardiac

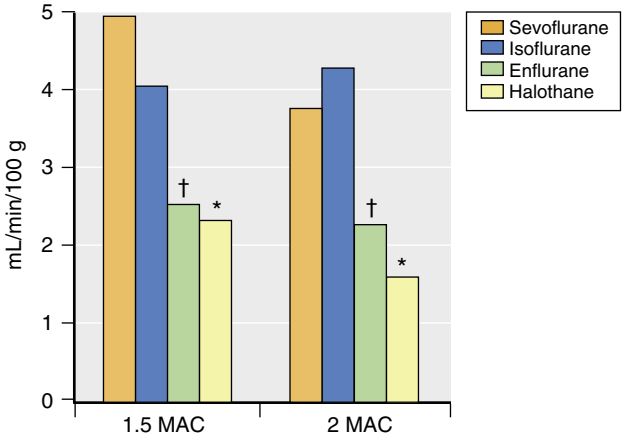

Figure 66-2 Impact of halothane, enflurane, isoflurane, and sevoflurane at 1.5 and 2.0 minimum alveolar concentration (MAC) on hepatic arterial oxygen delivery in chronically instrumented dogs. Halothane produced the greatest reduction in hepatic arterial oxygen delivery, whereas sevoflurane and isoflurane had insignificant effects on oxygen delivery at any MAC level. *Differs from isoflurane and sevoflurane at comparable MAC values ($P < .05$). †Differs from sevoflurane at comparable MAC values ($P < .05$). (*Data from Frink EJ, Morgan SE, Coetzee A, et al: The effects of sevoflurane, halothane, enflurane, and isoflurane on hepatic blood flow and oxygenation in chronically instrumented greyhound dogs. Anesthesiology 76:85-90, 1992.*)

output with halothane than with any other volatile anesthetics.[5] Gelman and associates[9] demonstrated that during surgical stress in pigs, fentanyl or isoflurane anesthesia, which decreases blood pressure by less than 30%, provides adequate oxygen supply whereas halothane anesthesia, which produces decreases in blood pressure greater than 30%, provides inadequate hepatic oxygen supply. This finding also applied to episodes of hepatic ischemia, where fentanyl or isoflurane provided better protection than halothane or enflurane. In addition to vascular changes, hepatic function, as measured by serum transaminase levels, also suggests an unfavorable impact of halothane versus isoflurane.[3]

Volatile anesthetic-induced alterations in hepatic blood flow are, in part, mediated by an autoregulatory mechanism that maintains constant THBF. This physiologic adaptation is termed the *hepatic arterial buffer response* (HABR), which matches reductions in PBF with increases in HABF to maintain total blood flow to the liver constant in the presence of profound hypovolemia, indirect effects of major abdominal surgery, or severe hemorrhage.[15] Halothane appears to disrupt this compensatory response, whereas sevoflurane and isoflurane maintain HABR.[15,16] Sevoflurane further suppresses hepatic arterial vasoconstriction and thus maintains HABF more effectively than halothane does.[17] Sevoflurane is also consistently equivalent or superior to isoflurane in maintaining HABF, hepatic O_2 delivery, and O_2 delivery-to-consumption ratios.[10,18,19] In addition, laboratory studies demonstrate insignificant changes in conventional liver function test results after exposure to isoflurane or desflurane.[3,20-22]

The encouraging results obtained with sevoflurane versus older volatile anesthetics are further supported by the observation that compound A produced by prolonged, low-flow sevoflurane anesthesia does not adversely affect hepatic function in adult surgical patients as determined by liver function testing or measurement of arterial ketone body ratios, a putative measure of hepatocyte function.[23-27] In the largest clinical study of sevoflurane, Bito and colleagues[27] noted mild postoperative increases in bilirubin and transaminase values in 100 surgical patients receiving low- and high-flow sevoflurane or isoflurane anesthesia but no evidence of clinical hepatotoxicity. It is notable that routine liver function test results are often mildly elevated after surgery and anesthesia using a variety of different volatile anesthetics, although the specific contribution of the anesthetic itself is debatable.[3,23,24,28]

Administration of either sevoflurane[25,26,29] or desflurane[30,31] to human volunteers not undergoing surgery produced no significant abnormalities in liver function test results, thus suggesting that other perioperative surgical factors may induce mild, transient alterations in plasma transaminase levels. In fact, early human investigations found steep declines in estimated hepatic blood flow immediately after the induction of anesthesia that correlated with the decrease in blood pressure[32]; hepatic blood flow rapidly returned to normal soon after the start of surgery, suggesting global reductions in cardiac output and blood pressure as mechanisms responsible for the reduced hepatic blood flow rather than a sustained adverse influence of specific volatile or intravenous anesthetics on hepatic blood flow.

Desflurane has effects similar to those of isoflurane on hepatic blood flow and function when assessed in animal and human investigations. In chronically instrumented dogs, Merin and associates[33] demonstrated slight, but significant decreases in THBF at 1.75 MAC as a result of decreased PBF but no significant differences between desflurane and isoflurane in any measure of hepatic blood flow over a range of MAC values. Armbruster and coworkers[21] observed decreased THBF at 1 MAC desflurane in pigs, but only at levels of hypotension unlikely to be encountered clinically and without alterations in liver function test results. Other canine data suggest better preservation of THBF with desflurane than with halothane or isoflurane (Fig. 66-3).[34] Subsequent studies in human volunteers examining hepatic function rather than hepatic blood flow failed to demonstrate any hepatotoxic effects of desflurane.[29-31]

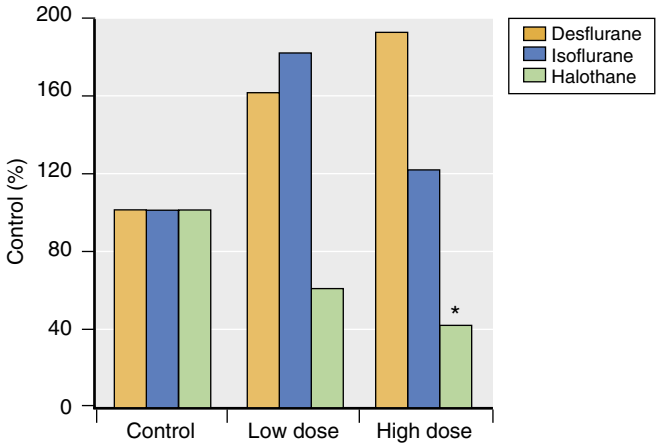

Figure 66-3 Influence of low- and high-dose desflurane, halothane, and isoflurane on total hepatic blood flow (THBF) as measured with radioactive microspheres in chronically instrumented dogs. In contrast to desflurane and isoflurane, which increased THBF, halothane caused a significant decrease in THBF at high doses. *Significantly different from conscious control ($P < .05$). (*Data from Hartman JC, Pagel PS, Proctor LT, et al: Influence of desflurane, isoflurane and halothane on regional tissue perfusion in dogs. Can J Anaesth 39:877-887, 1992.*)

In contrast to healthy volunteers and surgical patients, substantially less information is available describing the impact of anesthetics on hepatic function in patients with advanced liver disease. Limited data suggest that desflurane and isoflurane do not change perioperative liver function test results in adult surgical patients with chronic liver disease.[35] Isoflurane seems to be more efficient at preserving hepatic blood flow in cirrhotic animals than ketamine or halothane,[36] although other studies show no difference in hepatic function in cirrhotic rats exposed to fentanyl, halothane, enflurane, or isoflurane.[37] However, based on the less favorable effects of halothane on both hepatic blood flow and hepatic function, its use should be avoided in patients with advanced liver disease. Given the current availability of suitable alternative volatile anesthetics and the overall declining use of halothane, this issue has become primarily of historical interest. Moreover, as a consequence of the hepatotoxic potential of halothane, many authorities currently consider it unjustifiable to use halothane in healthy adults or any patient with significant hepatic dysfunction.

In this regard, consideration for newer inhaled anesthetics devoid of hepatotoxicity bear mentioning. Xenon, an inert gas, first described as having anesthetic properties in 1951,[38] has been considered to be an ideal inhaled anesthetic because it is nonexplosive and nonflammable, exhibits low toxicity, has no known teratogenic effects, and has rapid induction and recovery profiles owing to its extremely low blood-gas coefficient of 0.115, the lowest of all known anesthetics.[39,40] It has no significant effect on

left ventricular function, systemic vascular resistance, or systemic blood pressure.[40-42] Its hemodynamic profile is similar to propofol anesthesia in humans[41] and was associated with less hypotension and no effect on left ventricular function when compared with isoflurane in human studies.[42,43] Whereas animal investigations suggest a substantial increase in cerebral perfusion with xenon when compared with intravenous anesthetics, it appears to have no effect on other regional organ perfusion, including liver perfusion. It does not alter HABF; and given the absent effect on cardiac output, it should, in theory, have no impact on THBF (unlike all other volatile anesthetic agents). It also does not alter the results of liver function tests. In an experimental model, Reinelt and associates noted higher hepatic venous oxygen content levels in pigs exposed to 73% to 78% xenon versus intravenous anesthesia with pentobarbital and buprenorphine.[44] Their observations were considered to be secondary to a possible reduction of plasma catecholamine levels and subsequent reduced hepatic metabolism and increased hepatic venous oxygen content. Xenon may therefore prove to be an ideal anesthetic relative to hepatic perfusion. Larger clinical trials in patients with both normal and abnormal hepatic function are necessary before definitive conclusions can be reached relative to its safety in patients with acute and chronic liver disease. Unfortunately such a trial with xenon is unlikely.

In summary, the influence of volatile anesthetics on hepatic blood flow and function is complex and related not only to features unique to the anesthetic itself but also to other patient-related variables such as the severity of underlying liver dysfunction, the presence of advanced age, and the impact of surgical stress and intra-abdominal surgical manipulation. However, sevoflurane, desflurane, and isoflurane have been consistently shown to better preserve hepatic blood flow and function than halothane or enflurane. Large-scale prospective studies will be necessary to better define the impact of newer volatile anesthetics on hepatic blood flow in patients with advanced liver disease.

Intravenous Anesthetics

When compared with volatile anesthetics, less information is available regarding the impact of intravenous anesthetics on hepatic function (see Chapters 26 and 27). Early investigations suggested that etomidate and thiopental decreased hepatic blood flow, either from increased hepatic arterial vascular resistance or from reduced cardiac output and blood pressure,[45] whereas ketamine has little impact on hepatic blood flow, even with large doses.[46] With the use of sensitive radiolabeled microsphere determinations of organ blood flow in animals, propofol increased THBF in both the hepatic arterial and portal venous circulation, suggesting a significant splanchnic vasodilator effect of propofol.[47,48] THBF was maintained in some animal models even with significant reductions in MAP,[49] whereas others showed decreased mean hepatic blood flow despite increased MAP, a finding attributed to species-specific effects of propofol.[50] Propofol probably has a more favorable splanchnic and hepatic oxygen delivery balance than halothane.[51] Based on limited clinical and experimental data, intravenous anesthetics have only a modest impact on hepatic blood flow and no meaningful adverse influence on postoperative liver function when arterial blood pressure is adequately maintained.

Central Neuraxial Blockade

The effect of spinal or epidural anesthesia on liver blood flow and hepatic function is not clearly an anesthetic drug-induced alteration in hepatic function (see Chapter 51). Early human investigations by Kennedy and colleagues[52,53] showed that hepatic blood flow decreased during high spinal and epidural anesthesia and appeared to mirror simultaneous reductions in systemic arterial blood pressure. Other animal data have suggested reduced PBF and unchanged HABF with high epidural blockade, thus causing a decrease in THBF.[54] These adverse changes may be reversed and hepatic blood flow may be maintained with the administration of vasopressor drugs (e.g., dopamine or ephedrine) to restore PBF[55-57] or fluid administration to maintain normal arterial blood pressure.[58] Presumably, hypotension-induced reductions in hepatic blood flow are secondary to decreased splanchnic blood flow and, thus, reduced PBF. More recently, Vagts and coworkers noted no change in hepatic oxygen delivery and uptake in anesthetized pigs undergoing thoracic epidural anesthesia with bupivacaine, despite a decrease in HABF. In this study, administration of fluids intravenously before thoracic epidural anesthesia had no effect on THBF.[59]

Effect of Hepatic Dysfunction and Hepatobiliary Disease on Anesthetic Drug Pharmacokinetics

Liver disease may have a significant impact on drug metabolism and pharmacokinetics as a result of alterations in protein binding, reduced levels of serum albumin and other drug-binding proteins, altered volume of distribution because of ascites and increased total-body water compartments, and reduced metabolism secondary to abnormal hepatocyte function (see Chapter 19). In addition, sedatives and opioids may have exaggerated effects in patients with advanced liver disease and may either induce or worsen hepatic encephalopathy.[60] The impact of chronic alcohol ingestion on hepatic enzyme induction may also influence the ultimate effect of drugs in patients with cirrhosis.

The impact of liver disease on drug disposition depends not only on the elimination pathways for a given drug but also on the severity of the underlying hepatic dysfunction. The efficiency of drug removal by the liver is determined by several factors, including hepatic blood flow, hepatic enzyme activity and efficiency, the extent of plasma protein binding, cholestasis-induced alterations in the enterohepatic circulation and metabolism of enteral drugs, and the presence of portosystemic shunts that exclude certain drugs from elimination by the diseased liver.[61] In addition, the influence of liver disease on drug elimination differs for enteral and parenteral drugs.[60] In general, severe liver disease predictably alters the metabolism of drugs with large extraction ratios, such as lidocaine and meperidine, where clearance is primarily dependent on hepatic blood flow or portosystemic shunting. Conversely, the metabolism of low-extraction drugs, such as the benzodiazepines, is influenced mainly by protein binding, where unbound drug is available for elimination,

and by intrinsic hepatic clearance and metabolism, which is reduced in accordance with the severity of hepatocellular dysfunction.[60,61] However, an increased free fraction of a drug because of reduced levels of plasma proteins may counter the impact of reduced hepatic metabolism and lead to modest changes in the ultimate effect of the drug.[61] Finally, greater free fractions of available drug as a result of reduced protein binding may lead to greater drug deposition in tissues (and a potentially increased volume of distribution), which in conjunction with reduced hepatic metabolism may increase drug half-life.[61] It is evident that drug pharmacokinetics in the presence of advanced liver disease is complex. The impact on different classes of drugs is discussed separately.

Opioids

The significantly reduced metabolism of morphine in patients with advanced cirrhosis leads to a prolonged elimination half-life, markedly increased bioavailability of orally administered morphine, decreased plasma protein binding, and potentially exaggerated sedative and respiratory-depressant effects (see Chapter 27).[61] Although extrahepatic metabolism may contribute to morphine clearance in patients with cirrhosis, the administration interval probably should be increased 1.5- to 2-fold in these patients and the oral dose of the drug should be reduced because of increased bioavailability.[61] Similar changes occur with meperidine, for which there is a 50% reduction in clearance and a doubling of the half-life. In addition, clearance of normeperidine is reduced and patients with severe liver disease may experience neurotoxicity from accumulation of normeperidine.[61]

In contrast to these drugs, fentanyl is a highly lipid-soluble synthetic opioid that has a short duration of action after a single intravenous bolus dose because of rapid redistribution into storage sites. With repeated administration or continuous infusions, accumulation may occur and lead to prolonged effects.[61] Because fentanyl is almost completely metabolized in the liver, its elimination should be predictably prolonged in patients with advanced liver disease. However, fentanyl elimination is not appreciably altered in patients with cirrhosis.[61,62] Whether the limited extent of liver disease in the study patients affected the pharmacokinetic data or whether continuous infusions or repeated dosing in cirrhotic patients will produce more exaggerated and pronounced effects is unknown.

Sufentanil, a more potent but similar synthetic lipophilic opioid, is also extensively metabolized by the liver and is highly protein bound. A single-dose pharmacokinetic is not significantly altered in patients with cirrhosis, although the impact of continuous infusions and reduced protein binding is as ill defined for sufentanil as for fentanyl.[63] Alfentanil, a short-acting opioid less potent than fentanyl, is also exclusively metabolized by the liver and is highly protein bound.[61] However, unlike fentanyl or sufentanil, the half-life of alfentanil is almost doubled in patients with cirrhosis and higher free fractions of the drug are observed, which can potentially lead to a prolonged duration of action and enhanced effects.[64,65] Remifentanil is a synthetic opioid with an ester linkage that allows for rapid hydrolysis by blood and tissue esterases; such hydrolysis leads to high clearance, rapid elimination, and recovery that is almost independent of the dose or duration of infusions.[61] Predictably, its clearance should be unaffected by hepatic dysfunction, and available data indicate that remifentanil elimination is indeed unaltered in patients with severe liver disease or in those undergoing liver transplantation.[61,66-68] (See Chapter 67.)

Sedative/Hypnotic Drugs

Thiopental has a small hepatic extraction ratio, and therefore its metabolism and clearance should be adversely affected in patients with liver disease. However, the elimination half-life of thiopental is unchanged in cirrhotic patients, possibly because of a large volume of distribution.[69,70] A prolonged effect from standard doses of thiopental thus seems unlikely in this patient population. In contrast, other intravenous anesthetics, including methohexital, ketamine, etomidate, and propofol, are highly lipid soluble, are metabolized by the liver, have a large hepatic extraction ratio, and would be expected to have diminished clearance in the presence of advanced liver disease.[71] Despite this pharmacokinetic profile, etomidate clearance is unchanged in cirrhotic patients, although increased volumes of distribution may prolong the elimination half-life and result in unpredictable recovery times.[72] Methohexital and propofol also have an elimination kinetic profile in cirrhotic individuals that is similar to that in normal patients,[71] both after single-bolus administration of propofol[73] and after propofol infusion.[74] However, mean clinical recovery times may be longer after discontinuation of propofol infusions in cirrhotic patients.[74] The reduced clearance of midazolam in patients with end-stage liver disease produces prolonged elimination half-lives.[75,76] In conjunction with reduced protein binding and increased free fractions of midazolam, a prolonged duration of action and an enhanced sedative effect should be anticipated in patients with severe liver disease, especially after multiple doses or prolonged infusions. Similar changes have also been observed with diazepam.[76]

Dexmedetomidine, an α_2-adrenergic agonist with sedative and analgesic properties, is primarily metabolized in the liver with minimal renal clearance. Generally, patients with hepatic failure of varying severity have decreased clearance, prolonged half-lives, and lower bispectral index values than in patients with normal liver function.[77] Dosage adjustments are therefore indicated when dexmedetomidine is used in patients with significant hepatic dysfunction. This evidence mirrors, in part, findings from dexmedetomidine use in individuals with renal dysfunction, where prolonged sedation despite unchanged pharmacokinetics has been attributed to altered protein binding, a factor that also applies to patients with hepatic dysfunction.[78,79]

In summary, despite substantial hepatic metabolism of most intravenous anesthetics, cirrhosis has minimal impact on the pharmacokinetic profile of sedative/hypnotic drugs. Given that the clinical effect and duration of action of benzodiazepines are more pronounced in the presence of severe liver disease, these drugs should be given cautiously when using repeated dosing or prolonged infusions, either in the operating room or in the intensive care unit, where drug accumulation, prolongation of effects, and increased risk of hepatic encephalopathy can be anticipated.

Neuromuscular Blocking Drugs

In contrast to the scant pharmacokinetic data described earlier for opioids and intravenous anesthetics, more comprehensive

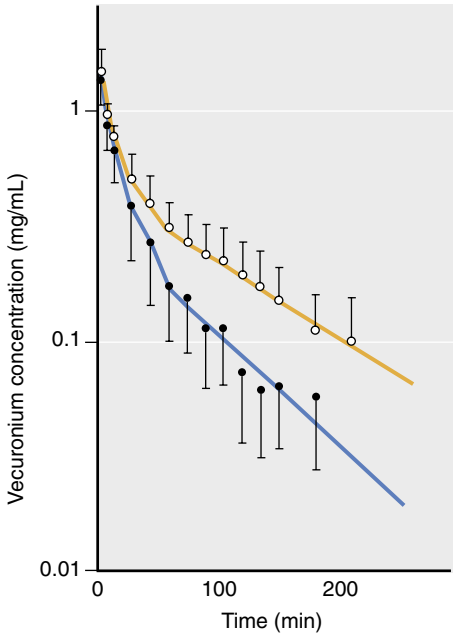

Figure 66-4 Disappearance of vecuronium from plasma after a single bolus dose of 0.2 mg/kg. A semi-logarithmic plot of plasma concentration versus time shows that the vecuronium concentration remained at a much higher level during the elimination phase in patients with cirrhosis (*open circles*) than in normal control patients (*black circles*). This difference reflects the markedly decreased plasma clearance of vecuronium, increased elimination half-life, and increased duration of neuromuscular blockade in patients with cirrhosis versus normal individuals. (*From Lebrault C, Berger JL, D'Hollander AA, et al: Pharmacokinetics and pharmacodynamics of vecuronium (ORG NC 45) in patients with cirrhosis. Anesthesiology 62:601-605, 1985.*)

information is available regarding the impact of cirrhosis on the pharmacokinetics and pharmacodynamics of muscle relaxants (see Chapter 29). Vecuronium is a steroidal muscle relaxant that undergoes hepatic elimination[80,81] and has decreased clearance, a prolonged elimination half-life, and prolonged neuromuscular blockade in patients with cirrhosis (Fig. 66-4).[82,83] The impact of alcoholic liver disease is less definite, with clearance and elimination half-lives typically unchanged.[84] Rocuronium, another steroidal muscle relaxant with a faster onset of action than vecuronium, also undergoes hepatic metabolism and elimination.[85] Hepatic dysfunction can increase the volume of distribution of rocuronium, thereby prolonging its elimination half-life[85] and producing a longer clinical recovery profile and return of normal twitch tension.[85,86] Gao and associates observed a 24% decrease in rocuronium infusion requirement in 17 patients during the anhepatic phase of liver transplantation.[87] (See Chapter 67.) Although the initial clinical recovery of neuromuscular function is not affected by liver disease, larger initial doses or repeated administration will typically prolong the effect of rocuronium in the presence of significant hepatic dysfunction.[85]

The increased volume of distribution for some drugs observed in cirrhotic patients can also prolong the elimination half-life of pancuronium.[88] In patients with end-stage liver disease, muscle relaxants that undergo organ-independent elimination, such as atracurium (nonspecific ester hydrolysis) and cisatracurium (Hofmann elimination), have elimination half-lives and clinical durations of action similar to those in normal patients.[89-92] Laudanosine, a metabolite of both atracurium and cisatracurium, is eliminated primarily by the liver; and although its concentration may increase in patients undergoing liver transplantation, clinically relevant neurotoxicity has not been reported.[93] The unique elimination of mivacurium by plasma cholinesterase is, however, altered by cirrhosis.

Mivacurium will be discussed even though it is not available in some countries and is associated with significantly longer recovery of twitch tension and has a longer elimination half-life (18 versus 34 minutes in normal versus cirrhotic patients, respectively) and a longer residence time in patients with hepatic failure than in normal patients, a finding closely correlated to reduced plasma cholinesterase activity in cirrhotic patients.[94-96] This reduced activity appears to be related to reduced clearance by plasma cholinesterase of the two active isomers of mivacurium, *cis-trans* and *trans-trans*.[96] Infusion rates of mivacurium should be adjusted accordingly in patients with advanced liver disease. The changes observed with mivacurium are predictably expected with succinylcholine if decreased plasma cholinesterase levels are present because of advanced liver disease. Lowered cholinesterase levels have been observed in these individuals[97] and may prolong the effect of succinylcholine.

In summary, cirrhosis and other forms of advanced liver disease will predictably reduce the elimination of vecuronium, rocuronium, and mivacurium and prolong the duration of neuromuscular blockade, especially after repeated doses or the use of prolonged infusions. Atracurium and cisatracurium are not dependent on hepatic elimination and can be used without modification of dosing in patients with end-stage liver disease.

Risk Factors for Postoperative Hepatobiliary Complications

The anesthesia literature is replete with detailed descriptions regarding the preoperative assessment of cardiac risk for noncardiac surgery.[98] In addition, preoperative renal risk factors have been delineated.[99] Defining preoperative risk factors for the development of postoperative hepatic dysfunction or failure after nonhepatic surgery, however, has not been clearly elucidated, and, as such, anesthesiologists have based decisions regarding the care of patients with preoperative hepatic dysfunction on data derived 4 to 5 decades ago. Unfortunately, prospective studies addressing these issues in the current era of newer anesthetic and surgical techniques are lacking. Assessment of risk factors for postoperative hepatic insufficiency requires consideration of (1) asymptomatic elevations in preoperative liver enzyme test results; (2) acute hepatitis (viral, drug, toxin), steatosis, chronic hepatitis, and cirrhosis; and (3) the types of surgery that potentially predispose to postoperative liver dysfunction.

Asymptomatic Preoperative Liver Enzyme Test Abnormalities

Indiscriminate laboratory test screening may reveal abnormally elevated liver enzyme test results in otherwise healthy patients. Abnormalities in standard liver enzyme tests, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), and

alkaline phosphatase, occur in 0.1% to 4% of the general population[100,101] and in as many as 36% of psychiatric patients in whom alcohol and illicit drug abuse is prominent.[102] However, the overall prevalence of clinically significant hepatic dysfunction in asymptomatic patients is less than 1%. Thus, pursuing more extensive evaluation with costly tests such as ultrasonography, radionuclide imaging, or liver biopsy is rarely indicated.

In general, the most appropriate initial approach to a surgical patient with abnormal liver enzyme test results is a detailed history and physical examination. Symptoms of fatigue, anorexia, nausea, vomiting, biliary colic, pruritus, fever, or dark-colored urine warrant further evaluation because they may suggest clinically active hepatobiliary disease and thus potentially preclude elective surgery. If, however, the patient is asymptomatic, the significance of abnormal enzyme test results can be questioned. The patient should be further queried about a history of associated diseases such as chronic hepatitis, a family history of Wilson's disease, hemochromatosis, α_1-antitrypsin deficiency, diabetes mellitus, hyperthyroidism or hypothyroidism, and previous transfusion history. All medications, including vitamins and herbal or other homeopathic remedies, should be reviewed for potential hepatotoxic side effects. The patient should be further questioned regarding alcohol or other illicit drug use, the presence of tattoos, sexual promiscuity, and consumption of raw seafood because they are potential risk factors for infectious hepatitis.

Physical examination may reveal findings consistent with active liver disease, such as icterus, palmar erythema, spider angiomas, gynecomastia, hepatosplenomegaly, ascites, or peripheral edema. Although these findings invariably suggest a diagnosis of cirrhosis, it is reasonable to repeat the test if a complete history and physical examination fail to suggest an etiology of the biochemical abnormality. Minor elevations in liver enzyme test results are considered to be less than twice the normal value[103] and, given a negative history and physical examination, do not warrant additional testing before anesthesia and surgery. Assessment of larger elevations in liver enzyme test results requires an analysis of the specific abnormality.

AST and ALT are sensitive indicators of hepatocyte integrity. AST is present in hepatocyte cytoplasm and mitochondria, but it is also ubiquitous in cardiac and skeletal muscle; kidney, brain, pancreas, and lung tissue; and red and white blood cells. AST is therefore a less specific index of cellular injury than ALT is, which is primarily found in the cytoplasm of hepatocytes. Both enzymes are released when the hepatic cell membrane is injured, although there appears to be a correlation between the degree of injury and serum aminotransferase levels. The AST/ALT ratio may also be helpful in distinguishing between alcohol-induced hepatitis and viral hepatitis. Alcohol tends to preferentially damage hepatocyte mitochondria, thereby causing an elevation in AST usually greater than twice the ALT.[104] In addition, ALT activity is diminished in patients with alcohol-induced liver disease because these individuals tend to have deficiencies of pyridoxal 5-phosphate, a vitamin necessary for ALT function. In contrast, a decrease in the AST/ALT ratio is more consistent with a diagnosis of viral hepatitis. Aminotransferases also increase in choledocholithiasis, cholangitis, and ischemic hepatitis. Ischemic hepatitis may not uncommonly produce levels greater than 10,000 IU/L.

Similar to AST, alkaline phosphatase is present in many tissues, including bone, intestine, kidney, and placenta, as well as in leukocytes. The enzyme catalyzes the hydrolysis of orthophosphate from ester substrates at an alkaline pH. In hepatocytes, alkaline phosphatase is synthesized by biliary epithelial cells and is released in relation to the degree of bile duct obstruction. Measuring serum γ-glutamyltransferase (GGT), an enzyme found predominantly in hepatocytes and biliary epithelial cells, may aid in distinguishing between hepatic and bone etiologies of increased alkaline phosphatase. Although GGT is a very sensitive indicator of the presence or absence of hepatobiliary disease, by itself it lacks specificity because it is also increased in patients with myocardial infarction, renal disease, diabetes mellitus, and chronic obstructive pulmonary disease. If alkaline phosphatase and GGT are elevated, the abnormality probably reflects hepatobiliary disease. Increased levels of alkaline phosphatase and GGT usually occur with extrahepatic bile duct obstruction and intrahepatic cholestasis from infiltrative diseases such as sarcoidosis, from mass lesions such as primary or metastatic carcinoma, or from drug-induced cholestasis.

Although liver enzyme elevation is an indication of active disease, synthetic hepatic function is best measured by serum bilirubin, albumin, and the prothrombin time. The bilirubin concentration in plasma varies in accordance with its production and inversely with hepatic clearance. Hepatic microsomal enzymes convert unconjugated bilirubin to the more water-soluble form, thereby permitting excretion in bile and preventing central nervous system toxicity. Total bilirubin levels represent conjugated (direct bilirubin) and unconjugated (indirect bilirubin) forms. Unconjugated hyperbilirubinemia suggests hemolysis or an inherited disorder of bilirubin metabolism such as Gilbert's syndrome. If more than 50% of the total serum bilirubin is conjugated, cholestasis or hepatocellular dysfunction is implied. Albumin is synthesized solely in the liver and, in healthy adults, has a half-life of approximately 21 days. The normal level of 3.5 g/dL usually decreases in long-standing and severe liver disease but is also influenced by overall nutritional status.

Finally, hepatobiliary dysfunction can cause an abnormal prothrombin time by impairing synthesis of the essential clotting factors II (prothrombin), VII, IX, and X. Hepatic synthesis of these factors is dependent on vitamin K, a fat-soluble vitamin found in certain foods and produced by intestinal bacteria, so abnormalities in prothrombin activity (as expressed by the international normalized ratio [INR]) may also occur in patients with malnutrition or malabsorption syndromes. The plasma half-time of these vitamin K–dependent factors is very short (less than 24 hours) and hence the INR responds rapidly to changes in synthetic function, which makes this test a more sensitive index of hepatic function than serum albumin.

Although no prospective, randomized, controlled studies have been designed to assess the perioperative risk of anesthesia or surgery in asymptomatic patients with elevated liver enzyme test results, a suggested approach to these patients is outlined in Figure 66-5. Abnormal liver enzyme test results in an otherwise healthy patient reflect either a subclinical acute process such as viral or toxin-mediated hepatitis or a chronic disorder such as chronic hepatitis.

Acute Hepatitis

The diverse role of the liver in drug metabolism, hemostasis, and coagulation function, in association with surgery and anesthesia-related alterations in hepatic perfusion, make it an organ extremely susceptible to clinically important viral-, alcohol-, or other

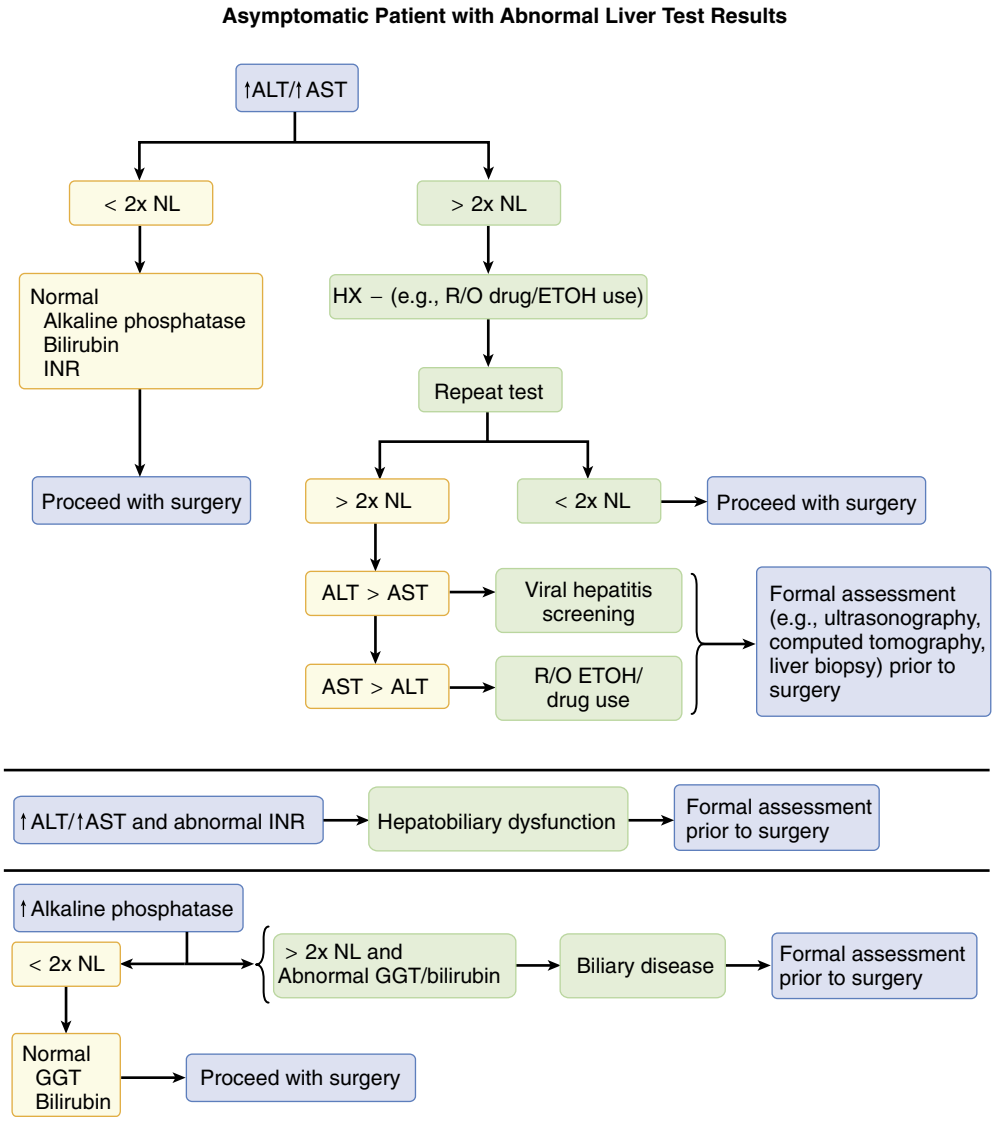

Figure 66-5 Approach to asymptomatic patients with abnormal liver test results presenting for surgery. ALT, alanine aminotransferase; AST, aspartate aminotransferase; ETOH, ethyl alcohol; GGT, γ-glutamyl transferase; HX, history; INR, international normalized ratio; NL, normal limit; R/O, rule out.

drug-induced hepatocellular injury. Consensus opinion, based largely on data derived from older, predominantly retrospective studies, is that acute hepatitis, whether viral, alcohol, or drug induced, is a risk for the development of hepatic failure or death after elective surgery. In 1982, Powell-Jackson and coauthors[105] described 36 patients who underwent exploratory laparotomy for either suspected extrahepatic biliary tract obstruction or intra-abdominal malignancy, all of whom were ultimately found to have viral or alcoholic hepatitis, cirrhosis, or Budd-Chiari syndrome. Of these patients, 61% suffered significant morbidity, including postoperative liver failure, and 31% died within 1 month of surgery. All of the patients with histologically proven hepatitis died. Greenwood and associates[106] also reported high mortality rates in patients with alcoholic hepatitis undergoing open liver biopsy. Bell and colleagues,[107] however, noted that survival rates were not influenced by the presence of biopsy-proven hepatitis in 164 patients with alcoholic cirrhosis requiring emergency portocaval shunts for esophageal variceal bleeding.

In the current era of advanced diagnostic testing and imaging where nonoperative management of extrahepatic biliary tract obstruction can be performed with endoscopic retrograde cholangiopancreatography (ERCP), invasive procedures such as open liver biopsy or exploratory laparotomy can often be avoided. Elective surgery should be delayed in patients with acute hepatitis of any etiology until resolution of hepatocellular dysfunction can be confirmed.[60] The influence of the type of surgery on patients with hepatitis is described later.

Steatosis and Steatohepatitis

Patients with chronic, asymptomatic elevations in serum aminotransferase levels are often found by liver biopsy to have steatosis (fatty liver) or steatohepatitis.[108] Hultcrantz and coworkers[109] studied 149 asymptomatic patients with at least a 6-month history of elevated aminotransferase levels found incidentally during

routine laboratory screening.[109] Liver biopsy confirmed the diagnosis of steatosis in 64% of these patients, most of whom were obese or diabetic or had a history of excessive alcohol use. In a subsequent study, Hay and colleagues[108] demonstrated a 21% incidence of steatohepatitis in a similar patient population. Both studies concluded that chronic hepatitis or cirrhosis cannot be differentiated from steatosis or steatohepatitis based solely on clinical laboratory or noninvasive radiologic or ultrasonographic criteria. In a retrospective analysis of 135 patients who underwent hepatic resection, Behrns[110] noted an increased incidence of postoperative liver failure and mortality when the histopathology revealed hepatocytes with greater than 30% fatty infiltration. Brolin and associates[111] noted a 6% incidence of biopsy-proven nonalcoholic steatohepatitis and subclinical cirrhosis in patients undergoing gastric bypass surgery; postoperative mortality was higher in affected patients than in those with normal hepatic histology. Despite recommendations to the contrary,[112] steatosis and steatohepatitis should probably be considered significant risk factors for postoperative complications, especially after abdominal procedures. For this reason, patients with asymptomatic, chronic (>6 months) elevations in hepatic enzyme levels should be thoroughly evaluated before elective surgery.

Chronic Hepatitis

The extent of anesthetic or surgical risk imposed by chronic forms of hepatitis primarily relates to the severity of associated hepatic synthetic dysfunction. Runyon[113] retrospectively studied 20 asymptomatic patients who had chronic hepatitis B or C and were undergoing general or spinal anesthesia for a total of 34 surgical procedures, most of which were at operative sites distant from the liver. Liver enzyme test results did not worsen postoperatively, nor did any patient experience postoperative liver failure or death. Subsequently, Higashi and colleagues[114] assessed the postoperative outcomes of 119 patients with chronic hepatitis who were undergoing liver resection for primary hepatocellular carcinoma (HCC). Patients with the most impaired liver enzyme test results had a higher incidence of hepatic failure, recurrent HHC, and death.[115]

These observations suggest that asymptomatic patients with any form of chronic hepatitis should be screened before elective surgery for evidence of hepatic dysfunction, with the INR being the most sensitive indicator of the severity of hepatocellular dysfunction. When surgery cannot be avoided, meticulous care should be taken perioperatively to maintain hepatic perfusion and avoid factors that might precipitate liver failure, hepatic encephalopathy, or both (see later).

Cirrhosis as a Perioperative Risk Factor

Cirrhosis is a syndrome of end-stage liver disease pathologically characterized by severe fibrosis and nodular regeneration of the liver parenchyma (see Chapter 67). Alcohol abuse remains the most common cause of cirrhosis. Other causes include chronic hepatitis, primary biliary cirrhosis, hemochromatosis, Wilson's disease, and idiopathic cirrhosis. In the past, the Child-Turcotte-Pugh (CTP) scoring system was the most frequently used tool to predict perioperative risk in cirrhosis patients undergoing abdominal surgery, exclusive of portosystemic shunt procedures (Table 66-1).[116] This scoring system assigned points based on levels of serum albumin and bilirubin, the INR, the degree of ascites, and the presence and grade of encephalopathy and stratified risk in order of severity as class A, B, or C. A number of studies have used this system to predict perioperative outcome in cirrhosis patients undergoing a variety of surgeries.

Table 66-1 Modified Child-Turcotte-Pugh Scoring System

Parameters	Modified Child-Turcotte-Pugh Score*		
	1	2	3
Albumin (g/dL)	>3.5	1.8-3.5	<2.8
Prothrombin time			
Seconds prolonged	<4	4-6	>6
International normalized ratio	<1.7	1.7-2.3	>2.3
Bilirubin (mg/dL)†	<2	2-3	>3
Ascites	Absent	Slight-moderate	Tense
Encephalopathy	None	Grade I-II	Grade III-IV

*Class A = 5.6 points, B = 7 to 9 points, and C = 10 to 15 points.
†For cholestatic diseases (e.g., primarily biliary cirrhosis), the bilirubin level is disproportionate to the impairment in hepatic function and an allowance should be made. For these conditions, assign 1 point for a bilirubin level less than 4 mg/dL, 2 points for a bilirubin level of 4 to 10 mg/dL, and 3 points for a bilirubin level over 10 mg/dL.

Garrison and coworkers[117] retrospectively evaluated outcomes in 100 patients with histologically proven cirrhosis who were undergoing surgery predominantly for biliary tract procedures (cholecystectomy, choledochotomy), as well as for gastroduodenal repair, colon and small bowel resection, and open liver biopsy. An overall operative mortality of 30% and an additional perioperative morbidity of 30% were noted, with sepsis-mediated multiorgan system failure being the major cause of death (87%). When stratified to CTP classes A, B, or C, mortality was 10%, 31%, and 76%, respectively. Excluding the CTP classification, the authors also performed a multivariate analysis of other perioperative variables and concluded that preoperative prolongation of the prothrombin time, decreased serum albumin, and a total leukocyte count greater than 10,000/cm^3 predicted increased mortality. Finally, operative mortality was considerably more frequent in patients requiring urgent versus elective surgery (57% versus 10%). Over a decade later, Mansour and associates[118] retrospectively analyzed 92 cirrhotic patients undergoing abdominal procedures and described nearly identical results, with mortality rates of 10%, 30%, and 82% in patients with CTP classes A, B, and C, respectively. Other retrospective studies have also shown that perioperative risk is exceedingly high when performing major abdominal surgery, especially under emergency circumstances and in CTP class C cirrhotic patients.[119-122]

In contrast, Rice and colleagues,[123] described the lack of predictability of the CTP classification in patients with chronic liver failure undergoing not only abdominal surgery but also coronary bypass grafting, orthopedic procedures, as well as other peripheral surgeries. In this retrospective analysis of 40 patients, perioperative prolongation of the INR and clinical evidence of encephalopathy were the only variables most associated with

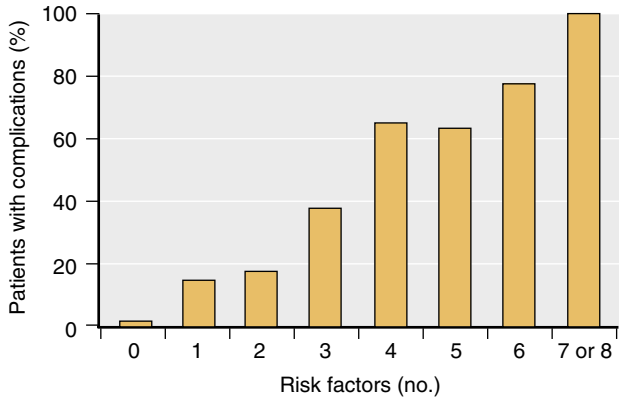

Figure 66-6 Effect of the number of risk factors on the perioperative complication rate in cirrhotic patients undergoing surgery. Risk factors included the CPT score, the presence of ascites, a diagnosis of cirrhosis other than primary biliary cirrhosis, serum creatinine concentration, a diagnosis of chronic obstructive pulmonary disease, preoperative infection, preoperative upper gastrointestinal bleeding, higher American Society of Anesthesiologists physical status score, intraoperative hypotension, and higher surgical severity score. (*From Ziser A, Plevak DJ, Wiesner RH, et al: Morbidity and mortality in cirrhotic patients undergoing anesthesia and surgery. Anesthesiology 90:42-53, 1999.*)

increased mortality (10 and 35 times that of normal individuals, respectively).

Ziser and coworkers,[124] in the largest of all these retrospective studies, established an 11.6% 30-day mortality rate in 773 patients with cirrhosis who were undergoing a variety of surgical procedures involving local, regional, or general anesthesia. Multivariate analysis identified male gender, CTP class C, ascites, azotemia, perioperative infection, higher American Society of Anesthesiologists (ASA) physical classification, a diagnosis of cryptogenic cirrhosis, and surgery on the respiratory system as risk factors independently associated with mortality. Further analysis identified additional risk factors for perioperative complications (Fig. 66-6).

Predicting perioperative risk of cirrhosis and other forms of acute and chronic liver disease may be further enhanced by the incorporation of the Model for End-stage Liver Disease (MELD) score.[125] Although the MELD score was introduced as a tool to better prioritize organ allocation for orthotopic liver transplantation (see Chapter 67), retrospective and prospective studies suggest the superiority of MELD to CPT in predicting both intermediate and long-term survival for patients with cirrhosis, acute alcoholic hepatitis, and other forms of chronic liver disease.[126-128] Refinements to the predictive value of this scoring system include the MELD score over time[129] and the incorporation of the serum sodium level.[130] Relative to surgical risk, Salerno and associates noted improved accuracy of MELD over CPT scores in predicting survival of patients undergoing transjugular intrahepatic portosystemic shunting (TIPS).[131] However, large prospective studies comparing MELD to CPT in cirrhotic patients undergoing other nonhepatic surgeries are lacking, and, as such, CPT continues to be employed as a measure of assessing perioperative risk.

Despite the lack of prospective studies, cirrhosis is still considered a major risk factor for patients undergoing nonhepatic surgery, with elective surgery considered contraindicated in CTP class C patients.[132] In addition, it is probably prudent to avoid elective surgery in cirrhotic patients with a prolonged INR, hypoalbuminemia, and evidence of preoperative infection or encephalopathy. Alternatives to extensive abdominal procedures, such as cholecystostomy or laparoscopic cholecystectomy versus open cholecystectomy, should be considered for the treatment of cholelithiasis.[133,134] Preoperative decompression of portal hypertension by TIPS may also improve postoperative outcomes in certain patients.[135] Finally, elective abdominal surgery should probably be avoided if a diagnosis of cirrhosis is made fortuitously at the time of surgery.[111]

Surgical Procedures That Increase the Risk of Postoperative Liver Failure

In addition to the severity of preoperative hepatic dysfunction, the actual surgical procedure performed may be the most important risk factor for postoperative liver failure.[136] Under normal circumstances, the liver is able to adapt to changes in perfusion pressure by altering either HABF or PBF. In a diseased state, pathologic changes may diminish the adaptive capacity of this dual blood supply and predispose the liver to the deleterious effects of surgery. Abdominal surgery per se appears to significantly reduce THBF. Surgical manipulation of the splanchnic bed may reduce both PBF and HABF, in part because of resultant systemic arterial hypotension mediated by prostacyclin-induced dilation of the venous capacitance vessels.[137] The effect of pneumoperitoneum on hepatic blood flow remains controversial; however, Meierhenrich and colleagues, utilizing transesophageal echocardiography, noted an increase in hepatic perfusion with carbon dioxide insufflation in healthy patients undergoing laparoscopic hernia repair.[138]

In addition to surgery on the biliary tract, stomach, and colon, hepatic resection for HCC is a known risk factor for the development of liver failure in patients with preoperative hepatic dysfunction. Most patients with HCC have liver dysfunction associated with either chronic hepatitis or cirrhosis.[115,139] The diminished functional hepatic reserve of these patients may decrease the amount of tissue that can be resected without compromising viable parenchyma and causing liver failure, the most common cause of death after this surgery. Wu and coworkers[140] retrospectively analyzed cirrhotic patients undergoing hepatic resection for HCC based on degree of hepatic dysfunction. By limiting the amount of tissue resection in patients with significant hepatic dysfunction (i.e., poorer CPT class), the authors noted 5-year survival rates comparable to those in patients with less severe forms of cirrhosis who underwent more extensive resections. Perioperative hemorrhage is a common occurrence in cirrhotic patients undergoing resection for HCC because of contributing factors such as portal hypertension, coagulation abnormalities, and highly vascular adhesions in those with previous abdominal surgery. Preoperative evaluation of patients with HCC by indocyanine green 15-minute retention[140,141] or direct measurement of the hepatic venous pressure gradient[142] can be beneficial in predicting postoperative outcomes in cirrhotic patients undergoing hepatic resection for HCC.

Cardiothoracic surgery is associated with a high mortality rate in patients with preexisting liver disease.[124,143-145] Hepatic dysfunction is often exacerbated by cardiopulmonary bypass (CPB), although the precise mechanism of this dysfunction has not been clearly elucidated. In a canine model of hypothermic nonpulsatile

CPB, Koizumi and colleagues[146] noted a decrease in PBF and HABF without a concomitant change in hepatic oxygen metabolism. Normothermic CPB was associated with a similar decline in PBF, but HABF was maintained. Increasing the dose of fentanyl from 10 to 50 µg/kg/hr significantly suppressed HABF and impaired hepatic oxygen metabolism in normothermic and hypothermic CPB, suggesting the possibility of fentanyl-mediated peripheral venous pooling and subsequent lowering of cardiac output. More recently, Okano and coworkers[147] assessed hepatosplanchnic oxygenation in 25 patients with no history of hepatic dysfunction who were undergoing elective coronary artery bypass grafting with either normothermic (>35°C) or hypothermic (<32°C) CPB. Hepatic venous desaturation and functional impairment of hepatic sinusoidal endothelial cells occurred in both groups, but hepatocellular dysfunction was not observed.

In addition to the possible effects of hepatic artery and portal venous perfusion, other potential determinants of hepatic dysfunction after CPB include hypotension, low cardiac output syndrome, hypoxemia, microembolism or macroembolism, cytokine and oxygen-free radical formation, and the influence of vasoactive and anesthetic drugs. Small retrospective studies have shown 11% to 30% mortality rates in CTP class A and B patients undergoing nonemergency cardiac surgery.[143-145] Although more deaths occurred in the CTP class B group, significant morbidity, particularly in the form of postoperative hemorrhage and infection, was seen in the CTP class A patients. Finally, noncardiac, thoracic surgery may be a risk factor for postoperative mortality in patients with cirrhosis, although the basis for this association remains speculative.[124]

Postoperative Jaundice

Postoperative jaundice occurs as a result of overproduction and underexcretion of bilirubin, direct hepatocellular injury, or extrahepatic obstruction.[148] Most causes of postoperative jaundice manifest within 3 weeks of surgery and can be classified as either mild (<4 mg/dL) or severe (>4 mg/dL). Table 66-2 lists the most common causes of postoperative jaundice based on the nature of the pathophysiology.[148] If jaundice is secondary to hemolysis, the liver's capacity to conjugate bilirubin (normal rate of production, 250 to 300 mg/day) has been exceeded. Hemolysis-induced anemia is therefore associated with unconjugated (indirect) hyperbilirubinemia and, in the perioperative period, can usually be attributed to either drug-induced or mechanically induced erythrocyte destruction. The primary mechanisms by which certain drugs cause hemolysis and subsequent jaundice are (1) the drug adsorption type, whereby an antibody (IgG) reacts with a drug bound to the red blood cell membrane; (2) the neoantigen type (so-called innocent bystander), whereby the drug combines with the erythrocyte membrane and an antibody reacts with the newly formed antigenic site to activate the complement cascade; and (3) the autoimmune type caused by an autoantibody (IgG) to erythrocytes. Medications commonly used perioperatively and associated with one or more forms of hemolytic anemia are listed in Table 66-3.[149]

The degree of associated jaundice is related to the rate of hemolysis and excess production of bilirubin, with the neoantigen mechanism most likely to cause acute anemia, hemoglobinuria, and renal failure. The diagnosis is made by the laboratory constellation of anemia, indirect hyperbilirubinemia, positive direct antiglobulin test, low serum haptoglobin, and the presence of fragmented erythrocytes and reticulocytosis on the peripheral blood smear. Mechanical destruction of erythrocytes can also occur from surgically implanted prosthetic heart valves or from intrinsically diseased valves.[150]

Multiple blood transfusions can increase levels of unconjugated bilirubin because approximately 10% of stored whole blood undergoes hemolysis within 24 hours of transfusion (see Chapter 55). Each 0.5-L unit of blood stored in citrate-phosphate-dextrose-adenine (CPDA-1) yields 7.5 g of hemoglobin, which is then converted to approximately 250 mg of bilirubin.[151] Multiple units of blood may therefore overwhelm the liver's ability to conjugate and excrete bilirubin. Finally, reabsorption of extravasated blood, as occurs with retroperitoneal or intra-abdominal hematomas, may increase the bilirubin load and cause postoperative jaundice. This etiology is not uncommon after major trauma or repair of ruptured aortic aneurysms.

Hepatocellular injury can cause postoperative jaundice (as previously discussed) by drug, ischemia, or virally mediated mechanisms. In addition to potential anesthetic-induced hepatotoxicity, a number of commonly prescribed drugs can cause hepatocellular injury that mimics either hepatitis or cholestasis based on liver test abnormalities (Tables 66-4 and 66-5[152-199]). exception of acetaminophen, which can directly cause hepatocyte necrosis, drug-induced hepatotoxicity is primarily the result of either idiosyncratic reactions or alterations in bile flow resulting in cholestasis.

Postoperative jaundice may also occur as a result of hepatic hypoperfusion. Cardiogenic and noncardiogenic shock can decrease HABF and PBF and cause hepatocellular necrosis. Marked increases in aminotransferase levels are common, with hyperbilirubinemia usually a late finding. In addition to hemodynamic alterations in hepatic blood flow, sepsis or the systemic inflammatory response syndrome is associated with cholestasis and jaundice, presumably because of the effects of circulating endotoxins or other inflammatory mediators on bile formation and flow.[200] Finally, it is important to exclude viral hepatitis as the cause of postoperative jaundice because viral exposure may have occurred before surgery.

Obstruction of the common bile duct from a gallstone, stricture, or tumor can result in failure to excrete conjugated bilirubin (obstructive jaundice) and has been associated with significant perioperative morbidity and mortality. Factors associated

with a poor outcome after surgery in patients with obstructive jaundice include extrahepatic obstruction as a result of malignancy, malnutrition, hypoalbuminemia, low hematocrit (<30%), azotemia, and the level and duration of hyperbilirubinemia.[201,202] Dixon and coauthors[203] cited an overall mortality rate of 9.1% in a retrospective analysis of 373 patients requiring surgery for obstructive jaundice, but a 60% mortality rate for patients with anemia, malignancy, and marked hyperbilirubinemia (>11 mg/dL). Of paramount significance is the association of acute renal failure with obstructive jaundice.[204,205] The incidence of postoperative acute renal failure is 8% to 10% and correlates directly with the degree of hyperbilirubinemia, with mortality rates as high as 70% to 80% reported. Neither bilirubin nor bile acids themselves are directly nephrotoxic, but experimental evidence suggests a negative chronotropic, vasodilatory, and diuretic effect of bile salts, resulting in systemic and thus renal hypoperfusion. The changes appear to be related to enhanced absorption of endotoxin from the gastrointestinal tract because of low intestinal levels and high serum levels of bile acids. This stimulates a release of inflammatory mediators, in particular endothelin, a potent renal vasoconstrictor that leads to a further decline in renal perfusion.[206,207] Other experimental data have implicated endotoxemia-induced nitric oxide release as a further mediator of renal hypoperfusion.[208] These patients clearly pose a challenge to the anesthesiologist, who is often forced to rely on the limitations of urine output as a method of monitoring renal perfusion. It is probably more reliable to monitor effective blood volume and cardiac function with either a central venous or pulmonary artery catheter or perform transesophageal echocardiography, with the goal of maintaining renal perfusion by augmenting cardiac output.[99] No data have documented the clinical benefit of mannitol, furosemide, or dopamine in perioperative renal protection,[99,209] and the potential benefit of endothelin receptor blockers has yet to be thoroughly assessed in clinical studies.[206]

Perioperative Management of Patients with Asymptomatic or Chronic Liver Dysfunction

The goal of perioperative management of patients with asymptomatic elevations in aminotransaminase, alkaline phosphatase, or bilirubin levels or those with preexisting chronic liver disease is prevention of acute liver failure or further hepatic deterioration. Acute liver failure, defined by encephalopathy in the setting of acute liver injury (e.g., viral hepatitis, toxin ingestion, idiosyncratic drug reaction, sepsis, or shock), is further categorized into hyperacute, acute, or subacute forms based on the time interval between the onset of jaundice and encephalopathy (0 to 7 days, 8 to 28 days, >28 days, respectively).[210] Patients with the hyperacute form of acute liver failure tend to have a more favorable survival rate (35%), whereas those with the acute and subacute forms have poorer prognoses, with mortality rates of 93% and 86%, respectively.[210] It is therefore imperative to identify perioperative risks and direct therapy to minimize hepatotoxicity and maximize hepatic oxygen delivery. For example, drugs such as acetaminophen or combined drugs such as acetaminophen/hydrocodone probably should not be administered to patients with asymptomatic elevation of liver enzyme test results or chronic liver dysfunction. In patients with cholelithiasis and biliary tract obstruction, it may be prudent to limit the use of opiates preoperatively because they have been reported to cause spasm of the choledochoduodenal sphincter (sphincter of Oddi) and a subsequent increase in intrabiliary tract pressure.[211,212] These effects appear to be more pronounced for fentanyl, morphine, and meperidine and less severe for opiate agonist-antagonists.[211,212] Intraoperatively, opiates may be used with the recognition that the possible development of sphincter of Oddi spasm can be treated directly with naloxone or by relaxing smooth muscle tone with either glucagon or nitroglycerin[212,213] (which induces release of nitric oxide).[214,215] (See Chapter 31.)

Remifentanil appears to have a similar effect as other opiates on the sphincter of Oddi. Fragen and colleagues[216] studied remifentanil given to six healthy adult volunteers who underwent radionuclide imaging of the gallbladder before and after remifentanil infusion. The recovery time for dye to appear in the duodenum after discontinuation of the infusion was significantly greater than in the control phase of the study. The authors noted, however, that this delay in recovery of gallbladder function was shorter than in studies using morphine or meperidine. Finally, no data support the benefit or detriment of regional versus general anesthesia, nor do data suggest particular anesthetic drugs that should be administered or avoided with preexisting hepatic dysfunction, with the exception of halothane, as previously discussed.

Patients with more advanced liver disease (e.g., CTP class B or C cirrhosis) require an anesthetic plan designed to maximize hepatic oxygen delivery and prevent and treat the complications of encephalopathy, cerebral edema, coagulopathy, hemorrhage, and portal hypertension. Hepatic encephalopathy commonly occurs in patients with chronic liver disease because of the accumulation of circulating neurotoxins such as unmetabolized ammonia, gut-derived false neurotransmitters, γ-aminobutyric acid (GABA), and endogenous GABA receptor agonists; altered

neurotransmission by the excitatory neurotransmitter glutamate; or altered cerebral energy homeostasis.[217] Clinically, hepatic encephalopathy is manifested by neuropsychiatric abnormalities ranging from subtle personality changes and cognitive dysfunction to more advanced depression of consciousness, delirium, and coma. Clinical signs include abnormalities in psychometric testing and apraxia, as well as the more severe findings of asterixis, hyperreflexia, and decerebration. When hepatic encephalopathy occurs with acute liver failure, it often has a rapid onset and is invariably complicated by cerebral edema. Cerebral edema develops as a result of the osmotic effect of accumulated glutamine producing astrocyte cell swelling or as a result of cerebral vasodilation caused by loss of autoregulation, or because of both mechanisms.[218] These patients invariably require urgent liver transplantation. (See Chapter 67.)

A multitude of factors may precipitate hepatic encephalopathy in patients with chronic liver disease. Potassium levels should be monitored and hypokalemia should be treated to decrease the effect of decreased potassium levels on renal production of ammonia. Arterial pH should be maintained near normal because systemic alkalemia is also noted to increase the diffusion of ammonia across the blood-brain barrier, which can potentially worsen the degree of encephalopathy.[217] Effective circulating blood volume should be maintained and anemia should be corrected to maintain hepatic oxygenation and promote the metabolism of circulating toxins. Benzodiazepines should be used judiciously because they may activate the central GABA-benzodiazepine receptor ligand and worsen hepatic encephalopathy. In this regard, it should be noted that all psychoactive drugs will have potential deleterious effects on hepatic encephalopathy by further suppressing a vulnerable central nervous system. Hepatic encephalopathy is also a recognized complication of the TIPS procedure.[219]

When patients remain obtunded or comatose after anesthesia and surgery, therapy is often directed toward decreasing ammonia production. Lactulose is administered either by nasogastric tube or by enema to create an osmotic, cathartic effect and to lower intestinal pH, thereby decreasing the survival of ammonia-producing bacteria.[169] Flumazenil, a specific antagonist of central benzodiazepine receptors, can improve the level of consciousness in selected cirrhotic patients with severe hepatic encephalopathy.[220]

Perioperative hemorrhage in patients with significant liver dysfunction may occur because of bleeding diatheses or the complications of portal hypertension (or both). Synthetic hepatic function, as measured by the INR, is useful to assess the severity of the coagulopathy and to gauge therapy, including the subcutaneous administration of vitamin K, transfusion of fresh frozen plasma, use of recombinant factor VII or other factors, and plasmapheresis.[210] (See Chapter 55.) In patients with acute liver failure, plasmapheresis may have potential benefit because it promotes rapid correction of coagulopathy while minimizing volume overload, but no large prospective controlled studies have yet validated this practice.[221]

Hemorrhage may also occur as a result of gastrointestinal bleeding from rupture of esophageal or gastric varices as a complication of portal hypertension. Intraoperatively, it is advisable to avoid the placement of a transesophageal echocardiography probe to avoid initiation of bleeding in patients with esophageal varices. Pharmacologic therapy for acute esophageal variceal bleeding includes use of the combination of vasopressin and nitroglycerin, somatostatin, or octreotide, a synthetic analog of somatostatin.[222,223]

Portal hypertension may also lead to the development of ascites. Ascites occurs with advanced liver disease secondary to renal retention of sodium and water and localization of this excess fluid in the peritoneal cavity because of portal hypertension. In addition to the general measures of sodium and water restriction and diuretic therapy, therapeutic paracentesis may be indicated if a patient presents for surgery with tense ascites.[224] Relief of tense ascites may improve pulmonary gas exchange and reduce the risk of gastric aspiration. Care should be taken, however, to prevent circulatory collapse by the concomitant administration of intravenous colloid solutions because intravascular volume re-equilibration occurs 6 to 8 hours after the removal of a larger volume of ascitic fluid.[222] Finally, patients with end-stage liver disease are at risk for the development of either hepatorenal or hepatopulmonary syndrome. Hepatorenal syndrome is a state of functional renal failure characterized by azotemia, hyperosmolar urine, and urinary sodium excretion less than 10 mEq/L.[225] Although the pathogenesis of this syndrome has not been clearly elucidated, there appears to be a decrease in renal perfusion pressure related to systemic vasodilation in combination with a loss of renal autoregulation because of increased sympathetic activity.[224] The diagnosis of hepatorenal syndrome in patients with end-stage liver disease usually signals the need for orthotopic liver transplantation. In the event that transplantation is not possible, management is supportive and consists of the use of intravenous volume challenges and large-volume paracentesis to relieve tense ascites.

The hepatopulmonary syndrome, which is defined by the triad of end-stage liver disease, increased alveolar-arterial gradient, and intrapulmonary vascular dilation, is characterized by the clinical features of digital clubbing, cyanosis, dyspnea, platypnea, and orthodeoxia, in addition to the other clinical characteristics of portal hypertension. Orthodeoxia, defined as arterial oxygen desaturation that is more pronounced in the upright position and relieved by recumbency, is a common phenomenon of hepatopulmonary syndrome.[226] The pathogenesis of hepatopulmonary syndrome is considered to be primarily related to intrapulmonary vascular dilation diagnosed by contrast-enhanced echocardiography, perfusion lung scanning, or pulmonary arteriography. Current pharmacologic therapy for this disorder is limited; however, orthotopic liver transplantation may lead to a reversal of these pulmonary changes (see Chapter 67).

Anesthetic Considerations for Procedures Involving the Liver and Biliary System

Transjugular Intrahepatic Portosystemic Shunt Procedure

TIPS is a percutaneously created intrahepatic connection of the portal and systemic circulations. This procedure is typically used in patients with end-stage liver disease to decrease portal pressure and attenuate the complications related to portal hypertension, such as variceal bleeding or refractory ascites. Diversion of PBF into the hepatic vein is achieved by placement of an expandable intraparenchymal tract (Fig. 66-7).

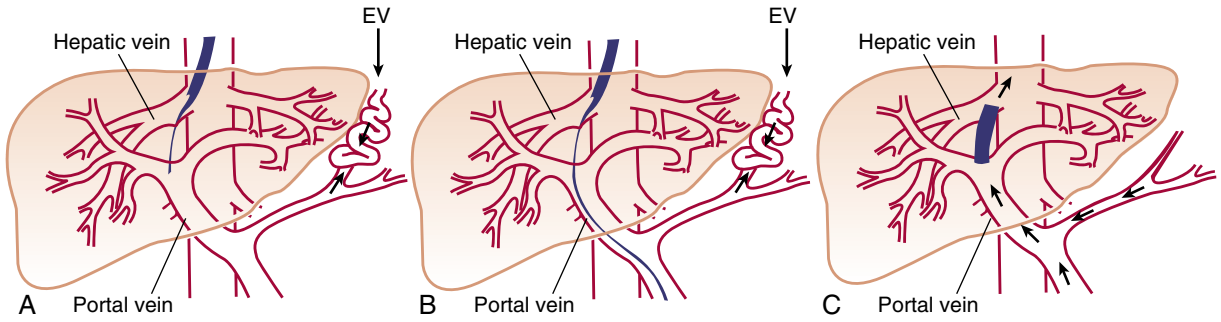

Figure 66-7 Transjugular intrahepatic portal-systemic shunt (TIPS) procedure. A stent (or stents) is passed through the internal jugular vein over a wire into the hepatic vein (**A**); dilated esophageal varices (EV) are apparent. The wire and stent or stents are then advanced into the portal vein (**B**), after which blood can pass through the portal vein into the hepatic vein and bypass and decompress dilated esophageal veins (**C**). (*Reproduced with permission from www.med.umich.edu/1libr/topics/liver09.htm.*)

Although most patients can undergo TIPS placement with sedation, some clinicians prefer to use general anesthesia in selected patients because of the prolonged nature of the procedure, the potential respiratory-depressant effects of sedatives in cirrhotic patients with underlying pulmonary dysfunction as a result of ascites and/or hypoxemia from the hepatopulmonary syndrome, and concern regarding possible gastric aspiration. Regardless of the anesthesia chosen, appropriate intravascular volume resuscitation is necessary before the procedure, especially in patients who have had variceal bleeding. In addition, patients with cirrhosis undergoing a TIPS procedure frequently have a severe coagulopathy that requires preprocedural procoagulant therapy.

Several complications can occur during placement of TIPS that may require intervention by the anesthesiologist. Pneumothorax or neck vessel injury can occur during vessel puncture. These complications may be reduced by ultrasonographic guidance during jugular vein puncture. Additionally, cardiac dysrhythmias can be mechanically induced during intracardiac catheter passage. Finally, the anesthesiologist should be prepared to manage acute, life-threatening hemorrhage caused by hepatic artery puncture in conjunction with a hepatic capsular tear or by extrahepatic portal venous puncture. Hemodynamic status can deteriorate with the development of pulmonary edema and congestive heart failure in patients with borderline cardiac reserve.[227]

Hepatic Resection

Preoperative considerations before hepatic resection involve risk assessment primarily utilizing the CTP or MELD classification. Upper endoscopy, CT scan, and/or MRI are often performed to rule out significant esophageal varices. Severe thrombocytopenia or large varices represent major perioperative risk and should preclude surgery until treated.[228] Significant anemia and coagulopathy, if present, should be corrected preoperatively. Decisions regarding the choice and dosing of anesthetic drugs should account for any baseline hepatic parenchymal dysfunction as well as the potential postoperative dysfunction resulting from resection of a major portion of the liver parenchyma.

Although the risk of significant intraoperative blood loss is well known and the need for appropriate monitoring and sufficient vascular access to permit rapid transfusion is widely accepted, overall fluid management during major hepatic resection is controversial. At some centers, fluid and blood administration is used liberally beginning early in the course of resection with the goal of increasing intravascular volume as a buffer against sudden blood loss. Other centers favor maintenance of a low central venous pressure during resection to minimize blood loss from hepatic venous radicals, major hepatic veins, or the vena cava. These sites typically contribute to most bleeding during hepatic resection. Notably, reduction of intrahepatic venous pressure can also be achieved by using a modest degree of the Trendelenburg position, an approach that will potentially maintain or even increase cardiac preload and cardiac output, as well as reduce the risk of air embolism from disrupted hepatic veins. In patients without preexisting renal dysfunction, the latter approach does not appear to have a significant impact on postoperative renal function.[229]

Although basic postoperative management concerns are similar to those of other major abdominal procedures, several aspects of care are notable. Intravenous fluids should be supplemented with either sodium or potassium phosphate, which is often needed to prevent severe hypophosphatemia and also to facilitate liver regeneration. Decreased clearance of hepatically metabolized drugs is important in selecting and titrating methods of postoperative analgesia.

Hepatic Cryotherapy

Hepatic cryotherapy involves the application of material at subzero temperature by multiple-lumen probes positioned intraoperatively under sonographic guidance. This procedure is used to treat nonresectable malignant hepatic tumors. Preanesthetic considerations for hepatic cryotherapy are similar to those for hepatic resection. Heat conservation measures should be instituted during the procedure, with continual monitoring of core temperature. Intraoperative bleeding is rarely significant enough to cause hemodynamic instability. Postoperative pulmonary, renal, and coagulation problems may be manifested as sequelae of the "cryoshock syndrome," even after a procedure with unequivocal intraoperative stability.[230]

67 Anesthesia for Abdominal Organ Transplantation

Key Points

Solid Organ Transplantation

1. Solid organ transplantation is an accepted treatment of end-stage organ disease.
2. The discrepancy between the number of organ donors and organ recipients is increasing.
3. To increase the donor pool, living organ donors and extended criteria donors are being used.
4. Preoperative evaluation of organ systems should consider interval changes.

Kidney Transplantation

1. Patients with end-stage renal disease are subject to accelerated atherosclerosis and should be considered to have a significant perioperative cardiac risk.
2. Maintenance of adequate perfusion pressure to the newly transplanted kidney is crucial for initial graft function.
3. Anesthetic drugs that are dependent on renal excretion, especially muscle relaxants or their metabolites, should be used with caution.

Pancreas Transplantation

1. Patients may undergo pancreas transplantation alone, in combination with kidney transplantation, or after kidney transplantation.
2. Close glucose monitoring is required throughout the procedure.
3. Administration of colloids is preferred intraoperatively.
4. The immunosuppressive drug OKT3 can cause significant hemodynamic instability and noncardiogenic pulmonary edema.

Liver Transplantation

1. The model of end-stage liver disease calculates the severity of liver disease.
2. Preparation for massive transfusion and significant hemodynamic instability is essential.
3. Extubation in the operating room can be safely performed in selected patients.

Improvement in the success of solid organ transplantation over the past decades is remarkable and well documented. Refinement of perioperative care and improved post-transplant patient management over recent years have resulted in dramatic improvements in 1-year and 5-year graft survivals. These changes have led to a significant increase in the number of medical centers performing solid organ transplantation and increased public awareness. In addition, the indications for solid organ transplantation have been broadened. Some perceived contraindications, such as concomitant human immunodeficiency virus (HIV) infection and advanced age, are being overlooked in selected cases.[1,2] Similarly, patients receiving methadone maintenance therapy are considered for transplantation.[3,4]

As of the end of 2004, 153,245 people were living with a functioning organ transplant in the United States. The number of patients wait-listed for solid organ transplantation is steadily increasing and is currently around 90,000. The organs most frequently transplanted are the kidney and liver, which together accounted for more than 70% of all transplanted organs.

Only 54% of all donated organs from deceased donors were actually recovered in 2001. This fact, in conjunction with public perception about organ donation and brain death and limited awareness of health care professionals, has contributed to a severe shortage of cadaver donor organs. Different strategies have been adopted to increase the donor pool, including extension of donor criteria and the use of living related and unrelated donors, particularly for kidney and liver transplantation. These attempts alone are unlikely, however, to ameliorate the donor organ shortage in the long run. To help address the issue of maximizing the number of organs available for transplant, the Health Resources and Services Administration launched the Organ Donation Breakthrough Collaborative in 2005. As outlined in the mission statement, the collaborative intends to identify and promote the best practices in organ donation for adoption by hospitals and

organ procurement organizations, ultimately with the goal to increase transplantable organs from deceased donors. One recognized need is the identification of beneficial interventions in donors after determination of neurologic death.

The success of organ transplantation is based on a highly specialized team approach, including the cooperation of procurement organizations, transplant coordinators, and nurses, and physicians from many specialties. Except for kidney transplantation, most solid organ transplantations are performed at tertiary medical centers, which can provide all the needed medical, logistic, and technical expertise necessary to support a successful transplant program. Increasingly, medical subspecialties are providing physicians dedicated to the field of transplantation. In addition to transplant surgeons, most major centers rely on dedicated transplant hepatologists and nephrologists.

Anesthesia for kidney and pancreas transplantation is performed by most anesthesiologists, whereas most major centers have a dedicated liver transplant anesthesia team. Smaller centers may not have enough transplant volume or personnel, however, to staff a separate liver transplant anesthesia team. As a result, anesthesiologists who have experience in major hepatic surgery or cardiothoracic surgery are frequently called on to provide anesthesia for these complex and challenging cases. New guidelines regarding perioperative anesthesia coverage are currently being considered by the American Society of Anesthesiologists and United Network for Organ Sharing (UNOS).

This chapter reviews anesthetic considerations for kidney, liver, pancreas, and intestinal transplantation in adult recipients. Solid organ transplantation in pediatric patients is not addressed in this chapter (see Chapter 82).

Care of Organ Donors after Neurologic Determination of Death

Most potential deceased donors are previously healthy or relatively healthy individuals who have experienced brain death and do not have an extracranial malignancy or untreatable infection. Less than 5% of deaths satisfy these criteria, and only 10% to 20% of these eligible subjects actually become organ donors. In addition, a significant proportion of potential organ donors are lost because of medical exclusion (e.g., sepsis, malignancy, incurable infection) or inability to obtain consent for donation.[6,7] Historically, organs from older donors (>60 years old) have inferior survival rates than grafts from younger donors, but if proper selection criteria are applied, long-term graft survival reaches those of younger donors.[8]

In an attempt to fulfill the need for more organs, organs are being transplanted from extended criteria donors—donors who are considered not ideal because of underlying demographics or medical conditions (e.g., age, hypertension) or subsequent prolonged ischemia times. Outcomes data for all solid organs are not consistent with studies performed in kidney transplantation, reporting either similar or inferior post-transplant graft quality.

Nonetheless, significant ethical conflicts surrounding the definition of brain death in different social and cultural settings have been an obstacle in transplantation.[9] In the United States and Western Europe, a consensus has been reached among the scientific community with regard to the definition of brain death. There is, and will continue to be, considerable discussion, however, about concepts and definitions of death and the legal definition of death.[10] These issues are colored by the effects of cultural differences; concepts and definitions of death are not equally accepted from one culture to another. Many Western cultures have committed to deceased organ donation, and the emphasis of discussion is quite different from that in Japan or Taiwan, for example.

Determination and Declaration of Brain (Neurologic) Death

There is uniform agreement on the neurologic examination of adult brain-dead subjects, also called donors after determination of neurologic death, with the exception of the apnea test (see Chapter 98). Standardization of the procedures for diagnosing brain death is quite different among countries, however.[11] Criteria promulgated by the American Academy of Neurology in 1995 are generally applied in North, Central, and South America.[11,12] These standards grew out of the landmark Harvard Criteria published in 1968.[12] In Europe, criteria for the clinical evaluation of brain death also are fairly uniform, with the principal difference being the number of physicians needed to confirm the diagnosis.

Several requirements need to be met to declare brain death. At the time of examination, the patient must be comatose with neither spontaneous movement nor response to painful stimuli. A lack of brainstem activity should be confirmed by assessment of brainstem reflexes (Table 67-1) and the apnea test. Possible causes of reversible cerebral dysfunction should be excluded (e.g., hypothermia, residual drug effects). For the apnea test, the patient breathes 100% oxygen for 10 minutes, during which time the P_{CO_2} is confirmed to be in the normal range (35 to 45 mm Hg). Subsequently, mechanical ventilation is terminated, and blow-by oxygen is administered with a T-piece. After 7 to 10 minutes, an analysis of arterial blood gases is performed. A P_{CO_2} value greater than 60 mm Hg confirms lack of brainstem control of ventilation and represents a positive apnea test. No signs of spontaneous respiratory effort should be observed during this procedure. Confirmatory tests, such as transcranial Doppler, electroencephalography, and auditory evoked potentials, also may be used.

Intraoperative Management

Organ retrieval is not performed solely at major medical centers. Most organ retrievals are performed at community hospitals

Table 67-1 Brainstem Reflexes That Should Be Absent in Brain Death

without academic affiliation. Any anesthesiologist may be confronted with a brain-dead patient and the attendant pathophysiologic perturbations. The logistics of harvesting organs, the social circumstances (i.e., interaction with relatives of the potential organ donor), and the unusual sequence of intraoperative events may seem intimidating to the anesthesiologist.

Cessation of cerebral function invariably results in a sequence of pathophysiologic changes leading to death of the potential organ donor within a few days, unless appropriate intervention is undertaken. At the same time, it may take several days for identification of a possible organ donor, declaration of brain death, consent, and eventual organ recovery. Perioperative hemodynamic stabilization is crucial for prevention of donor organ damage or loss.

After an initial hyperdynamic response consisting of hypertension with or without tachycardia, brain-dead patients brought to the operating room for organ recovery experience hypotension, reduced cardiac output, myocardial dysfunction,[14] and vasodilation (decreased systemic vascular resistance). In addition, diminished oxygenation as a result of neurogenic pulmonary edema and diabetes insipidus secondary to decreased circulating levels of antidiuretic hormone may be observed. The latter also may lead to hypernatremia and hypokalemia. Hyperglycemia, coagulopathy, and hypothermia may be encountered and must be corrected when severe. The aggressiveness of treatment is determined by which organs are being recovered because the quality of resuscitation may have an impact on organ viability.

Certain guidelines[15] can be summarized as follows:

- Systolic blood pressure greater than 100 mm Hg (mean 70 to 110 mm Hg)
- Po_2 greater than 100 mm Hg
- Urine output greater than 100 mL/hr (1 to 1.5 mL/kg/hr)
- Hemoglobin concentration greater than 100 g/L
- Central venous pressure (CVP) 5 to 10 mm Hg
- Fio_2 less than 40% (if tolerated) for lung retrieval
- Glucose concentrations less than 200 mg/dL (or even <150 mg/dL)

To achieve these goals, the anesthesiologist should use standard monitors, measure urine output, and use invasive measurements of arterial pressure and CVP (frequently with a pulmonary artery catheter).

Hypotension should be treated initially by intravenous administration of fluids. A mixture of crystalloid and colloid solutions, and occasional administration of blood, most rapidly corrects hypovolemia with the goal of increasing urine output. For lung and pancreas transplant retrieval, colloids are preferred over crystalloids. Frequent communication with the surgical team regarding intravascular volume replacement is essential. Excessive fluid administration may result in swelling and even loss of the organ. To decontaminate the intestines for retrieval of the pancreas, a mixture of povidone-iodine (Betadine), amphotericin, and normal saline is administered through an orogastric/nasogastric tube. If pharmacologic support of the circulation is necessary, the inotrope of choice is usually dopamine; however, other cardiovascular drugs, such as norepinephrine, epinephrine, vasopressin, and dobutamine, may be added to maintain hemodynamic stability during the later stages of organ dissection and harvest.

Surgical techniques may vary depending on whether the procedure is for recovery of a single organ or multiple organs.[13] Generally, wide exposure of the surgical field is established, cannulas are placed for in situ perfusion, and the organs to be removed are isolated with preservation of their central vascular structures. Heparin is administered (approximately 20,000 to 30,000 IU) when requested by the recovery team. If recovery of the heart or lung is anticipated, pulmonary artery catheters or central venous catheters need to be withdrawn before cross-clamping. If lung recovery is anticipated, the lungs are ventilated well beyond cross-clamping and initiation of organ recovery other than the lung. Removal of the organs is performed under cold protection by applying ice to the surgical field. Organs are removed according to their susceptibility to ischemia, with the heart first and the kidney last in a multiorgan donor. Excellent communication between the often different surgical teams (e.g., abdominal organ team versus thoracic organ team) and the anesthesiologist is crucial to ensure optimal organ quality.[13] In the United States, several donor management initiatives critically review current standard-of-care practices and develop new and uniform management algorithms. In several Western European countries, uniform treatment algorithms are already successfully used.

Vasodilators such as phentolamine or alprostadil (lung recovery) may be administered during cross-clamping with the goal of decreasing systemic vascular resistance and allowing even distribution of the preservation solution. Long-acting nondepolarizing muscle relaxants should be used for optimal intra-abdominal and intrathoracic exposure. Clinically significant bradycardia in brain-dead patients does not respond to atropine, so a direct-acting chronotrope such as isoproterenol must be readily available. Patients declared brain-dead do not have pain perception, so analgesia is not required. Volatile anesthetics or narcotics may facilitate hemodynamic stability, however. The changes in heart rate and arterial blood pressure that may occur with surgical stimulation are the result of intact spinal reflexes. Although these hemodynamic changes can often be easily controlled with vasoactive agents alone, the anesthesiologist probably would be most comfortable responding to these changes by increasing the amount of volatile anesthetics.

Finally, the anesthesiologist may be asked to draw blood for several pretransplant tests. The volume may vary in different organ procurement organizations, but is generally 60 to 200 mL in adults.

Donation after Cardiac Death

A more recent development to increase the organ supply is the use of donation after cardiac death, formerly known as non–heart-beating organ donors. Originally introduced in the 1960s, it was subsequently abandoned and has been reintroduced only more recently. Medical centers re-explored this source of potential donors for abdominal organs (mainly kidneys).[16] In the United States, the use of organs from donations after cardiac death has steadily increased over the past decade, and these donors now represent about 7% of kidney transplants.[17] In 1993, the number of non–heart-beating organ donors in the United States was 42; it increased to 167 by 2001 and increased further to 561 by 2005.[18]

Policies were developed by organ procurement officials and hospitals to allow organ donation as an option to be considered for relatives of patients who potentially qualify as donors after cardiac death. In contrast to deceased donors, whose heart function, circulation, and tissue oxygenation are preserved until the organs are retrieved, organs from donors after cardiac death can be removed only after cardiac arrest. The difference invariably introduces a longer warm ischemia time that can potentially result in suboptimal donor organs. Donation after cardiac death can be categorized as controlled or uncontrolled, and these categories determine the extent of warm ischemia experienced by the organ donors. Controlled donations after cardiac death are from patients for whom the transplant team is awaiting the cardiac arrest, and all necessary preparations for rapid organ recovery are in place. In contrast, uncontrolled donations after cardiac death are from patients who have experienced unanticipated cardiac arrest; resuscitation has been unsuccessful, and consideration is being given to possible organ donation.

In addition to a prolonged warm ischemia time, legal, ethical, and logistic concerns prevent many centers from adopting this form of organ donation.[19] More recent studies from Switzerland and the United States have shown favorable long-term results, however, with regard to graft function in recipients of organs donated after cardiac death.[20-22] It remains to be seen whether this form of organ procurement from donation after cardiac death will achieve wider acceptance in the transplant community and provide a means to augment the donor organ pool significantly.

Organ Preservation

Solid organ harvesting and transplantation invariably cause injury to the donor organ. Three main distinct periods have been identified that contribute to injury: (1) storage of recovered organs ex vivo during transport (generally under hypothermic conditions) from the donor to the recipient, (2) the implantation phase (rewarming phase) without reperfusion, and (3) the initial reperfusion phase with the reintroduction of oxygen. Each period contributes to deterioration of the organ through a different pathway. Ex vivo storage involves immediate cooling and flushing of the organ after recovery with several available preservation solutions. Currently, most organs are stored at 4°C without continuous perfusion after initial flushing. At some centers and organ procurement organizations, organs are continuously perfused, in some cases with normothermic preservation.

Various cold storage solutions used worldwide include Collins, Euro-Collins (Fresenius, Germany), Bretschneider/Histidin-Tryptophan-Ketogluterat (HTK) (Franz Koehler Chemie, Germany), Celsior (Sangstat Medical Corporation, United States), Perfadex (Vitrolife, Sweden), and University of Wisconsin (UW) (Du Pont, United States).[23,24] Although the UW solution is probably the most frequently used solution, especially for intra-abdominal organs, the significantly cheaper HTK solution has been increasingly used with good results.[25] Most solutions are modified with additives (e.g., oxygen radical scavengers) that are believed to improve organ storage conditions. The content of the various organ preservation solutions varies widely, as does the amount used. UW solution contains 120 mmol/L of potassium versus only 10 mmol/L in the HTK solution. These differences may have clinical implications, such as a greater potential for hyperkalemia after reperfusion of organs (mainly liver) preserved in UW solution. Hyperkalemia is seen mainly, however, in cases in which the preservation solution is not adequately flushed with colloids before implantation. Organ-specific flush solution is commonly used with Euro-Collins solution, and more recently, Perfadex solution especially for lung storage. The heart is frequently stored in Celsior preservation solution, but medical centers occasionally may have center-specific cardioplegia solutions. Sometimes perfluorocarbons are used as a component of the two-layer method for preservation of the pancreas.[26] Organ preservation solutions are under constant review and undergo frequent modifications.

The maximum cold preservation time varies among organs and solutions used. Typically, kidneys can be stored in cold preservation solution for up to 24 to 30 hours before transplantation, although the ischemia time does have an impact on outcome. In contrast, hearts must be transplanted within hours of retrieval. Continuous machine perfusion (as opposed to cold storage) of the organ has attracted some attention.[27] This method is not widely adopted currently, however, and large randomized trials are necessary to show its feasibility.[28]

Care of Living Organ Donors

The first living donor transplantation was performed in 1954, when a kidney was transplanted from one man to his twin brother.[29] The lack of effective immunosuppressive treatment at that time prohibited the use of deceased organs. With the introduction of immunosuppressive drugs, improved long-term graft survival was achieved, and the use of deceased donors rapidly accelerated in most Western countries. In Japan, transplantation from deceased donors has not been well accepted, mainly because of cultural and ethical norms. In 1997, legislation was passed in Japan that allowed organ donation from selected brain-dead donors.[30] Organ transplantation from living donors has become an important, well-developed alternative for patients with end-stage organ disease in Japan and other Asian countries.[31] The benefits to donor and recipient must outweigh the risk associated with the recovering of a living donor organ.[32]

Living donors generally are very healthy and almost exclusively classified as American Society of Anesthesiologists grade I or II patients. In the past, donors were usually relatives of the prospective recipient. More recently, candidates unrelated to the recipient are increasingly being accepted as donors. By the time that they are determined to be eligible for donation, donors have undergone an extensive medical, psychological, and social evaluation.[33,34] Many living donor and recipient pairs are turned down during the screening process for medical and nonmedical reasons (e.g., social or psychological concerns) that may affect the donor or recipient. A major concern surrounding living organ donation is the potential for great harm to be inflicted on entirely healthy individuals who undergo major surgery for purely altruistic reasons. The ethical and psychological aspects (e.g., coercion of the donor) of living organ donation, particularly liver donation, continue to be widely examined and discussed.[32,35-39] In addition, the quality of life after organ donation and the financial impact on the donor are of great concern.[40,41]

Organ donation from living donors has significant advantages over deceased organ donation. In contrast to deceased

donors, living donors are always hemodynamically stable, and the procedure can be planned on an elective basis. In addition, the cold ischemia time of the organ can be minimized compared with that associated with deceased donors. Perhaps the most important advantage of living donor transplantation is the significant reduction in time spent on the waiting list to receive an organ from a deceased donor.

Living Kidney Donor

Renal transplantation with organs from living donors has rapidly been increasing in recent years. In the past, donor nephrectomy was done by the traditional approach through a subcostal lateral incision, by minimal incision nephrectomy, or by the laparoscopic approach. Laparoscopic live donor nephrectomy now has almost completely replaced the traditional open approach via subcostal lateral flank incision. Melcher and colleagues[42] reported 500 consecutive laparoscopic donor nephrectomies without the need to open or reoperate for technical difficulties. The laparoscopic approach has been shown to be advantageous with regard to decreased postoperative pain, time of hospitalization, recovery, and improved cosmetic results.[43,44]

Morbidity after living kidney donation is low, and the type of complication (e.g., reoperation, ileus, readmission to the hospital) depends on the surgical technique. Matas and coworkers[45] reported two donor deaths and one donor who has remained in a persistent vegetative state in a series of 10,828 living kidney donations between 1999 and 2001. Shokeir[46] performed a meta-analysis of 69 studies comparing open versus laparoscopic donor nephrectomy and discovered eight perioperative deaths after laparoscopic nephrectomy. More recent studies confirmed that laparoscopic donation results in a safer procedure, a more rapid convalescence, and a lower opioid consumption compared with open donation. Placement of an epidural catheter is not indicated.[46-48] Nevertheless, Ellison and colleagues[49] caution that the long-term risks may not yet be apparent, and that long-term follow-up data are needed.

Either kidney can be used for donation; however, the left kidney is usually preferred because of easier surgical exposure and a longer vascular supply. The patient is placed in either a right or a left lateral position with the table flexed and the kidney rest elevated. Invasive monitoring is not required, and one or two large peripheral intravenous lines suffice. Some centers have 2 U of blood (frequently autologous) available in the operating room in case of injury to major vascular structures, which would require emergency exploratory laparotomy. To maintain good diuresis and to optimize graft function, fluid administration is generous (10 to 20 mL/kg/hr), even though blood loss is minimal in most cases. The preferred type of fluid in this setting is unknown because no human trial has yet addressed this issue. In the absence of scientific data, most centers use isotonic crystalloids. The anesthetic technique in these healthy patients is not different from that used for other laparoscopic procedures. Nitrous oxide is contraindicated because it causes bowel distention and worsens surgical exposure.[50] Similarly, the potential complications seen during any laparoscopic procedure (e.g., pneumothorax, subcutaneous emphysema) can be encountered during this procedure.

The first phase of the procedure consists of mobilization of the colon followed by the upper portion of the kidney, with subsequent identification and dissection of the ureter, renal vein, and artery. Division of the adrenal vein also is performed.[51] The surgeon may request administration of furosemide or mannitol (or both) during the operation to maintain adequate urine output. Shortly before the renal vessels are clamped, intravenous heparin (3000 to 5000 IU) is administered. Protocols may vary among institutions, and close communication with the transplant surgeon is essential. After complete mobilization of the kidney and clamping of the vascular structures, the kidney is retrieved by either a hand-assisted or non–hand-assisted[52] technique through a small periumbilical or infraumbilical incision under direct laparoscopic vision. If heparin has been given, protamine may be administered to normalize coagulation. After the kidney is removed, the surgical field is inspected again for bleeding. Closure, as in all laparoscopic cases, is rapid, and care should be taken to maintain reversibility of neuromuscular blocking agents at the conclusion of the procedure. Postoperative pain is usually mild to moderate and can be managed easily in most cases with supplemental intravenous opioids in the immediate postoperative period.

Living Liver Donor

Living donor liver transplantation began in the early 1990s and quickly became a widely accepted technique in children.[37,53] The regenerative capability of the liver has long been recognized and exploited, and complete recovery of liver function in the donor and the recipient can be expected after donation of a portion of the liver. The primary presurgical consideration is determination of the mass of transplanted liver that is needed to support a given patient and to leave enough liver mass with the donor. Several formulas, including the graft-recipient body weight ratio and graft weight as percentage of standard liver mass, are used to ensure adequate liver mass in the donor and recipient.[33,54]

Pediatric living donor liver transplantations generally require resection of only the left lateral segment (segments II and III) or a total left hepatic lobectomy (segments II, III, and IV) to provide sufficient liver mass. These types of grafts are expected to grow along with the patients as they mature. From a surgical point of view, a left hepatectomy is less complex, and the duration of surgery is shorter.[55,56]

This technique has been extended to adult patients as well. The number of living donor liver transplantations performed annually in the United States grew slowly through most of the 1990s (representing about 1% of liver transplants), but increased dramatically beginning in 1998 (from 56 in 1996 to 515 in 2001). The number has now plateaued between 200 and 300. This rapid increase is primarily due to increased numbers of right hepatic lobectomy for adult-to-adult living donor liver transplantation. The surgical technique for right hepatectomy involves separation of the right hepatic lobes (segments V, VI, VII, and VIII) from the left (Fig. 67-1). This technique results in a graft weighing 500 to 1000 g, which leaves the donor with about one third of the original liver mass. In select cases, the left lobe of a large donor may suffice for a small recipient, either with or without a portal shunt.

Volumetric studies have shown that the donor's liver regains its original size in a short time, often within weeks to months.[57,58] Functional recovery may take much longer, however.[59,60]

Most living donor liver transplantations are done in patients with chronic liver failure and are done on an elective basis.

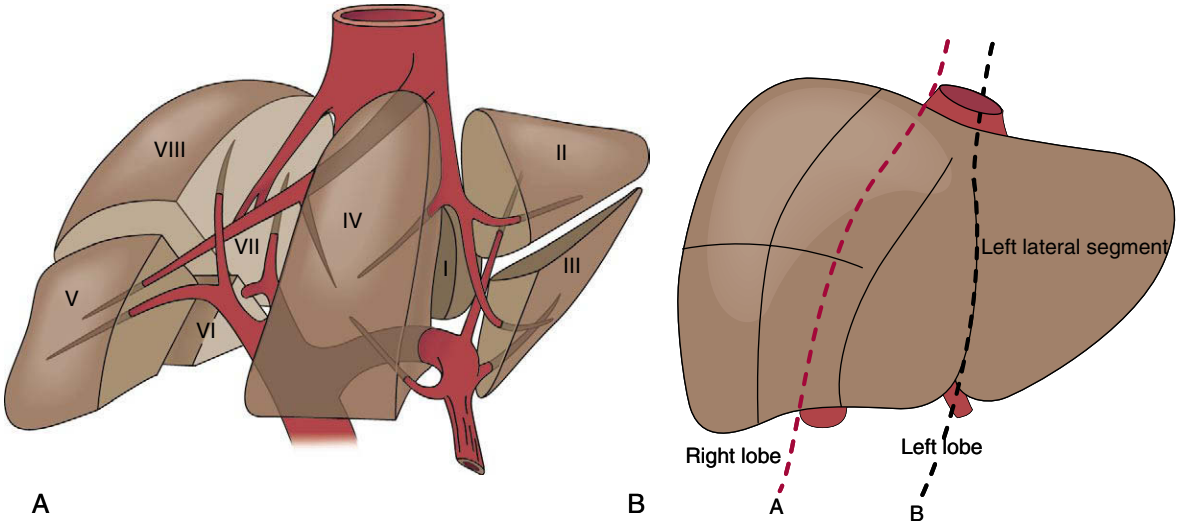

Figure 67-1 **A,** Segmental liver anatomy. Each segment is supplied by a portal pedicle consisting of the hepatic artery, portal vein branch, and bile duct. **B,** Segments V to VIII are frequently used for adult-to-adult living donor transplantation. *(Redrawn from Renz JF, Yersiz H, Farmer DG, et al: Changing faces of liver transplantation: Partial-liver grafts for adults. J Hepatobil Pancreat Surg 10:31-44, 2003.)*

Although it is controversial, living donor transplantation may be performed in rare cases in patients with very advanced disease or decompensated end-stage liver disease.[61,62] In contrast, in children with subacute or acute liver failure, living donation, mostly from parents, is commonly accepted. The ethical issues, such as coercion of the donor, involved in these cases are even more pronounced.[63,64] In addition, relative inexperience with the procedure may lead to an unacceptably high complication rate. Worldwide, several donor deaths related to the surgical procedure have occurred. The overall complication rate is variable[35] and ranges from 0% to 67%, with a crude morbidity rate of 31%. This large variation can be attributed to differing definitions of morbidity and study design.[66] Editorials have raised significant concern about donor safety, the lack of adequate outcome data, and the need for regulation and oversight.[39,67,68]

The intraoperative care of patients undergoing right hepatectomy for liver donation is similar to care of other patients having hepatic surgery. Preoperative placement of a thoracic epidural catheter is done in some transplant centers; however, other centers use only patient-controlled analgesia for postoperative pain control. The choice of postoperative pain control seems to depend partly on the postoperative monitoring capabilities and the familiarity of the nursing staff on the floor with each technique. Avoidance of epidural catheter placement based on concerns of postoperative coagulopathy from extensive hepatectomy does not seem to be justified. The prothrombin time usually peaks on postoperative day 2 to 3 and returns to baseline by day 5. Several studies have failed to show any adverse effect of epidural catheters in this patient population.[60,69] The largest study was reported from Japan and involved 755 donors who received an epidural catheter for postoperative pain management.[70] No complications associated with the epidural catheter were reported. A study from South Korea including 242 living liver donors also showed that epidural analgesia seems to be a safe option when used carefully.[71] Because of the very low incidence of epidural hematomas overall, however, these studies lack the power to assess the risk of epidural hematoma developing in this patient population. General anesthesia is standard and may consist of a balanced technique or be combined with intraoperative supplementation of epidural analgesia.

Intraoperatively, the patient is placed in a supine position, frequently with one arm tucked (right or left) at the side and the other abducted. An orogastric/nasogastric tube is placed for decompression of the stomach and improved surgical exposure, particularly when a left hepatectomy is performed. Two large-bore intravenous catheters and invasive arterial blood pressure monitoring are used in most centers.[60,70] Continuous monitoring of CVP has been advocated by some authors to ensure a low CVP because an elevated CVP is considered to be a prime determinant of bleeding from liver parenchyma during transection.[72] Fluid is administered sparingly until the donor liver lobes are removed. In a retrospective study, CVP monitoring did not seem to reduce blood loss compared with patients without CVP monitoring. In centers with extensive experience, CVP monitoring may be unnecessary.[73] As an alternative to conventional CVP measurements, Choi and colleagues[74] suggested peripheral venous pressure measurements in the arm. An autotransfusion system is used at most centers, and patients frequently donate 1 to 2 U of whole blood preoperatively. At centers where this procedure is done on a routine basis, blood loss is generally less than 1 L.[60,75] Because of the nature of the procedure, however, preparation and vigilance for sudden extensive blood loss are always warranted.

Frequently and especially for right lobe donation, an L-shaped (hockey stick) or standard bilateral subcostal incision with a midline extension is used. The procedure can be divided into three stages: (1) mobilization of the liver and identification of vascular structures, (2) transection of the liver, and (3) hemostasis and closure. During the first stage of the operation, manipulation of the liver occasionally can result in decreased venous return to the heart with consequent brief episodes of hypotension. It is important to be aware of this possibility before initiating any therapy. The parenchymal division is completed with several

different devices, such as the CUSA ultrasonic surgical aspirator (Valley Lab, Boulder, CO) or the Harmonic Scalpel (Ethicon Endo-Surgery, Somerville, NJ).[59,60] After the vasculature of the donor lobe is clamped and divided, the graft is removed, and the vasculature and bile duct are oversewn. Subsequently, hemostasis is achieved, and the abdomen is closed.

In uncomplicated cases, the patient can be extubated in the operating room and transferred to the postoperative care unit. Admission to the intensive care unit (ICU) is generally unnecessary. Nevertheless, standard practice in some institutions has been to manage living liver donors in the ICU in the early postoperative period.

Contraindications to Solid Organ Transplantation

For all transplant candidates, the number of absolute and relative contraindications has diminished in recent years. Overall, candidates for kidney transplantation are increasingly older and have more complex medical problems. Active infection is an absolute contraindication until it has been treated, and the infection has resolved. Evidence of malignancy is not a contraindication per se. Hepatocellular carcinoma with underlying cirrhosis is considered an indication for liver transplantation as long as the tumor burden does not exceed established guidelines, such as the Milan[76] or the University of California San Francisco criteria.[77] Similarly, select patients are reconsidered for renal transplantation after successful treatment of malignancy and no evidence of recurrence. Relative contraindications, such as noncompliance or a history of drug abuse, exist, but vary among centers. Contraindications to specific transplant procedures are outlined as necessary in each section.

Kidney Transplantation

The first description of anesthesia for kidney transplantation appeared in the early 1960s. It detailed the pioneering efforts in Boston with living donor kidney transplantation between identical twins.[78] The only monitors used then were a blood pressure cuff and electrocardiogram (ECG), and the recipient received spinal anesthesia. Much has changed in the anesthetic management of these cases. What was previously seen as heroic and exceptional is now commonplace. These patients are challenging to anesthetize because end-stage renal disease (ESRD) often causes dysfunction of other organ systems, which may produce less predictable responses to anesthetic drugs and techniques. In addition, these patients are at high risk for cardiac and other perioperative complications because of their underlying disease.

Kidney transplantation is indicated for patients with ESRD caused by glomerular disease, diabetes mellitus, hypertensive kidney disease, polycystic kidney disease, other familial or congenital diseases, and tubulointerstitial disease. Kidney transplantations are the most commonly performed transplantations in each of three major regions of the world—the United States, Europe, and Asia.[79] This number represents a steady increase throughout the 1990s. Considerable variation in the proportion of organs that come from deceased versus living donors occurs worldwide, with some countries relying almost entirely on deceased donors (e.g., China) and some relying largely on living donors (e.g., Japan, Taiwan). In the United States, transplantation of kidneys from deceased donors were 8849, down from 10,659 in 2006, whereas the number of living donors also decreased from 6432 in 2006 to 5094 in 2007.

In early 2008, approximately 78,700 patients were awaiting kidney transplantation in the United States, with an average waiting time of longer than 3 years.[5] This fact implies that recipients as a group are older and sicker than previously. Nonetheless, kidney transplantation is one of the most important, cost-effective methods of treating ESRD; it confers a 40% to 60% decrease in the death rate compared with patients remaining on dialysis. The overall graft survival rate among cadaver kidney transplant recipients at 3 years is greater than 88%, and it is approximately 93% in recipients who receive a kidney from a living donor.[80]

Organ Matching and Allocation

Initial testing is done to determine major blood group (ABO) compatibility. A second test determines the HLA profile of the recipient. Finally, a crossmatch is done by mixing recipient blood with donor blood cells to determine the presence of preformed reactive antibodies against donor antigens.[81]

Pathophysiology of End-Stage Renal Disease

The kidneys are essential for adjusting body fluid volumes, electrolyte composition, acid-base balance, and hemoglobin concentration. The kidneys receive about 25% of cardiac output and function as filters for toxins and drugs in the circulation. When kidney function declines, these functions are impaired. Chronic renal failure results in a steady decline in glomerular filtration and urine production, which has deleterious effects on multiple organ systems throughout the body. Patients with glomerular filtration rates less than 30 mL/min/1.72 m^2 (normal 120 mL/min) show an increase in blood nitrogenous wastes, mainly urea, and begin to retain fluid and electrolytes. When urine production declines to less than 400 mL/day, the patient becomes oliguric and is unable to excrete dietary fluid and electrolyte loads. Abnormalities in Na^+, K^+, Ca^{++}, Mg^{++}, and phosphate levels can develop, with the most life-threatening being hyperkalemia.

Cardiovascular disease is the predominant cause of death in patients with ESRD, and even after renal transplantation it is a major cause of death.[82] Acute myocardial infarction, cardiac arrest of unknown etiology, cardiac arrhythmia, and cardiomyopathy account for greater than 50% of deaths in patients maintained on dialysis.[83] The death rate from cardiac causes in dialysis patients increases with age; it is approximately twofold higher for patients 45 to 64 years old and four times higher in patients older than 65 compared with patients 20 to 44 years old. When echocardiography is done as a screening tool, a high incidence of abnormalities is found. Furtermore, left ventricular or right ventricular hyper-

trophy or pericarditis was detected in 60% of autopsies performed on dialysis patients.[84]

Dilated cardiomyopathy and concentric hypertrophy can develop in response to increases in intravascular volume and afterload. Fluid overload and congestive heart failure occur when the kidneys cannot excrete the daily fluid intake, and hypervolemia ensues. The accumulation of uremic toxins and metabolic acids contributes to poor myocardial performance. Cho and coworkers[85] documented that some patients with a low ejection fraction secondary to uremic cardiomyopathy completely normalized their cardiac function after successful renal transplantation. ESRD with significantly depressed ventricular function is not a contraindication to renal transplantation, but it may complicate the anesthetic management.

Hypertension produced by renal disease is the result of (1) deranged renal handling of Na^+ and fluids leading to volume expansion and (2) alterations in levels of vasoactive substances resulting in systemic and local changes in arterial tone. Hyperreninemia may lead to increased systemic vascular resistance and elevated systemic blood pressure, but it is not always present. If untreated, the elevated systemic pressure within the kidney causes damaging sclerotic changes in the renal vasculature. A vicious cycle ensues in which hypertension damages the kidney and creates the conditions for escalating hypertension. Hypertension also can be a manifestation of fluid overload when oliguria has developed, causing increased myocardial afterload and wall stress, which, in conjunction with uremia, produce changes in the heart consistent with cardiomyopathy. Chronically elevated systemic pressure lead to left ventricular hypertrophy and increased myocardial oxygen requirements.

Renal failure also accelerates the progression of atherosclerosis, especially in the coronary circulation. Uremia causes changes in lipid metabolism, leading to increased concentrations of serum triglycerides and reduced levels of protective high-density lipoproteins.

Other cardiac conditions, such as pericardial disease and arrhythmia, may be encountered in patients with ESRD. Pericarditis, which may coexist with hemorrhagic pericardial effusion, is reversible with dialysis. Generally, patients who are adequately dialyzed have resolution of their pericardial effusion. The occurrence of arrhythmias may be the consequence of electrolyte abnormalities, or may represent episodes of myocardial ischemia.

Diabetes mellitus is the cause of ESRD in nearly 30% to 40% of cases, and these patients represent more than 30% of individuals on the waiting list for a kidney transplant. Nephropathy develops in nearly 60% of insulin-dependent diabetics. Patients with ESRD and diabetes mellitus have higher cardiovascular risk than patients with uremia alone because of the associated acceleration of small-vessel atherosclerosis.

Chronic uremia also causes delayed gastric emptying. The mechanism for this is unknown, but gastric dysrhythmia with discoordinated myoelectric activity has been found in uremic patients on maintenance hemodialysis.[86] There seems to be no difference in delayed gastric emptying whether patients are undergoing peritoneal dialysis or hemodialysis. All patients presenting for kidney transplantation should be considered to have full stomachs, regardless of the period of preoperative fasting. Rapid-sequence induction should be considered, especially in patients with diabetes. This recommendation is underscored by the finding that gastric volumes greater than 0.4 mL/kg were found in 50% of diabetic uremic patients, but in only 4 of 24 nondiabetic uremic patients.

Patients in renal failure generally have normochromic, normocytic anemia because of decreased erythropoiesis and retained toxins secondary to kidney failure. Treatment with recombinant erythropoietin frequently can increase hemoglobin levels to 10 to 14 g/dL, which reduces symptoms of fatigue and improves cerebral and cardiac function.[87-89] In some patients, preexisting hypertension can worsen with erythropoietin therapy.[87]

An association between renal failure and bleeding tendency has long been recognized. A qualitative defect in platelet function produced by uremia itself seems to be central. The defect results from accumulation of the compound guanidinosuccinic acid in uremic blood, which inhibits adenosine diphosphate–induced platelet aggregation.

Although a qualitative platelet defect can be identified in uremic patients, more recent studies have pointed out that a prothrombotic state also may coexist with uremia. A thromboelastographic study of whole-blood clotting found increased coagulability and decreased fibrinolysis in uremic patients versus controls.[90] Platelet-derived microparticles (small vesicles with procoagulant activity that are released from activated platelets) may be involved in clinical thrombogenesis.[91]

Uremia may cause central nervous system disturbances ranging from drowsiness, memory loss, and decreased concentration to myoclonus, seizure, stupor, and coma. Signs of peripheral or autonomic neuropathy are considered strong indications for dialysis.

Surgical Procedure

Donor kidneys, whether from a living or a deceased source, are usually implanted in the iliac fossa. Either side of the abdomen can be used. An incision approximately 8 to 10 inches (20 to 25 cm) provides sufficient exposure. Usually, the incision extends from the midline of the pubic symphysis to a point 2 to 3 cm superomedial to the anterior superior iliac spine. Anatomic variations are common and often require repair or reconstruction of vessels or the ureter. Two or more renal arteries can supply the donor kidney, with both originating from the aorta. Although vascular anastomoses can be done with different recipient vessels, the external iliac artery and vein are frequently used for the vascular anastomoses (Fig. 67-2). Distal and proximal clamps are placed on the external iliac artery and vein, and the donor renal artery (occasionally two) and vein are connected by end-to-side anastomosis. The period of warm ischemia generally lasts 15 to 30 minutes.

After completion of the anastomoses, the clamps are released in staged fashion. The bladder is subsequently filled through a Foley catheter to facilitate implantation of the ureter directly into the bladder. The wound is closed in layers with special attention paid to urine output to identify vascular or ureteral compromise during closure.

Preoperative Considerations

Fifty percent of patients with ESRD have one or more of the comorbid conditions described previously. The presence of these

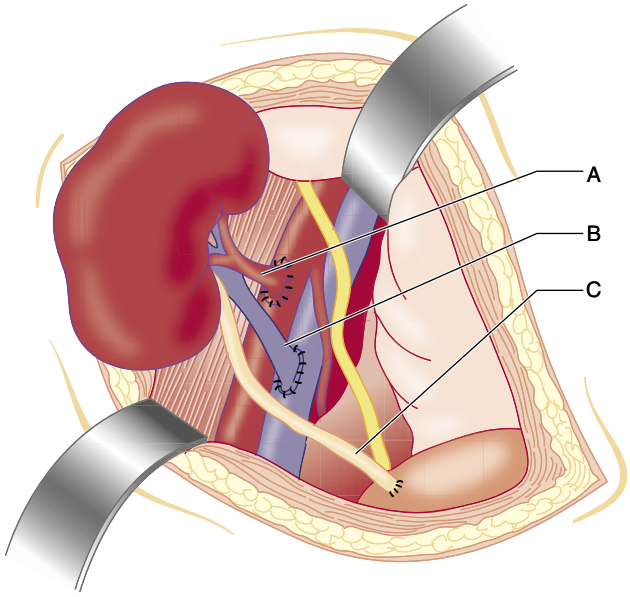

Figure 67-2 **A,** Renal artery anastomosis performed end-to-side to the external iliac artery. **B,** Renal vein anastomosis performed end-to-side to the external vein. **C,** Ureteral anastomosis to the bladder mucosa. *(From Hardy JD: Hardy's Textbook of Surgery, 2nd ed. Philadelphia, JB Lippincott, 1988.)*

comorbidities greatly influences the approach to anesthesia chosen for these patients. Although transplants involving deceased donor organs are often scheduled as urgent or emergency cases, prolonged cold preservation of the kidney is well tolerated and should provide enough time to allow transplant candidates to be reasonably well prepared for surgery. If possible, recipients should be dialyzed to correct electrolyte imbalances and volume status before surgery. Patients not maintained on dialysis generally produce sufficient urine volume to prevent fluid overload. Electrolyte concentrations, particularly K^+ and HCO_3^-, still may be grossly abnormal, however, and suggest a worsened homeostatic condition.

One method to estimate volume status is to compare patients' weight with their "dry weight," which hemodialysis patients usually know. Occasionally, continuous ambulatory peritoneal dialysis is used as an alternative to hemodialysis. Patients undergoing hemodialysis may have fluid removed just before surgery to facilitate perioperative fluid management. Such removal of fluid may render patients hypovolemic and put them at risk for significant hypotension on induction of anesthesia. Potassium levels should be reviewed immediately before surgery, especially in patients who may have missed a regular dialysis appointment. Although unlikely after immediate preoperative completion of dialysis, potassium levels greater than 6 mEq/L may require a delay in surgery and correction of potassium levels.

Preoperative evaluation of cardiac function is of central importance and is dictated by the underlying renal disease, its duration, and attendant comorbidities. A preoperative ECG and stress test may be sufficient for a patient who is young with newly diagnosed ESRD unrelated to diabetes, whereas a stress echocardiogram or a cardiac catheter may be indicated for symptomatic patients or patients with long-standing ESRD associated with diabetes. Many older and diabetic patients are unable to undergo exercise ECG testing and may have "silent" cardiac ischemia.[92] There is not absolute consensus at this point on the optimal cardiac workup for ESRD patients coming for kidney transplant.

Several noninvasive screening tests have been studied to determine their ability to identify coronary artery disease (CAD) in this patient population. In a prospective study, Herzog and coworkers[93] performed dobutamine stress echocardiography before quantitative coronary angiography in a mixed population of ESRD patients who were candidates for transplantation. More than 50% of patients had some degree of CAD (coronary stenosis >50%). Dobutamine stress echocardiography displayed a sensitivity of only 52% to 75% and a specificity of 74% to 76%, however, in identifying patients with CAD. These patients were monitored for 2 years. During this time, 20% of patients with negative dobutamine stress echocardiography experienced cardiac death or myocardial infarction or underwent coronary revascularization. Herzog and coworkers[93] concluded that dobutamine stress echocardiography was a useful, but imperfect tool for identifying patients needing further workup. Dobutamine stress echocardiography detects functionally significant stenosis; however, most sudden cardiac deaths occur in functionally insignificant lesions (e.g., acute thrombosis in patients with coronary stenosis of 20% to 30%). Other noninvasive tests also have been found to have limited usefulness in identifying ESRD patients with CAD. In one study, dipyridamole thallium scintigraphy showed adequate sensitivity (80%), but poor specificity (37%).

Other studies suggest that determination of cardiac risk should begin with the analysis of easily obtainable clinical variables, rather than widely pursuing expensive tests with limited sensitivity and specificity.[94] A history of chest pain is a helpful starting point in detecting CAD in these patients because it has a sensitivity and specificity of 65% for CAD.[92] A more comprehensive system, such as the revised cardiac risk index, was originally derived from retrospective data and shown in a prospective population to be a good predictor of the cardiac risk for patients without renal failure undergoing noncardiac surgery. It focuses on the presence or absence of six variables: high-risk surgical procedure, history of ischemic heart disease (excluding previous coronary revascularization), history of heart failure, history of stroke or transient ischemic attacks, preoperative insulin therapy, and preoperative creatinine levels greater than 2 mg/dL (>152.5 µmol/L).

These risk factors appear with high frequency in patients presenting for kidney transplantation. With zero or one risk factor, the rate of a major perioperative cardiac event is quite low; however, the rate increases rapidly to 6.6% and 11% when two and three or more of these risk factors are present. In addition, it is now widely understood that patients awaiting kidney transplantation require repeated cardiovascular surveillance. In the case of an initial negative cardiovascular evaluation, patients are risk-stratified (e.g., diabetic ESRD, nondiabetic risk factors) and assessed annually, biannually, or less frequently. Patients with a positive initial cardiovascular workup (with or without a previous medical intervention) are mostly evaluated annually.[65]

Patients can be initially stratified into basic risk groups (low, medium, or high) based on history, symptoms, and basic examination (see Chapter 34). Low-risk patients may proceed to

transplantation without additional workup, and high-risk patients should probably undergo invasive studies (e.g., cardiac catheterization). For intermediate-risk patients, it may be useful to perform a screening stress test, such as dobutamine stress echocardiography or radionuclide scintigraphy.

The use of perioperative β-blockade is suggested as a means of decreasing perioperative risk in these high-risk patients undergoing kidney transplantation. Several studies throughout the late 1990s established that perioperative β-blockade provides significant risk protection from major cardiac events in high-risk, nontransplant patients, although the POISE trial has questioned this contention. No prospective, randomized trials have been conducted with perioperative β-blockade in kidney transplant patients. It is unknown at present whether such treatment can be applied safely to these patients, especially patients with diabetes mellitus (see Chapter 35).

Diabetic patients have a higher incidence of autonomic neuropathy, which can be manifested as a higher heart rate and blood pressure than in nondiabetic ESRD patients.[95] Type 2 diabetics often have a combination of visceral obesity, atherogenic dyslipidemia (low levels of high-density lipoprotein and elevated levels of triglycerides), hypertension, and insulin resistance. This combination leads to a heightened risk of CAD and cardiovascular disease.

It should be determined when antiglycemic agents were last taken. Oral agents should not be taken the day of surgery because of the potential for unrecognized hypoglycemia under anesthesia. Insulin-dependent patients who are extremely brittle and have declining insulin levels are at risk for the development of ketosis and intraoperative acidemia.

Coagulation status, as reflected by prothrombin time, international normalized ratio, partial thromboplastin time, fibrinogen, and platelet count, is routinely assessed before surgery. Although ESRD patients may be consuming protein-restricted diets, it is rare for such diets to cause a significant clotting factor deficiency. A helpful preoperative screen to predict bleeding is a carefully conducted history that includes family, dental, obstetric, surgical, transfusion, and drug histories; the bleeding time is not a useful screening test to predict intraoperative bleeding.[96]

Intraoperative Management

Although spinal anesthesia was used exclusively for the first reported anesthetics,[78] and other centers have more recently reported successful use of regional anesthesia for these cases,[97] most centers now use general endotracheal anesthesia to provide stable hemodynamics, excellent muscle relaxation, and predictable depth of anesthesia. A balanced technique combining volatile anesthetics with opioids has been compared with total intravenous anesthesia using opioids and propofol, with no differences found.[98] Standard American Society of Anesthesiologists monitors may be all that are needed for these cases. Patients with more advanced stages of comorbid conditions may require more extensive monitoring, such as continuous arterial pressure or CVP monitoring, or both. Major swings in blood pressure may occur, with hypotension (49.6%) being more likely than hypertension (26.8%) in one large series. Patients with the most severe comorbid conditions, such as symptomatic CAD or a history of congestive heart failure, should be monitored for the development of ischemia or severe hemodynamic impairment intraoperatively with a pulmonary artery catheter or transesophageal echocardiography (TEE). The status of hemodialysis shunts or fistulas should be monitored during positioning and intraoperatively to confirm the presence of a thrill and to document patency.

With CVP monitoring, the goal is to keep CVP 10 to 15 mm Hg to optimize cardiac output and renal blood flow. Immediate graft function has been associated with a blood volume greater than 70 mL/kg and a plasma volume greater than 45 mL/kg.[99] Another study showed that pulmonary arterial pressure correlated with graft function. Higher filling pressure (pulmonary arterial pressure >20 mm Hg/diastolic pulmonary arterial pressure >15 mm Hg) resulted in better graft function than lower filling pressure. Recently, there has been some discussion of whether a particular crystalloid is better than others in terms of postoperative renal function. A national survey of fluid choice at 49 hospitals in the United States found that greater than 90% of patients receive normal saline or normal saline–based solutions during their transplant.[100] However, a single prospective randomized, double-blind study comparing normal saline with lactated Ringer solution for intraoperative intravenous fluid therapy for kidney transplantation showed significantly higher rates of severe hyperkalemia and metabolic acidosis in the normal saline group.[101] Although the recipient's blood should be typed and screened, transfusion is unlikely to be necessary because blood loss is usually minimal.

Patients with uremia and other comorbid conditions (e.g., diabetes) should be considered at risk for aspiration during induction of anesthesia. Pretreatment with a clear, nonparticulate antacid, such as 30 mL of sodium citrate, increases gastric pH. To prevent reflux and aspiration, rapid-sequence induction while maintaining cricoid pressure should be considered.

Several studies have shown that the induction dose of propofol needed to achieve clinical hypnosis and reduction of the bispectral index to 50 was 40% to 60% higher than needed for normal patients.[102,103] In the study of Goyal and colleagues,[103] 0.2 mg/kg of propofol was titrated every 15 seconds to predefined end points. The authors found a negative correlation between the propofol dose and preoperative hemoglobin levels. The exact mechanism is not understood, and administering an increased bolus induction dose based on these findings is strongly discouraged.

Patients with preexisting hypertension are at risk for large fluctuations in arterial blood pressure and heart rate during induction of anesthesia and endotracheal intubation. Because these patients have a high prevalence of CAD and myocardial ischemia, goals at induction should include careful control of the heart rate and blood pressure to minimize the possibility of myocardial ischemia. Several methods have been used to achieve adequate heart rate and blood pressure control during induction. Moderate to large doses of opioids such as fentanyl can blunt the response to laryngoscopy; however, blood pressure frequently may be more difficult to maintain without the use of vasoconstrictors after induction. In recent years, the short-acting opioid remifentanil, metabolism of which occurs in plasma, has been an effective drug for good heart rate control. The rate of remifentanil administration can be titrated to allow for rapid adjustment of anesthetic depth. The short-acting β-adrenergic blocker esmolol (0.5 to 1 mg/kg) is used to blunt the hemodynamic response to intubation and is ideally suited in this patient population with adequate ventricular function.

The use of succinylcholine is not absolutely contraindicated in patients with ESRD (see Chapter 29).[104] Plasma cholinesterase activity is less than normal in more than 20% of ESRD patients

regardless of whether they were receiving any form of dialysis. Whether receiving peritoneal dialysis, hemodialysis, or no dialysis, the patients did not experience prolonged paralysis after an intubating dose of succinylcholine, unless they also had an atypical form of serum cholinesterase. The increase in serum potassium after an intubating dose of succinylcholine is the same, approximately 0.6 mEq/L, for patients with and without ESRD. This increase can be tolerated without significant cardiac risk even with an initial serum K^+ concentration greater than 5 mEq/L.

Long-acting muscle relaxants (e.g., pancuronium) depend on the kidney for elimination and have a prolonged duration of action in patients with ESRD. Atracurium and cisatracurium are metabolized by spontaneous Hofmann degradation and plasma cholinesterase, which makes their duration of action independent of either liver or kidney function. Patients with ESRD have an increased sensitivity to vecuronium with a prolonged duration of action.[105] Rocuronium at a bolus dose of 0.6 mg/kg also has a prolonged duration of action (25% T1 recovery: 49 minutes versus 32 minutes with normal renal function).[106]

Inhaled anesthetic include desflurane, isoflurane, and sevoflurane. The metabolism of sevoflurane has been implicated in renal toxicity, but no controlled studies are available to indicate clearly either safety concerns or danger when using sevoflurane in the setting of a newly transplanted kidney. There are two concerns with regard to toxicity: (1) production of fluoride ion from the metabolism of sevoflurane and (2) generation of "compound A" by the breakdown of sevoflurane by sodium or barium hydroxide lime. However, sevoflurane seems to have a very good safety record. It has been administered to tens of millions of patients worldwide with no conclusive evidence of renal toxicity. Two volunteer studies have found biochemical evidence of renal injury during sevoflurane anesthesia, whereas five other volunteer studies have not.[107-110] Kidney transplantation represents a situation of increased renal risk, however, as defined more recently by Artru.[111] Two studies have shown that sevoflurane, at fresh gas flow rates greater than 4 L/min, did not change renal function indices or biochemical markers in patients with mildly impaired renal function (baseline creatinine >1.5 mg/dL).[112] In addition, no significant effect on renal function parameters such as serum creatinine or creatine clearance were found in patients with baseline renal insufficiency (creatinine >1.5 mg/dL) after exposure to low-flow sevoflurane or low-flow isoflurane.[113]

With regard to perioperative pain control, drugs such as morphine, meperidine (Demerol), or oxycodone should be used with caution in patients with renal failure because these agents or their active metabolites depend on renal excretion and may accumulate.[114-116] Fentanyl, sufentanil, alfentanil, and remifentanil are safe alternatives. The pharmacokinetic parameters of sufentanil are very similar in patients with ESRD and healthy control patients.[114,117] The duration of action of remifentanil is short, even in patients with ESRD.[118] The principal metabolite of remifentanil, GR90291, is eliminated primarily by the kidneys. The fact that it is only $\frac{1}{4000}$ as potent as the parent compound makes remifentanil safe to use in these patients.[119]

Hypotension may occur after unclamping the iliac vessels and reperfusion of the graft. Because renal graft function depends on adequate perfusion, every effort should be made to avoid episodes of marked hypotension. It is generally thought that vasoconstrictors with strong α-adrenergic effects, such as phenylephrine, should be drugs of last resort. Several animal models have shown that vessels in the transplanted organ seem to be more sensitive to sympathomimetics, which are thus more likely to compromise renal blood flow to the transplanted kidney.[120,121]

Immediate urine production is seen in more than 90% of living donor kidney transplants and 40% to 70% of deceased transplants. During the latter stages of closure of the surgical wound, a decrease in urine output strongly suggests mechanical impingement of the graft, vessel, or ureter. The Foley catheter should be irrigated to ensure that clot or tissue has not affected its patency. If intraoperative ultrasound is immediately available, it can be used to examine flow in the arterial and venous anastomoses. In addition to maintaining adequate intraoperative perfusion pressure, urine production is frequently enhanced intraoperatively by mannitol, loop diuretics, and occasionally dopamine, albeit the evidence is controversial.

Mannitol is freely filtered and not reabsorbed by the nephron, which causes osmotic expansion of urine volume. It also may have a protective effect on the cells lining the renal tubule. Mannitol is usually administered to donors before recovery and to recipients just before unclamping the arterial blood flow. In this way, mannitol may protect from ischemic injury and induce osmotic diuresis in the newly transplanted kidney. In most centers, low doses of mannitol are administered, 0.25 to 0.5 mg/kg, and reports of large changes in electrolyte concentrations are unwarranted. Delayed graft function of deceased kidneys can be prevented by the intraoperative administration of mannitol.[122]

Loop diuretics work by blocking the action of Na^+/K^+ pumps present in the thin ascending limb of Henle, preventing reabsorption of electrolytes in this segment of the nephron. The high-osmolar fluid that is carried along to the distal tubule prevents the reabsorption of water, and causes the excretion of large volumes of urine with high electrolyte content. Although the main effect of loop diuretics is increased urine output, the ability to prevent oliguria (<400 mL/day) can be a significant achievement.

"Renal-dose" or low-dose dopamine (2 to 3 μg/kg/min) is commonly used to stimulate DA_1 dopaminergic receptors in the kidney vasculature to induce vasodilation and increased urine output. Some small trials have shown improved urine output and creatinine clearance[123] with low-dose dopamine during kidney transplantation, whereas other larger studies have shown no significant improvement.[124,125] The utility of this approach has been questioned because a newly transplanted, denervated kidney may not respond to low-dose dopamine the way normal kidneys do. Doppler ultrasound examination of newly transplanted kidneys found no significant change in blood flow at dopamine infusion rates of 1 to 5 μg/kg/min.[126]

Another dopamine agonist, fenoldopam, maintains renal blood flow during cardiopulmonary bypass and during surgery involving aortic cross-clamping and in critically ill patients. The effects of fenoldopam on the function of newly transplanted kidneys have not been systematically studied.

Postoperative Care

All renal transplant patients should have muscle relaxants fully reversed, be extubated if possible, and be taken to the postoperative recovery area. Renal transplant patients generally have a low incidence of postoperative ICU admission—around 1% in one large series. If ICU admission is required, it is usually for sepsis or fluid overload.[127]

Urine output is closely monitored, and any significant decline should raise suspicion of a possibly correctable mechanical problem with the newly transplanted kidney. Re-exploration of the wound should not be delayed if kinking of the vascular attachments or obstruction of the ureter along its course or at the site of bladder reimplantation is suspected.

Postoperative pain is usually mild to moderate after kidney transplantation. One study showed that the choice of intraoperative anesthetic influenced postoperative pain control—patients who received propofol as a component of anesthesia had better recovery of psychomotor function and used patient-controlled analgesia more effectively than patients receiving halothane or isoflurane.[128] Placement of intercostal nerve blocks did not change the use of patient-controlled analgesia or pain scores after surgery.[129]

Anesthesia for Patients after Kidney Transplantation

Patients with good graft function as determined by laboratory values (e.g., blood urea nitrogen, creatinine) and with sufficient urine volume should be considered to have adequate renal function. The average glomerular filtration rate 6 months after deceased renal transplantation is almost 50 mL/min.[130] About 50% of patients show a slow decline in glomerular filtration rate over the course of years, but 30% have a stable glomerular filtration rate.

Given the improvement in patient survival after renal transplantation, it is likely that the rapid progression of cardiovascular disease is slowed, but not halted. These patients are still at higher cardiac risk than individuals who did not have ESRD; this is mainly due to persistent risk factors, such as hypertension, diabetes, dyslipidemia, and secondary hyperparathyroidism. Considerable progression of coronary artery calcification was found in renal transplant patients at least 1 year after surgery. Findings were related to ethnicity of patients, blood pressure, body mass index, renal function, and baseline coronary artery calcification.[131] Patients who do require cardiac surgery after successful kidney transplantation showed no difference in the 30-day complication rate, however, compared with a nontransplant control population, except for a significantly increased likelihood of postoperative renal dysfunction and need for hemodialysis.[132] Aside from cardiac risk, graft rejection, viral infection, anemia,[83,133] and treatment with immunosuppressive drugs such as cyclosporine may cause significant cardiovascular morbidity (e.g., hypertension), but newer immunosuppressants seem to be better tolerated.[134] Congestive heart failure (e.g., cardiomyopathy), left ventricular hypertrophy, and ischemic heart disease remain important complications in renal transplant recipients.[83]

Pancreas and Kidney-Pancreas Transplantation

Pancreas transplantation is a primary cure for diabetes mellitus because it provides nearly physiologic insulin replacement. Nephropathy develops in about 50% to 60% of insulin-dependent diabetic patients, so it is common also to transplant a kidney at the time of pancreas transplantation. The appearance of new immunosuppressants, such as tacrolimus and mycophenolate mofetil, has dramatically increased pancreas graft survival.[135] The best results in terms of graft survival are obtained with simultaneous pancreas-kidney transplantation (SPK), but good results also are achieved with a pancreas transplant alone (PTA) or a pancreas transplant after successful kidney transplantation (PAK). Diabetic patients who undergo SPK have greater long-term survival than diabetics who receive a deceased kidney alone.[136]

In 2005, 540 pancreas transplants and more than 900 SPKs were performed in the United States. More than 23,000 pancreas transplants have been performed worldwide according to the International Pancreas Transplant Registry through 2004. The 3-year graft survival rate is around 65%. In early 2008, approximately 1600 patients were waiting for a pancreas transplantation and 2350 patients were waiting for a kidney and pancreas transplantation.

Organ Matching and Allocation

Solid organ pancreas transplantation is indicated for the treatment and cure of patients with type 1 diabetes mellitus and select patients with type 2 diabetes mellitus (<5%). Pancreas transplantation also can be considered in patients with diabetes mellitus secondary to chronic pancreatitis or cystic fibrosis.

The initial testing determines the major blood group (ABO) compatibility and HLA profile of the recipient. These data are used for the initial matching of donor to recipient. A final check is made at crossmatch when recipient blood is mixed with donor blood cells to determine whether the recipient has preformed reactive antibodies against donor antigens.

Pathophysiology of Pancreatic Insufficiency

The primary defect in diabetes mellitus is a relative deficiency of insulin for regulation of blood and tissue glucose levels. Two forms of the disease are recognized. Type 1 diabetes mellitus is characterized by a significant deficiency in insulin production by the islet cells of the pancreas, possibly from autoimmune destruction. In type 2 diabetes mellitus, insulin levels may be normal, but patients have a relative resistance to the action of the hormone. Patients with type 1 diabetes mellitus are more likely to require daily administration of exogenous insulin, to be prone to ketosis, and to have wide fluctuations in blood glucose levels. The symptoms can be completely relieved by successful pancreas transplantation, but it is still uncertain whether the progression of comorbidities in all organ systems is abated.

Diabetes mellitus severely affects the cardiovascular system by accelerating atherosclerotic vascular disease. Accelerated atherosclerosis and autonomic nervous system dysfunction are the major cardiovascular changes present in diabetic patients. If ESRD also is present, the cardiovascular risk increases dramatically. Diabetic patients with severe CAD may not recognize anginal symptoms due to impairment of the autonomic nervous system. Autonomic dysfunction also can limit control of the car-

diovascular reflexes and result in increased lability of blood pressure and heart rate. One index of autonomic dysfunction that has been studied is a decrease in heart rate variability, which reflects a defect in the autonomic nervous system. These defects may give rise to dysrhythmias and put patients at increased risk for sudden death during pancreas transplantation.[137]

Patients with ESRD superimposed on diabetes mellitus are subject to the same hemodynamic, fluid, volume, and electrolyte problems as patients with ESRD alone. They probably are maintained on some form of dialysis to manage fluid overload and accumulation of electrolytes. They may also have significant systemic hypertension for the reasons discussed in the section on kidney transplant. Finally, they may have the same problems of chronic anemia and uremic coagulopathy as patients with renal failure alone.

After successful SPK, pathologic cardiac changes, such as diastolic dysfunction and left ventricular hypertrophy, can improve or stabilize.[138] It has not been proved whether other manifestations of diabetes mellitus, such as accelerated atherosclerosis, neuropathy, or vascular insufficiency, improve or stabilize.

Surgical Procedure

The usual exposure for pancreatic transplantation requires a generous midline incision extending from the epigastrium to the symphysis pubis (Fig. 67-3). The pancreas is placed in the abdomen with an arterial blood supply from the aorta via a vessel graft. Several options are available for venous drainage and implantation of the exocrine duct. Venous outflow from the pancreas, which is the source of insulin, may go into the inferior vena cava directly into the systemic circulation, or it may be directed in a more physiologically correct manner into the portal vein draining the splanchnic circulation. The exocrine pancreatic flow may be connected to the small bowel or, less often, through a cuff of donor intestine into the bladder. The latter method allows for monitoring of urine amylase as a marker of rejection or injury to the transplanted pancreas. Enteric drainage is preferred for SPK because it is more physiologic and avoids bladder complications. Bladder drainage may be a better option for PTA and PAK, however, because of the greater likelihood of rejection with these types of transplantation. Surveillance of urine amylase allows for early detection of rejection.

Preoperative Considerations

Diabetic patients have a more frequent incidence of autonomic neuropathy, which can be manifested as a higher heart rate and higher blood pressure than in nondiabetic ESRD patients (see Chapter 35).[95] Patients with type 2 diabetes often have metabolic syndrome, a combination of visceral obesity, atherogenic dyslipidemia (low levels of high-density lipoprotein and elevated levels of triglycerides), hypertension, and insulin resistance. This combination leads to a heightened risk for CAD and cardiovascular disease. Orally administered drugs should not be taken the day of surgery to avoid the potential for unrecognized hypoglycemia under anesthesia. Insulin-dependent patients who are extremely brittle and have declining insulin levels are at risk for ketosis and intraoperative acidemia.

Historically, the principal candidates for pancreas transplantation have been younger than individuals receiving kidney transplants, with most being in the age range of 18 to 35 years. Younger patients tended to have fewer of the long-term manifes-

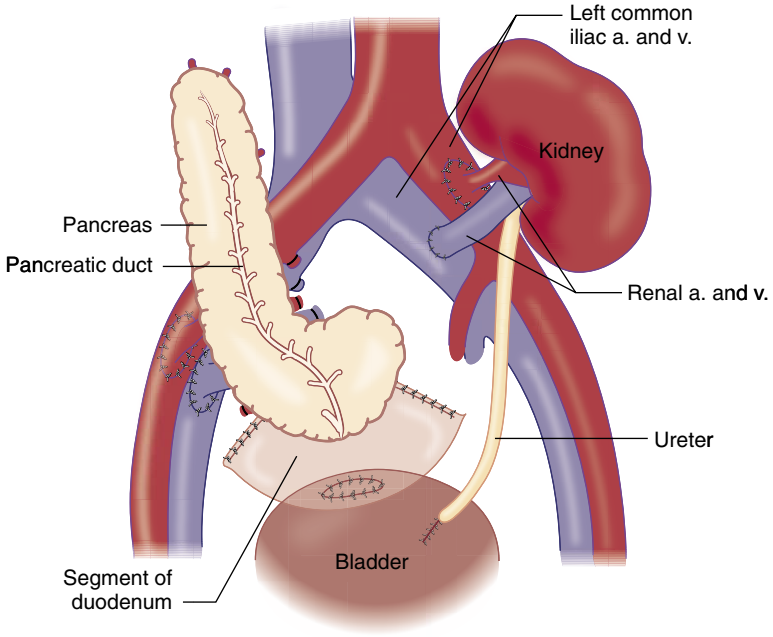

Figure 67-3 Transplantation of the pancreas with drainage of the bladder through a pancreaticoduodenocystostomy. A renal transplant also is shown with the common iliac vessels used for vascular anastomoses. *(Modified from Moody FG [ed]: Surgical Treatment of Digestive Disease, 2nd ed. St Louis, Mosby-Year Book, 1990.)*

tations of diabetes mellitus, such as atherosclerotic vascular disease and severe autonomic dysfunction. More recently, increasing numbers of older diabetic patients are being considered for pancreas transplantation. These patients are at higher risk for a major cardiovascular event perioperatively. An extensive cardiac workup is indicated before surgery to rule out severe CAD. Preoperative evaluation by history and physical examination, ECG, treadmill testing, echocardiography with or without dobutamine stress, radionuclide scintigraphy, and cardiac angiography represents the full spectrum of workup that may be applicable.

It was suggested in the early 1990s that tracheal intubation should be considered more difficult in diabetic patients as a group because of changes in their upper airway tissues from exposure to high serum glucose levels. One study found a 31% incidence of difficult intubation conditions in this patient population. Subsequently, a large study by the Mayo Clinic reviewed the anesthetic records of 150 patients with diabetes who underwent general anesthesia and tracheal intubation, and found only a slightly increased incidence of "more difficulty visualizing" airway structures.[139] Halpern and associates[140] reported only one difficult intubation in a series of 130 patients presenting for pancreas transplantation. It seems that long-standing diabetes mellitus alone does not predispose to airway difficulties, but may be considered a contributing factor in a patient with other potentially problematic airway features.

Intraoperative Management

Because pancreas transplantation procedures can be long and surgically tedious, and involve extensive abdominal exposure, general endotracheal anesthesia with muscle relaxation is the best choice. Patients may have significant postoperative pain from the extensive abdominal dissection, so placement of an epidural catheter for postoperative pain control may be warranted. Splanchnic perfusion to the transplanted organs is a major concern, however, and some centers opt to defer placement of an epidural catheter.

Because the pancreas seems to be a highly immunogenic organ, intensive immunosuppression is needed to prevent graft loss. The anesthesia team administers the initial dose of immunosuppressant, so it is essential that the desired drugs be present and administered correctly in the operating room.

Standard monitors (e.g., five-lead ECG, noninvasive blood pressure measurement, pulse oximetry, end-tidal gas concentrations) plus arterial and central venous lines are usually required. The arterial line enables careful tracking of blood pressure and the ability to draw samples for blood gas, glucose, and electrolyte determinations. Insertion of a central venous catheter permits monitoring of cardiac filling pressure and central administration of drugs.

Diabetic patients, by virtue of their high incidence of autonomic dysfunction, are likely to have gastroparesis and large residual gastric volumes. This risk is even greater if the patient has ESRD and uremia. Administration of a nonparticulate antacid along with maintenance of cricoid pressure during rapid-sequence induction should be considered.

Patients with autonomic neuropathy apparently are not at greater risk for severe cardiovascular depression during induction of anesthesia. A study of uremic patients undergoing kidney transplantation found, that diabetic patients with known preexisting autonomic neuropathy had hemodynamic responses to induction that were similar to the responses of nondiabetic uremic patients.[141] Hemodynamic stability for long periods is probably best achieved by using a balanced anesthetic technique. As with kidney transplantation alone, adequate arterial blood pressure is desired to provide good perfusion pressure for a newly anastomosed pancreas.

One of the most challenging aspects of these cases is determining the amount and type of fluids to administer. If fluid is given, it is probably best from a surgical standpoint to use colloid-based fluid, rather than a large volume of crystalloid solutions alone. Although no controlled studies have been conducted, swelling of the pancreas graft seems to be less with colloids than with crystalloids.

Abdominal muscle relaxation is essential for these procedures. The same issues outlined previously for patients undergoing kidney transplantation apply to the choice of muscle relaxant to be used in patients undergoing SPK. Because of the duration of these cases, a continuous infusion of cisatracurium allows for titration of the level of block with reliable reversibility. Alternatively, the intermittent administration of vecuronium, if titrated by train-of-four monitoring,[105] can produce excellent relaxation conditions. For patients who are undergoing PTA or PAK and have adequate renal function, the use of any intermediate-acting nondepolarizing muscle relaxant should not cause problems.

Control of blood glucose intraoperatively is important to prevent the development of ketoacidosis in patients with unopposed counter-regulatory hormone secretion and to allow assessment of the function of the transplanted pancreas. Before unclamping the pancreas, glucose should be checked hourly. Hyperglycemia may cause depressed immune function and decreased wound healing and put patients at an increased risk for worsened neurologic injury if brain ischemia occurs.[142] After the pancreas is unclamped, glucose should be monitored every 30 minutes. Typically, glucose concentrations decrease approximately 50 mg/dL/hr after unclamping the pancreas.

A randomized trial of insulin administration to patients with insulin-dependent type 2 diabetes compared a continuous glucose-insulin infusion with intermittent intravenous insulin injection in major and minor surgery. Very little difference was found in the ability to control intraoperative and postoperative glucose levels and metabolism.[143] The manner of reducing glucose does not seem to be as important as the glucose level itself.

Postoperative Care

Successful transplantation usually results in rapidly declining insulin requirements. Blood glucose levels should be monitored closely in the recovery room or ICU to avoid hypoglycemia (see Chapter 92). If simultaneous kidney transplantation is performed, close monitoring of urine output to detect reversible graft impingement is necessary.

Anesthesia for Patients after Pancreas Transplantation

Surgical complications after these complex operations are frequent and often require one or more re-explorations during the perioperative period. If pancreas graft function is good, blood glucose levels are corrected within days of transplantation. During

the perioperative period, the same cardiac concerns that were present before transplantation apply.

Liver Transplantation

In 2007, the number of liver transplantations performed in the United States decreased slightly to 6494 from 6650 in 2006. In 2007, 1559 liver transplantations were reported by Eurotransplant, which covers seven central European states.* As of early 2008, approximately 17,200 patients were on the waiting list for liver transplantation in the United States; approximately 1600 to 1800 patients die each year while awaiting liver transplantation. Nationwide, the 3-year patient survival rate after transplantation is greater than 75%.[144] This rate underscores the fact that liver transplantation should not be considered experimental and is the treatment of choice for eligible patients with end-stage liver disease.

The growing discrepancy between organ supply and recipients on the waiting list has made finding alternatives to deceased liver transplantation of paramount importance. This discrepancy may become greater in view of the fact that cirrhosis is likely to develop in 25% to 30% of the more than 4 million Americans with hepatitis C.[145,146] Recurrent disease, especially with hepatitis C, necessitates retransplantation in future years, which aggravates the acute organ shortage problem further.[147] Based on UNOS data, there has been no improvement in long-term liver transplant graft survival in the last decade. This finding could be explained by an increase in patients with hepatitis C virus and an increase in patients with hepatitis C virus antibody.[148] The challenge of meeting organ shortages may be overcome if donor liver allocation is optimized, and the donor pool can be increased with new approaches, such as the use of living liver donors or extended criteria donors.

Combined liver-kidney transplantation is done infrequently and constitutes only a very small fraction of abdominal transplant volume. Renal disease in the setting of cirrhosis can be due to primary renal disease, hepatorenal syndrome, and acute tubular necrosis.[149] Considerable controversy exists with regard to patient selection for this procedure because of the organ shortage and the possibility of inferior patient and graft survival compared with single-organ transplantation. It is advocated that patients be highly selected, and that hemodynamically stable patients with primary disease in both organs be preferred.[149]

Organ Matching and Allocation

The ABO blood group system is the primary immunologic barrier to transplantation,[150] and this classification system is the most important for liver transplantation. The four ABO groups are not proportionally distributed among cadaver donors and possible recipient candidates. The matching strategy between donor and possible recipient is crucial in liver allocation. Donor and recipient ABO blood type matching can be classified as follows: identical (e.g., A to A), compatible (e.g., O to A), and incompatible (e.g., A to O).[151] Identical matching generally is preferred because patient and graft survival is superior with compatible organs. In select cases, such as acute hepatic failure or acute deterioration of chronic liver disease, incompatible organs are transplanted. Graft survival is poorer in patients receiving incompatible organs compared with patients receiving identical matching. Acceptable patient survival may be achieved by retransplantation, however.

The organ allocation policy varies among countries. In the United States, deceased donor livers are allocated to patients who are registered with a national registry. In contrast, several European countries allocate donor livers primarily to transplant centers. These centers subsequently identify a suitable recipient candidate. Regardless of the respective organ allocation policy, recipient candidates have to be well screened regarding their eligibility for liver transplantation.

The number of diseases amenable to treatment with liver transplantation has steadily increased in recent years. Although there is regional variation, the most important cause of end-stage liver disease is chronic hepatitis C, which is responsible for almost 40% of all liver transplantations, especially in the United States. Causes of chronic disease in adults can be classified as follows: (1) noncholestatic (e.g., alcohol, hepatitis A, hepatitis B, hepatitis C), (2) cholestatic (e.g., primary biliary cirrhosis, primary sclerosing cholangitis), (3) metabolic disease (e.g., Wilson's disease), and (4) selected cases of hepatocellular carcinoma often associated with hepatitis B or C. Fulminant hepatic failure can be drug induced (e.g., acetaminophen overdose, idiosyncratic), caused by the ingestion of poisonous mushrooms or herbs, and secondary to acute viral hepatitis.[152,153]

Reasons to deny transplantation may vary among centers. Liver transplantation is an extremely stressful procedure for patients. Significant CAD, cardiac dysfunction, and moderate to severe pulmonary hypertension are considered contraindications to liver transplantation. Uncontrolled infection or sepsis also excludes a patient from transplantation. A positive HIV test, without evidence of acquired immunodeficiency syndrome, is no longer a contraindication. Recent case series have reported good results in HIV-infected patients undergoing liver or kidney transplantation.[1] Advanced malignant hepatic disease or metastatic disease generally is considered to be a contraindication, as is uncontrolled and markedly documented elevated intracerebral pressure in the setting of fulminant hepatic failure. Psychosocial factors, such as active alcohol abuse or the lack of a good social support system, may prevent a patient from being a candidate for transplantation. Advanced age per se is not a reason to deny liver transplantation. Patients older than 65 years are increasingly undergoing transplantation.

In the past, the Child-Turcotte-Pugh (CTP) classification had been used widely as an index of disease severity for patients with end-stage liver disease. This classification, in conjunction with UNOS status, was the determining factor for organ allocation in the United States until early 2002. Because of shortcomings of CTP scores and subsequent limitations in organ allocation, the model for end-stage liver disease (MELD) has been introduced for adults in the United States.[154,155] This model resulted from a growing realization that the previous UNOS scoring system, which was based on the CTP score of liver disease severity plus the amount of time on a waiting list, did not always ensure that organs were allocated to the sickest patients with the greatest risk of mortality.

*Austria, Belgium, Croatia, Germany, Luxembourg, the Netherlands, Slovenia.

The MELD risk score is a mathematical formula based on the following factors:

1. Creatinine (for adult patients undergoing dialysis twice a week within the last week, the creatinine value would be automatically set to 4 mg/dL)
2. Bilirubin (mg/dL)
3. International normalized ratio

MELD calculates a single numerical value from a formula that gives each value particular weighting. Most patients on the liver transplant waiting list have a MELD score between 11 and 20.[144] The MELD system was originally devised as a means for predicting the risk of death in patients with liver failure after transjugular intrahepatic portosystemic shunting (TIPS).[156] TIPS patients with scores greater than 18 had a median survival of 3 months or less after a TIPS procedure. MELD scoring proved superior to the CTP score in predicting survival.[156]

Several adjustments in the new system have been introduced to make it as equitable as possible. Hepatocellular carcinoma confined to the liver can progress to inoperable lesions before manifesting changes in MELD criteria. UNOS has adopted the rule that patients with hepatocellular carcinoma be assigned a MELD score equivalent to the risk of death based on rapid disease progression.[157,158] Some studies have suggested that sodium should be added to MELD to improve accuracy of survival prediction. Finally, a peer review mechanism has been instituted, and the current classification is under constant review and adjustment. Nevertheless, reports indicate that use of the MELD criteria has been shown to be better associated with 1-year patient survival in liver transplant recipients than the former UNOS status.[159]

Pathophysiology of End-Stage Liver Disease

Although the reasons for end-stage liver disease may vary significantly, similar organ pathophysiology tends to develop in patients with advanced liver disease. Virtually all organ systems can be affected by end-stage liver disease. Consequently, a global assessment that includes consideration of all organ systems is of great importance. A significant number of the complications in patients with end-stage liver disease are the result of portal hypertension, which can be defined as portal venous pressure greater than 10 to 12 mm Hg.[160] The pathogenesis of portal hypertension is increased hepatic resistance to flow as a result of cirrhotic changes in the liver and a hyperdynamic circulatory state secondary to systemic vasodilation and presumably volume expansion.[161]

There is some controversy whether patients with end-stage liver disease have an excessively large or depleted intravascular volume. In advanced disease, abnormalities in fluid, such as altered extracellular fluid regulation and electrolyte balance, are frequently manifested as ascites, pleural effusion, and edema.[162] Subsequent changes in the splanchnic and renal circulation may lead to sodium and water retention. Abnormalities in sodium electrolyte levels are frequently observed and are often related to volume status and sodium retention; these abnormalities can result in either hyponatremia or hypernatremia.[163] Similarly, renal dysfunction and diuretic use can cause either hyperkalemia or hypokalemia along with hypomagnesemia.

Central nervous system changes in chronic liver disease are often manifested as hepatic encephalopathy, but the degree of encephalopathy may vary significantly among patients.[164,165] Ammonia levels are frequently monitored, but do not seem to correlate well with the degree of hepatic encephalopathy. Increased intracranial pressure (ICP) may develop in patients with acute hepatic failure, primarily because of cerebral edema. Accurate assessment of the severity of ICP and remaining neurologic function is of paramount importance because intractable elevated ICP is a significant reason to exclude a patient from transplantation. There is considerable controversy, however, whether the potential benefits of invasive monitoring for elevated ICP (e.g., bolt placements) outweigh the potential risk of devastating bleeding during placement.[166] The U.S. Acute Liver Failure Study Group recommends (beyond generally accepted supportive measures for elevated ICP) a stepwise approach to management of elevated ICP. When ICP is greater than 25 mm Hg, osmotic therapy should be started, and sodium should be kept within normal limits. Hypertonic saline may be considered as an alternative to mannitol. Additional treatment that may be considered is moderate hypothermia, broad-spectrum antibiotics, and barbiturate coma. Supporting scientific evidence for these interventions is insufficient, however.[167]

In addition to the standard treatment of elevated ICP, early studies have shown that the molecular adsorbents recirculating system (MARS) may be able to decrease ICP and improve cerebral perfusion pressure.[168] Designed as a liver support device for patients in fulminant hepatic failure or the acute decompensation of chronic failure,[169] MARS has been able to improve systemic vascular resistance and mean arterial blood pressure.[170] Presumably, these improvements in organ function may account for a reduction in mortality.[171,172] A clear survival benefit for patients treated with MARS has not been shown, however. MARS is based on dialysis across an albumin-impregnated membrane that removes plasma albumin-bound toxins. The dialysate is subsequently cleaned by activated charcoal and anion exchange resin.[173]

The cardiovascular system undergoes profound changes in patients with advanced liver disease that result in a hyperdynamic state. Generally, systemic vascular resistance is low, the heart rate is elevated, and arterial blood pressure is normal or slightly decreased.[174] These hemodynamic changes result in supranormal cardiac output in patients with end-stage liver disease, unless the patient is taking a β-blocker for the prevention of upper gastrointestinal bleeding. Occasionally, relatively depressed cardiac function can be associated with cirrhotic cardiomyopathy, alcoholic cardiomyopathy, or infiltrative cardiac involvement in unrecognized hemochromatosis, and these conditions should be kept in mind.[175,176] Left ventricular diastolic dysfunction seems to be more common than previously assumed. A more recent study in transplant candidates showed a high prevalence of atherosclerotic risk factors and a 26% prevalence of moderate to severe coronary artery disease. Severe CAD was found in older men with risk factors such as hypertension and diabetes.[177] The results mirror current practice of accepting older candidates with comorbidities for liver transplantation. Overall, more patients with cardiac disease and a history of interventions such as coronary artery stent placement are expected to be undergoing liver transplanta-

tion. In select cases, liver transplantation is combined with simultaneous cardiac surgery.

The pulmonary system in patients with end-stage liver disease can undergo changes, and two distinct pathophysiologic syndromes that can be recognized are hepatopulmonary syndrome and portopulmonary syndrome. The principal finding in hepatopulmonary syndrome is decreased oxygenation (Pao_2 <70 mm Hg or a $PAO_2 - Pao_2$ gradient >20 mm Hg on room air) associated with intrapulmonary vascular dilation. A hallmark of this syndrome is intrapulmonary shunting.[178,179] Patients with hepatopulmonary syndrome may show changes in oxygen saturation when changing from the supine to erect positions. The presence of orthodeoxia is a significant clue for the examining physician that the patient has hepatopulmonary syndrome.

The hepatopulmonary syndrome is an independent risk factor for mortality and an indication for liver transplantation. Frequently, but not always, hepatopulmonary syndrome resolves spontaneously months after liver transplantation.[180] After transplantation, long-term survival of patients with hepatopulmonary syndrome is favorable, albeit a small study suggested that postoperative mortality may be higher.[181]

Such resolution is not the case with portopulmonary hypertension, a fairly uncommon complication of portal hypertension,[182] which may worsen after liver transplantation. Patients with liver disease experience an increased prevalence of pulmonary vascular diseases compared with the normal population.[183] Although cirrhosis was thought to be the etiology, portal hypertension seems to be the only consistent factor predisposing patients to the development of pulmonary hypertension. Patients are considered to have portopulmonary hypertension if they meet the following three criteria: (1) mean pulmonary arterial pressure greater than 25 mm Hg, (2) pulmonary vascular resistance greater than 240 • sec • cm^{-5}, and (3) pulmonary capillary wedge pressure less than 15 mm Hg in the setting of portal hypertension.[184] Although these criteria are reasonable, diagnostic caution should be exercised because interpretation of measured hemodynamic values may be obscured by the hyperdynamic circulation that occurs in patients with liver disease.[178] Portopulmonary hypertension may progress rapidly and carries high perioperative morbidity and mortality when significant. Therapeutic agents used to treat primary pulmonary hypertension not associated with liver disease also have been administered to patients with this condition, with mixed results.[185-188]

Renal dysfunction also develops in many patients with end-stage liver disease. Calculated glomerular filtration rate tends to overestimate actual glomerular filtration rate in patients with end-stage liver disease. Renal dysfunction is usually the result of primary renal disease, acute tubular necrosis, or hepatorenal syndrome. Hepatorenal syndrome develops in the setting of severe liver disease and in the absence of other causes, such as hypovolemia, drug toxicity, or underlying intrinsic renal disease. There are two types of hepatorenal syndrome. Type I develops rapidly over weeks and is progressive and associated with high mortality.[189,190] Renal function may recover spontaneously when liver function improves, or the patient receives a liver transplant. It is most frequently seen in patients with acute liver failure, alcoholic hepatitis, or acute decompensation of chronic liver disease. Type II follows a less acute course and is seen mainly in patients who become resistant to diuretic therapy.

Patients who experience spontaneous bacterial peritonitis are at risk to develop renal failure. Spontaneous bacterial peritonitis is considered the most frequent cause of renal failure in patients with cirrhosis.[190] The mechanism of hepatorenal syndrome is thought to be a combination of reversible renal vasoconstriction in structurally normal kidneys and changes in vasoconstrictor and vasodilator factors.[190] The degree of preoperative renal dysfunction correlates with increased patient mortality postoperatively.[149,191] This correlation is mainly observed in patients undergoing only liver transplantation from a deceased donor, but not in patients undergoing combined kidney and liver transplantation.[192]

Various hemostatic abnormalities are found in patients with end-stage liver disease who present for liver transplantation. These changes can be caused by preoperative coagulation disorders or may be related to the procedure itself. Levels of procoagulant factors (II, V, VII, IX, X) and anticoagulant factors (protein C and S, antithrombin III) are frequently decreased in patients with end-stage liver disease.[193-195] Thrombocytopenia as a result of hypersplenism, qualitative platelet dysfunction, and disorders of the fibrinolytic system (reduced levels of plasminogen, α_2-antiplasmin, and factor XIII, and increased plasma tissue-type plasminogen activator levels) are often encountered during the perioperative period.[196] Although end-stage liver disease often increases the risk of bleeding, thrombotic complications such as portal vein thrombosis also are seen in this patient population. Several case reports and case series have shown intraoperative thrombus formation in the cardiopulmonary system.[197-201] Frequently, thrombus formation was associated with the coadministration of antifibrinolytics, such as aprotinin or aminocaproic acid. A conclusive statement with regard to antifibrinolytics and thrombus formation cannot be made because of the lack of sufficient data and the absence of large controlled studies.

Surgical Procedure

Liver transplantation generally can be divided into three stages: (1) the dissection phase, which includes lysis of adhesion and mobilization of the liver; (2) the anhepatic phase, which consists of removal of the native liver and implantation of the donor liver; and (3) the reperfusion (neohepatic) phase, which involves the completion of several anastomoses, hemostasis, and closure. Each phase is described in more detail.

Preoperative Considerations

Patients who are candidates for liver transplantation will have undergone a rigorous preoperative evaluation by multiple medical specialists (see Chapters 34 and 35). Patient evaluation is usually conducted in different phases and may take weeks to months to complete. Pathophysiologic changes as described previously should be identified and addressed. An increasing proportion of patients are now admitted for liver transplantation from home, which often results in a significant interval between the last evaluation or diagnostic test and admission for liver transplantation. All cases should be considered emergency cases (with the exception of living donor recipients).

It is important to perform a detailed medical and physical examination with a strong emphasis on changes that have

occurred since the last evaluation. Of great importance is the time span between performance of the diagnostic test and the anticipated liver transplantation. Patients may wait several years for liver transplantation, and tests performed early in the evaluation process may not reflect the progression or new onset of organ-specific disease. Simultaneously, all diagnostic tests (i.e., echocardiogram, cardiac catheterization, pulmonary function tests, renal function tests) performed during the workup for liver transplantation and any recent notes from the primary team should be evaluated. In the case of pulmonary hypertension, two-dimensional echocardiography has been shown to be a sensitive tool for detecting portopulmonary hypertension. Because echocardiography has a poor positive predictive value, however, catheterization of the right side of the heart is recommended to confirm portopulmonary hypertension.[202]

Most tests are likely to show that either the patient is fit for surgery without any further medical therapy, or medical management is needed before liver transplantation (e.g., treatment of moderate pulmonary hypertension before transplantation). Knowledge and documentation of preoperative testing are essential because the results of such testing dictate the perioperative management of the patient. Evidence of moderate pulmonary hypertension on echocardiography in a patient without cardiac catheterization may warrant perioperative placement of a pulmonary artery catheter with pressure measurements before incision. Ideally, placement of the pulmonary artery catheter should be done in the ICU before taking the patient to the operating room. Conversely, immediate preoperative right cardiac catheterization with no evidence of pulmonary hypertension may render placement of a perioperative pulmonary artery catheter for monitoring purposes unnecessary.

Preoperative renal dysfunction has been shown to be an independent risk factor for postoperative morbidity and mortality in patients undergoing liver transplantation.[191] Longitudinal assessment is crucial because previously diagnosed borderline renal function may have progressed to renal failure requiring intraoperative interventions such as continuous venovenous hemofiltration or dialysis,[203] or even a combined liver-kidney transplant. Screening for any new infections on the day of surgery also is crucial because new-onset or uncontrolled ongoing infections may require postponement of surgery.[204]

Intraoperative Management

The intensity of intraoperative resource and personnel usage varies widely among liver transplant centers and is influenced by institutional practice, caseload, and personal experience. Standardization of clinical practice has not been fully established for liver transplantation as it has for other procedures. Hemodynamic monitoring may include a pulmonary artery catheter, TEE, or simple CVP monitoring. The type of high-volume infusion equipment differs among transplant centers, as does the use of venovenous bypass (VVBP) during the anhepatic phase. In a survey of 62 transplant centers in the United States done by Schumann, a pulmonary artery catheter was used in approximately 30%, TEE was in 11.3%, and VVBP was used in roughly half of adult transplants. A tendency toward decreased use of pulmonary artery catheters and VVBP was shown with increasing case volume.[205] Binding recommendations with regard to resource use are difficult to make and depend on various factors. More recently, TEE has been increasingly used for management of fluid therapy, monitoring of cardiac function, and identification of intraoperative complications (e.g., pulmonary embolus).

Close communication with the blood bank before surgery is crucial. Standard protocols should be instituted with a recommended setup for blood products. Blood products may include 10 U of red blood cells and 10 U of fresh frozen plasma to be brought to the operating room, with 4 U of single-donor platelets available on request. Because of the magnitude of fluids that may be administered, separate laboratory and fluid flow sheets can facilitate more accurate record keeping and aid in identification of trends. The frequency of blood sampling for laboratory analysis is dictated by the medical condition of the patient, progress of the procedure, and experience of the transplant team.

Most patients already have intravenous access on arrival at the operating room that can be used during induction. The use of epidural catheters is discouraged in this procedure because a significantly prolonged perioperative coagulopathy can persist. Placement of an arterial line to monitor blood pressure or a central line/pulmonary artery catheter before induction is not essential. Many patients presenting for liver transplantation may receive nonspecific β-blockade for secondary prophylaxis of upper gastrointestinal bleeding (e.g., esophageal varices). These patients tend to be stable during the induction.

Most patients have well-preserved cardiac function and no significant arterial or pulmonary hypertension. Induction can be achieved with an intravenous anesthetic, such as propofol, thiopental, or etomidate, with or without opioids and short-acting or intermediate-acting neuromuscular blocking agents.

End-stage liver disease results in changes in hepatic blood flow, decreased ability to biotransform certain drugs, hypoalbuminemia, and altered volume of distribution.[174] Several studies in patients with end-stage liver disease have shown changes in the pharmacokinetics and pharmacodynamics of drugs commonly used in anesthesia, including nondepolarizing muscle relaxants and benzodiazepines. Extrapolation of this information to intraoperative management is difficult, however, in view of the dynamic nature of the procedure (i.e., anhepatic phase, major blood loss, hypothermia). Most importantly, a functioning liver is implanted at a given point, which makes longitudinal pharmacokinetics and pharmacodynamics studies very difficult to interpret. Most studies have focused on one particular aspect of liver transplantation, such as the impact of the anhepatic phase or hypothermic preservation on drug metabolism. Such studies have suggested that drugs such as sufentanil and propofol exhibit some degree of extrahepatic metabolism.[206]

Based on existing knowledge, it is reasonable to choose cisatracurium or atracurium over vecuronium as the muscle relaxant of choice for liver transplantation. The pharmacokinetics and pharmacodynamics of vecuronium have been shown to be substantially altered by liver disease, whereas cisatracurium and atracurium are cleared independently of liver function.[207] Muscle relaxants have been used as a probe to evaluate the function of the newly implanted liver.[208-211] Nonetheless, all nondepolarizing agents have been used successfully in liver transplantation as long as appropriate neuromuscular monitoring is performed.

Similarly, different opioids, such as fentanyl, sufentanil, alfentanil, and remifentanil, have been used during liver transplantation. A rapid-sequence or modified rapid-sequence induction is often warranted because patients frequently have significant ascites or experience delayed gastric emptying. Postinduction hypotension may occur as a result of the very low systemic vas-

cular resistance and relative hypovolemia of these patients. It usually can be treated with small amounts of vasoconstrictors (e.g., phenylephrine). With the exception of halothane, all volatile anesthetics are suitable for liver transplantation. Isoflurane and desflurane are the most frequently used.

Correction of severe coagulopathy before line placement may be considered, and the use of ultrasound may facilitate central venous cannulation, but there are no generally accepted guidelines. Line placement should include a radial arterial line for invasive blood pressure monitoring and two to three large-bore intravenous catheters, ideally including a rapid-infusion catheter. The choice of hemodynamic monitoring is determined by institutional practice. When pulmonary hypertension is suspected or known, a pulmonary artery catheter should be placed, and pulmonary arterial pressure should be determined before induction or incision. Newly diagnosed moderate to severe pulmonary hypertension should be considered a reason to abort the procedure. These patients can be relisted for transplantation after successful medical therapy has been initiated. The diagnosis alone does not imply that the patient is denied a necessary transplant.

An orogastric/nasogastric tube is placed to decompress the stomach and improve surgical exposure. This is important during the dissection phase, and even more so during the anhepatic phase when the vascular anastomoses are performed. Patients are frequently severely coagulopathic, and the placement of a nasogastric tube may result in significant bleeding. Rarely, patients undergoing liver transplantation experience uncontrolled upper gastrointestinal bleeding during surgery that may require placement of a Minnesota or Sengstaken-Blakemore tube.

Before the incision is made, appropriate antibiotic and immunosuppressive (e.g., steroid administration) coverage should be ensured. Immunosuppressive protocols vary among medical centers, and clear communication is crucial.

The patient should be kept normothermic throughout the operation. A large surgical field combined with prolonged exposure, major fluid shifts, and the implantation of a cold organ renders the patient susceptible to significant hypothermia, which may worsen coagulopathy and drug metabolism. It also may prevent extubation of the patient at the end of the procedure. All administered fluids should be delivered through a fluid warmer, and forced-air heating blankets should be applied to all patients.

No optimal anesthetic technique has been established for maintenance of anesthesia. A balanced technique using volatile anesthetics in an oxygen/air mixture and opioids results in stable intraoperative hemodynamics. A combination of opioids and benzodiazepines and total intravenous anesthesia with propofol also have been used for liver transplantation. Nitrous oxide should not be used to avoid intestinal distention, and because in selected cases (not always predictable) a Roux-en-Y choledochojejunostomy is done at the end of the procedure.

Significant coagulopathy, blood loss, and electrolyte and metabolic derangements require frequent intraoperative laboratory tests. Measurement of arterial blood gases, blood glucose, electrolytes (sodium, potassium, and ionized calcium), and hematocrit is routine in most transplant centers. Monitoring of arterial blood gases allows one to assess oxygenation and base deficits and possibly lactate levels. Correction of the base deficit and reduction in lactate levels may be indirect indicators that the donor liver is functioning adequately.

The glucose-insulin pathway is frequently impaired in patients with end-stage liver disease. In contrast to patients with acute liver failure who may have hypoglycemia, patients with chronic end-stage liver disease experience impaired insulin-mediated glucose uptake. Glucose metabolism may worsen during liver transplantation, and progressive hyperglycemia may ensue, especially in the reperfusion phase. Several mechanisms have been implicated, including enhanced glycogenolysis by the donor liver, decreased glucose use, and insulin resistance.[163,212]

Close observation of electrolytes is essential. Hyperkalemia/hypokalemia may be present as a result of either renal dysfunction and massive transfusion or aggressive diuresis.[213] Hyponatremia frequently is encountered in end-stage liver disease, but overzealous correction during the perioperative phase should be avoided because of the associated risk of central pontine myelinolysis. Ionized calcium levels are often significantly decreased during liver transplantation, particularly during the dissection and anhepatic phases.[163] An exogenous citrate load from transfused blood products and the decreased ability of the diseased liver to metabolize citrate are thought to be responsible for the severely depressed ionized calcium levels, and calcium infusions are frequently required. Treatment of ionic hypocalcemia can be similarly accomplished with calcium chloride or calcium gluconate.[214] After reperfusion, and with the onset of function of the grafted liver, calcium hemostasis is often corrected, and calcium supplementation generally is unnecessary.

Less consistency is found among centers regarding the monitoring of coagulation parameters. The prothrombin time, international normalized ratio, partial thromboplastin time, fibrinogen, and platelets are measured by most programs. Thromboelastography is used in approximately 33% of liver transplant centers, and the activated clotting time is used in approximately 18%.[205] Severe coagulopathy and intraoperative blood loss remain the most significant problems encountered in patients undergoing liver transplantation. Impaired hemostasis, especially after receiving an extended criteria liver, is usually multifactorial and includes hyperfibrinolysis, depletion of coagulation factors, thrombocytopenia, and platelet dysfunction.[215] Approaches to correct hemostasis vary significantly among institutions and depend partly on institutional transfusion preferences and the coagulation monitoring method.[216,217]

The administration of fresh frozen plasma, red blood cells, platelets, and cryoprecipitate remains the mainstay of therapy for blood loss and coagulopathy during liver transplantation. Overall use of blood products during liver transplantation has been significantly reduced in recent years because of improved surgical technique, intraoperative management, and patient selection. This is an important accomplishment because blood transfusion results in immunomodulation and seems to affect long-term outcome adversely.[218] Pharmacologic agents known to alter hemostasis also have been investigated as adjunctive therapies. Aprotinin, aminocaproic acid, tranexamic acid, and conjugated estrogen all have been studied in this context[219-225]; one study showed improved hemodynamics with the administration of aprotinin.[227] These studies have produced conflicting results, however, partly because of study designs. In a meta-analysis including 1043 patients, Warnaar and colleagues[228] showed that aprotinin apparently is safe and results only in transient renal dysfunction. Aprotinin was withdrawn from the market in late 2007, however, based on complication rates in the cardiac surgery population.

The true efficacy of a drug can be determined only when the optimal treatment dosage (established through rigorous

dose-finding studies) is used.[229] To compare the efficacy of different drugs, knowledge of the optimal dosage of each is necessary. Similarly, the safety profile of a drug has to be taken into account. A dosage that maximally reduces blood loss and transfusion requirements during liver transplantation also may increase the risk of hepatic artery or portal vein thrombosis. It is not surprising that there is no consensus on the use of any of these hemostatic agents at liver transplant centers worldwide, despite promising studies.[229]

Another drug, recombinant factor VIIa, has attracted significant attention for improving coagulopathy and reducing intraoperative blood loss.[230] Recombinant factor VIIa was initially developed for patients with hemophilia and particularly for patients unable to receive conventional therapy because of antibodies against factors VIII and IX. Recombinant factor VIIa increases thrombin generation in conjunction with activated platelets.[231] Several case reports, case series, and noncontrolled studies have shown the potential usefulness of recombinant factor VIIa in the setting of liver transplantation.[226,232,233] In 2005, two prospective randomized trials in liver transplant patients resulted in disappointing results, in part because of poor patient selection.[234-235] A small retrospective study showed that in a select group of patients with prolonged prothrombin time and high MELD score, the prophylactic application of recombinant factor VIIa at the start of orthotopic liver transplantation may reduce perioperative transfusion requirements.[236] In view of the very high cost of the drug and the lack of scientific data, it can be recommended only for compassionate use in extreme situations.

As outlined earlier, liver transplantation can be divided into three stages: dissection, anhepatic, and reperfusion (neohepatic) phases. The surgical goals of the dissection phase are to mobilize the vascular structures around the liver (suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery) and isolate the common bile duct. Frequently, adhesions between the liver, diaphragm, and retroperitoneal areas must be dissected to allow full mobilization of the liver within the right upper quadrant. Manipulation of the liver can impede venous return and result in hypotension. Similarly, acute decompression of ascites early during the dissection phase can result in hypotension. During this phase, adequate fluid replacement is crucial, and colloids frequently are used.

Diuresis should be established early during the procedure to facilitate fluid management, and it may produce some renal protection in anticipation of relative renal ischemia during the anhepatic period. Commonly used drugs to maintain good urine output are loop diuretics, dopamine, mannitol, and, more recently, fenoldopam. It has not yet been established which regimen, if any, is the most protective during liver transplantation. As for dopamine, sound scientific data on the beneficial effect of fenoldopam are lacking in the liver transplant population. In a review article on fenoldopam, only two small studies were referenced that showed potential renal protective properties during liver transplantation under defined study conditions.[237,238] The comparably high cost probably excludes fenoldopam as a first-line drug for renal protection in routine liver transplantation. However, interventions frequently used for perioperative renal protection either are without beneficial effect[239] or are possibly harmful in the noncardiac patient population.[240]

During the end of the dissection stage, the donor organ, which is stored in preservation solution, is flushed with crystalloid or colloid solution on a separate table (back table). During the anhepatic stage, the new liver is primarily implanted by either infracaval interposition or piggyback technique. The choice of surgical technique has important anesthetic implications.

During infracaval interposition, complete vascular occlusion is established by clamping the hepatic artery, portal vein, infrahepatic vena cava, and suprahepatic vena cava (Fig. 67-4A). Because the inferior vena cava is occluded, cardiac preload becomes dependent on collateral flow, and severe hypotension can occur. Cardiac output often decreases significantly with an accompanying increased heart rate. If VVBP is not used, volume loading with a target CVP of 10 to 20 mm Hg and occasionally small infusions of vasopressors (e.g., phenylephrine) are needed before the infrahepatic and suprahepatic caval clamps are placed to prepare for the anhepatic phase. In a retrospective study, Schroeder and colleagues[241] suggested that a low CVP during liver transplantation may decrease the rate of blood transfusion, but it increases postoperative renal failure and 30-day mortality. The results have to be interpreted with caution, however, because of significant shortcomings in the study design. Massicotte and associates[242] showed in a prospective study that reducing CVP (e.g., phlebotomy) reduces blood loss, but does not result in increased adverse outcomes.

Because the response to caval occlusion may differ among patients, a temporary "test clamp" on the inferior vena cava may help guide management before vascular clamps are permanently placed for the anhepatic phase. Alternatively, VVBP can be instituted before vascular exclusion of the liver is established. Bypass is usually accomplished by cannulation of the femoral and portal veins with diversion to the suprahepatic vena cava through the axillary, subclavian, or jugular vein.[243,244]

Extensive research was conducted in the 1980s and 1990s to understand the advantages and disadvantages of VVBP, particularly after one group reported a 10% intraoperative mortality without VVBP that was attributed to hemodynamic instability during the anhepatic phase. Advantages of VVBP include improved hemodynamic stability, improved perfusion of organs during the anhepatic phase, decreased red blood cell and fluid requirements, splanchnic decompression, reduced renal impairment, limited metabolic impairment, and a reduced incidence of pulmonary edema.[243] Several disadvantages also were reported, with complications related to cannula placement being the most significant. Lymphocele, hematoma, major vascular injury, nerve injury, pulmonary air embolism, and death have been associated with VVBP; in one study, the complication rate was reported to be 10% to 30%. A more recent retrospective study noted that VVBP can be initiated during liver transplantation with acceptable risks.[245] More recent North American studies have reported, however, that most centers rarely use VVBP, if at all.[205,246,247]

Even centers not routinely using VVBP may consider it for selected patients, such as patients with significant preexisting cardiac disease, severe pulmonary hypertension, significant hemodynamic instability, or when the anesthesiologist is unfamiliar with caval clamping.[247,248] In the past, a greater than 50% reduction in cardiac output after vena cava clamping was considered an indication for VVBP. This indication has been challenged in a study in which it was shown that a reduction in cardiac output of more than 50% after vena cava clamping was not associated with increased perioperative morbidity and mortality com-

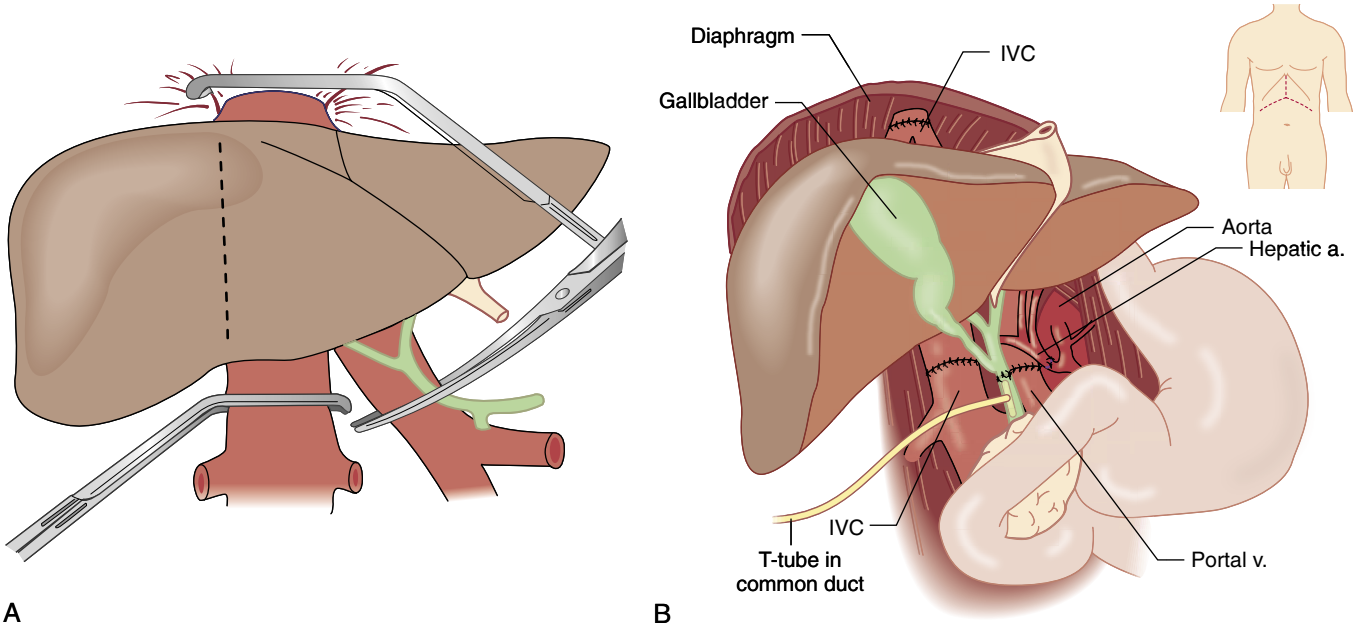

Figure 67-4 A, With the use of a caval interpositional technique immediately before the anhepatic phase, the suprahepatic vena cava, the infrahepatic vena cava, and the portal vein are clamped. The hepatic artery is frequently clamped late in the dissection phase. **B,** Anastomoses during liver transplantation. The donor's suprahepatic vena cava and infrahepatic vena cava are anastomosed to the recipient, followed by the portal vein. Frequently, the hepatic artery and bile duct are anastomosed in the reperfusion phase. A Roux-en-Y loop of the small intestine is an alternative biliary drainage conduit. Reconstruction of the hepatic artery, portal vein, or bile duct is occasionally necessary. Placement of a T-tube for drainage of the bile duct is not mandatory and is increasingly not being done. IVC, inferior vena cava. *(From Hardy JD: Hardy's Textbook of Surgery, 2nd ed. Philadelphia, JB Lippincott, 1988.)*

pared with patients with a less pronounced reduction in cardiac output.[249]

Alternatively, a piggyback technique can be used. During this approach, the vena cava is either partially or entirely occluded during the anhepatic phase. Although improved hemodynamics has been shown (with partial occlusion) with this technique, it is considered surgically more difficult than caval interposition, and may lead to greater technical complications.[250]

The anhepatic stage begins with excision of the native liver and control of bleeding. The ice-cold liver donor graft is placed into the surgical field. The suprahepatic, infrahepatic, and portal vein anastomoses are completed in that order. The hepatic artery anastomosis can be performed before reperfusion or after restoration of blood flow (Fig. 67-4B). Profound acidosis and hypocalcemia frequently develop during the anhepatic stage, so laboratory parameters should be monitored closely. Fluid management can be challenging during this phase, and the return of significant volume when the clamps are released at completion of the vascular anastomoses must be anticipated. Overly aggressive fluid management to maintain adequate blood pressure during the anhepatic phase may result in fluid overload with possible cardiopulmonary compromise and considerable liver and intestinal swelling. An engorged liver and intestines may pose a significant technical challenge for the surgeon during the reperfusion phase, especially when performing a Roux-en-Y choledochojejunostomy.

At the end of the anhepatic phase, the vascular clamps are removed in staged fashion, and each anastomosis is inspected for leakage. The return of preload by establishment of continuous caval flow results in normal or supranormal filling pressure. Removal of the portal vein clamp allows blood flow from the splanchnic circulation into the donor liver and constitutes the beginning of the reperfusion phase. The most critical part of the reperfusion phase is the period immediately after the vascular clamps are removed from the liver graft. Significant hemodynamic instability and cardiac arrest can occur within seconds to minutes of unclamping, particularly after unclamping the portal vein. Reduced cardiac contractility,[251] arrhythmias, severe bradycardia, profound hypotension, and hyperkalemic arrest all have been reported, and anesthetic management is directed at maintaining or recovering cardiovascular stability. This goal may require immediate pharmacologic intervention, such as the administration of epinephrine, atropine, calcium, or occasionally sodium bicarbonate. Methylene blue has been shown in one small study to attenuate hemodynamic changes of the reperfusion syndrome.[252] Preoperative placement of external pads may be helpful for immediate postreperfusion cardiac arrest.

The physiologic perturbations seen in the immediate reperfusion phase are often described as reperfusion syndrome. The exact mechanism is unknown and remains elusive.[253] Several factors alone or in combination are postulated to produce this hemodynamic instability, including high potassium concentrations[254] in the preservative solution (UW solution), donor demographics,[255] the surgical technique,[256] and decreased systemic vascular resistance.[257] Less well established, and in part controversial, factors, such as hypothermia, metabolic acidosis, endogenous vasoactive peptides from the intestine, and sudden atrial stretching in response to unclamping and reperfusion, are some mechanisms that have been postulated to cause the observed hemodynamic changes.

After the initial reperfusion phase, the hepatic artery anastomosis is completed, the gallbladder (in liver grafts from deceased donors) is removed, and the bile duct is reconstructed. Hepatic artery reconstruction is mostly done by end-to-end anastomosis and, in select cases (with unfavorable anatomy), by a jump graft from the aorta. Bile drainage is usually accomplished by choledochocholedochostomy and occasionally by Roux-en-Y choledochojejunostomy. Attention should be paid to the diagnosis and management of significant coagulopathy (e.g., dilution and consumption of clotting factors, platelet entrapment, endogenous heparinoid-like substances, primary fibrinolysis) and resultant bleeding in the reperfusion phase. Laboratory analysis (with consideration of its limitations) and clinical evidence of surgical bleeding should guide management of the coagulopathy.

The immediate function of the newly transplanted liver can be assessed by monitoring obtainable parameters in the operating room. Intraoperative parameters associated with prediction of the outcome of liver transplantation include transfusion requirements, intraoperative bile and urine production, technical complications, and total operating time. The lack of bile production, the need for platelet transfusion, and decreased urine output seem to be associated with a significant increase in ICU and hospital stay.[258]

When adequate hemostasis is established, the abdomen is closed. Hypertension may develop toward the end of the procedure in some patients, and treatment should be initiated before leaving the operating room.

Postoperative Care

Postoperative tracheal intubation is no longer mandatory as long as significant respiratory compromise or concern for airway protection is absent, and established criteria for extubation are fulfilled. Immediate postoperative extubation of liver transplant patients while still in the operating room was reported in 1997 in a cooperative study between the University of Colorado and the University of California at San Francisco.[259] A small group of patients with characteristics associated with few postoperative complications were studied. The successful outcome of this study was followed by reports of immediate or early extubation from institutions in the United States and Europe.[260-264] More recent studies have reported that 75% of first-time deceased liver transplant patients without fulminant failure could be extubated in the operating room by physicians who had experience with early extubation protocols.[263,265] A prospective multicenter study confirmed that early extubation in liver transplantation patients is safe when strict guidelines are followed.[266]

Fluid shifts or blood loss per se should not be considered an indication for postoperative intubation. The standard criteria for extubation in addition to some patient-specific considerations (e.g., significant preoperative hepatic encephalopathy, fulminant hepatic failure) suffice to assist in determining whether a patient should be considered for extubation. Nevertheless, regardless of whether the patient is extubated in the operating room, most centers admit patients to the ICU for close monitoring purposes. There have been more recent reports of uncomplicated cases with patient disposition to the postoperative anesthesia care unit and subsequent floor admission.

Postsurgical pain control is not generally a problem. Several studies have shown that analgesic requirements in patients with end-stage liver disease undergoing liver transplantation appear to be significantly decreased compared with other major abdominal surgery.[267-269] In one study, the neuropeptide metenkephalin, which is involved in pain modulation, was shown to be significantly elevated in liver transplant patients compared with the control population. The exact mechanism of this clinical observation is unknown, and preoperative administration of large doses of steroids may play some role. Whether this applies to transplant patients with hepatocellular carcinoma and preserved synthetic liver function is unknown. The postoperative course of patients who have undergone liver transplantation is primarily dictated by the degree of immediate liver function and recovery of organs that were compromised before transplantation (e.g., hepatorenal syndrome, hepatopulmonary syndrome).

Recovery can range from uncomplicated to extremely complex. Frequent assessment of cardiac and pulmonary function, serum glucose and electrolytes, renal and liver function, and coagulation and the blood count is crucial. In most cases, therapy is supportive and follows the guidelines established for all ICU patients. Certain aspects require special attention, however. Patients occasionally need fresh frozen plasma therapy postoperatively to offset an initially low graft liver function. Fresh frozen plasma requirements also are considered an indirect measure of postoperative liver function. The need for administering platelets or cryoprecipitate postoperatively is low, and such administration is reserved for selected cases. One should have a low threshold for re-exploration. Leakage from vascular anastomosis sites, or "bleeders," and diminished flow or thrombosis in the hepatic artery or portal vein should always be considered. Patients who have adequate postoperative liver function and have received steroids tend to be hyperglycemic, which may warrant an infusion of insulin.

Anesthesia for Patients after Liver Transplantation

Liver transplant recipients occasionally return to the operating room shortly after the procedure for exploratory laparotomy. Reasons for exploration include bleeding, biliary leak, bowel obstruction, and abscess formation. Liver function may not have returned to baseline in the immediate post-transplant period, and additional surgical stress may result in significant worsening of hepatic function. Coagulation studies should be monitored carefully throughout the case, and fresh frozen plasma should be made readily available.

The most common reason to operate after liver transplantation is for biliary reconstruction. At this point, liver function is generally normal, and anesthetic considerations (including regional techniques such as epidural catheters) are similar to those for any abdominal procedure. These patients have been receiving powerful immunosuppressive therapy, however, which leads to an increased risk for infectious complications, drug toxicity, and adverse drug interaction. Placement of any intravenous or epidural catheters should be done under strict sterile conditions with maximum barrier protection. The patient's drug regimen should be reviewed and screened for known interactions with drugs used during the perioperative period. The medical history and physical examination done at this point should include screening for these adverse immunosuppressive drug effects, including, but not limited to, neurotoxicity and renal toxicity.

Intestine Transplantation

Intestinal transplantation is done much less frequently than transplantation of other solid organs. In 2007, 198 intestinal transplants were done in the United States, and there were approximately 222 patients on the waiting list. Short-gut syndrome accounted for more than 60% of these transplants, and half the recipients were younger than 6 years.[144]

The overall graft survival rate at 1 year was 66% and at 5 years was 20%. These outcomes are markedly improved compared with earlier years, when early universal graft failure was very common. Changes in immunosuppressive therapy are thought to be responsible for the improved graft survival.[270] Only a few centers perform this procedure as either an isolated intestinal transplantation or a combined liver-intestinal transplantation. Dependence on total parenteral nutrition can lead to steatotic liver disease with hepatic failure requiring combined liver-intestinal transplantation. Optimization of hepatosplanchnic blood flow is essential for these cases. Fluid loading and inotropic support may be beneficial.[271] No studies have investigated the perioperative anesthetic management and graft and patient outcome.

Infection after Abdominal Solid Organ Transplantation

After transplantation, organ recipients are at significant risk for various complications, including bacterial, fungal, and viral infections. Infections in this patient population are associated with increased morbidity and mortality because transplant recipients have unique infectious risks compared with immunocompetent ICU patients. Studies of patients receiving different transplanted abdominal organs show the importance of postoperative infection in transplant recipients. In the first month after transplantation, the sources of infection are primarily nosocomial secondary to the surgical technique or technical complications. After transplantation of any abdominal organ, there is a risk of surgical site infections, intra-abdominal abscesses, and infected hematomas. Multidrug-resistant microorganisms are increasingly seen in this population and are likely to represent a significant challenge in the future.

In liver transplantation, surgical complications such as biliary leaks can lead to subsequent infections, including peritonitis, cholangitis, and hepatic abscesses.[272] The risk of fungal infections after orthotopic liver transplantation increases with renal failure, transfusions, retransplantation, repeat laparotomy, and creation of a Roux-en-Y biliary duct anastomosis.

Surgical site infections of the soft tissue are usually diagnosed clinically by the presence of erythema, tenderness, purulence, and crepitus around the wound.[9] Often, superficial surgical site infections can be treated with antibiotics only; however, any rapidly progressing soft tissue infection requires prompt surgical treatment. Gram-positive organisms usually cause superficial surgical site infections, but necrotizing infections are often polymicrobial. Surgical site infection involving deeper tissue structures may be more difficult to recognize. Diagnostic procedures include culturing and Gram staining of any fluid from the wound or drains, ultrasound or CT scanning to localize possible fluid collections, and possible repeat laparotomy. Laparotomies are associated with an increased mortality, but are often necessary in critically ill transplant patients, especially patients with sepsis and multiorgan failure.[273] CT-guided drains successfully treat 80% of abdominal abscesses in general surgical patients.[274] Intra-abdominal abscesses in orthotopic liver transplantation are often near the biliary tract, especially if a Roux-en-Y choledochojejunostomy was used for the biliary reconstruction.

Renal allograft recipients with high serum creatinine, urinary fistulas or leaks, and prolonged urinary bladder catheterization have a higher risk for wound infections.[275] After simultaneous pancreas and kidney transplant, the risk of an intra-abdominal surgical site infection may be increased slightly if pancreatic exocrine secretions are drained enterically, rather than drained via pancreatic duct anastomosis to the bladder.[276] Additionally, kidney transplant recipients with a peritoneal dialysis catheter present before transplantation may have increased risk for intra-abdominal, bloodstream, and wound infections.[275]

Frequently, transplant patients require extensive postoperative critical care with prolonged intubation and indwelling central venous and urinary catheters. These devices are significant risk factors for ventilator-associated pneumonia, urinary tract infections, and catheter-related bloodstream infections in a significantly immunocompromised patient population.

Comorbidities, such as diabetes and persistent renal dysfunction, can contribute to increased susceptibility to infections. Renal failure incurs a 15-fold to 21-fold increased risk of invasive fungal infection. Pneumonia accounts for 41% of febrile episodes in the ICU in the first 7 days postoperatively; the risk of catheter-related bloodstream infections increases threefold after the first week. Patients are often taking multiple immunosuppressants that act through multiple inhibitory mechanisms and may facilitate infection.

Immunosuppression

Recognition of a foreign alloantigen after organ transplantation triggers an immune response in the host. An immediate goal of immunosuppressive therapy is to prevent the rejection of grafts from genetically nonidentical donors. Various immunosuppressive drugs have been developed to diminish the immunologic attack on grafts and target T-cell activation, which triggers the predominant form of acute rejection. Individual immunosuppressants inhibit different steps in T-cell activation, which is a very complex process that can be divided into two stages—a sensitization phase and an effector stage. The first stage of T-cell activation involves interaction between antigen-presenting cells of the graft and host T cells, such as CD3. The second stage involves participation of costimulatory receptors such as B7, CD28, and CD40, which also activate the T-cell response, and subsequent secretion of cytokines by activated T cells. An interaction of intracellular adhesion molecules and cytokines (e.g., interleukin-2, interferon-γ, and tumor necrosis factor-β) activates the transcription cascade, which further amplifies T-cell activation through DNA synthesis and T-cell proliferation, and plays a central role in graft rejection. Graft rejection reactions have various time courses: hyperacute rejection occurs within the first 24 hours after transplantation, acute rejection reactions usually

begin in the first few weeks after transplantation, and chronic rejection can occur months to years after transplantation.[277,278]

Immunosuppressive drugs are used for the prevention or treatment of acute and chronic rejection of a transplanted organ. The growing success of organ transplantation is closely linked to the evolution of immunosuppressive therapy. The first immunosuppressive drug, azathioprine, was introduced in 1962 and increased the possibilities for successful human transplants, earning a Nobel Prize for innovative pharmacologic progress. In the last 20 years, important medical breakthroughs, such as tissue typing and the introduction of calcineurin inhibitor–based immunosuppression, have dramatically improved the survival rate of transplant recipients. In 1983, the "calcineurin inhibitors era" was ushered in after the discovery of cyclosporine (1979). Transplantation of extrarenal organs became routine, with excellent outcomes for liver, pancreas, heart, and lung transplants.[279]

Immunosuppressive therapy is increasingly being tailored to the specific organs transplanted and their individual risk factors. Patients who are presensitized or who receive a blood group–incompatible organ are, from an immunologic point of view, considered to be high-risk patients. They are likely to require more potent, aggressive immunosuppressive therapy than needed for other transplant patients.[280] Frequently, the type of immunosuppressive drug (e.g., calcineurin inhibitors) or increased doses of immunosuppressive drugs are linked, however, to increased end-organ toxicity, such as neurotoxicity or nephrotoxicity. In patients with delayed renal graft function after transplantation, initial omission of calcineurin inhibitors is crucial to avoid further renal damage. Immunosuppressive drugs are frequently combined to take advantage of additive or synergistic immunosuppressive interaction and to limit drug-specific toxicity (Table 67-2).[281]

Therapy must be maintained lifelong, although isolated cases without graft loss after complete withdrawal of all immunosuppressive drugs have been reported. A typical regimen consists of different phases, starting with the induction phase, therapy during hospitalization, the maintenance phase, and, if necessary, antirejection treatment. Each phase may consist of different drugs or doses and is constantly adjusted as dictated by the medical condition of the patient. The major limitation of current immunosuppressive drugs is that no currently available therapy is entirely effective in preventing rejection.[280] The use of multiple immunosuppressive drugs predisposes patients to a host of infectious and malignant complications. Long-term survival of patients after solid organ transplantation has improved with adequate immunosuppressive therapy. Modification of the immune system also has increased the risk of malignancy, however, especially types of malignancy involving viruses.[282] Azathioprine has been associated with a significant increase in skin cancer, and prolonged cyclosporine administration has been associated with Kaposi's sarcoma. Malignancy is now responsible for substantial morbidity and mortality in this patient population.

With many different available immunosuppressant combinations, acute rejection rates are acceptable, and the focus of interest in transplantation has significantly shifted and expanded toward tolerability and long-term graft and patient survival. The goals of therapy for new immunosuppressants drugs should include (1) prevention of the immune response (i.e., acute and chronic rejection and vascular remodeling); (2) prevention of the complications of immunodeficiency, such as opportunistic infections and malignancies; and (3) minimization of drug-induced toxicity. Many new trials are under way to identify the best immunosuppressant regimen.

Table 67-2 Immunosuppressive Drugs Used in Solid Organ Transplantation and Their Side Effects

Mechanism of Action	Side Effects
Inhibition of T-cell interaction	
Prednisolone	As with all steroids: osteoporosis, diabetes mellitus, glaucoma, infections
Muromonab-CD3 (Orthoclone OKT3)	Fever, lymphoproliferative disease, pulmonary edema, anaphylactic reaction, neoplasia
15-Deoxyspergualin	Bone marrow suppression, gastrointestinal syndromes, paresthesia
Inhibition of adhesion molecules	
Rabbit/horse antithymocyte globulin	Fever, nausea, anaphylactic reaction, higher incidence of cytomegalovirus and Epstein-Barr virus infection
Antilymphocyte globulin	Fever
Enlimomab	Fever, hypertension, chills, nausea, vomiting
OKT4A	Unknown
Inhibition of cytokine synthesis	
Cyclosporine	Nephrotoxicity, hepatotoxicity, neurotoxicity, hypertension, hyperlipidemia, hirsutism, tremor, gingival hyperplasia, diabetes
Tacrolimus (FK506)	Nephrotoxicity, neurotoxicity, hypertension, hyperlipidemia, hyperglycemia
Sirolimus (rapamycin)	Hyperlipidemia, myelosuppression, infections
SDZ-RAD (everolimus)	Hyperlipidemia, myelosuppression, infections
Inolimomab	Headache, leukopenia, thrombocytopenia
Basiliximab	No major adverse effects
Daclizumab	No major adverse effects
Inhibition of DNA synthesis	
Azathioprine	Myelosuppression, hepatotoxicity, development of malignancy
Mycophenolate mofetil	Leukopenia, gastrointestinal syndromes

Because the therapeutic range of most immunosuppressive drugs is narrow, perioperative monitoring of drug levels is important. Several immunosuppressives (e.g., cyclosporine, tacrolimus, and sirolimus) are substrates or modulators (or both) of cytochrome P4503A and P-glycoprotein.[283,284] P-glycoprotein is a member of the ABC (adenosine triphosphate [ATP]–binding cassette) transport protein family. It is found in various tissues, including the blood-brain barrier, gastrointestinal tract, kidneys, adrenal cortex, and several more. One of the functions of P-glycoprotein is the energy-dependent transport of drug acquired from the cytoplasm or plasma membrane into the extracellular space.[285] Several other drug classes (e.g., antifungals, calcium channel blockers, HIV protease inhibitors) administered to transplant

patients also are substrates or modulators (or both) of cytochrome P4503A and P-glycoprotein. These drugs themselves may interact with drugs commonly administered during the perioperative period.[286,287]

Although interactions between immunosuppressive and anesthetic drugs are likely to occur, few studies have examined in a prospective randomized fashion the impact of immunosuppressive drugs on selected anesthetics. In animal studies, cyclosporine was shown to alter barbiturate, fentanyl, and isoflurane requirements.[288-291] However, the clinical relevance of these interactions remains to be investigated, however. Similarly, cyclosporine seems to enhance the effects of neuromuscular blockade, as shown in several animal studies and case reports.[292-295] Despite the lack of adequate trials in humans, it seems to be reasonable to anticipate reduced requirements of nondepolarizing muscle relaxants in patients taking cyclosporine. Azathioprine, in contrast, produced a small and transient antagonism to nondepolarizing muscle blockade in patients with renal failure that was considered clinically insignificant. An animal study also showed no effect of azathioprine on atracurium requirements.

The complexity of the immunosuppressive regimen in conjunction with adjunct therapies makes clinically relevant drug-drug interactions likely. A detailed preoperative review of the patient's medication should focus on possible side effects, drug-drug interactions, and potential implications for the anesthetic plan.[296]

Jean L. Joris

68 Anesthesia for Laparoscopic Surgery

Key Points

1. CO_2 pneumoperitoneum results in ventilatory and respiratory changes. Pneumoperitoneum decreases thoracopulmonary compliance. $Paco_2$ increases (15% to 25%) due to CO_2 absorption from the peritoneal cavity. Capnography reliably reflects this increase, which plateaus after 20 to 30 minutes.
2. In compromised patients, cardiorespiratory disturbances aggravate the increase in $Paco_2$ and enlarge the gradient between $Paco_2$ and $Petco_2$.
3. Any increase in $Petco_2$ larger than 25% or occurring later than 30 minutes after the beginning of peritoneal CO_2 insufflation should suggest CO_2 subcutaneous emphysema, the most frequent respiratory complication during laparoscopy.
4. Peritoneal insufflation induces alterations of hemodynamics, characterized by decreases of cardiac output, elevations of arterial pressure, and increases of systemic and pulmonary vascular resistances. Hemodynamic changes are accentuated in high-risk cardiac patients.
5. The pathophysiologic hemodynamic changes can be attenuated or prevented by optimizing preload before pneumoperitoneum and by vasodilating agents, α_2-adrenergic receptors agonists, high doses of opioids, and β-blocking agents.
6. Similar pathophysiologic changes occur during pregnancy and in children. Laparoscopy can be safely managed in pregnant women before the 23rd week of pregnancy provided that hypercarbia is prevented. The open laparoscopy approach should be considered to avoid damaging the uterus.
7. Gasless laparoscopy may be helpful to reduce pathophysiologic changes induced by CO_2 pneumoperitoneum but unfortunately increases technical difficulty.
8. Laparoscopy results in multiple postoperative benefits, allowing for quicker recovery and shorter hospital stay. These advantages explain the increasing success of laparoscopy, which is proposed for many surgical procedures.
9. Although no anesthetic technique has proved to be clinically superior to any other, general anesthesia with controlled ventilation seems to be the safest technique for operative laparoscopy.
10. Improved knowledge of the intraoperative repercussions of laparoscopy permits safe management of patients with more and more severe cardiorespiratory disease, who may subsequently benefit from the multiple postoperative advantages offered by this technique.

Surgical procedures have been improved to reduce trauma to the patient, morbidity, mortality, and hospital stay, with consequent reductions in health care costs. The provision of better equipment and facilities, along with increased knowledge and understanding of anatomy and pathology, has allowed the development of endoscopy for diagnostic and operative procedures. Starting in the early 1970s, various pathologic gynecologic conditions were diagnosed and treated using laparoscopy. This endoscopic approach was extended to cholecystectomy in the late 1980s. Since the introduction of the first laparoscopic cholecystectomy procedures,[1] laparoscopy has expanded impressively both in scope and volume. It quickly became apparent that laparoscopy results in multiple benefits compared with open procedures[2,3] and was characterized by better maintenance of homeostasis. Overenthusiasm ensued, which explains the effort to use the laparoscopic approach for gastrointestinal (e.g., colonic, gastric, splenic, hepatic surgery), gynecologic (e.g., hysterectomy), urologic (e.g., nephrectomy, prostatectomy), and vascular (e.g., aortic) procedures.

The pneumoperitoneum and the patient positions required for laparoscopy induce pathophysiologic changes that complicate anesthetic management. An understanding of the pathophysiologic consequences of increased intra-abdominal pressure (IAP) is important for the anesthesiologist who must ideally prevent or, when prevention is not possible, adequately respond to these

changes and who must evaluate and prepare the patient preoperatively in light of these disturbances. The pathophysiologic changes and the complications of laparoscopy are reviewed first. The postoperative period is considered next, with examination of the benefits of laparoscopy and certain specific postoperative problems (e.g., pain, nausea). Practical consequences for the anesthetic management of laparoscopy are presented. Many animal and human studies of the consequences of laparoscopy have been published since the early 1970s. Because much higher IAPs (>20 mm Hg) were previously used and because of potential species differences, we have focused on the human literature published after 1990 using low IAP (<15 mm Hg) and modern anesthesia techniques.

Ventilatory and Respiratory Changes During Laparoscopy

Intraperitoneal insufflation of carbon dioxide (CO_2), the currently routine technique to create pneumoperitoneum for laparoscopy, results in ventilatory and respiratory changes and can cause four principal respiratory complications: CO_2 subcutaneous emphysema, pneumothorax, endobronchial intubation, and gas embolism.[4]

Ventilatory Changes

Pneumoperitoneum decreases thoracopulmonary compliance by 30% to 50% in healthy[5-7] and obese patients.[8,9] Reduction in functional residual capacity[10] and development of atelectasis due to elevation of the diaphragm[11] and changes in the distribution of pulmonary ventilation and perfusion from increased airway pressure can be expected.[11] However, increasing IAP to 14 mm Hg with the patient in a 10- to 20-degree head-up or head-down position does not significantly modify either physiologic dead space or shunt in patients without cardiovascular problems.[12,13]

Increase in the Partial Pressure of Arterial Carbon Dioxide

During uneventful CO_2 pneumoperitoneum, the partial pressure of arterial carbon dioxide ($Paco_2$) progressively increases to reach a plateau 15 to 30 minutes after the beginning of CO_2 insufflation in patients under controlled mechanical ventilation during gynecologic laparoscopy in the Trendelenburg position[14] or during laparoscopic cholecystectomy in the head-up position (Fig. 68-1).[15,16] Any significant increase in $Paco_2$ after this period requires a search for a cause independent of or related to CO_2 insufflation, such as CO_2 subcutaneous emphysema. The increase in $Paco_2$ depends on the IAP.[17] During laparoscopy with local anesthesia, $Paco_2$ remains unchanged but minute ventilation significantly increases.[18]

Capnography and pulse oximetry provide reliable monitoring of $Paco_2$ and arterial oxygen saturation in healthy patients and in the absence of acute intraoperative disturbances (see Figure 68-1).[15,16] Although mean gradients (Δa-$ETCO_2$) between $Paco_2$ and the end-tidal carbon dioxide tension ($Petco_2$) do not change significantly during peritoneal insufflation of CO_2, individual patient data regularly show variations of this difference during pneumoperitoneum.[19,20] $Paco_2$ and Δa-$ETCO_2$ increase more in ASA class II and III patients than in ASA class I patients (Fig. 68-2).[21,22] These findings have been documented in patients with chronic obstructive pulmonary disease (COPD)[23] and in children with cyanotic congenital heart disease.[24] These data therefore highlight the lack of correlation between $Paco_2$ and $Petco_2$ in sick patients, particularly those with impaired CO_2 excretion capacity, and in otherwise healthy patients with acute cardiopulmonary disturbances. Consequently, hypercapnia can develop, even in the absence of abnormal $Petco_2$. Postoperative intra-abdominal CO_2 retention results in increased respiratory rate and $Petco_2$ of patients breathing spontaneously after laparoscopic cholecystectomy as compared with open cholecystectomy.[25]

During CO_2 pneumoperitoneum, the increase of $Paco_2$ may be multifactorial: absorption of CO_2 from the peritoneal cavity, impairment of pulmonary ventilation and perfusion by mechanical factors such as abdominal distention, patient posi-

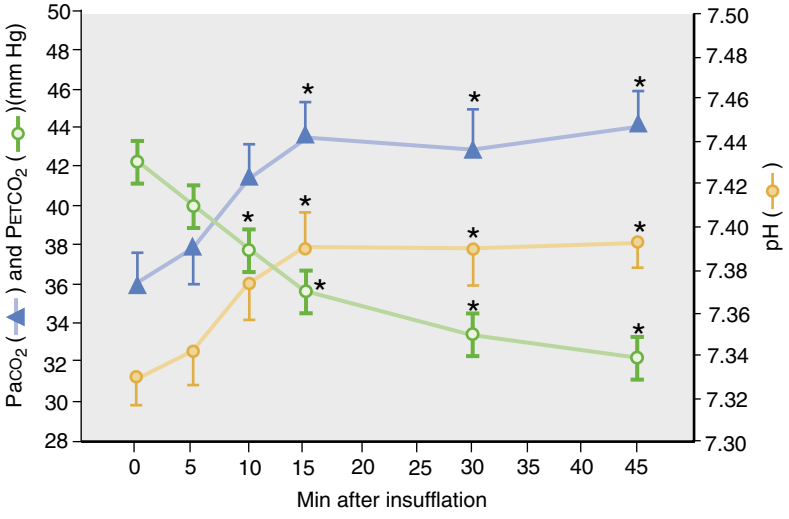

Figure 68-1 Ventilatory changes (pH, $Paco_2$, and $Petco_2$) during CO_2 pneumoperitoneum for laparoscopic cholecystectomy. For 13 American Society of Anesthesiologists (ASA) class I and II patients, minute ventilation was kept constant at 100 mL/kg/min with a respiratory rate of 12 breaths/min during the study. Intra-abdominal pressure was 14 mm Hg. Data are given as the mean ± SEM.*, P < .05 compared with time 0.

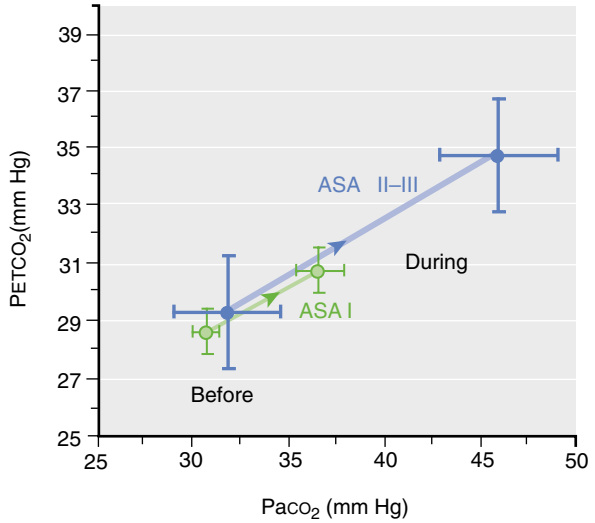

Figure 68-2 Ventilatory changes as a function of patient physical status. The $Paco_2$ and $Petco_2$ were measured before and during CO_2 insufflation. Patients were grouped according to ASA classification: group 1 (*green circles*), ASA I ($n = 20$); group 2 (*blue circles*), ASA II-III ($n = 10$). *(Data from Wittgen CM, Andrus CH, Fitzgerald SD, et al: Analysis of the hemodynamic and ventilatory effects of laparoscopic cholecystectomy. Arch Surg 126:997, 1991.)*

tion, and volume-controlled mechanical ventilation. The observation of an increase in $Paco_2$ when CO_2, but not nitrous oxide (N_2O) or helium, was used as the insufflating gas suggests that the main mechanism of the increased $Paco_2$ during CO_2 pneumoperitoneum is absorption of CO_2 rather than the mechanical ventilatory repercussions of increased IAP.[26,27] Accordingly, direct measurement of CO_2 elimination $(\dot{V}co_2)$ using a metabolic monitor combined with investigation of gas exchange showed a 20% to 30% increase of $\dot{V}co_2$ without significant changes in physiologic dead space in healthy patients undergoing pelvic laparoscopy (IAP of 12 to 14 mm Hg) in the head-down position[14,28] or laparoscopic cholecystectomy in the head-up position.[14,29] The time courses of the increase in $\dot{V}co_2$ and $Paco_2$ are similar. The absorption of a gas from the peritoneal cavity depends on its diffusibility, the absorption area, and the perfusion of the walls of that cavity. Because CO_2 diffusibility is high, absorption of large quantities of CO_2 into the blood and the subsequent marked increases in $Paco_2$ would be expected to occur. The limited rise of $Paco_2$ actually observed can be explained by the capacity of the body to store CO_2[30] and by impaired local perfusion due to increased IAP.[17] During deflation, CO_2 that accumulated in collapsed peritoneal capillary vessels reaches the systemic circulation, leading to transient increases in $Paco_2$ and $\dot{V}co_2$.[31]

Respiratory changes during the laparoscopic procedure may contribute to increasing CO_2 tension. Mismatched ventilation and pulmonary perfusion can result from the position of the patient and from the increased airway pressures associated with abdominal distention.[18,32] Lister and colleagues[17] investigated the relationship between $\dot{V}co_2$ and intraperitoneal CO_2 insufflation pressure in pigs. For an IAP up to 10 mm Hg, increased $\dot{V}co_2$ accounts for the increased $Paco_2$. At higher IAPs, the continued rise of $Paco_2$ without a corresponding increase in $\dot{V}co_2$ results from an increase in respiratory dead space, as reflected by a widening of the $\Delta a\text{-}ETCO_2$ gradient.[17] If controlled ventilation is not adjusted in response to the increased dead space, alveolar ventilation will decrease and $Paco_2$ will rise. In healthy patients, absorption of CO_2 from the abdominal cavity represents the main (or the only) mechanism responsible for increased $Paco_2$,[13] but in patients with cardiorespiratory problems, ventilatory changes also significantly contribute to increasing $Paco_2$.[21] Pao_2 values and intrapulmonary shunt do not significantly change during laparoscopy.[12,13]

It is wise to maintain $Paco_2$ within a physiologic range by adjusting the mechanical ventilation. Except in special circumstances, such as when CO_2 subcutaneous emphysema occurs (see later), correction of increased $Paco_2$ can be easily achieved by a 10% to 25% increase in alveolar ventilation.

Respiratory Complications

CO_2 Subcutaneous Emphysema

CO_2 subcutaneous emphysema can develop as a complication of accidental extraperitoneal insufflation[33] but can also be considered as an unavoidable side effect of certain laparoscopic surgical procedures that require intentional extraperitoneal insufflation, such as inguinal hernia repair, renal surgery, and pelvic lymphadenectomy (Fig. 68-3).[14,34,35] During laparoscopic fundoplication for hiatal hernia repair, the opening of the peritoneum overlying the diaphragmatic hiatus allows passage of CO_2 under pressure through the mediastinum to the cervicocephalic region. In these circumstances, $\dot{V}co_2$, $Paco_2$, and $Petco_2$ increase.[14] Any increase in $Petco_2$ occurring after $Petco_2$ has plateaued should suggest this complication. The increase in $\dot{V}co_2$ may be such that prevention of hypercapnia by adjustment of ventilation becomes almost impossible. In this case, laparoscopy must be temporarily interrupted to allow CO_2 elimination and can be resumed after correction of hypercapnia using a lower insufflation pressure. Indeed, CO_2 pressure determines the extent of the emphysema and the magnitude of CO_2 absorption. CO_2 subcutaneous emphysema readily resolves once insufflation has ceased. CO_2 subcutaneous emphysema, even cervical, does not counterindicate tracheal extubation at the end of surgery.[36] We recommend keeping the patient mechanically ventilated until hypercapnia is corrected, particularly in COPD patients, to avoid an excessive increase in the work of breathing.

Pneumothorax, Pneumomediastinum, Pneumopericardium

Movement of gas during the creation of a pneumoperitoneum can produce pneumomediastinum,[37] unilateral and bilateral pneumothoraces,[38] and pneumopericardium.[39] Embryonic remnants constitute potential channels of communication between the peritoneal cavity and the pleural and pericardial sacs, which can open when intraperitoneal pressure increases. Defects in the diaphragm or weak points in the aortic and esophageal hiatus may allow gas passage into the thorax. Pneumothoraces may also develop secondary to pleural tears during laparoscopic surgical procedures at the level of the gastroesophageal junction (e.g., fundoplication for hiatal hernia). Although opening of peritoneopleural ducts is associated with mainly right-sided pneumothoraces (in the same way that ascites or peritoneal dialysis may be associated with right-sided pleural effusions[40]), the pneumothorax associated with fundoplication is more frequently in the left side of the chest.

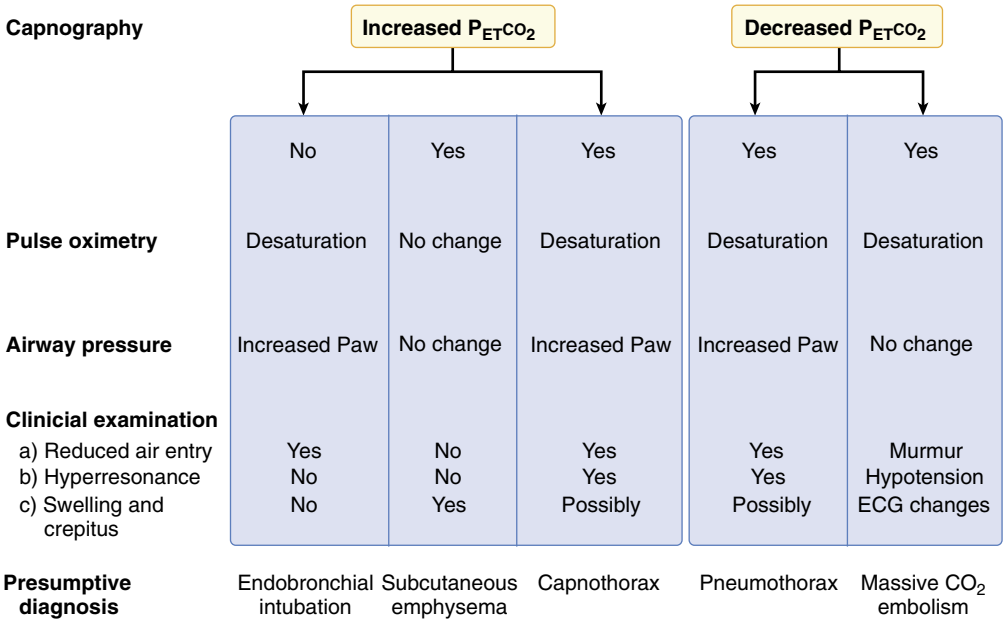

Figure 68-3 Diagnosis of respiratory complications during laparoscopy. ECG, electrocardiographic; Paw, airway pressure; P_{ETCO_2}, end-tidal carbon dioxide tension. (*Data from Wahba RW, Tessler MJ, Kleiman SJ: Acute ventilatory complications during laparoscopic upper abdominal surgery. Can J Anaesth 43:77, 1996.*)

These complications are potentially serious and may lead to respiratory and hemodynamic disturbances. Capnothorax (CO_2 causing a pneumothorax) reduces thoracopulmonary compliance and increases airway pressures. $\dot{V}_{CO_2}$, Pa_{CO_2}, and P_{ETCO_2} also increase.[41] In effect, the absorption surface of CO_2 is increased and the absorption from the pleural cavity is greater than from the peritoneal cavity. When a pneumothorax occurs secondary to alveolar rupture, the P_{ETCO_2} decreases because of decreased cardiac output. Hemodynamic changes and oxygen desaturation should suggest the presence of a tension pneumothorax. The laparoscopist may observe abnormal motion of one hemidiaphragm when a tension pneumothorax has occurred. It should be noted that cervical and upper thoracic subcutaneous emphysema can develop without the presence of a pneumothorax.

When a pneumothorax is caused by highly diffusible gas such as N_2O or CO_2 without associated pulmonary trauma, spontaneous resolution of the pneumothorax occurs within 30 to 60 minutes without thoracocentesis.[42] When capnothorax develops during laparoscopy, treatment with positive end-expiratory pressure (PEEP) is an alternative to chest tube placement.[41] In contrast, if the pneumothorax is secondary to rupture of preexisting bullae, PEEP must not be applied and thoracocentesis is mandatory.

Endobronchial Intubation

Cephalad displacement of the diaphragm during pneumoperitoneum results in cephalad movement of the carina in children[43] and adults,[44] potentially leading to an endobronchial intubation. Cases of endobronchial intubation associated with laparoscopy are reported during procedures in the head-down position[45] and in the head-up position.[44,46] This complication results in a decrease in the oxygen saturation as measured by pulse oximetry (Spo_2) associated with an increase in plateau airway pressure (see Fig. 68-3).

Gas Embolism

Although rare, gas embolism is the most feared and dangerous complication of laparoscopy. Intravascular injection of gas may follow direct needle or trocar placement into a vessel, or it may occur as a consequence of gas insufflation into an abdominal organ. This complication develops principally during the induction of pneumoperitoneum,[47,48] particularly in patients with previous abdominal surgery.[49] Gas embolism may also occur later during surgery.[50,51] CO_2 is used most frequently for laparoscopy because it is more soluble in blood than either air, oxygen, or N_2O.[30] Rapid elimination also increases the margin of safety in case of intravenous injection of CO_2. All these characteristics explain the rapid reversal of the clinical signs of CO_2 embolism with treatment. Consequently, the lethal dose of embolized CO_2 is approximately five times greater than that of air.

The pathophysiology of gas embolism is also determined by the size of the bubbles and the rate of intravenous entry of the gas.[52,53] During laparoscopy, the rapid insufflation of gas under high pressure probably causes a "gas lock" in the vena cava and right atrium; obstruction to venous return with a fall in cardiac output or even circulatory collapse can result. Acute right ventricular hypertension may open the foramen ovale, allowing paradoxical gas embolization.[50,54] Paradoxical embolism, however, may occur without patent foramen ovale.[55] Volume preload diminishes the risk of gas embolism[56] and of paradoxical embolism.[57] Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching develops with increases in physiologic dead space and hypoxemia.

The diagnosis of gas embolism depends on the detection of gas emboli in the right side of the heart or on recognition of the physiologic changes from embolization. Early events, occurring with 0.5 mL/kg of air or less, include changes in Doppler sounds and increased mean pulmonary artery pressure. The low incidence of gas embolism during laparoscopy precludes the routine use of invasive or expensive monitors to detect embolization of small quantities of gas. When the size of the embolus

increases (2 mL/kg of air), tachycardia, cardiac arrhythmias, hypotension, increased central venous pressure, alteration in heart tones (i.e., millwheel murmur), cyanosis, and electrocardiographic changes of right-sided heart strain can develop; all these changes are rarely consistently positive.[58] Pulmonary edema can also be an early sign of gas embolism.[54] Although pulse oximetry is helpful in recognizing hypoxemia, capnometry and capnography are more valuable in providing early diagnosis of gas embolism and determining the extent of the embolism. P_{ETCO_2} decreases in the case of embolism owing to the fall in cardiac output and the enlargement of the physiologic dead space. Consequently, $\Delta a\text{-}ET CO_2$ increases. The decrease in P_{ETCO_2} may be preceded by an initial increase secondary to pulmonary excretion of the CO_2, which has been absorbed into the blood.[53] Aspiration of gas or foamy blood from a central venous line establishes the diagnosis. Routine preoperative insertion of a central venous line, however, does not appear justified for these procedures.

Treatment of CO_2 embolism consists of immediate cessation of insufflation and release of the pneumoperitoneum. The patient is placed in steep head-down and left lateral decubitus (Durant) position. The amount of gas that advances through the right side of the heart to the pulmonary circulation is less if the patient is in this position because the buoyant foam is displaced laterally and caudally away from the right ventricular outflow tract. Discontinuing N_2O will allow ventilation with 100% O_2 to correct hypoxemia and reduce the size of the gas embolus and its consequences.[53] Hyperventilation increases CO_2 excretion and is made necessary by the increase in the physiologic dead space. If these simple measures are not effective, a central venous or pulmonary artery catheter may be introduced for aspiration of the gas. Cardiopulmonary resuscitation must be initiated if necessary. External cardiac massage may be helpful in fragmenting CO_2 emboli into small bubbles. The high solubility of CO_2 in blood, resulting in rapid absorption from the bloodstream, accounts for the rapid reversal of the clinical signs of CO_2 embolism with treatment.[48] CO_2 embolism, however, may be fatal. Cardiopulmonary bypass has been used successfully to treat massive CO_2 embolism.[50] Hyperbaric oxygen treatment should be strongly considered if cerebral gas embolism is suspected.[54]

Risk of Aspiration of Gastric Contents

Patients undergoing laparoscopy might be considered to be at risk for acid aspiration syndrome (see also Chapter 50). However, the increased IAP results in changes of the lower esophageal sphincter that allow maintenance of the pressure gradient across the gastroesophageal junction and that may therefore reduce the risk of regurgitation.[59,60] Furthermore, the head-down position should help to prevent any regurgitated fluid from entering the airway.

Hemodynamic Problems During Laparoscopy

Hemodynamic changes observed during laparoscopy result from the combined effects of pneumoperitoneum, patient position, anesthesia, and hypercapnia from the absorbed CO_2. In addition to these pathophysiologic changes, reflex increases of vagal tone and arrhythmias can also develop.

Hemodynamic Repercussions of Pneumoperitoneum in Healthy Patients

Peritoneal insufflation to IAPs higher than 10 mm Hg induces significant alterations of hemodynamics.[61,62] These disturbances are characterized by decreases in cardiac output, increased arterial pressures, and elevation of systemic and pulmonary vascular resistances. Heart rates remain unchanged or increased only slightly. The decrease in cardiac output is proportional to the increase in IAP.[63] Cardiac output has also been reported to be increased[64] or unchanged during pneumoperitoneum.[65,66] These discrepancies might be caused by differences in rates of CO_2 insufflation, IAP,[67] steepness of patient tilt, time intervals between insufflation and collection of data, techniques used to assess hemodynamics, and anesthetic techniques. However, most studies have shown a fall of cardiac output (10% to 30%) during peritoneal insufflation whether the patient was placed in the head-down[68,69] or head-up position.[70,71] These adverse hemodynamic effects of pneumoperitoneum have been confirmed by studies using pulmonary artery catheterization,[69,71] thoracic electrical bioimpedance,[68,70] esophageal echo-Doppler,[72] and transesophageal echocardiography.[73-75] Normal intraoperative values of venous oxygen saturation ($S\bar{v}O_2$) and lactate concentrations suggest that changes in cardiac output occurring during pneumoperitoneum are well tolerated by healthy patients.[71,76] Cardiac outputs, which decrease shortly after the beginning of the peritoneal insufflation, subsequently increase, probably as a result of surgical stress.[70,71] Hemodynamic perturbations occur mainly at the beginning of peritoneal insufflation.

The mechanism of the decrease of cardiac output is multifactorial (Fig. 68-4). A decrease in venous return is observed after a transient increase in venous return at low IAPs (<10 mm Hg).[77,78] Increased IAP results in caval compression,[79] pooling of blood in the legs,[80] and an increase in venous resistance.[77,78] The decline in venous return, which parallels the decrease in cardiac output,[63] is confirmed by a reduction in left ventricular end-diastolic volume measured using transesophageal echocardiography.[74] Cardiac filling pressures, however, rise during peritoneal insufflation.[69,71] The paradoxical increase of these pressures can be explained by the increased intrathoracic pressure associated with pneumoperitoneum.[70,81,82] Right atrial pressure and pulmonary artery occlusion pressure can no longer be considered reliable indices of cardiac filling pressures during pneumoperitoneum. The fact that atrial natriuretic peptide concentrations remain low despite increased pulmonary capillary occlusion pressure during pneumoperitoneum further suggests that abdominal insufflation interferes with venous return.[83] The reduction in venous return and cardiac output can be attenuated by increasing circulating volume before the pneumoperitoneum is produced (Fig. 68-5).[77,84] Increased filling pressures can be achieved by fluid loading or tilting the patient to a slight head-down position before peritoneal insufflation, by preventing the pooling of blood with intermittent sequential pneumatic compression device,[85] or by wrapping the legs with elastic bandages.[86]

The ejection fraction of the left ventricle, assessed by echocardiography, does not appear to decrease significantly when IAP increases to 15 mm Hg.[73,74] However, all studies describe an increase in systemic vascular resistance during the existence of the pneumoperitoneum. This increase in afterload is not a reflex sympathetic response to the decreased cardiac output.[73,82]

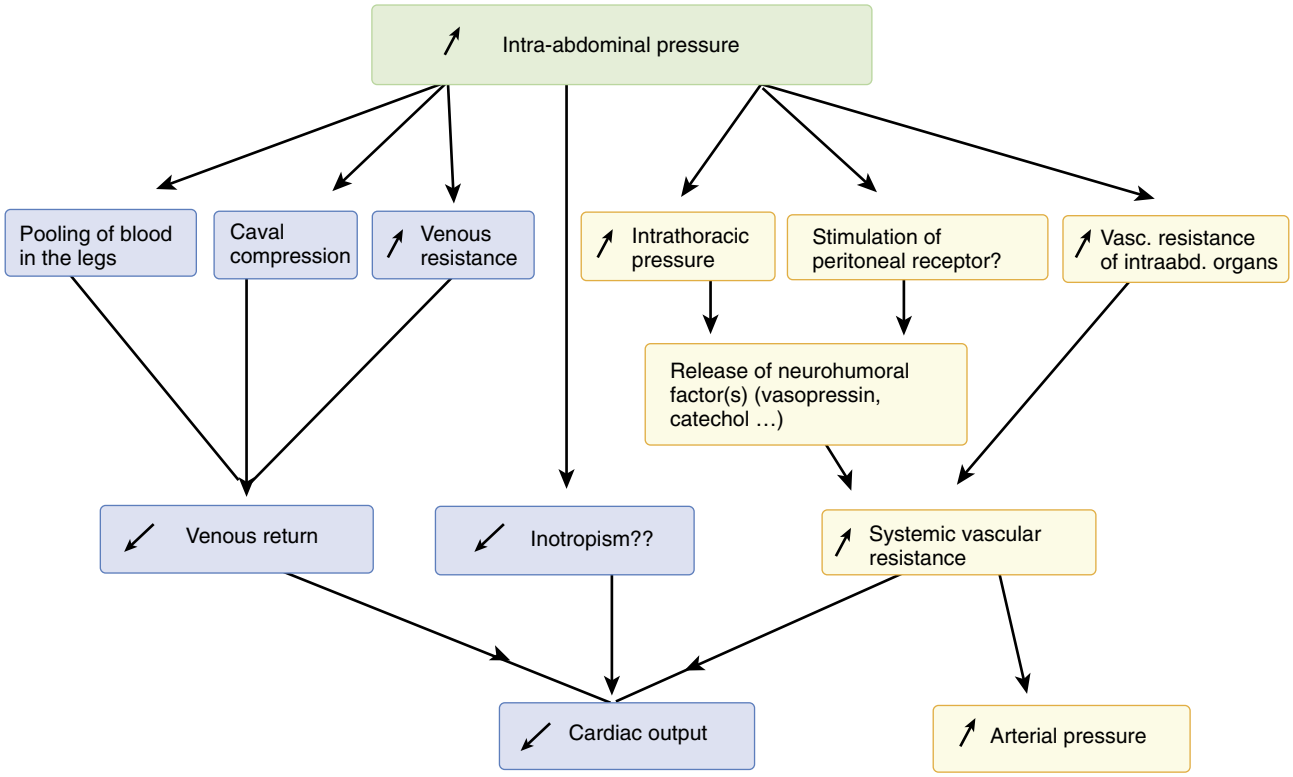

Figure 68-4 Schematic representation of the different mechanisms leading to decreased cardiac output during pneumoperitoneum for laparoscopy.

Systemic vascular resistance was reported to be increased in studies where no decrease in cardiac output was found.[73,76] Although the normal heart tolerates increases in afterload under physiologic conditions, the increases in afterload produced by the presence of a pneumoperitoneum can be deleterious to patients with cardiac disease.[87]

The increase in systemic vascular resistance is affected by patient position. The Trendelenburg position attenuates this increase; the head-up position aggravates it.[65,69,76,83] The increase in systemic vascular resistance can be corrected by the administration of vasodilating anesthetic agents, such as isoflurane,[82] or direct vasodilating drugs, such as nitroglycerin[88] or nicardipine.[89]

The increase in systemic vascular resistance is thought to be mediated by mechanical and neurohumoral factors.[90] The return of hemodynamic parameters to baseline values is gradual, taking several minutes, suggesting the involvement of neurohumoral factor(s).[68,82,87] Catecholamines, the renin-angiotensin system, and especially vasopressin are all released during the presence of the pneumoperitoneum and may contribute to increasing the afterload.[70,71,81,83,91,92] However, only the time course of vasopressin release parallels that of the increase in systemic vascular resistance.[70,71,92] Increases in plasma vasopressin concentrations correlate with changes in intrathoracic pressure and transmural right atrial pressure.[81] Mechanical stimulation of peritoneal receptors also results in increased vasopressin release,[93] systemic vas-

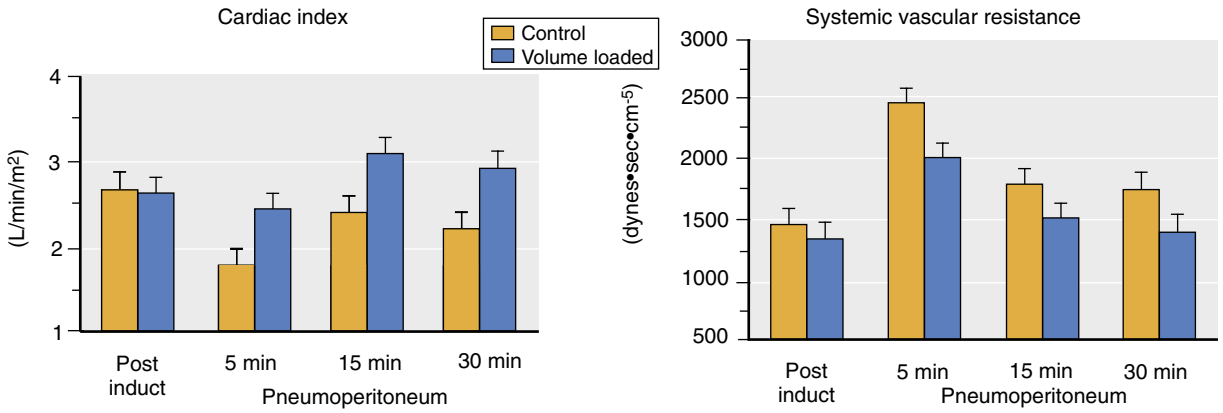

Figure 68-5 Changes in the cardiac index and systemic vascular resistance during laparoscopy in two groups of patients. For group 1 (controls, $n = 10$, *yellow bars*), pneumoperitoneum was induced with patients in a 10-degree head-up position. Group 2 (volume loaded, $n = 10$, *blue bars*) patients received 500 mL of lactated Ringer's solution before anesthesia induction and were insufflated in the supine position. Data are presented as the mean ± SEM.

cular resistance, and arterial pressure.[94] However, whether increasing IAP to 14 mm Hg is sufficient to stimulate these receptors is unknown. The increase in systemic vascular resistance also explains why the arterial pressure increases but the cardiac output falls.[62,90] Use of α_2-adrenergic agonists such as clonidine[71,95] or dexmedetomidine[96,97] and of β-blocking agents[98] significantly reduces hemodynamic changes and anesthetic requirements. Use of high doses of remifentanil almost completely prevents the hemodynamic changes.[66]

Effect of Pneumoperitoneum on Regional Hemodynamics

Increased IAP and the head-up position result in lower limb venous stasis.[80,85,99] Femoral vein blood flow decreases progressively with increasing IAP, and no adaptation to the reduced femoral venous outflow occurs, even during prolonged procedures.[100] These changes may predispose to the development of thromboembolic complications. Although cases of thromboembolism have been reported in the literature, their actual incidence does not seem to be increased by laparoscopy.[101-103]

The effect of CO_2 pneumoperitoneum on renal function has also been investigated.[104-106] Urine output, renal plasma flow, and glomerular filtration rate decrease to less than 50% of baseline values during laparoscopic cholecystectomy and are significantly lower than those during open cholecystectomy.[104] Urine output significantly increases after deflation.

Controversy exists regarding the effect of the CO_2 pneumoperitoneum on splanchnic and hepatic blood flow. A significant reduction was reported in animals[107] and humans.[108-110] However, others have not observed any significant changes.[111-114] Blobner and coworkers,[112] comparing CO_2 pneumoperitoneum and air pneumoperitoneum in pigs, observed a reduction in splanchnic blood flow during air pneumoperitoneum but not during CO_2 pneumoperitoneum. They suggest that the direct splanchnic vasodilating effect of CO_2 may counteract the mechanical effect of increased IAP.

Cerebral blood flow velocity increases during CO_2 pneumoperitoneum in response to the increased $Paco_2$.[115,116] When normocarbia is maintained, pneumoperitoneum combined with the head-down position does not induce harmful changes in intracranial dynamics.[117] Intracranial pressure nevertheless rises during CO_2 pneumoperitoneum, independently of changes in $Paco_2$, in pigs with preoperative induced intracranial hypertension or normal intracranial pressure[118,119] and in children with ventriculoperitoneal shunts.[120] Intraocular pressure is not affected by pneumoperitoneum in women with no preexisting eye disease.[121] In an animal model of glaucoma, pneumoperitoneum only slightly increases intraocular pressure.[122]

Hemodynamic Repercussions of Pneumoperitoneum in High-Risk Cardiac Patients

The demonstration of significant hemodynamic changes during pneumoperitoneum raises the question of tolerance of these changes in cardiac patients (see Chapters 35 and 60). In patients with mild to severe cardiac disease, the pattern of change in mean arterial pressure, cardiac output, and systemic vascular resistance is qualitatively similar to that in healthy patients.[87,88,123-126] Quantitatively, these changes appear to be more marked. In a initial study including ASA class III or IV patients, $S\bar{v}o_2$ decreased in 50% of patients despite preoperative hemodynamic optimization using a pulmonary artery catheter.[124] Patients who experienced the most severe hemodynamic changes with inadequate oxygen delivery were patients with low preoperative cardiac outputs and central venous pressures and high mean arterial pressures and systemic vascular resistances—a profile suggesting depleted intravascular volume. The investigators suggest preoperative preload augmentation to offset the hemodynamic effect of pneumoperitoneum. Intravenous nitroglycerin, nicardipine, or dobutamine has been used to manage the hemodynamic changes induced by increased IAP in selected patients with heart disease.[88,126] Nitroglycerin was chosen to correct the reduction in cardiac output associated with increased pulmonary capillary occlusion pressures and systemic vascular resistance. The administration of nicardipine may be more appropriate than that of nitroglycerin. Right atrial and pulmonary capillary occlusion pressures are not reliable indices of cardiac filling pressure during pneumoperitoneum. Increased afterload is a major contributor to the altered hemodynamics seen during pneumoperitoneum in cardiac patients. Nicardipine acts selectively on arterial resistance vessels and does not compromise venous return.[127] This drug is beneficial in case of congestive heart failure.[128] Because normalization of hemodynamic variables does not occur for at least 1 hour postoperatively in certain patients,[87,125] congestive heart failure can develop in the early postoperative period. Dhoste and associates[129] did not observe impaired hemodynamics in elderly ASA class III patients, but they used low IAP (10 mm Hg) and slow insufflation rates (1 L/min). The hemodynamic consequences of pneumoperitoneum are minor in heart transplant recipients who have good ventricular function.[130,131] Laparoscopic adrenalectomy in patients with pheochromocytoma can be successfully managed using a continuous infusion of nicardipine.[89,132] Several studies suggest that hemodynamic changes during pneumoperitoneum are well tolerated by morbidly obese patients.[8,133,134]

Cardiac Arrhythmias During Laparoscopy

Arrhythmias during laparoscopy have several causes. The increased $Paco_2$ may not be the cause of the arrhythmias occurring during laparoscopy. Arrhythmias do not correlate with the level of the $Paco_2$ and may develop early during insufflation, when high $Paco_2$ is not present.

Reflex increases of vagal tone may result from sudden stretching of the peritoneum and during electrocoagulation of the fallopian tubes.[135] Bradycardia, cardiac arrhythmias, and asystole can develop. Vagal stimulation is accentuated if the level of anesthesia is too superficial or if the patient is taking β-blocking drugs. These events are easily and quickly reversible. Treatment consists of interruption of insufflation, atropine administration, and deepening of anesthesia after recovery of the heart rate.

Cardiac irregularities occur most often early, during insufflation, when pathophysiologic hemodynamic changes are the most intense. For this reason, arrhythmias may also reflect intolerance of these hemodynamic disturbances in patients with

known or latent cardiac disease. Gas embolism can also result in cardiac arrhythmias.

Problems Related to Patient Position

Patient positioning (see Chapter 36) depends on the site of surgery; whereas head-down tilt is used for pelvic and lower abdominal surgery, the head-up position is preferred for upper abdominal surgery. The patient is often placed in the lithotomy position. These positions may be responsible for, or contribute to, the development of pathophysiologic changes or injury during laparoscopy. The steepness of the tilt also affects the magnitude of these changes.

Cardiovascular Effects

In normotensive subjects, the head-down position results in an increase in central venous pressure and cardiac output. The baroreceptor reflex response to increased hydrostatic pressure consists of systemic vasodilation and bradycardia. Although these different reflexes may be impaired during general anesthesia, the hemodynamic changes induced by this position during laparoscopy remain insignificant.[69,76] However, central blood volume and pressure changes are greater in patients with coronary artery disease, particularly with poor ventricular function, leading to potentially deleterious increased myocardial oxygen demand.[32] The Trendelenburg position may also affect the cerebral circulation, particularly in case of low intracranial compliance,[136] and result in elevation of the intraocular venous pressure (which can worsen acute glaucoma).[121] Although the intravascular pressure increases in the upper torso, the head-down position decreases transmural pressures in the pelvic viscera, reducing blood loss but increasing the risk of gas embolism.[32,56]

With the head-up position, a decrease in cardiac output and mean arterial pressure results from the reduction in venous return.[69,76,82] This decrease in cardiac output compounds the hemodynamic changes induced by pneumoperitoneum. The steeper the tilt, the greater the fall in cardiac output.

Venous stasis in the legs occurs during the head-up position and may be aggravated by the lithotomy position with knees flexed.[32] Because pneumoperitoneum further increases blood pooling in the legs,[80,99] any additional factor contributing to circulatory dysfunction should be avoided. The legs must be freely supported and not tightly strapped, and pressure on the popliteal space must be prevented.

Respiratory Changes

The head-down position facilitates the development of atelectasis. Steep head-down tilt results in decreases in the functional residual capacity, the total lung volume, and the pulmonary compliance. These changes are more marked in obese, elderly, and debilitated patients. In healthy patients no major changes are seen.[32] The head-up position is usually considered to be more favorable to respiration.[30,32]

Nerve Injury

Nerve compression is a potential complication during the head-down position. Overextension of the arm must be avoided. Shoulder braces should be used with great caution and must not impinge on the brachial plexus. Lower extremity neuropathies (e.g., peroneal neuropathy, meralgia paresthetica, femoral neuropathy) have been reported after laparoscopy.[137,138] The common peroneal nerve is particularly vulnerable and must be protected when the patient is placed in the lithotomy position. Prolonged lithotomy position, such as required for some operative laparoscopies, can result in lower extremity compartment syndrome.

Postoperative Benefits and Consequences of Laparoscopy

Implicit in the decision to use the laparoscopic approach is the assumption that the intraoperative consequences of pneumoperitoneum described in the previous sections are counterbalanced by multiple postoperative benefits. In contrast to laparotomy, improved and more rapid recovery, reduced postoperative fatigue,[139,140] and a heightened feeling of well-being are commonly reported and reflect better maintenance of homeostasis.[3,139]

Stress Response

In patients undergoing cholecystectomy, the laparoscopic approach allows for a reduction of the acute phase reaction seen after open cholecystectomy. Plasma concentrations of C-reactive protein and interleukin-6, which reflect the extent of tissue damage, are significantly lower after laparoscopy as compared with laparotomy.[3,139,141-143] The metabolic response (e.g., hyperglycemia, leukocytosis) is also reduced after laparoscopy. As a consequence, nitrogen balance and immune function might be better preserved.[144-147] Laparoscopy avoids prolonged exposure and manipulation of the intestines and decreases the need for peritoneal incision and trauma. Consequently, postoperative ileus and fasting, duration of intravenous infusion, and hospital stay are significantly reduced after laparoscopy.[2,3,141,147-149] The duration of postoperative ileus is less shortened when compared with laparotomy than previously reported.[150] The economic implications of these factors are self-evident and beneficial.[151-153]

Surprisingly, whereas laparoscopy allows for a reduction of surgical trauma, the endocrine response to laparoscopic and open cholecystectomy does not differ significantly; plasma concentrations of cortisol and catecholamines,[3,139,154,155] urinary concentrations of cortisol and catecholamine metabolites,[141] and anesthetic requirements[3] are similar after both procedures. Combined general and epidural anesthesia for laparoscopic cholecystectomy does not result in a decreased stress response compared with general anesthesia alone.[154] Several hypotheses can be invoked to explain these observations. Pain and discomfort from peritoneal stretching, hemodynamic disturbances, and ventilatory changes induced by pneumoperitoneum may contribute to the stress response of laparoscopy. Although parietal afference, which is markedly reduced by laparoscopy, appears to be an important stimulus for postoperative hyperglycemia, visceral nociception, which is less

affected by laparoscopy, may contribute more to adrenocortical stimulation.[139] The intraoperative stress response, however, can be reduced by preoperative administration of α_2-agonists.[71,96,97]

Postoperative Pain

Surgical trauma contributes to pain and pulmonary dysfunction. Laparoscopy allows a significant reduction in postoperative pain and analgesic consumption (see Chapter 87).[3,141,154,156-160] Nevertheless, pain intensity may be significant.[161-163] The nature of pain varies depending on the surgical technique; after laparotomy, patients complain more of parietal pain (e.g., abdominal wall), whereas after laparoscopic cholecystectomy, patients report also visceral pain (e.g., biliary colic [cholecystectomy], pelvic spasm [tubal ligation]), and shoulder-tip pain resulting from diaphragmatic irritation.[162,163] Pain after laparoscopy is multifactorial, and different treatments have been proposed to provide pain relief.[164,165] Local anesthetic infiltration (e.g., intraperitoneal, port-site infiltration) for postoperative pain relief after laparoscopic cholecystectomy produces contradictory results.[166-170] Benefits of intraperitoneal local anesthetic are greater after gynecologic laparoscopy.[166,171] Mesosalpinx block decreases postoperative pain and analgesic consumption after laparoscopic sterilization.[166] Residual CO_2 pneumoperitoneum contributes to postoperative pain. Careful evacuation of residual CO_2 after desufflation was shown to be effective.[164,172,173] Preoperative administration of nonsteroidal anti-inflammatory drugs (NSAIDs) and of cyclooxygenase-2 inhibitors decreases pain, as does opiate consumption after gynecologic laparoscopy[174-177] and laparoscopic cholecystectomy.[178-182] However, others have failed to demonstrate any significant effect of preoperative NSAID on pain after laparoscopic sterilization more severe than after diagnostic gynecologic laparoscopy.[183-186] Dexamethasone is also effective in reducing postoperative pain.[187] Multimodal analgesia is now recommended to prevent and treat post-laparoscopy pain.[188-190]

Pulmonary Dysfunction

Upper abdominal surgery results in postoperative changes in pulmonary function (see also Chapter 93). Respiratory dysfunction is less severe and recovery is quicker after laparoscopy.[3,90,141,154,156,157,191-193] Nevertheless, diaphragmatic function remains significantly impaired after laparoscopy.[194-196] Thoracic epidural analgesia does not improve lung function after laparoscopic cholecystectomy.[154] Greater reductions in expiratory volumes and slower recovery of pulmonary function after laparoscopy are reported in older patients,[197] obese patients,[159,198] smokers, and patients with COPD[198] than in healthy patients. Postoperative pulmonary function of these patients, however, is improved after laparoscopy as compared with laparotomy.[159,160,198] Postoperative pulmonary function is less impaired after gynecologic laparoscopy than after upper abdominal laparoscopic surgery.[199]

Postoperative Nausea and Vomiting

Laparoscopy is frequently associated with minor postoperative sequelae that can persist more than 48 hours and that can significantly delay discharge of outpatients.[200] In addition to postoperative pain of various types, one of the main complaints is postoperative nausea and vomiting (PONV) (40% to 75% of patients).[201-203] Whereas perioperative opioids increase the incidence of PONV,[204-206] propofol anesthesia can markedly reduce the high incidence of these side effects.[206,207] The effect of N_2O on the incidence of nausea is still controversial.[206,208,209] Intraoperative drainage of gastric contents also reduces PONV.[210] Intraoperative administration of droperidol and a 5-hydroxytryptamine type 3 antagonist appears to be helpful in the prevention and treatment of these side effects.[206,211-215] Transdermal scopolamine reduces nausea and vomiting after outpatient laparoscopy.[201] Perioperative liberal intravenous fluid therapy can contribute to decreasing these symptoms and to improve postoperative recovery.[216-218]

Alternatives to CO_2 Pneumoperitoneum

New approaches have been investigated to reduce pathophysiologic consequences of CO_2 pneumoperitoneum.

Inert Gases

Insufflation of inert gas (e.g., helium, argon) instead of CO_2 avoids the increase in $Paco_2$ from absorption.[219,220] Consequently, hyperventilation is not required.[27,221-223] Also, the ventilatory consequences of the increased IAP persist. The hemodynamic changes produced by pneumoperitoneum using inert gas are similar to those observed with CO_2. However, the use of these gases accentuates the decrease in cardiac output, whereas the increase in arterial pressure is attenuated.[27,90,223,224] Unfortunately, the low blood solubility of the inert gases raises the issue of safety in the event of gas embolism.[225,226]

Gasless Laparoscopy

Another alternative is gasless laparoscopy. The peritoneal cavity is expanded using abdominal wall lift obtained with a fan retractor. This technique avoids the hemodynamic and respiratory repercussions of increased IAP and the consequences of the use of CO_2.[227-231] Renal and splanchnic perfusion is not altered.[108,232] Port-site metastases after laparoscopic surgery for cancer are reduced after gasless laparoscopy.[233,234] This technique, therefore, is appealing for patients with severe cardiac or pulmonary disease. However, gasless laparoscopy compromises surgical exposure and increases technical difficulty.[229,233,234] Combining abdominal wall lifting with low pressure CO_2 pneumoperitoneum (5 mm Hg) may improve surgical conditions.

Laparoscopy During Pregnancy and in Children

The most common nonobstetric surgical procedures during pregnancy are adnexal surgery, appendectomy, and cholecystectomy,

and they are amenable to laparoscopic surgery (see Chapter 69).[235] Laparoscopy during pregnancy raises several concerns. Abdominal surgery increases the risk of miscarriage or premature labor. However, all the reports in the literature of laparoscopy carried out between 4 and 32 weeks of estimated gestational age have resulted in uncomplicated pregnancies.[236-240] Another concern is the risk of damaging the gravid uterus. This can be avoided by alternative entry sites for the Veress needle and trocars. CO_2 pneumoperitoneum induces significant fetal acidosis. Fetal heart rate and arterial pressure increase, but these changes are minimal.[241] Provided maternal $Paco_2$ is maintained at normal levels, fetal placental perfusion pressure and blood flow, pH, and blood gas tensions are unaffected by insufflation or desufflation.[242] Capnography is adequate to guide ventilation during laparoscopy in pregnant patients.[243] Hemodynamic changes induced by pneumoperitoneum are similar in pregnant and nonpregnant women.[244] The following recommendations are for safe laparoscopy in pregnant patients[236]:

1. The operation should occur during the second trimester, ideally before the 23rd week of pregnancy, to minimize the risk of preterm labor and to maintain adequate intra-abdominal working room.
2. Tocolytics are beneficial to arrest preterm labor, but their prophylactic use is debatable.
3. Open laparoscopy should be used for abdominal access to avoid damaging the uterus.
4. Fetal monitoring may be performed using transvaginal ultrasonography.
5. Mechanical ventilation must be adjusted to maintain a physiologic maternal alkalosis.

Gasless laparoscopy is an alternative to avoid the potential side effects of CO_2 pneumoperitoneum and can sometimes be managed using epidural anesthesia.[245,246]

Laparoscopy is frequently performed in infants and children (see Chapter 82). Knowledge of the pathophysiologic changes induced by laparoscopy in children is necessary to adapt their monitoring and anesthetic technique.[247] CO_2 pneumoperitoneum induces the same changes in respiratory mechanics to those reported in adults.[248-250] $Paco_2$ and $Petco_2$ increase during pneumoperitoneum, but $Petco_2$ may sometimes overestimate $Paco_2$.[251] The profile of CO_2 absorption and the magnitude of CO_2 absorption compared with metabolic $\dot{V}co_2$ are similar in infants and children to those recorded in adults.[252] The hemodynamic changes observed in children are similar to those reported in adults.[253-257] Pneumoperitoneum results in oliguria or anuria in children, reversible after desufflation.[258] Controversy concerning the benefits (improved analgesia and postoperative recovery) of laparoscopy for appendectomy, the most frequent indication for laparoscopy in children, persists.[259-261]

Complications of Laparoscopy

With the development of more sophisticated endoscopic operations, it is important to consider the risks and benefits of laparoscopy. Although the benefits of the laparoscopic approach are well documented, knowledge of the incidence of complications is more imprecise and is frequently based on retrospective studies.

The experience of gynecologic laparoscopists extends over a relatively long time and, as a result, large surveys are available.[262,263] Mortality rates have varied from 1 per 10,000 to 1 per 100,000 cases. The number of serious complications requiring laparotomy was 2 to 10 per 1000 cases. Intestinal injuries accounted for 30% to 50% of these and remained undiagnosed during laparoscopy in one half of the cases. Vascular complications also accounted for 30% to 50%. Burns were responsible for 15% to 20% of the reported complications. Although the death rate decreased, the complication rate was slightly higher in the most recent surveys, probably because of the increased complexity of the laparoscopies performed over the past few years.

Large surveys of complications after laparoscopic cholecystectomy are available.[152,264-268] The overall mortality rate is 0.1 to 1 per 1000 cases.[268] Conversion to laparotomy was necessary in approximately 1% of patients. Bowel perforation occurred in about 2 per 1000 cases, common bile duct injury in 2 to 6 per 1000 cases, and significant hemorrhage in 2 to 9 per 1000 cases. Laparoscopic cholecystectomy was accompanied by a greater frequency of minor operative complications, whereas open cholecystectomy had a more frequent rate of minor general complications. A learning curve was demonstrated for laparoscopic cholecystectomy; experience was associated with decreased operative times and rates of minor or moderate complications. Some of these complications might be prevented by open laparoscopy.[269]

Although large vessel injury (e.g., aorta, inferior vena cava, iliac vessels) caused emergency situations, retroperitoneal hematoma can develop insidiously and result in significant blood loss without major intraperitoneal effusion, leading to delayed diagnosis. During gynecologic laparoscopy, complications occur more frequently during the creation of pneumoperitoneum and the introduction of trocars, whereas during gastrointestinal surgery they are more closely related to the surgical procedure itself.[152,270,271] Injuries provoked by the Veress needle are usually less severe than those by trocars and may even remain undiagnosed. Unrecognized gastrointestinal tract injury and subhepatic abscess formation can lead to potentially lethal septic complications.[272] The rate of postoperative infections (e.g., surgical site, respiratory) seems to be significantly lower after laparoscopy than after laparotomy.[273] Although all these events are surgery related, the anesthesiologist must be aware of the complications and timing of their occurrence. He or she must be ready to respond promptly and adequately to these mishaps and to help the surgeon diagnose a complication.

Anesthesia for Laparoscopy

Preoperative Evaluation of the Patient and Premedication

Without regard to surgical contraindications, absolute contraindications to laparoscopy and pneumoperitoneum are rare, and some still require characterization (see Chapter 34). Pneumoperitoneum is undesirable in patients with increased intracranial pressure (e.g., tumor, hydrocephalus, head trauma) and hypovolemia. Laparoscopy can be performed safely in patients with ventricular peritoneal shunt and peritoneojugular shunt that are

provided with unidirectional valve resistant to IAPs used during pneumoperitoneum. In case of glaucoma, the effects on intraocular pressure do not seem to be clinically significant but deserve further confirmation.[122]

In patients with heart disease, cardiac function should be evaluated in light of the hemodynamic changes induced by pneumoperitoneum and patient position, particularly in case of compromised ventricular function (Table 68-1). Patients with severe congestive heart failure and terminal valvular insufficiency are more prone to develop cardiac complications than patients with ischemic cardiac disease during laparoscopy. Whether laparoscopy is more dangerous than laparotomy in these patients has not yet been explored directly but deserves careful consideration. For these patients, the postoperative benefits of laparoscopy must be balanced against the intraoperative risks when the choice of laparoscopy versus laparotomy is discussed. Gasless laparoscopy may represent an alternative for these patients.

Because of the side effects of increased IAP on renal function, patients with renal failure deserve special care to optimize hemodynamics during pneumoperitoneum, and the concomitant use of nephrotoxic drugs should be avoided.

In patients with respiratory disease, laparoscopy appears preferable to laparotomy because of reduced postoperative respiratory dysfunction. This positive effect counterbalances the risk of pneumothorax during pneumoperitoneum and the risk of inadequate gas exchange from $\dot{V}/\dot{Q}$ mismatching.

Because of venous stasis in the legs during laparoscopy, prophylaxis of deep vein thrombosis should be the same as for laparotomy.

Premedication should be adapted to the duration of the laparoscopy and to the necessity for quick recovery in the outpatient setting. Preoperative administration of NSAIDs may be helpful in reducing postoperative pain and opiate requirements. Preoperative clonidine and dexmedetomidine decrease the intraoperative stress response and improve hemodynamic stability.[71,95-97]

Table 68-1 Management of Patients with Cardiac Disease for Laparoscopy

Preoperative Evaluation: Echocardiography
If left ventricular ejection fraction < 30%:
Intraoperative monitoring
Intra-arterial line
Pulmonary artery catheter?
Transesophageal echocardiography
Continuous ST-segment analysis?
Gasless laparoscopy?
Laparotomy?
Intraoperative Management
Slow insufflation
Low intra-abdominal pressure
Hemodynamic optimization before pneumoperitoneum (preload augmentation)
Patient tilt after insufflation
Anesthesia: remifentanil, vasodilating anesthetic and drugs (nicardipine, nitroglycerin), cardiotonic agents
Experienced surgeon
Postoperative Care
Slow recovery from anesthesia (benefit of clonidine)

Patient Positioning and Monitoring

Patients must be positioned (see Chapter 36) with great care to prevent nerve injuries; padding should protect from nerve compression, and shoulder braces, if needed, should be placed overlying the coracoid process. Patient tilt should be reduced as much as possible and should not exceed 15 to 20 degrees. Tilting must be slow and progressive to avoid sudden hemodynamic and respiratory changes. The position of the endotracheal tube must be checked after any change in patient position. Induction and release of the pneumoperitoneum must be smooth and progressive. Mask ventilation before intubation can inflate the stomach with gas, which must be aspirated before trocar placement to avoid gastric perforation, particularly for supramesocolic laparoscopy. The bladder should be emptied before pelvic laparoscopy or prolonged procedures.

During laparoscopy, arterial blood pressure, heart rate, electrocardiography, capnometry, and pulse oximetry must be continuously monitored. Although this level of monitoring is valuable for detection of cardiac arrhythmias, gas embolism, CO_2 subcutaneous emphysema, and pneumothorax, it provides only indirect evidence of the hemodynamic changes induced by the pneumoperitoneum. Although more invasive hemodynamic monitoring may be necessary in patients with cardiac diseases, increased intrathoracic pressure complicates the interpretation of measured central venous and pulmonary artery pressures. Transesophageal echocardiography may be more helpful in patients with severe cardiac disease (see Table 68-1). P_{ETCO_2} and Spo_2 reliably reflect $Paco_2$ and arterial oxygen saturation (Sao_2). However, the $\Delta a\text{-}ETCO_2$ may vary from patient to patient and during the course of laparoscopy in the same patient. P_{ETCO_2} must be monitored carefully to avoid hypercapnia and to detect gas embolism. Because $\Delta a\text{-}ETCO_2$ may increase more in patients with cardiac and pulmonary diseases, cannulation of a radial artery may be helpful to allow direct measurement of $Paco_2$ from an arterial blood sample.

Anesthetic Techniques

General, local, and regional anesthesia have all been used successfully and safely for laparoscopy.

General Anesthesia

General anesthesia with endotracheal intubation and controlled ventilation is certainly the safest and most commonly used technique and therefore is recommended for inpatients and for long laparoscopic procedures. During pneumoperitoneum, controlled ventilation must be adjusted to maintain P_{ETCO_2} between 35 and 40 mm Hg. In our experience, this requires no more than a 15% to 25% increase of minute ventilation, except when CO_2 subcutaneous emphysema develops. Increase of respiratory rate rather than of tidal volume may be preferable in patients with COPD and in patients with a history of spontaneous pneumothorax or bullous emphysema to avoid increased alveolar inflation and reduce the risk of pneumothorax. Infusion of vasodilating drugs, such as nicardipine,[89,132] α_2-adrenergic

receptor agonists,[71,95-97] and remifentanil[66] reduces the hemodynamic repercussions of pneumoperitoneum and may facilitate management of cardiac patients (see Table 68-1). The actual contribution of N_2O to PONV is probably less than previously considered.[206] Although N_2O does not seem to be contraindicated for laparoscopic cholecystectomy,[208] omission of N_2O improves surgical conditions for intestinal and colonic surgery.[274] The choice of anesthetic technique does not seem to play a major role in patient outcome.[275-277] Propofol, nevertheless, results in fewer postoperative side effects.[278-280] Propofol anesthesia for laparoscopic fertility procedures involving genetic material transfers, however, is associated with lower clinical and ongoing pregnancy rates compared with isoflurane.[281] IAP should be monitored, kept as low as possible to reduce hemodynamic and respiratory changes, and not allowed to exceed 20 mm Hg. Increases in IAP can be avoided by ensuring a deep plane of anesthesia. Whether profound muscle relaxation is necessary for laparoscopy is not clear.[282] Liberal perioperative intravenous fluid therapy decreases hemodynamic changes from pneumoperitoneum[77,84] and PONV and improves postoperative recovery.[216-218] Because of the potential for reflex increases of vagal tone during laparoscopy, atropine should be available if necessary.

The laryngeal mask airway results in fewer cases of sore throat and may be proposed as an alternative to endotracheal intubation[283-287] (also see Chapter 50) even if this device does not protect the airway from aspiration of gastric contents.[288,289] It allows controlled ventilation and accurate monitoring of P_{ETCO_2}. However, decreased thoracopulmonary compliance during pneumoperitoneum frequently results in airway pressures exceeding 20 cm H_2O. The ProSeal laryngeal mask airway may be an alternative to guarantee an airway seal up to 30 cm H_2O.[290,291]

General anesthesia in patients breathing spontaneously without intubation can be performed safely and avoids tracheal irritation as well as administration of muscle relaxant. This anesthetic technique must be restricted to short procedures performed using low IAP and small degrees of tilt.[292] In these conditions, the laryngeal mask airway might improve the safety of anesthesia[283,286,293] and is therefore recommended.

Local and Regional Anesthesia

Local anesthesia offers several advantages: quicker recovery, decreased PONV, early diagnosis of complications, and fewer hemodynamic changes (see Chapters 30, 51, and 52).[294,295] However, this anesthetic approach requires precise and gentle surgical technique and may result in increased patient anxiety, pain, and discomfort during the manipulation of pelvic and abdominal organs. For these reasons, local anesthesia is routinely supplemented with intravenous sedation. The combined effect of pneumoperitoneum and sedation can lead to hypoventilation and arterial oxygen desaturation.[296] Complex laparoscopic procedure must not be managed with local anesthesia.

Regional anesthesia, including epidural and spinal techniques, combined with the head-down position can be used for gynecologic laparoscopy without major impairment of ventilation.[18,297,298] Laparoscopic cholecystectomy has been successfully performed using epidural anesthesia in COPD patients.[299,300] The metabolic response is reduced by regional anesthesia.[301] Globally, epidural and local anesthesia share the same benefits and disadvantages. Regional anesthesia reduces the need for sedatives and narcotics, produces better muscle relaxation, and can be proposed for laparoscopic procedures other than sterilization. Shoulder-tip pain from diaphragmatic irritation and discomfort from abdominal distention are incompletely alleviated using epidural anesthesia alone.[302] Extensive sensory block (T4-L5) is necessary for surgical laparoscopy and may also lead to discomfort. The epidural administration of opiates or clonidine, or both, may help to provide adequate analgesia.[302] The hemodynamic effects of pneumoperitoneum under epidural anesthesia have not been studied. Regional anesthesia can provide adequate relief of pain and discomfort in case of gasless laparoscopy, thus avoiding most of the side effects of CO_2 pneumoperitoneum.[246,303]

Recovery and Postoperative Monitoring

Hemodynamic monitoring should be continued in the PACU (see Chapter 85). Hemodynamic changes induced by the pneumoperitoneum, and more particularly the increased systemic vascular resistance, outlast the release of the pneumoperitoneum. The hyperdynamic state developing after laparoscopy could conceivably lead to a precarious hemodynamic situation in patients with cardiac disease.[87,125]

Despite the reduction in postoperative pulmonary dysfunction, Pao_2 still decreases after laparoscopic cholecystectomy.[3,156,192] Increased oxygen demand is observed after laparoscopy. Although laparoscopy tends to be considered a minor surgical procedure, oxygen should be administered postoperatively, even to healthy patients.[304]

Finally, prevention and treatment of nausea, vomiting, and pain are important, particularly after outpatient laparoscopic procedures.

Summary

Laparoscopy results in multiple postoperative benefits including less trauma, less pain, less pulmonary dysfunction, quicker recovery, and shorter hospital stay. These advantages are regularly emphasized and explain the increasing success of laparoscopy, which is now proposed for many surgical procedures. Intraoperative cardiorespiratory changes occur during pneumoperitoneum. $Paco_2$ increases because of CO_2 absorption from the peritoneal cavity. In compromised patients, cardiorespiratory disturbances aggravate this increase in $Paco_2$. Hemodynamic changes are accentuated in high-risk cardiac patients. Improved knowledge of the pathophysiologic hemodynamic changes in healthy patients allows for successful anesthetic management of cardiac patients, by optimizing preload before pneumoperitoneum and through judicious use of vasodilating agents. Alternative insufflating gases (e.g., He, Ar, N_2O) do not seem to reduce the hemodynamic changes. Gasless laparoscopy may be more helpful but unfortunately increases technical difficulty. The incidence of complications has now been reported in several large surveys and compares favorably with that of open surgery. The death rate during operative laparoscopy is 0.1 to 1 per 1000 cases; the incidence of hemorrhagic complications and visceral injury is 2 to 5 per 1000 cases. Whereas no anesthetic technique has proved to be clinically superior to any other, general anesthesia with controlled ventilation

seems to be the safest technique for operative laparoscopy. Improved knowledge of the intraoperative repercussions of laparoscopy permits safe management of patients with more and more severe cardiorespiratory disease, who may subsequently benefit from the multiple postoperative advantages offered by this approach.

69 Anesthesia for Obstetrics

Key Points

1. Functional residual capacity (FRC) begins to decrease in the second trimester of pregnancy and is decreased to 80% of the nonpregnant value at full term. This decrease in FRC causes maternal hypoxemia to develop very quickly after apnea associated with the induction of general anesthesia. Although general anesthesia is no longer routinely used for elective cesarean deliveries, it continues to have a place in current practice.
2. The presence of fetal heart rate (FHR) variability is predictive of fetal well-being and early neonatal health. FHR accelerations signal fetal well-being, whereas late decelerations are suggestive of fetal hypoxia.
3. Animal studies have suggested that vasopressors with predominantly α-adrenergic activity cause a reduction in uterine blood flow that can adversely affect the fetus. Studies in women undergoing elective cesarean section have not confirmed these animal data and have suggested that small doses of phenylephrine may improve the mother's hemodynamics without adversely affecting the fetus.
4. No epidural test dose will exclude all instances of intravenous or intrathecal placement of catheters; however, aspiration of a multiorificed catheter will detect many of them. The combination of aspiration, test dose, and fractionation of doses increases the safety of epidural anesthesia.
5. If an accidental dural puncture occurs during placement of an epidural block, threading the epidural catheter into the spinal space to provide continuous spinal anesthesia offers many advantages. If the epidural block is relocated to another interspace, however, the loss of resistance to air technique should not be used because of the risk of pneumocephalus and severe headache.
6. Many cases of failed intubation occur when a "difficult airway" is not recognized before induction of general anesthesia. Airways change during pregnancy and may worsen during labor, especially in a preeclamptic patient. Careful airway evaluation, although imperfect, must be performed before initiation of general anesthesia.
7. Uterine rupture is a rare event that can cause maternal and fetal mortality. Its incidence during vaginal birth after cesarean section is greater than previously thought. A sudden increase in baseline uterine tone or the sudden absence of uterine pressure coupled with evidence of acute fetal bradycardia may indicate uterine rupture.
8. Magnesium sulfate is the agent of choice for seizure control in preeclamptic patients and is a first-line tocolytic therapy for preterm labor. Treatment with magnesium can produce hypotension and may later potentiate the maternal hemodynamic response to pressors. Magnesium also potentiates the action of both depolarizing and nondepolarizing muscle relaxants.

The challenges presented by a parturient requiring anesthesia or analgesia, or both, make the role of the obstetric anesthesiologist both challenging and rewarding. Those providing anesthetic services to the labor and delivery suite must be familiar with the unique physiology of the parturient and the effects of numerous drugs and techniques on the parturient and fetus.

Continuous improvements in drugs and techniques have led to a significant decrease in anesthetic-related deaths in the delivery suite. The maternal mortality rate in the United States is estimated at 7.5 per 100,000 live births[1]; however, many suggest that this statistic is misleading because of underreporting of maternal deaths.[2] A retrospective analysis of maternal mortality during hospitalization by Panchal and colleagues suggested that anesthesia-related complications accounted for 5.2% of maternal deaths.[3]

In 1992, the American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics made recommendations concerning anesthetic coverage in the labor and delivery suite. These recommendations included the availability of 24-hour coverage in larger facilities for complicated patients, the ability to perform an emergency cesarean section in all facilities with delivery suites, and the availability of properly trained personnel to manage anesthetic complications.[4]

Appreciation of the roles of the obstetrician, anesthesiologist, pediatrician, and other personnel who care for the mother and child will facilitate the highest level of care. Communication between the various members of the labor and delivery team is paramount. This chapter provides an overview of the principles and techniques that can be used by the anesthesiologist in the labor and delivery suite.

Physiologic Changes of Pregnancy

Maternal physiologic changes in pregnancy occur as a result of hormonal alterations, mechanical effects of the gravid uterus, increased metabolic and oxygen requirements, metabolic demands of the fetoplacental unit, and hemodynamic alterations associated with the placental circulation. Such changes become more significant as pregnancy progresses, and they have major implications for anesthetic management, especially in high-risk parturients.

Cardiovascular System

The cardiovascular system adjusts throughout pregnancy to meet the changes that occur. Hemodynamic and maternal cardiovascular changes in pregnancy are outlined in Table 69-1. Although the physiologic changes in the cardiovascular system appear to begin in the first trimester, these changes continue into the second and third trimesters, when cardiac output increases by approximately 40% of nonpregnant values. Cardiac output increases from the fifth week of pregnancy and reaches its maximum levels at approximately 32 weeks, after which there is only a slight increase until labor, delivery, and the postpartum period.[5] Approximately 50% of the increase in cardiac output has occurred by the eighth week of pregnancy.[6] Although this increase in cardiac output is due to an increase in both stroke volume and heart rate, the more important factor is stroke volume, which increases by 20% to 50% at term from nonpregnant values. Changes in heart rate are extremely difficult to reliably quantify, but it is thought that the approximately 20% increase in heart rate is present by the fourth week of pregnancy. Although the normal variability in heart rate does not change in pregnancy, there does appear to be a reduction in the sympathetic component.[7] Tachyarrhythmias are more common, especially later in pregnancy as a result of both hormonal and autonomic factors.[8]

Because of the decrease in peripheral vascular resistance, arterial blood pressure does not change in a normal pregnant woman. Cardiac output decreases during the third trimester due to effects of the supine position in the patient at term.[9] Ueland and colleagues found that the decrease in cardiac output was due to obstruction of the inferior vena cava by the gravid uterus, which did not occur when women were placed in the lateral position.[10] A venogram performed before and after cesarean delivery (Fig. 69-1) demonstrates this phenomenon. Despite the increase in blood volume and cardiac output, parturients at term are susceptible to hypotension, especially when in the supine position. Up to 10% of pregnant patients at term show signs of severe hypotension when assuming the supine position. This phenomenon has been termed the *syndrome of supine hypotension*. To compensate, collateral routes of venous return develop, including the paravertebral veins to the azygos vein. Unlike compression of the vena cava, compression of the aorta is generally not associated with maternal symptoms in a healthy parturient but it may be associated with decreased uteroplacental perfusion.[11] Anesthetics and drugs that cause vasodilation or anesthetic techniques that cause sympathectomy (e.g., neuraxial techniques) may exacerbate the impact of aortocaval compression. In the operating room, a small pillow or "wedge" should be used to provide left uterine displacement of 15 to 20 degrees. This angle can be increased as necessary by increasing the wedge or tilting the table. Although tilting the table will also accomplish uterine displacement, the amount of tilt necessary may prove too anxiety provoking to parturients and staff.

The changes in blood volume and cardiac output are often associated with clinically significant implications in parturients who have concomitant cardiac disease, but they may also have an impact on healthy parturients. Many pregnant patients will complain of symptoms suggestive of cardiovascular disease at term, including shortness of breath, palpitations, dizziness, edema, and poor exercise tolerance.[12] Physical examination of the term pregnant woman may also be abnormal when compared with the prepregnant state, with auscultation commonly revealing a wide, loud, split first heart sound, an S_3 sound, and a soft systolic ejection murmur. As illustrated in Table 69-2, pregnancy has numerous effects on cardiac evaluation, including changes in the electrocardiogram, chest radiograph, and echocardiogram. Although these minor changes occur in healthy pregnant women at term, symptoms and signs such as chest pain, syncope, severe arrhythmias, systolic murmur more than grade 3, or diastolic murmur suggest severe disease and warrant further investigation.[13] A gradual return to the prepregnancy blood volume occurs at 6 to 9 weeks post partum.

Table 69-1 Cardiovascular Changes in Pregnancy

Parameter	Change	Amount (%)
Heart rate	Increased	20-30
Stroke volume	Increased	20-50
Cardiac output	Increased	30-50
Contractility	Variable	±10
Central venous pressure	Unchanged	
Pulmonary capillary wedge pressure	Unchanged	
Systemic vascular resistance	Decreased	20
Systemic blood pressure	Slight decrease	Midtrimester 10-15 mm Hg, then rises
Pulmonary vascular resistance	Decreased	30
Pulmonary artery pressure	Slight decrease	

From Birnbach DJ, Gatt SP, Datta S (eds): Textbook of Obstetric Anesthesia. New York, Churchill Livingstone, 2000, p 34.

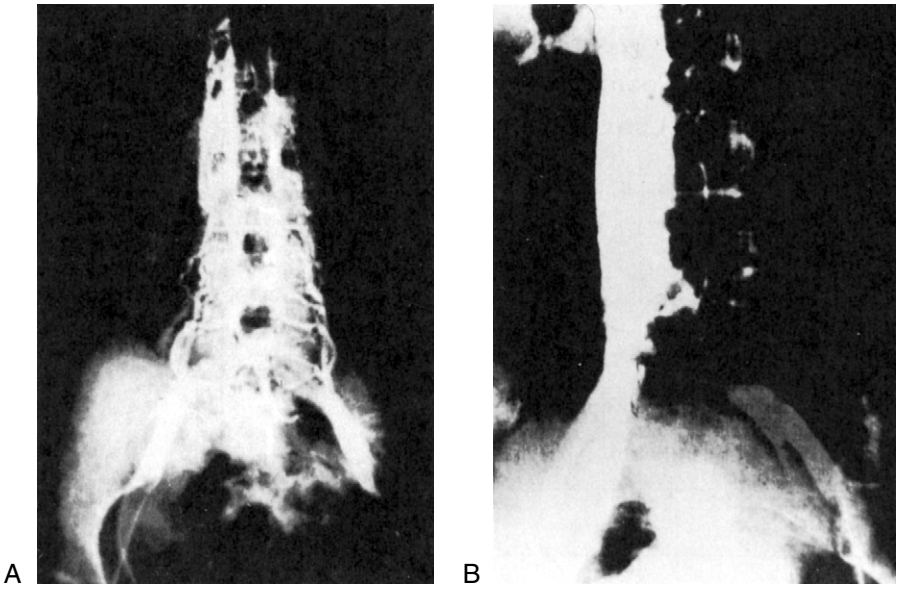

Figure 69-1 **A,** Venogram in a term patient in the supine position before cesarean section. Radiopaque dye injected into the femoral veins fails to reach the inferior vena cava (IVC) but reaches the paravertebral veins. **B,** After cesarean section, blood is seen in the IVC. (*From Kerr MG, Scott DB, Samuel E: Studies of the inferior vena cava in late pregnancy. BMJ 1:532, 1964.*)

Hematologic System

Maternal blood volume begins to increase early in pregnancy as a result of changes in osmoregulation and the renin-angiotensin system, causing sodium retention and increasing total body water to 8.5 L.[14] By term, blood volume increases by up to 45% whereas red cell volume increases by only 30%. This differential increase leads to the "physiologic anemia" of pregnancy with an average hemoglobin and hematocrit of 11.6 g/dL and 35.5%, respectively.[15] However, oxygen transport is not impaired by this relative anemia because the mother's body compensates for it by increased cardiac output, increased Pao_2, and a rightward shift in the oxyhemoglobin dissociation curve.

A state of hypercoagulability exists in pregnancy, with increased levels of most coagulation factors (Table 69-3). Fibrinogen and factor VII are markedly increased, whereas the other factors increase to a lesser extent. This increase in coagulation factors has been verified by thromboelastography[16] and is probably a protective adaptation to lessen the risks associated with the acute hemorrhage that occurs at delivery. This hypercoagulable state, however, may lead to thromboembolism, which remains a leading cause of maternal mortality. The platelet count remains unchanged throughout most of pregnancy, but it may be slightly reduced in the third trimester with increased activity in vivo. The platelet count increases in the postpartum period, probably because of activation of hemostasis at the time of delivery. The incidence of low platelet counts in normal pregnancy is approxi-

Table 69-2 Effect of Pregnancy on Cardiovascular Investigations

Investigation	Findings
Chest radiography	Apparent cardiomegaly Enlarged left atrium (lateral views) Increased vascular markings Straightening of left-sided heart border Postpartum pleural effusion
Electrocardiography	Right-axis deviation Right bundle branch block ST-segment depression of 1 mm on left precordial leads Q waves in lead III T-wave inversion in leads III, V_2, and V_3 Small decrease in PR and QT interval (heart rate dependent) Rotation ± 15 degrees (QRS axis)
Echocardiography	Trivial tricuspid regurgitation (up to 43%-93% at term) Pulmonary regurgitation (up to 94% at term) Increased left atrial size by 12%-14% Increased left ventricle end-diastolic dimensions by 6%-10% Inconsistent increase in left ventricle thickness Mitral regurgitation (28% at term) Pericardial effusion (40% postpartum)

mately 8%.[17] However, thrombocytopenia during the latter part of pregnancy is not associated with adverse sequelae. Obstetric management of parturients with stable platelet counts above $50,000 \times 10^9$/L should be no different from that of normal parturients.[18] In addition, although the cutoff for initiation of neuraxial blocks was considered to be $100,000 \times 10^9$/L in the past, this level is no longer considered absolute. Currently, most anesthesiologists feel comfortable initiating a regional technique with platelet counts above $75,000 \times 10^9$/L and with counts between 50,000 and 75,000 if the level is stable and clinical laboratory abnormalities or signs of a coagulopathic state are absent.

Respiratory System

To accommodate the increased oxygen demand and requirement for carbon dioxide elimination, pregnancy is associated with an increase in the respiratory minute volume and work of breathing. Because of difficulties in performing clinical research on pregnant women, few investigations of respiratory changes in pregnancy have been conducted. Unfortunately, many of the findings quoted in the literature are inconsistent and often based on older techniques that were applied to a very limited number of subjects.[19]

The most impressive change in maternal lung dynamics is a decrease in functional residual capacity (FRC), which at term may have changed by as much as 20% of prepregnancy values. Minute ventilation increases by 45%, primarily as a result of an increase in tidal volume because the respiratory rate is essentially unchanged. Hormonal changes and an increase in the rate of carbon dioxide production are responsible for the increase in ventilation. Progesterone sensitizes the respiratory center to carbon dioxide. $Paco_2$ falls to approximately 30 mm Hg by the 12th week of gestation, and it remains at this level for the remainder of pregnancy. Tidal volume increases by 50%, with half of this increase occurring during the first trimester. The parturient's breathing pattern changes; it becomes more diaphragmatic as pregnancy progresses because of the effects of the gravid uterus and limitation of thoracic cage movement. Closing capacity (CC), however, remains unchanged. The resulting decrease in the FRC/CC ratio causes faster small-airway closure when lung volume is reduced; thus, parturients can desaturate at a much faster rate as compared with nonpregnant women. The rapid development of hypoxia as a result of decreased FRC, increased oxygen consumption, and airway closure may be minimized by administration of 100% oxygen for 3 to 5 minutes before the induction of anesthesia. In an emergency setting, four maximal capacity breaths with 100% oxygen should be sufficient.

Other changes in the respiratory tract and oropharynx during pregnancy may have profound anesthetic implications. Capillary engorgement of the mucosa and edema of the oropharynx, larynx, and trachea may result in a difficult intubation. Any manipulation of the upper airway such as suctioning, insertion of airways, or laryngoscopy may cause edema, bleeding, and upper airway trauma. Because of the particularly friable mucosa of the nasopharynx, instrumentation of the nose should be avoided if at all possible. In performing intubation of a pregnant patient, a smaller than usual endotracheal tube (size 6.0 to 7.0) should be used and repeated attempts at laryngoscopy minimized. Management of a difficult airway is discussed later in the chapter.

Gastrointestinal System

Gastrointestinal function in pregnancy and during labor is a topic that continues to be controversial. However, there is no doubt that the gastrointestinal tract undergoes significant anatomic and physiologic changes that increase the risk of aspiration associated with general anesthesia. Progesterone relaxes smooth muscle; consequently, it impairs esophageal and intestinal motility during pregnancy. Whether gastric emptying is delayed during pregnancy is controversial. Wong and coworkers suggest that the ingestion of 300 mL of water may actually enhance gastric emptying in healthy, term, nonobese, nonlaboring parturients.[20] However, the risk of pulmonary aspiration of gastric contents remains real in parturients, especially when undergoing an emergency cesarean delivery under general anesthesia. Even if gastrointestinal motility has not been affected during pregnancy, established labor and the administration of parenteral opioids delay gastric emptying.[21,22]

Epidural analgesia using local anesthetics without opioids does not affect gastric emptying, and the use of small doses of epidural fentanyl also has no effect on gastric function.[23-25] Large doses of fentanyl, however, may slow gastric emptying.

The pain of labor, however, may delay gastric emptying and promote emesis. These changes may be caused by the effects of placentally derived gastrin.[26] Because of the gastrointestinal alterations associated with pregnancy, the use of endotracheal intubation is warranted to reduce the risk of aspiration of gastric contents if general anesthesia is required.

Renal System

The renal system undergoes major changes in pregnant patients, mainly because of the effects of progesterone and the mechanical effects of compression of the enlarging uterus. Urea, creatinine, and uric acid clearance all rise in pregnancy (as illustrated in Table 69-4). Renal plasma flow and the glomerular filtration rate (GFR) both increase rapidly in pregnancy as a result of the increase in cardiac output. The GFR rises by almost 50%; this increase, accompanied by the dilutional effect of plasma volume expansion, accounts for the decrease in plasma creatinine and urea. Hence, "normal" renal indices in pregnancy are lower than in the nonpregnant state. Therefore, blood urea nitrogen and creatinine levels that would be considered marginally elevated in

Table 69-4 Values for Renal Function

Parameter	Pregnant	Nonpregnant
Creatinine clearance	140-160 mL/min	90-110 mL/min
Urea	2.0-4.5 mmol/L	6-7 mmol/L
Creatinine	25-75 µmol/L	100 µmol/L
Uric acid	0.2 mmol/L	0.35 mmol/L
pH	7.44	7.40
Bicarbonate	18-22 mmol/L	23-26 mmol/L

From Birnbach DJ, Gatt SP, Datta S (eds): Textbook of Obstetric Anesthesia. New York, Churchill Livingstone, 2000, p 37.

prepregnant patients are usually indicative of severe renal impairment in parturients. The increase in GFR generally precedes the expansion of blood volume and is considered to be a marker of pregnancy-induced vasodilation.[27] Glycosuria is a common finding that is attributable to the increase in GFR and reduced renal tubular resorption capacity.

Central Nervous System

Pregnant women demonstrate increased sensitivity to both regional and general anesthetics. From early stages, when neuraxial anesthesia is administered, pregnant women require less local anesthetic than nonpregnant women do to reach a given dermatomal sensory level. The minimum alveolar concentrations of halothane and isoflurane are reduced by 25% and 40%, respectively, during pregnancy.[28] The underlying mechanism of the decreased anesthetic requirements remains unclear. Furthermore, reduced local anesthetic requirements predate the mechanical effects of the gravid uterus.[29] In animal studies, chronically administered progesterone to reduced anesthetic requirements.[30] In addition, the increased concentrations of endorphins and dynorphins found in pregnant rats may be related to altered pain thresholds.[31,32] Obviously a multifactorial explanation for the decreased anesthetic requirements is likely.

The Fetus

The circulations of the mother and fetus amalgamate in the placenta; this organ has a variety of functions, including endocrine support of pregnancy and transport of nutrients. The pharmacologic and physiologic interactions at this site can be explained in terms of the maternal-placental-fetal unit. This model, as seen in Figure 69-2, can be compartmentalized into maternal, placental, and fetal components.

The placenta is composed of both maternal and fetal tissues that consist of a basal and a chorionic plate. In its simplest description, it can be viewed as a semipermeable membrane that provides an interface for the maternal and fetal circulation. The intervillous space separates the plates and is subdivided by decidual tissue. Chorionic villi and spiral arteries protrude into this intervillous space. Maternal blood flows into the intervillous space from the spiral artery while placental transfer from the mother to the fetus occurs. Approximately 80% of the uterine blood flow passes through the intervillous space.

Forty percent to 50% of fetal cardiac output goes to the placenta, and a similar amount returns to the heart through the umbilical vein (Fig. 69-3). Fetal blood enters the placenta through the two umbilical arteries, which arise from the internal iliac arteries. These arteries subdivide and eventually form umbilical capillaries that traverse the chorionic villi. Fetal blood flow is approximately 75 mL/kg/min, a rate far less than maternal flow. Although fetal and parturient pressures are uneven, placental transfer occurs rapidly for most drugs.

The umbilical-placental circulation is regulated by physiologic reflex changes and the neuroendocrine axis. Numerous substances, including prostaglandins, endorphins, catecholamines, and vasopressin, all play roles in fine-tuning of umbilical-placental perfusion.

Uterine Blood Flow

Uterine blood flow increases progressively during pregnancy and reaches a mean value of 500 to 700 mL by term. Blood flow through the uterine vessels is high and has low resistance; this change in resistance occurs most dramatically after 20 weeks of gestation.[33] Uterine blood flow lacks autoregulation (vessels are maximally dilated during pregnancy), and uterine artery flow is therefore dependent on maternal blood pressure and cardiac output. Consequently, factors that alter blood flow through the

uterus will adversely affect the fetal blood supply. Uterine blood flow is determined by the following relationship:

$$\text{Uterine blood flow} = \frac{\text{Uterine artery pressure} - \text{Uterine venous pressure}}{\text{Uterine vascular resistance}}$$

Uterine blood flow decreases during periods of maternal hypotension, which can occur as a result of hypovolemia, hemorrhage, aortocaval compression, and sympathetic blockade. Similarly, uterine hypercontractility (or conditions that increase the frequency or duration of uterine contractions) and changes in uterine vascular tone, as seen in hypertensive states, may also adversely affect blood flow.

Anesthetics may dramatically influence uterine blood flow either by alterations in perfusion pressure or by changes in uterine vascular resistance. Sympathetic blockade after neuraxial techniques may reduce maternal blood pressure, and the decrease in pressure will affect uterine blood flow. This response may be exaggerated in patients who are not adequately prehydrated. Giving fluids intravenously (preloading) before neuraxial anesthesia does not completely prevent maternal hypotension, but it does increase maternal cardiac output; thus, it may help to preserve uteroplacental blood flow.[34] Maternal cardiac output correlates with the uterine artery pulsatility index and umbilical artery pH.[35,36] High concentrations of volatile anesthetics during general anesthesia may cause systemic vasodilatation and produce depressant effects on the myocardium. Aortocaval compression may further compound these effects.

Vasopressors with direct α-adrenergic receptor activity (e.g., phenylephrine) have been associated in animal studies with increased intrinsic vascular resistance and, as a consequence, a reduction in uterine blood flow.[37] There has been renewed interest in phenylephrine as a vasopressor for use in routine clinical practice; studies have demonstrated that this drug can be used safely in healthy parturients and is as efficacious as ephedrine in maintaining maternal blood pressure and umbilical artery pH values.[38-40] Although it has been suggested that combination therapy with ephedrine and phenylephrine may be optimal,[41] ephedrine is still the vasopressor of choice for many anesthesiologists.[42] Its mixed α- and β-adrenergic effects cause an increase in arterial blood pressure that is secondary to increased cardiac output and increased peripheral vascular resistance.

Traditionally, ephedrine has been the vasopressor of choice in pregnant women, on the basis of observations in pregnant sheep that showed that it was more effective for increasing arterial pressure with better preservation of uteroplacental blood flow compared with other vasopressors.[43,44] The use of α-agonists has generally been avoided since the 1970s because of concerns about their potential adverse effect on uterine blood flow. However, in a quantitative, systematic review of randomized controlled trials of ephedrine versus phenylephrine for the management of hypotension during spinal anesthesia for cesarean delivery, Lee and colleagues[45] showed that there was no difference between ephedrine and phenylephrine in efficacy. They did find, however, that women given phenylephrine had neonates with higher umbilical cord blood pH values than women given ephedrine, although the risk of true fetal acidosis (umbilical pH value of 7.20) was similar in both groups. Because acidotic changes in the umbilical arterial pH are sensitive indicators of reduced uteroplacental perfusion,[46] the authors concluded that their finding was indirect evidence that uterine blood flow may in fact be better with phenylephrine compared with ephedrine. In addition, a meta-analysis by Reynolds and colleagues[47] showed that spinal anesthesia for cesarean delivery is associated with lower cord pH, compared with general or epidural anesthesia. They suggested that the use of larger doses of ephedrine in patients who received spinal anesthesia largely contributed to these findings. There are two reasons why phenylephrine may be associated with a better fetal acid-base status than ephedrine. First, ephedrine readily crosses the placenta and has been shown to increase fetal heart rate.[48] Ephedrine may also stimulate fetal metabolism by a direct β-adrenergic effect as well as by stimulating endogenous release of fetal catecholamines. Thus, a direct metabolic effect on the fetus is a likely explanation for the acidosis associated with the use of ephedrine.[49] The second possible explanation for improved fetal acid-base status with phenylephrine compared with ephedrine is that the sympathectomy resulting from regional anesthesia shunts blood into the mesenteric bed and that α-agonists like phenylephrine have a greater selective vasoconstrictive effect on the mesenteric bed than on the uteroplacental vasculature.[50] Vasoconstriction in the mesenteric bed increases cardiac preload, which allows for improved uteroplacental perfusion.[51]

Placental Transfer of Anesthetic Drugs

Many medications administered to a pregnant woman cross the placenta, and these medications may have far-reaching effects on the fetus. Commonly used medications have both direct pharmacologic actions and indirect effects on the in utero environment. After administration of a medication to the mother, a certain amount will cross the placenta and enter the fetal circulation. Drugs cross the placenta by three main processes: simple diffusion, active transport, or pinocytosis. The extent of drug transfer is dependent on numerous factors, including molecular weight, protein binding, degree of lipid solubility, maternal drug concentration, and maternal and fetal pH. The Fick principle governs the rate of transfer of a drug across a membrane:

$$Q/t = \frac{K \times A \times (C_m - C_f)}{D}$$

where Q/t is the rate of diffusion, K is the diffusion coefficient, A is the surface area of membrane available for exchange, $C_m - C_f$ is the concentration gradient between the maternal and fetal circulations, and D is the thickness of the membrane.

Larger molecules are less likely to cross the placenta, but those with weights under 500 daltons will cross easily. Most drugs administered to a parturient in labor have low molecular weights; therefore, they transfer easily to the fetus. Drugs with high lipid solubility will also readily cross the placenta. Highly ionized substances with poor lipid solubility (e.g., nondepolarizing muscle relaxants) have limited transfer.

Once a drug crosses the placenta, fetal pH and protein binding affect drug disposition.[52] The degree of ionization greatly influences drug transfer because only nonionized portions of the drug can cross the placenta.

The degree of ionization of a drug is determined by the Henderson-Hasselbalch equation:

$$PH = pK_a + \log \frac{[base]}{[acid]}$$

where pK_a is the negative logarithm of the acid dissociation constant. The pK_a of a drug is the pH at which it is 50% ionized and 50% un-ionized. Most local anesthetic pK_a values range from 7.7 to 9.1, which is near physiologic pH values. Changes in maternal and fetal blood pH may alter the extent of ionization of a drug and its placental transfer. A phenomenon known as "ion trapping" may occur in a fetus with acidosis because lower fetal pH favors ionization of basic local anesthetics (e.g., lidocaine) and may explain the accumulation of drugs in a compromised fetus.[53]

Because of its unique characteristics, the fetal circulation can have a major impact on drug distribution within the fetus. After drugs cross the placenta, they enter the fetal circulation through the umbilical vein. The liver is the first fetal organ perfused by umbilical venous blood, and substantial hepatic uptake has been described for many drugs. However, approximately 40% of the umbilical venous blood bypasses the liver.[54] Hepatic drug uptake in the fetus may protect the fetus from the deleterious effects of certain drugs on the central nervous system.[55] Dilution of umbilical venous blood across the foramen ovale and ductus arteriosus may also modify fetal drug distribution.

Evaluation of the Fetus

Fetal well-being is of major importance to both the obstetrician and anesthesiologist and should be addressed in the preanesthetic evaluation of the parturient. An understanding of current methods available to evaluate fetal well-being allows better communication with other staff members of the labor delivery suite, especially when faced with emergency situations.

Electronic fetal heart rate (FHR) monitoring was first developed in the 1960s; it allows continuous monitoring during labor onto a paper chart.[56] Continuous FHR monitoring is now routinely used during labor for most women in developed countries. FHR can be monitored externally by surface ultrasound or internally with a fetal scalp electrode. The normal FHR varies between 120 and 160 beats/min. Variability of 5 to 25 beats/min occurs as a result of the opposing effects of the sympathetic and parasympathetic innervation of the atrial pacemaker. Reduced variability may be observed during quiescent phases of the fetal activity cycle (corresponding to "sleep") or be pharmacologically induced by drugs administered to the mother (e.g., meperidine). It also occurs during fetal hypoxia and acidosis.

FHR decelerations are classified according to their timing related to uterine contractions. If they occur in the absence of contractions, they are almost always pathologic. Early decelerations (type I) tend to mirror uterine contractions measured with a tocograph (internal or external) and are generally related to vagal discharge in response to fetal head compression. Variable decelerations vary in both configuration and timing of uterine contractions. These decelerations usually show an abrupt rise and fall and are caused by compression of the umbilical cord. Late decelerations (type II) occur after the peak of the uterine contraction and are an indication of fetal compromise. Fetal scalp blood pH sampling may be used in combination with evaluation of FHR patterns to assess the fetal status in labor. It should be noted, however, that there is not an exact correlation between the severity of fetal hypoxia and the depth of FHR deceleration.[57] In fact, although fetal monitoring is almost always used, it has been suggested that the only clinically significant benefit from continuous FHR monitoring is a reduction in neonatal seizures against an increased rate of instrumental deliveries and cesarean sections.[58] An increase in FHR may also indicate fetal asphyxia, but it may be due to maternal fever or drug effect.

Fetal pulse oximetry is a recent addition to the tools available to monitor the fetus and is still being investigated. A probe is inserted through the cervix and placed between the fetal cheek and uterine wall. To date, investigators have reported a wide range of fetal pulse oximetry values varying between 28% and 71%.[59] Values less than 30% are considered abnormal. Persistently low recordings lead to fetal acidosis.[60] This technology may allow early detection of acidosis when used in combination with continuous FHR monitoring. An American College of Obstetricians and Gynecologists' committee opinion, however, has stated that the Committee on Obstetric Practice "cannot endorse the adoption of this device in clinical practice at this time because of concerns that its introduction could further escalate the cost of medical care without necessarily improving clinical outcome."[61] A recent Cochrane review of randomized control trials of maternal and fetal outcomes when fetal pulse oximetry was employed in labor failed to reduce the overall cesarean section rate. The

authors concluded that a better method to evaluate fetal well-being in labor was required.[62]

Role of Intrauterine Resuscitation

Intrauterine resuscitation (IUR) refers to the application of certain measures in an attempt to improve both oxygen delivery to the placenta and umbilical blood flow for reversal of fetal hypoxia and acidosis. With a better understanding of the mechanisms at play during acute fetal "distress" in labor, specific IUR maneuvers may be applied to individual patients. Short-lived reductions in fetal oxygenation may be a result of aortocaval compression, uterine hyperstimulation, umbilical cord compression, or maternal hypoxemia. Maneuvers used during such situations include left lateral or knee-chest positioning, discontinuation of oxytocin infusion, supplemental maternal oxygen administration, rapid infusion of crystalloid solution, vasopressor administration to treat hypotension, and terbutaline- or nitroglycerin-induced tocolysis.[63] In addition, amnioinfusion may be initiated.

Although few studies have evaluated the use of IUR in a randomized fashion, its application is increasing dramatically. As anesthesiologists, we may become actively involved in IUR, especially during the establishment of regional analgesia and when urgent delivery of the fetus is required by cesarean section or instrumental delivery.[64] The ability to temporarily improve a problematic FHR can often allow the anesthesiologist to use a neuraxial technique in a setting that might otherwise require general anesthesia (e.g., late decelerations in a patient with a Mallampatti Class 4 airway).

Normal Progress of Labor

Labor can be defined as progressive dilatation of the cervix in association with repetitive uterine contractions. This process is illustrated in Figure 69-4. Labor can be either spontaneous or induced, and the activity of the uterus is measured in frequency, duration, and intensity of contractions. Although labor is a continuous process, it has traditionally been divided into three stages. The first stage of labor consists of at least two phases: a latent phase of variable duration (which is defined as the period between the onset of labor and the point at which a change in the slope of cervical dilatation is noted) and a phase of maximal dilatation (which usually begins at approximately 3-cm dilation).[65] During the active phase of labor, uterine contractions occur approximately every 3 minutes, have a duration of about 1 minute, and achieve an intrauterine pressure of 50 to 70 mm Hg. The most commonly used measure of uterine activity by obstetricians, however, is the Montevideo unit, which is defined as the average intensity frequency per 10 minutes. During the normal progress of labor, the cervix should dilate at a rate of approximately 1 cm/hr. When uterine activity is not optimal (contractions < 50 mm Hg every 3 minutes or <250 Montevideo units), an oxytocic drug is usually administered by the obstetrician. The second stage of labor is defined as the interval between full cervical dilation and delivery of the infant. The duration of this second stage is typically 1 to 2 hours, with allowances made for epidural analgesia. The third stage of labor encompasses delivery of the placenta. The

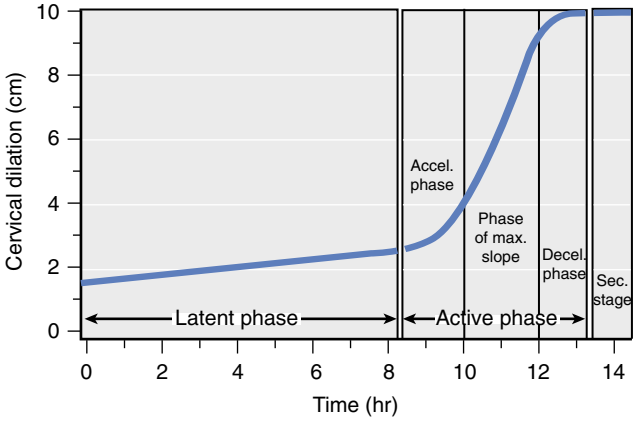

Figure 69-4 Composite of the average dilation curve for nulliparous labor based on analysis of the data derived from the patterns traced by a large, nearly consecutive series of gravidas. (*Redrawn with modification from Friedman EA: Primigravid labor: A graphicostatistical analysis. Obstet Gynecol 6:1567, 1955.*)

progress of labor may be abnormal and can be classified as a slow latent phase, arrest of active phase, and arrest of descent. Table 69-5 lists the diagnostic features of abnormal progress of labor.

The impact of neuraxial analgesia techniques on uterine activity and the progress of labor is a controversial issue. An association between epidural analgesia and cesarean delivery is based on uncontrolled and confounding variables. Actually, women with abnormal labor may have more than expected pain early in labor; therefore, they may require epidural analgesia for what is already a dysfunctional labor with a more frequent risk of cesarean section. Prospective randomized trials evaluated the controversy between epidural and cesarean deliveries; whereas earlier studies did show an association, more recent studies have demonstrated no significant differences between groups in the rate of cesarean delivery.[66] Furthermore, although methodologically limited, several studies of sentinel events that evaluated the impact of the introduction of an epidural service on stable labor and delivery units have failed to demonstrate a change in the cesarean section rate after initiation of an epidural service.[67] A meta-analysis of these sentinel event studies that included more

Table 69-5 Diagnostic Features of Prolonged Labor

Feature	Nulliparas	Multiparas
Slow latent phase	>20 hr	>14 hr
Slow-slope active	<1.2 cm/hr	<1.5 cm/hr phase
Active phase arrest	No cervical dilation for 2 hr	
Slow descent	<1 cm/hr	<2 cm/hr fetus
Arrest of descent	No descent for 1 hr	
Second Stage		
Nulliparous	More than 2 hr without regional analgesia More than 3 hr with regional analgesia	
Multiparous	More than 1 hr without regional analgesia More than 2 hr with regional analgesia	

than 37,000 parturients showed that the sudden availability and high utilization of an epidural service had no effect on the overall incidence of cesarean delivery or on the frequency of cesarean deliveries performed for dystocia.[68]

Anesthesia for Spontaneous Vaginal Delivery

Before deciding on one of the various analgesic options available to the parturient, it is important to understand the mechanisms and pain pathways of labor so that the most appropriate technique of labor analgesia will be utilized.

Pain perception by the parturient is a dynamic process that involves both peripheral and central mechanisms. Many factors have an effect on the degree of pain experienced by a woman during labor, including psychological preparation, emotional support during labor, past experiences, the patient's expectations of the birthing process, and induction or augmentation of labor with oxytocin. An abnormal presentation (e.g., occiput-posterior) may also cause early labor pain to be more intense. There is, however, no doubt that for most women, childbirth is associated with very severe pain, and it often exceeds all expectations.[69] In fact, as reported on the McGill pain questionnaire, labor pain is one of the most intense pains that a woman can experience, and it is typically worse than a toothache, back pain, and pain associated with a deep laceration (Fig. 69-5). A study of women in the first stage of labor reported that 60% of primiparous women described the pain of uterine contractions as being "unbearable, intolerable, extremely severe, or excruciating."[70]

During the first stage of labor, pain impulses arise primarily from the uterus. Uterine contractions may result in myometrial ischemia, which ultimately causes the release of bradykinin, histamine, and serotonin. In addition, stretching and distention of the lower uterine segment and cervix may stimulate mechanoreceptors. These noxious impulses follow the sensory nerve fibers that accompany sympathetic nerve endings; they travel through the paracervical region and the hypogastric plexus to enter the lumbar sympathetic chain.[71] These stimuli enter the spinal cord at the T10, T11, T12, and L1 spinal segments. Parturients describe this pain as dull in nature and often poorly localized. With onset of the second stage of labor and stretching of the perineum, somatic afferent nerve fibers transmit impulses through the pudendal nerve to the spinal cord at the S2, S3, and S4 levels (Figs. 69-6 and 69-7).

Analgesia for Labor and Vaginal Delivery

A variety of labor analgesia options are available, including psychoprophylaxis, transcutaneous electrical nerve stimulation (TENS), systemic medication, inhalational techniques, and neuraxial blocks. In addition, other regional techniques such as caudal or paracervical block are used infrequently.

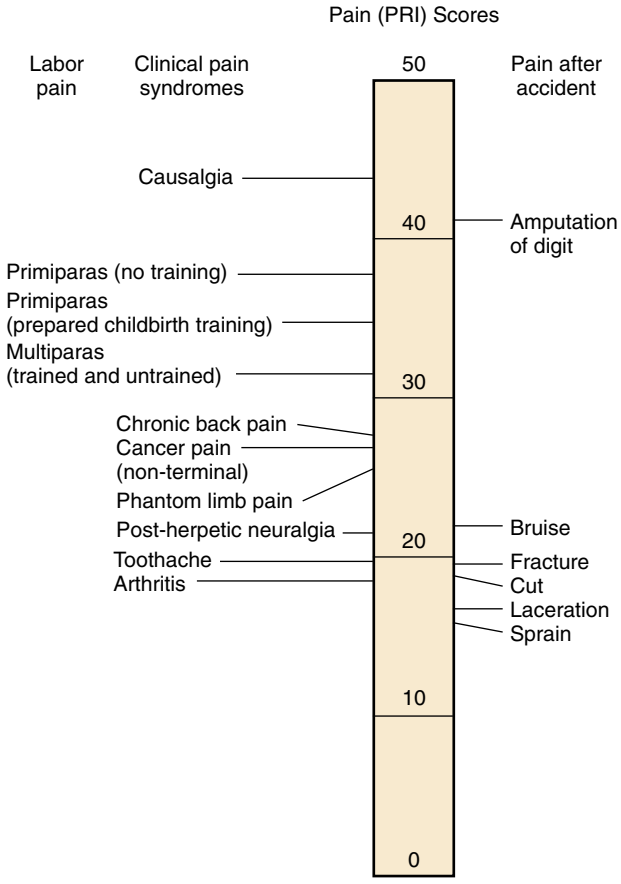

Figure 69-5 McGill pain questionnaire comparing pain scores for women in labor and those of patients in a general hospital pain clinic and emergency department for 20 conditions. (*Redrawn from Melzack R: The myth of painless childbirth. The John J. Bonica Lecture. Pain 19:321-337, 1984.*)

Psychoprophylaxis

"Natural childbirth" stems from a phrase coined by Grantley Dick-Read in 1933; he believed that childbirth was a painless process that did not need medical intervention if the mother was adequately prepared.[72] The Pavlovian methods of childbirth used in Russia were adapted by the French obstetrician Fernand Lamaze in the late 1950s, and "natural childbirth" was popularized as an option for parturients. This method focuses on teaching the mother conditioned reflexes to overcome the pain and fear of childbirth. It also uses an education program, human support during labor, breathing techniques, relaxation techniques of voluntary muscles, a strong focus of attention, and specific activities to concentrate on during contractions to block pain. Indeed, even the presence of another woman during labor to support the expectant mother has a positive effect on outcomes, including the duration of labor.[73]

Transcutaneous Electrical Nerve Stimulation

TENS is thought to reduce pain by nociceptive inhibition at a presynaptic level in the dorsal horn by limiting central transmission (see Chapter 58). Electrical stimulation preferentially acti-

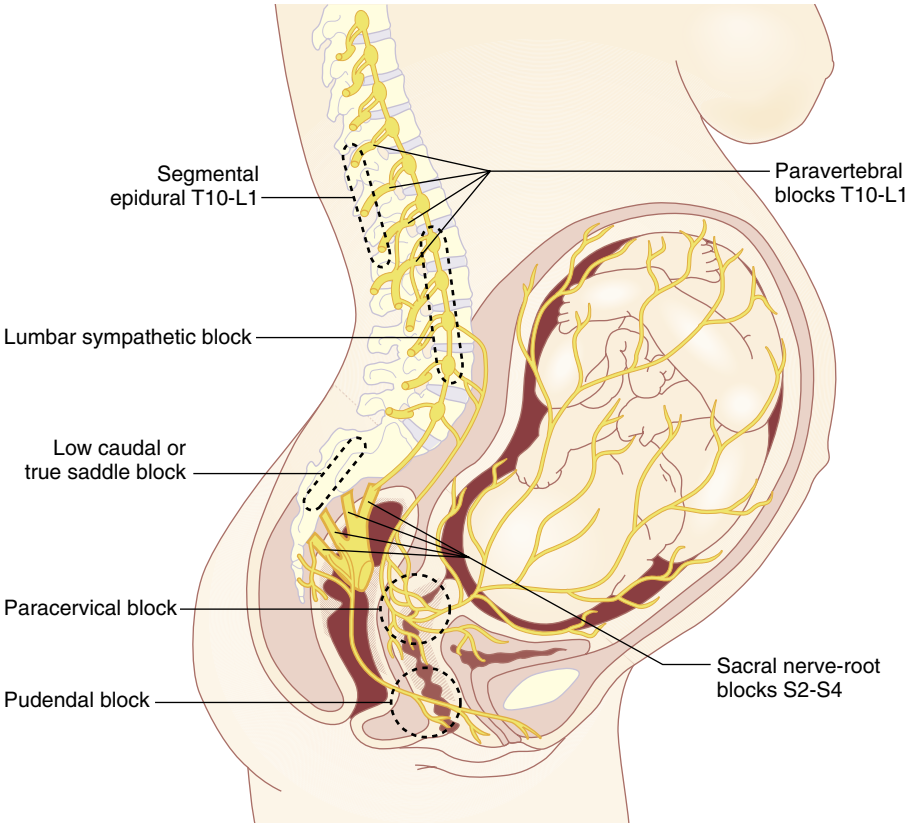

Figure 69-6 Pathways of labor pain illustrating the nerve pathways responsible for pain in the various stages of labor and the types of blocks that can block nerve impulse transmission through these pathways to alleviate labor pain. (*Redrawn from Eltzchig HK, Lieberman ES, Camann WR: Regional anesthesia and analgesia for labor and delivery. N Engl J Med 348:319, 2003.*)

vates low-threshold myelinated nerves. Afferent inhibition effects inhibit propagation of nociception along unmyelinated small c fibers by blocking impulses to target cells in the substantia gelatinosa of the dorsal horn. TENS is also thought to enhance release of endorphins and dynorphins centrally.[74] Placement of electrode pads over the lower back region in the distribution of T10-L1 may provide some analgesia for parturients in early labor.[75] However, Tsen and colleagues could not demonstrate its effectiveness for labor analgesia or as an adjunct to epidural analgesia.[76]

Systemic Medication

Opioids are the most commonly used class of drugs for systemic medication in laboring women (see Chapter 27). All opioids have various degrees of side effects, including respiratory depression, nausea, and vomiting, as well as mental status changes ranging from euphoria to excessive sedation. All opioids cross to the placental circulation freely because of their physicochemical characteristics, and they may cause respiratory depression in the newborn. However, when used appropriately, systemic opioids can partially alleviate labor pain for short periods. Other systemic drugs used in the treatment of labor pain include sedative-tranquilizers and ketamine.

Meperidine

Meperidine is the most commonly used parenteral opioid analgesic during labor. A recent survey carried out in the United States examined the use of parenteral opioids in obstetric units and reported their use in 39% to 56% of patients. In units with over 1500 deliveries per annum, parenteral opioids were administered to 39% of women; units with 500 to 1500 deliveries and units with under 500 per annum reported use in 56% and 50% of women, respectively.[77] The intramuscular dose ranges from 50 to 100 mg with a peak onset of effect at 40 to 50 minutes; intravenous doses of 25 to 50 mg start to act within 5 to 10 minutes. The analgesic effect lasts up to 3 to 4 hours. Fetal exposure to meperidine is highest between 2 and 3 hours after maternal administration,[78] as shown in Figure 69-8. Meperidine is thought to cause less respiratory depression in the neonate than morphine does; therefore, it is more commonly used.[79] It may, however, cause loss of beat-to-beat variability of FHR tracings.

A meta-analysis failed to prove that other tested opioids (tramadol, meptazinol, diamorphine, pentazocine, nalbuphine, and butorphanol) were superior to meperidine for labor analgesia[80]; however, some investigators have proposed fentanyl and remifentanil as superior choices.[81,82]

Fentanyl

Fentanyl is an alternative analgesic option for patients in whom neuraxial anesthesia is contraindicated. Its short half-life makes it suitable for prolonged use in labor, either as an intravenous bolus or as an analgesic administered by means of a patient-controlled analgesia delivery system.[83] It provides reasonable levels of analgesia with minimal neonatal depression.[84] Although it is a potent opioid, its use in labor has been limited by side effects and short duration of action. Fentanyl crosses the placenta; one study that evaluated intravenous fentanyl for labor reported that 4 of 11 fetuses whose mothers received fentanyl for analgesia during labor required naloxone treatment.[85] The usual dose of fentanyl

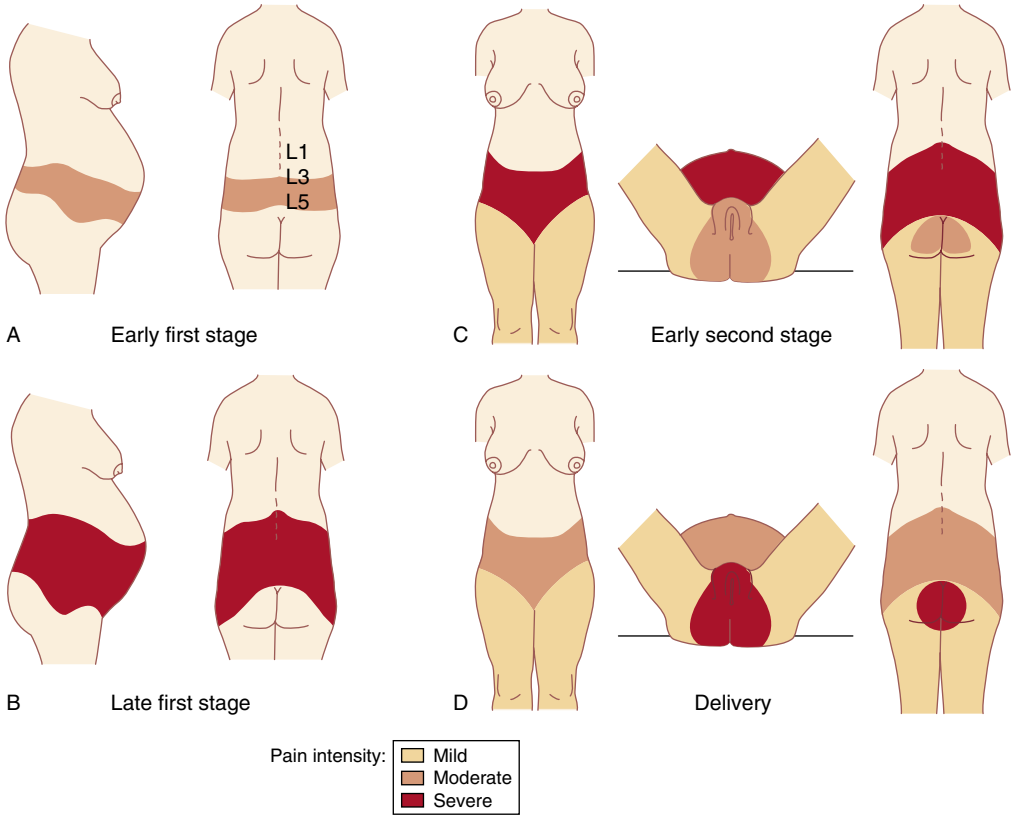

Figure 69-7 Distribution and intensity of labor pain during each stage of labor and delivery. In the early first stage (**A**), pain is referred to the T11 and T12 dermatomes. During the late first stage (**B**), pain also extends to the T10 and L1 dermatomes. In the second stage (**C**), in addition to the dermatomal distribution of late first stage, pain is also felt as pressure in the lower part of the back and perineum and the upper part of the legs. During the end of the second stage and for delivery (**D**), pain originates from the perineum. (*Redrawn from Bonica JJ: Obstetric Analgesia and Anesthesia. World Federation of Societies of Anesthesiologists. Seattle, University of Washington Press. As modified by Bonica JJ: The nature of pain in parturition. In Van Zundert A, Ostheimer GW [eds]: Pain Relief and Anesthesia in Obstetrics. New York, Churchill Livingstone, 1996, p 32.*)

for labor analgesia is 25 to 50 µg intravenously. The peak effect occurs within 3 to 5 minutes and has a duration of 30 to 60 minutes. Although adverse effects, as measured by acidotic umbilical cord blood gases or lower Apgar scores, have not been demonstrated after doses of 1 µg/kg, placental transfer is rapid.[86] A study evaluating fentanyl in labor has suggested that mild maternal sedation is apparent after the administration of 50 or 100 µg. In addition, a transient decrease in FHR variability was also noted.[87] Despite these limitations, several investigators have determined that intravenous fentanyl is preferable to meperidine as a labor analgesic.[84,88] Fentanyl offers another advantage in that it can be administered in nonparenteral modalities, including subcutaneously, orally, and by patch. These uses, however, have not been adequately evaluated in laboring patients.

Butorphanol and Nalbuphine

Butorphanol and nalbuphine are opioid agonist-antagonists that are structurally related to oxymorphone and naloxone. They have the potential advantages of producing less nausea and vomiting than other opioids do. Butorphanol is a κ-agonist and a µ-antagonist and has minimal affinity for σ-receptors. Its dose is 1 to 2 mg intramuscularly or intravenously, and it has a duration of action of up to 4 hours. Nalbuphine is a partial κ-agonist and a potent µ-antagonist with minimal σ-receptor activity. A dose of 10 mg intramuscularly or intravenously is equivalent to 10 mg of morphine with an onset of 2 to 3 minutes and 10 to 15 minutes for the intravenous and intramuscular routes, respectively. It can offer analgesia for up to 6 hours.

One advantage of these agents over µ-agonists is that they demonstrate a "ceiling effect" whereby increasing doses do not produce further respiratory depression.[89] Unfortunately, the use of these drugs is limited in clinical practice because they are rapidly transferred across the placenta and have produced ominous sinusoidal FHR patterns.[90,91] Although it appears that this FHR pattern is a "false positive" and does not signify life-threatening fetal jeopardy as is usually associated with such a pattern, obstetricians are loathe to allow a drug to be used that might produce such a potentially devastating FHR tracing. The use of antagonists or agonist-antagonists may precipitate acute withdrawal syndrome in the mother and the newborn of an opioid-dependent parturient. This syndrome has been reported after parenteral or neuraxial routes of administration.[92]

Remifentanil

Remifentanil is a potent, short-acting µ-opioid receptor agonist that has been approved for clinical use in the United States since 1996. It is a piperidine derivative with a normal opioid configuration, but it contains an ester linkage that allows metabolism by nonspecific esterases throughout the blood and muscles. This metabolism gives it a unique pharmacologic profile in compari-

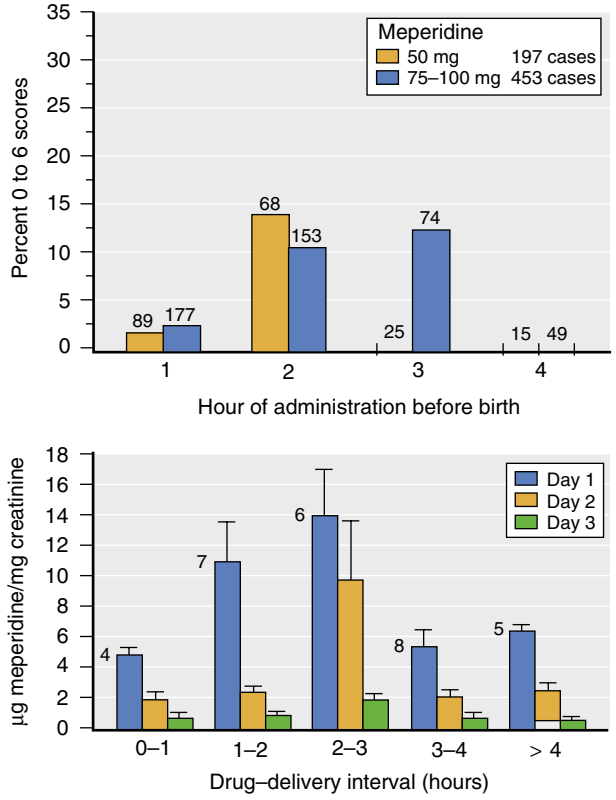

Figure 69-8 Effect of time of administration of meperidine before delivery on neonatal depression (Apgar scores of 0 to 6). (*Redrawn from Shnider SM, Moya F: Effects of meperidine on the newborn infant. Am J Obstet Gynecol 89:1009-1015, 1964.*)

son to other opioids. Consequently, remifentanil has an extremely rapid plasma clearance and offset of action. Its estimated half-life is 1.3 minutes,[93] and prolonged administration does not appear to cause accumulation of this drug. Studies have demonstrated an umbilical vein–to–maternal artery ratio of 0.88.[81] Thus, fetal exposure to the drug is minimized because of its rapid metabolism or redistribution, or both. These properties make it an attractive alternative systemic analgesic in parturients in whom regional anesthesia is contraindicated. Data in the literature from both case series and randomized trials are accumulating with regard to the use of remifentanil in obstetric anesthesia.[82,94] Dose-response studies using patient-controlled analgesia with intravenous remifentanil suggest that a median effective bolus dose of 0.4 µg/kg with a lockout time of 1 minute[95] or a continuous infusion of remifentanil at 0.05 µg/kg/min with a bolus of 25 µg and a lockout time of 5 minutes provides satisfactory labor analgesia.[82] Prolonged use for 34 hours has also been reported in a parturient with medical complications in whom regional techniques were contraindicated; no adverse effects occurred.[96] The studies in which remifentanil was administered, performed thus far, have not fully answered whether remifentanil will provide obstetric anesthesiologists with a superior systemic opioid analgesic for parturients.[97] Although preliminary reports have been promising, it is still somewhat premature to advocate the use of remifentanil until larger studies have fully evaluated its safety and optimum administration technique and dosing.

Sedative-Tranquilizers

Sedative-tranquilizers, including barbiturates, phenothiazines, hydroxyzine, and benzodiazepines, have been used for sedation, anxiolysis, or both during early labor and before cesarean delivery (see Chapter 28). Although barbiturates such as secobarbital were once popular, they are currently unfashionable because of antianalgesic effects in the mother and prolonged depressant effects in the neonate. Even with small doses of barbiturates that result in no depression of the Apgar score, the newborn's attention span may be depressed for more than 4 days.[98]

Promethazine is the most commonly administered phenothiazine in obstetrics. Used with meperidine, it can be given in doses of 25 to 50 mg to prevent emesis. Its ability to potentiate the analgesic effects of opioids, however, is in doubt.[99] Promethazine appears in fetal blood within 1 to 2 minutes after intravenous injection in the mother and reaches equilibrium within 15 minutes.[100]

Ketamine is an *N*-methyl-D-aspartate (NMDA) receptor antagonist that produces dissociative anesthesia and has been used in pregnant patients. As a phenylcyclidine derivative, its mechanism of action may be mediated by an interaction with phencyclidine receptors located in the limbic and corticothalamic areas of the brain. Some evidence, however, suggests that NMDA antagonism is central to the effects of ketamine. Ketamine has been used in subanesthetic doses (0.5 to 1 mg/kg or 10 mg every 2 to 5 minutes to a total of 1 mg/kg in 30 minutes) during labor.[101] In addition to its use in labor, ketamine in a dose of 25 to 50 µg can be used to supplement an incomplete neuraxial blockade for cesarean section. Its main disadvantages are the potential for hypertension and emergence reactions. High doses (>2 mg/kg) can produce psychomimetic effects and increased uterine tone, which may cause low Apgar scores and abnormalities in neonatal muscle tone.[102]

Benzodiazepines such as diazepam (Valium), lorazepam (Ativan), and midazolam (Versed) can be used as sedatives and anxiolytics in labor. However, these drugs readily cross the placenta, with elimination half-lives as long as 48 hours for diazepam and upward of 120 hours for its main metabolite *N*-desmethyldiazepam.[103] Anecdotal evidence suggests that exposure to benzodiazepines early in utero may result in malformations such as cleft lip.[104] Closer analysis involving first-trimester administration of benzodiazepines shows that most infants were normal at birth and had normal postnatal development.[103] The use of these drugs during labor will obviously have no effect on fetal malformations, but they may be associated with other problems in the neonate, including sedation, hypotonia, cyanosis, and impaired metabolic responses to stress. In addition, because these drugs are potent amnestic agents, a parturient may not be able to remember her birthing experience.[105] Many of the adverse effects can be reversed by the administration of flumazenil, which is a competitive benzodiazepine receptor antagonist.

Inhaled Analgesia

Inhaled analgesia can be defined as the administration of subanesthetic concentrations of inhaled anesthetics to relieve pain during labor. This pain relief technique should not be confused with inhaled anesthesia that produces unconsciousness and loss of protective laryngeal reflexes. Although inhaled analgesia provides a limited amount of pain relief, it is not adequate to provide

sufficient pain relief for most mothers. It may, however, have a place as an adjunct to neuraxial techniques or in parturients in whom regional anesthesia is not possible. Inhaled analgesics can be administered either intermittently (during contractions) or continuously. They can be self-administered, but the patient should have a health care provider present to ensure an adequate level of consciousness and proper use of the equipment. Although inhaled analgesics continue to be used in parts of Europe as well as developing countries, they are seldom used for labor analgesia in the United States and scavenging of gases remains a concern.

Entonox (50:50 N_2O/O_2 mixture) has been used for many years as both a sole analgesic and an adjuvant to systemic and regional techniques for labor. Associated side effects include dizziness, nausea, dysphoria, and lack of cooperation. The maximum analgesic effect occurs after 45 to 60 seconds, and it is therefore important that the parturient use Entonox at the early onset of her contractions and discontinue its use after the peak of the contraction. The lack of scavenging systems in labor rooms may theoretically put staff at risk of exposure to excessive levels over a prolonged period. The administration of nitrous oxide and oxygen in a 50:50 combination appears to have no effect on hepatic, renal, cardiac, or pulmonary functions. A recent meta-analysis by Kronberg and Thompson[106] concludes that inhaled nitrous oxide relieves labor pain to a significant degree in most patients but does not provide complete analgesia for many. The analgesic effect of nitrous oxide does also seem to be dose dependent, which supports its analgesic efficacy during labor.

Desflurane (0.2%), enflurane, and isoflurane (0.2% to 0.25%) have also been used to provide labor analgesia, but their effectiveness is comparable to that of nitrous oxide. More recent studies suggest sevoflurane as an effective labor analgesic. An inspired concentration of 0.8% appears to be acceptable and effective for labor analgesia. Sevoflurane, when compared with Entonox, provided superior pain relief but with more intense sedation, without adverse effects and which was acceptable to mothers.[107-109] The use of these volatile analgesics, however, is limited by drowsiness, unpleasant smell, and high cost. The major risk when using volatile analgesics is accidental overdose resulting in unconsciousness and loss of protective airway reflexes.

Regional Analgesia

A variety of regional techniques are used in obstetric anesthesia to provide optimal analgesia with minimal depressant effects on the mother and fetus (see Chapters 51 and 52). These techniques are the most effective means of providing analgesia for labor and delivery. Regional techniques present the most flexible, effective, and least depressant options when compared with parenteral and inhalation techniques. Regional analgesia does not produce drug-induced depression in the mother or fetus. The most commonly performed regional techniques for labor are epidural, spinal, and combined spinal-epidural blocks. Less frequently, lumbar sympathetic blocks are performed.[110] Paracervical, pudendal, and local perineal infiltration techniques are occasionally performed by the obstetrician. Each technique has advantages and disadvantages and can be used to block pain transmission during parturition.

Patient Evaluation and Preparation

It is important to assess all patients before placement of a regional block by obtaining a focused medical and obstetric history, performing a clinical examination, and evaluating the airway. The use of herbal medications by the general population is gaining in popularity,[111] and obstetric patients are no different. A 7.1% incidence of herbal remedy use by parturients after 20 weeks' gestation has been reported.[112] Preparations containing garlic, ginkgo, ginseng, ginger, and feverfew may have anesthetic implications.

The obstetric plan and fetal well-being should be noted during this preoperative assessment. Informed consent must be obtained, and the anesthesiologist should explain the procedure and the potential complications of the technique. A retrospective study of patients' satisfaction with labor analgesia and their attitude toward the consent process revealed that distress during labor did not interfere with the women's ability to understand the information associated with the consent process before epidural placement. Furthermore, patients thought that the most valuable information received was either from the anesthesiologist who placed the epidural or from an antenatal course. Patients also wanted to know about the potential complications with the greatest morbidity and mortality before consenting.[113] A full check of emergency equipment should be performed to ensure the immediate availability of resuscitative drugs and equipment. An intravenous infusion should be started, and appropriate maternal and fetal monitoring should be in place before starting the procedure.

Epidural Analgesia

Lumbar epidural analgesia offers a safe and effective method of pain relief during labor. It is versatile and may be extended to provide anesthesia for instrumental or operative delivery. Low doses of local anesthetic or opioid combinations are administered (usually by infusion) to provide a continuous T10-L1 sensory block during the first stage of labor. Further supplementation may be required during the late first stage and second stage to achieve a sacral block. The benefits of epidural analgesia include effective pain relief without appreciable motor block, reduction in maternal catecholamines, and a means to rapidly achieve surgical anesthesia. Despite numerous relative contraindications, there are very few absolute contraindications to neuraxial analgesia. Such contraindications include patient refusal, overt maternal coagulopathy, frank infection at the needle site, and maternal hemodynamic instability. Other high-risk conditions, such as fixed cardiac output states (critical aortic stenosis), must be considered on a case-by-case basis, thereby allowing a risk-benefit analysis for each patient.

The use of ultrasound as aid when performing regional blocks and indeed for epidural placement is increasing (see Chapter 53). Ultrasound imaging of the lumbar spine can aid identification of necessary landmarks for epidural placement and estimate the depth of the epidural space in the pregnant patient. It may be especially beneficial in the obese parturient or in patients known to have previous difficult epidural placement.[114]

Epidural Test Dose

The issue of whether a test dose is needed when administering labor epidural analgesia is controversial. Because ultradilute solutions are commonly used and aspiration is often diagnostic, some authors believe that a test dose is unnecessary.[115] However, because catheter aspiration is not always predictive (especially when using a single-orifice epidural catheter), others maintain the importance of a test dose to improve detection of intrathecal or

intravascular placement of an epidural catheter.[116] Part of the controversy surrounding the testing of epidural catheters involves the use of epinephrine. Epinephrine has been shown to produce a reliable increase in heart rate in volunteers and surgical patients when the epidural has been sited in a blood vessel.[117] However, in a laboring patient, maternal heart rate variability from the pain of uterine contractions may confuse interpretation of the heart rate response, and intravenous epinephrine may have deleterious effects on uterine blood flow.[118] Means to improve the reliability of epinephrine include injecting the dose between uterine contractions and repeating the test dose when the response is equivocal. However, the lack of sensitivity and specificity of the test dose calls into question its usefulness as a diagnostic tool. Leighton and colleagues have described an alternative means of testing an epidural catheter for intravascular placement. They advocate the injection of 1 to 2 mL of air into the epidural catheter while listening over the precordium with the maternal external Doppler monitor for evidence of air.[119] If continuous infusion of dilute local anesthetic is administered and the patient remains comfortable without a motor block, proper epidural catheter placement is ensured. That is, after several hours, if the epidural catheter were intravascular the patient should have inadequate pain relief, and if the catheter were subarachnoid, a solid motor block would develop. Although infusions of ultradilute local anesthetics do not pose a serious threat, such is not true of concentrated local anesthetics used for operative delivery. Some authors have suggested that a test dose is essential for any parturient receiving epidural anesthesia (as opposed to "analgesia").[116] Regardless of the technique used, the safe practice of administering labor epidural analgesia dictates initial catheter aspiration, incremental injections, and continuous monitoring for evidence of local anesthetic toxicity.

Spinal Analgesia

A single-shot subarachnoid injection of local anesthetic or opioid provides effective and rapid onset of labor analgesia (see Chapter 51). It is particularly suitable in very early labor or in a distressed parturient to enable epidural placement under more controlled conditions. Single-shot spinal injections may also be used for instrumental deliveries in women who do not have an indwelling epidural catheter. Although used for routine labor analgesia in some hospitals, this technique does not provide the flexibility of an indwelling catheter. Continuous spinal analgesia with a "macrocatheter" may be considered in cases of accidental dural puncture or very high-risk parturients; it provides excellent analgesia and the assurance of a spinal catheter. This practice may also reduce the incidence of post–dural puncture headache (PDPH) after an accidental dural puncture with an epidural needle.[120] It is imperative to inform all personnel involved in the care of a parturient with a spinal catheter in place to avoid accidental overdose of local anesthetic. Small-bore spinal ("micro") catheters were introduced into clinical practice in the late 1980s and quickly gained popularity because of convenience, fast onset, and the potential for decreased risk of PDPH. However, reports of cauda equina syndrome associated with their use for cesarean section led the U.S. Food and Drug Administration (FDA) to withdraw these microcatheters from clinical practice. Possible explanations proposed for the occurrence of cauda equina syndrome included inadequate mixing of local anesthetic within the intrathecal space and the use of high concentrations of potentially neurotoxic local anesthetic (5% lidocaine) that can result in neural damage.[121,122] Recent work revisiting microcatheters in labor is still ongoing and may provide the necessary safety evidence to allow their reintroduction into clinical practice.[123]

Combined Spinal-Epidural Analgesia

The combined spinal-epidural (CSE) technique is widely used in obstetric practice to provide optimal analgesia for parturients (see Chapter 51). It offers effective, rapid-onset analgesia with minimal risk of toxicity or impaired motor block. In addition, this technique provides the ability to prolong the duration of analgesia, as required, through the use of an epidural catheter. Furthermore, should an operative delivery become necessary, that same catheter can be used to provide operative anesthesia. The onset of spinal analgesia is almost immediate, and the duration is between 2 and 3 hours, depending on which agent or agents are chosen. The duration of spinal analgesia, however, is decreased when administered to a woman in advanced labor versus one in early labor.[124] Patients may have greater satisfaction with CSE than with standard epidurals, perhaps because of a greater feeling of self-control.[125] The original description of spinal labor analgesia involved sufentanil or fentanyl,[126] but the addition of isobaric bupivacaine to the opioid produces a greater density of sensory blockade while still minimizing motor blockade.[127] Originally, 25 μg of fentanyl or 10 μg of sufentanil was advocated, but later studies have suggested using smaller doses of opioid combined with a local anesthetic.[128] For example, many clinicians are now routinely using 5 μg of sufentanil or 15 μg of intrathecal fentanyl. Other studies have suggested that ropivacaine and levobupivacaine can be substituted for intrathecal bupivacaine to provide labor analgesia.[129,130]

The CSE technique has also made ambulation possible for many women receiving neuraxial analgesia. Because of the minimal motor block with this technique, it has been termed "the walking epidural." This term, however, is imprecise because many neuraxial techniques allow ambulation in labor and many women who receive CSE never actually ambulate. In addition to the advantage of rapid onset of pain relief, the CSE technique may reduce the incidence of several potential problems associated with the conventional epidural technique, including incomplete (patchy) blockade, motor block, and poor sacral spread. Another potential advantage of the CSE technique is that early evidence suggests that it may be associated with a significantly reduced duration of the first stage of labor in primiparous parturients.[131,132]

Many methods may be used to perform a CSE block, including (1) epidural catheter insertion followed by spinal needle placement at a lower interspace; (2) an epidural needle beside the spinal needle at the same interspace with the use of specially designed needles; and (3) the most commonly used "needle-through-needle" technique, which involves identification of the epidural space and insertion of a long fine-bore atraumatic (pencil point) spinal needle through the epidural needle until the tip of the spinal needle pierces the dura, as shown in Figure 69-9. Free flow of cerebrospinal fluid (CSF) confirms correct placement, and the opioid, alone or in combination with a local anesthetic, is then injected. After spinal injection, the spinal needle is withdrawn and the epidural catheter is placed 4 to 5 cm into the epidural space via the epidural needle. Side effects of intrathecal opioid include pruritus, nausea and vomiting, and urinary retention. Respiratory depression as a result of cephalad spread of opioid is rare but has occurred when using lipid-soluble opioids. Use of a continuous

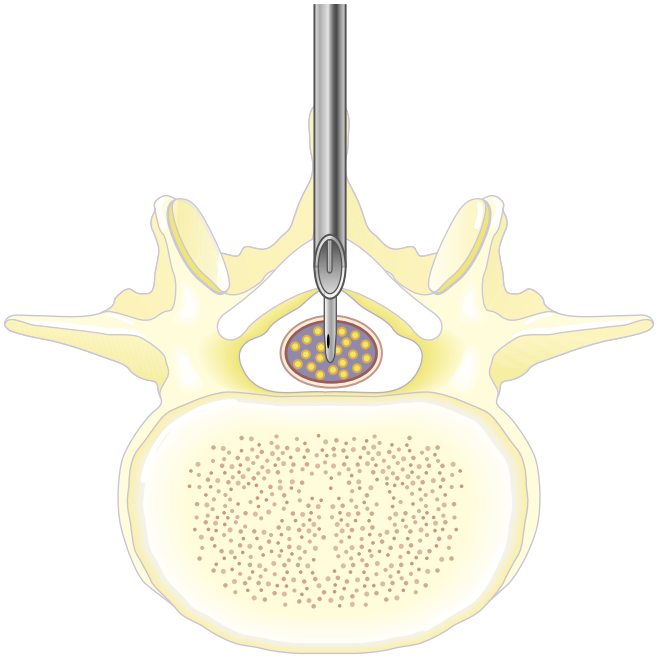

Figure 69-9 Illustration depicting the epidural and spinal spaces during combined spinal-epidural insertion.

epidural infusion of dilute local anesthetic plus opioid (e.g., 0.0625% to 0.1% bupivacaine) provides sensory analgesia without motor block; consequently, it permits many parturients to ambulate during labor. Before ambulation, however, women should be observed for the preceding 30 minutes to ensure maternal and fetal well-being, and they should be assessed for adequate motor function.

An increased frequency of nonreassuring FHR tracings and fetal bradycardia occurs with CSE.[133,134] The etiology of fetal bradycardia after CSE remains elusive, but it may be related to an acute reduction in circulating maternal catecholamine levels after the quick onset of analgesia. In addition, it has been postulated that an imbalance between epinephrine/norepinephrine levels causes unopposed α-adrenoceptor effects on uterine tone and decreases uterine blood flow. However, preliminary reports suggest that there may be no alteration in uteroplacental blood flow.[135]

The resulting fetal bradycardia is usually short in duration and typically resolves within 5 to 8 minutes.[133] A retrospective study of 1240 patients who received regional labor analgesia (mostly CSE) and 1140 patients who received systemic medication or no analgesia demonstrated no significant difference in the rate of cesarean delivery, with rates of 1.3% and 1.4%, respectively. That study also reported that no emergency cesarean deliveries for acute fetal "distress" were necessary in the absence of obstetric indications up to 90 minutes after intrathecal sufentanil administration.[64]

Continuous Epidural Infusion

Most obstetric anesthesiologists now advocate the use of continuous infusions of dilute local anesthetic solutions. Local anesthetics such as bupivacaine, ropivacaine, and levobupivacaine in concentrations ranging from 0.0625% to 0.125% are used either alone or in combination with opioid. The addition of epinephrine may enhance the quality of the analgesia by reducing vascular uptake and systemic absorption of local anesthetics and by a direct agonist effect on α_2 spinal receptors.[136,137] From a parturient's perspective, a continuous infusion offers numerous benefits because it allows for a continuous level of comfort rather than waiting for intermittent epidural top-ups. Typical doses for continuous infusions used for labor analgesia are reviewed in Table 69-6.

Table 69-6 Suggested Dosages for Continuous Lumbar Epidural Analgesia

Drug	Initial Injection	Continuous Infusion
Bupivacaine	10-15 mL of a 0.25%-0.125% solution	0.0625%-0.125% solution at 8-15 mL/hr
Ropivacaine	10-15 mL of a 0.1%-0.2% solution	0.5%-0.2% solution at 8-15 mL/hr
Fentanyl	50-100 µg in a 10-mL volume	1-4 µg/mL
Sufentanil	10-25 µg in a 10-mL volume	0.03-0.05 µg/mL
Epinephrine		1 : 200,000-1 : 800,000 concentration

From Birnbach DJ (ed): Ostheimer's Manual of Obstetric Anesthesia, 3rd ed. New York, Churchill Livingstone, 2000, p 92.

Patient-Controlled Epidural Analgesia

Patient-controlled epidural analgesia (PCEA) is a safe and effective technique. This method of delivery offers equally effective labor analgesia and excellent patient satisfaction. It reduces the total amount of local anesthetic used; consequently, it lessens unwanted effects such as motor block and hypotension. It also reduces the demands on staff on the labor floor, and it gives many parturients a feeling of empowerment. Typically, after analgesia is established by means of either a spinal or epidural block, the catheter is connected to the PCEA device and the patient can then self-administer further boluses as required. Some authors advocate a continuous infusion with patient-controlled top-ups, whereas others suggest a bolus-only technique.[138] Suggested regimens for PCEA settings are outlined in Table 69-7.

Paracervical and Pudendal Blocks

The paracervical block is an alternative technique for a pregnant woman who does not want or cannot receive a neuraxial block. It is a relatively simple block to perform, provides pain relief for the first stage of labor, and does not adversely affect the progress of labor. Local anesthetic is injected submucosally into the fornix of the vagina lateral to the cervix to block nerve transmission through the paracervical ganglion, which lies lateral and posterior to the junction of the cervix and uterus. Because this block does not affect somatic sensory fibers from the perineum, it offers no pain relief for the second stage of labor. Although this technique is still used by obstetricians for nonobstetric surgery, its use in obstetrics has been limited by profound fetal bradycardia, systemic local anesthetic toxicity, postpartum neuropathy, and infection.[139] The cause of this fetal bradycardia appears to be related to decreased uterine blood flow and high fetal blood levels of local anesthetic.[140,141]

The pudendal nerves are derived from the lower sacral nerve roots (S2-S4) and provide sensory innervation for the lower

Table 69-7 Suggested Regimens for Patient-Controlled Epidural Analgesia

	Basal Infusion			Lockout		
Mode	**Epidural Solution**	**Rate (mL/hr)**	**Bolus Dose (mL)**	**Interval (min)**		**Hourly Maximum (mL)**
Demand only	Bupivacaine	0	4	10-20	15-20	0.125%-0.25%
Continuous infusion plus demand	Bupivacaine	4-8	2-4	10-20	15-20	0.0625%-0.125%

From Birnbach DJ (ed): Ostheimer's Manual of Obstetric Anesthesia, 3rd ed. New York, Churchill Livingstone, 2000, p 93.

part of the vagina, the vulva, and the perineum, as well as motor innervation to the perineal muscles. The nerves are easily anesthetized through a transvaginal approach, which is accomplished by depositing local anesthetic behind each sacrospinous ligament.[142] This nerve block provides satisfactory analgesia for vaginal delivery as well as outlet forceps delivery, but it is not useful for labor analgesia. However, it is generally inadequate for midforceps delivery, repair of vaginal lacerations, or exploration of the uterine cavity.[143] Maternal complications from this technique are rare, but include systemic local anesthetic toxicity, infection, and hematoma formation.

Lumbar Sympathetic Blocks

Another nerve block that can be considered an alternative to central neuraxial blocks is the paravertebral lumbar sympathetic technique. This block can be used to impede transmission of pain from the uterus during the first stage of labor.[144] Although it is a technically difficult block to perform, it appears to be associated with far fewer complications than paracervical blockade.

Local Anesthetics

Bupivacaine

Bupivacaine is an amide local anesthetic commonly used for spinal and epidural anesthesia and analgesia in obstetric practice (see also Chapter 30). Its long duration of action, differential sensory to motor block,[145] and relative lack of tachyphylaxis make it a popular choice.

The placental transfer of bupivacaine, as with other amide local anesthetics, is governed by two factors: the degree of ionization at physiologic pH and the extent of protein binding. Bupivacaine has a pK_a of 8.05 (highly ionized at physiologic pH) and is 95% protein bound; thus, it has limited transfer to the placenta when compared with other local anesthetics. The UV/M ratio (the ratio at delivery of the concentration of local anesthetic in blood or plasma from the umbilical vein to the concentration of local anesthetic in maternal blood) for bupivacaine ranges from 0.31 to 0.44 and is much lower than that for lidocaine.[146] In the late 1970s and early 1980s, safety concerns were raised after reports of several deaths related to the cardiovascular or cardiac toxicity of bupivacaine.[147,148] After these reports, the FDA prohibited the use of a 0.75% epidural solution in obstetric practice. Changes in clinical practice have also lessened the risk of inadvertent intravascular local anesthetic injections with the increasing use of multiorifice catheters (which allow greater accuracy of aspiration of heme when the catheters have been placed intravascularly) and the practice of incremental dosing. Bupivacaine consists of two stereoisomers, S^- and R^+, and is marketed as a racemic mixture of these isomers. When separated, the R component was found to contribute to bupivacaine's unwanted toxicity.[149,150] This finding led researchers to develop the use of S isomers for clinical practice, which resulted in the introduction of ropivacaine (the S isomer of the propyl homolog of bupivacaine) and levobupivacaine (the S isomer of bupivacaine).

Lidocaine

Lidocaine has been used for many years in obstetrics. It has a quick onset of action with an intermediate duration of action. UV/M ratios reported in the literature are 0.4 to 0.6.[151] Even though lidocaine is very popular for use as an epidural local anesthetic for operative delivery (2% with epinephrine), it is not popular for labor analgesia because of motor block. Although early reports suggested that lidocaine compromises neonatal neurobehavioral function,[152] numerous follow-up studies have not substantiated this association.[153] Controversy has developed regarding the use of 5% hyperbaric lidocaine for spinal anesthesia because of reports of transient neurologic symptoms. In 1994, the FDA issued a letter concerning 5% hyperbaric lidocaine in which physicians were urged to dilute the lidocaine with saline or CSF before injection. These precautions were subsequently incorporated into the package insert for this drug. More recent data, however, indicate that the 2.5% and 2% solutions may still cause transient radicular irritation.[154] As a result, and despite many years of use without clinical evidence of neurotoxicity, many anesthesiologists have abandoned the use of spinal 5% hyperbaric lidocaine.

2-Chloroprocaine

2-Chloroprocaine is an ester local anesthetic with a rapid onset time and short-lived duration of action. Its rapid metabolism by ester hydrolysis (half-life, 45 seconds) makes it a safe agent for use in obstetrics because almost no drug crosses the placenta.[155] As a result of this property and its speed of onset, its primary role in obstetric anesthesia is for establishment of epidural anesthesia for emergency cesarean section when an epidural catheter is already in place. In addition to its short duration of action, a potential disadvantage of chloroprocaine is that it may interfere with the action of epidurally administered opioids.[156] This interaction with opioids may be due to antagonism at the μ- and κ-opioid receptors.[157] Furthermore, it has been reported that chloroprocaine may also interfere with the action of subsequently administered epidural bupivacaine.[158] Previous preparations of 2-chloroprocaine were considered to be neurotoxic because of reports of arachnoiditis after unintentional subarachnoid injection of this anesthetic.[159] Subsequent reports incriminated the low pH of the anesthetic along with the preservatives used for stabilization.[160] Replacement of metabisulfite and methylparaben has

eliminated the risk of neurotoxicity. However, caution is advised because despite the availability of preservative-free preparations marketed as MPF (methylparaben free), formulations containing preservatives are still commercially available.[161] Recent reports, in fact, even go so far as advocating the use of spinal chloroprocaine.[162]

Levobupivacaine

Based on data that the cardiotoxicity of bupivacaine was more pronounced with the R-enantiomer, the S-enantiomer (levobupivacaine) was developed for clinical use. Levobupivacaine is a long-acting local anesthetic with a clinical profile similar to that of bupivacaine. Both animal and human volunteer studies have demonstrated a safety profile greater than that of racemic bupivacaine. The lethal dose of levobupivacaine was 1.3- to 1.6-fold higher than that of racemic bupivacaine in most animal studies, thereby providing supportive evidence for the greater safety of levobupivacaine should accidental intravascular injection occur.[163] Like racemic bupivacaine, levobupivacaine crosses the placenta. The UV/M ratio for levobupivacaine was noted to be 0.3 in women undergoing elective cesarean section after the administration of 30 mL of 0.5% levobupivacaine by means of an epidural injection.[164] Levobupivacaine compares favorably with bupivacaine for epidural anesthesia for cesarean section.[164] Assessment of sensory block with 0.5% bupivacaine and 0.5% levobupivacaine demonstrated no difference in adequacy of the block or time taken to reach a surgically adequate block. Similarly, other authors have recently reported that they found no difference with regard to onset or duration of sensory block when patients received either 0.5% levobupivacaine or 0.5% bupivacaine for cesarean section. In addition, the onset and fade-out of sensory and motor blockade, the quality of anesthesia, and muscle relaxation were comparable between the two groups.[165] Levobupivacaine has also been used to provide epidural analgesia for labor. A multicenter study comparing levobupivacaine and bupivacaine reported that these drugs have equivalent analgesic efficacy. In addition, motor blockade was similar between the groups.[166] As with other local anesthetics, recent evidence suggests that fentanyl significantly reduces levobupivacaine requirements for epidural analgesia in labor.[167] Levobupivacaine is not currently being marketed in the United States but is available in many other countries.

Ropivacaine

Ropivacaine is a homolog of mepivacaine and bupivacaine. It was the first S (levo) isomer of a local anesthetic to be marketed. Ropivacaine is less soluble than bupivacaine; therefore, it may be less potent. Although clinical evidence suggests that the two drugs might be similar in potency,[168] minimum local anesthetic concentration (MLAC) studies have found that the analgesic potency of ropivacaine was 0.60 (0.47 to 0.75) relative to bupivacaine. Claims for reduced toxicity and motor block must be considered with differences in analgesic potency kept in mind.[169]

Anesthesia for Cesarean Section

The cesarean birth rate in the United States is now approximately 30% of all live births.[170] Increased use of the procedure has been attributed to the liberalization of indications for fetal "distress" as well as elective repeat cesarean sections.[171] The most common indications for cesarean delivery include "failure to progress," non-reassuring fetal status, cephalopelvic disproportion, malpresentation, prematurity, and previous uterine surgery. Although primary elective cesarean delivery without medical or obstetric indications has been previously considered inappropriate in the United States, a recent National Institutes of Health panel suggested that it should be considered under certain circumstances.[172] The choice of anesthesia for cesarean section depends on the indications for the surgery, the degree of urgency, maternal status, and desires of the patient.

Neuraxial Anesthesia

The use of neuraxial anesthesia has dramatically increased, and data since 1997 suggest that the use of general anesthesia for cesarean section has been steadily decreasing in the United States.[173] Neuraxial anesthesia techniques have several advantages, including a decreased risk of failed intubation and aspiration of gastric contents, avoidance of depressant agents, and the ability of the mother to remain awake and enjoy the birthing experience. In addition, it has been suggested that blood loss is reduced under regional anesthesia for cesarean delivery.[174]

Although epidural, spinal, continuous spinal, and CSE techniques have all been advocated, most straightforward cesarean sections are now performed with single-shot spinal anesthesia, which has been found to be faster, provides a superior block, and is more cost effective, especially as compared with epidural anesthesia.[175]

Spinal Anesthesia

Spinal (subarachnoid) anesthesia offers many advantages for cesarean delivery. It has a very rapid onset and provides a dense neural block. Because of the small doses used, there is little risk of local anesthetic toxicity and minimal transfer of drug to the fetus. In addition, failures (including incomplete or patchy blocks) are very infrequent with spinal anesthesia. Disadvantages of this technique include the finite duration of anesthesia and a higher incidence of hypotension.

Hyperbaric bupivacaine is the most commonly used agent in the United States for spinal anesthesia when performing cesarean sections. Its duration of action of 1.5 to 2 hours is well matched to the duration of surgery in most cases. Although some authors have advocated a sliding scale of doses that depend on patient height, most practitioners now use a set dose of hyperbaric bupivacaine.[176] As noted in Figure 69-10, neither patient height, weight, nor body mass index appears to correlate with block height.[176] Although increasing the dose of spinal anesthetic increases block height,[177] doses above 15 mg significantly increase the risk of complications, including high block, and are not recommended. Spinal hyperbaric bupivacaine is marketed in concentrations of 0.5%, 0.75%, and 1%; however, availability varies from country to country. Although the extent of the blockade does not appear to be greatly affected by concentration,[178] the density of the sensory block may be better with the 0.75% than the 0.5% concentration. However, there seems to be little advantage and potential disadvantage to use of the 1% concentration.

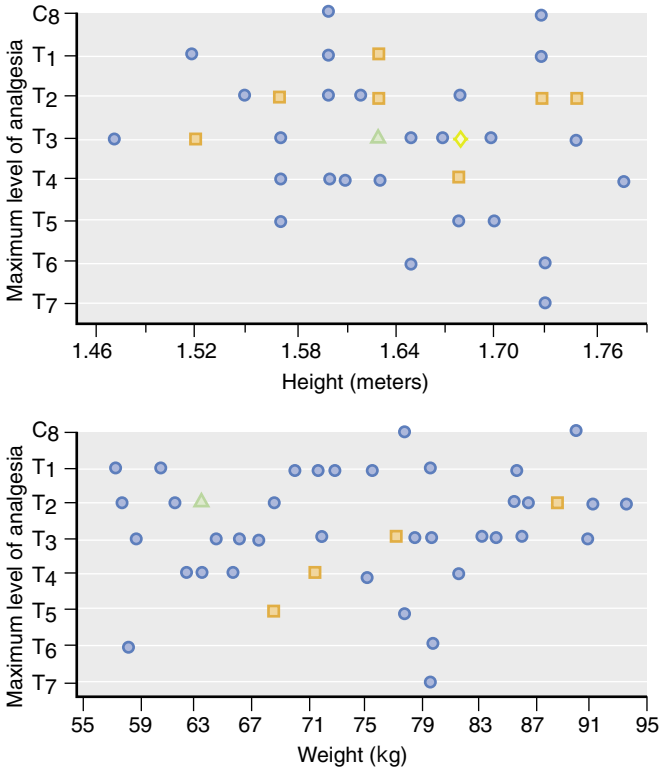

Figure 69-10 Relationship between patient weight and height and block height during spinal anesthesia with 12 mg of hyperbaric bupivacaine in 50 term parturients undergoing cesarean section. *Circles* represent one patient; *squares,* two patients; *triangles,* three patients; and *diamond,* four patients. (*From Shnider SM, Moya F: Effects of meperidine on the newborn infant. Am J Obstet Gynecol 89:1009-1015, 1964.*)

A comparison of 0.75% with 1% bupivacaine found no difference in onset time or quality of block, but an increased incidence of backache was reported in the 1% group.[179]

Spinal anesthesia can be initiated with the patient in either the sitting or the lateral position and with either plain or hyperbaric solutions. Each method has its advantages and disadvantages. The sitting position, however, appears to be optimal for placement of a neuraxial block in an obese parturient.[180] Hyperbaric solutions have the advantage of greater predictability of block height than plain solutions do, and they allow the anesthesiologist the ability to adjust block height by adjusting table position.[181]

Despite achieving an adequate (T4) block, some women under spinal anesthesia will experience some degree of visceral discomfort during cesarean section, particularly in situations in which the obstetrician exteriorizes the uterus. The quality of the spinal anesthesia has been reported to be improved by the addition of epinephrine,[182] morphine,[183] fentanyl, or sufentanil.[184]

Epidural Anesthesia

When flexibility is necessary (e.g., for a potentially prolonged cesarean section), a catheter technique is optimal and an epidural technique is often chosen. In addition, women with an indwelling epidural catheter for labor who require cesarean section usually receive the operative anesthetic through that catheter. In high-risk parturients, epidural catheters are often placed early so that they will be available for emergency cesarean section, again illustrating the importance of continual assessment of epidural catheters and their effectiveness during labor.

The ideal local anesthetic should provide rapid onset of sensory block with an appropriate duration of action. Commonly used agents include 2-chloroprocaine, lidocaine, and bupivacaine. When compared with spinal anesthesia, very large doses of local anesthetic are used to achieve adequate levels for cesarean section. Epidural catheters can migrate, and even negative aspiration of the catheter does not absolutely rule out intrathecal or intravascular placement. Because large volumes of potentially toxic local anesthetic are administered via an epidural catheter for cesarean section, several measures can be used to reduce the risk of local anesthetic toxicity. First, the catheter should be aspirated before use and an appropriate test dose administered. Second, the anesthetic should be administered in fractionated doses. Last, safer drugs (e.g., chloroprocaine and lidocaine) or the newer amide local anesthetics (e.g., ropivacaine and levobupivacaine) should preferably be used.

As with spinal anesthesia, adjuncts can be used to improve the quality of the block. Because local anesthetics are all weak bases and are commercially prepared in an acidic solution, they are ionized and do not readily cross lipid membranes. The addition of small quantities of bicarbonate increases the pH of the solution and the proportion of un-ionized local anesthetic; this practice shortens the time to onset of blockade.[185] The addition of bicarbonate to lidocaine and chloroprocaine clearly shortens their onset; however, not all studies have demonstrated this effect with bupivacaine.[186] In addition, bupivacaine may precipitate when alkalinized, so much smaller doses (0.1 mEq/20 mL local anesthetic) should be used.

Commercially prepared solutions of local anesthetics with epinephrine have a lower pH, so they may have a slower onset time. The addition of epinephrine to the local anesthetic immediately before injection may decrease the time of onset of the block for lidocaine,[187] but this effect does not seem to occur with bupivacaine.[188]

Intraoperative conditions under epidural anesthesia may be improved if fentanyl (50 to 100 μg)[189] or sufentanil (10 to 20 μg)[190] is added to the local anesthetic.

Clonidine has also been used as an additive to epidural local anesthetics, but it has been associated with sedation, bradycardia, and hypotension.[191]

Combined Spinal-Epidural Technique

The CSE technique, first reported as an option for cesarean section in 1984,[192] has recently increased dramatically in popularity. The advantage of this technique is that it provides rapid onset of dense surgical anesthesia while allowing the ability to prolong the block with an epidural catheter. In addition, because the block can be supplemented at any time, the CSE technique allows the use of smaller doses of local spinal anesthetics, which may in turn reduce the incidence of high spinal block and hypotension.[193] Potential problems of the CSE technique for cesarean delivery include an inability to test the catheter, the possibility of a failed

epidural catheter after spinal injection, and the risk of enhanced spread of previously injected spinal drug after use of the epidural catheter.[194] A recent study, however, found no difference in block height.[195] A detailed description of the CSE technique can be found in the section of this chapter on labor analgesia. Additionally, the reader is referred to a comprehensive review of the subject by Rawal and colleagues.[196]

Continuous Spinal Anesthesia

Continuous spinal anesthesia has many potential advantages when compared with single-shot spinal or epidural techniques. The classic technique required the use of large-bore epidural needles; newer techniques use a 32-gauge microcatheter inserted through a 26-gauge spinal needle.[197] The technique rapidly gained in popularity despite technical difficulties, but, as previously described, it was abandoned after withdrawal of these catheters by the FDA. The advantages of continuous spinal anesthesia, however, remain, and macrocatheters (e.g., placing an epidural catheter intrathecally) can be used in high-risk parturients. To perform continuous spinal anesthesia, the anesthesiologist pierces the dura with an epidural needle and then threads the epidural catheter 3 to 4 cm within the intrathecal space. Catheter placement can be tested by aspiration of CSF. Because a catheter is being used, smaller doses can be given in an incremental fashion. Such administration is particularly advantageous in high-risk parturients such as those with cardiac disease, respiratory disease, morbid obesity, and neuromuscular disease. To reduce the risk of headache after this technique, the epidural needle should be turned so that it is parallel to the dural fibers at the time of insertion. In addition, to further reduce the risk of headache, it has been suggested that several steps be taken, including leaving the epidural catheter in situ for more than 12 hours and injecting a bolus of preservative-free normal saline before removal of the catheter.[198]

General Anesthesia

Although the use of general anesthesia for cesarean delivery has dramatically declined during recent decades, it is still necessary for the management of several situations, including maternal hemorrhage, overt coagulopathy, life-threatening fetal compromise, or cases in which a patient refuses regional anesthesia. It has been reported that anesthesia-related maternal mortality associated with regional anesthesia has declined but that the number of deaths involving general anesthesia has remained relatively constant. Thus, the relative risk of fatality during general anesthesia has increased to more than 16 times that for regional anesthesia.[199] General anesthesia has the advantages of speed of induction, control of the airway, and superior hemodynamics. The frequency of the use of general anesthesia is dependent on many factors, including the number of patients who receive epidural analgesia for labor, the percentage of high-risk parturients, and the skills of the anesthesiologist. Although there are no absolute contraindications to general anesthesia, in certain conditions, such as malignant hyperthermia or a patient with a difficult airway, a modified anesthetic technique may be required. Potential problems associated with general anesthesia for cesarean section include failed intubation, pulmonary aspiration of gastric contents, neonatal depression, and maternal awareness. The technique for general anesthesia is outlined in Box 69-1. Although this "cookbook" recipe highlights the basics, it is essential that every anesthesiologist working on the labor and delivery floor be comfortable with the algorithm for the management of failed intubation, as illustrated in Figure 69-11.

Failed Endotracheal Intubation

A study of anesthesia-related deaths in the United States between 1979 and 1990 revealed that the case-fatality rate with general

Box 69-1 Suggested Technique of General Anesthesia for Cesarean Section

1. Administer a nonparticulate antacid. Additional agents such as metoclopramide or an H_2 blocker should be considered in patients at high risk for aspiration or failed intubation.
2. Apply routine monitors, including electrocardiography, pulse oximetry, and capnography. Ensure that suction is functioning and that equipment to correct failed intubation is readily available.
3. Position the patient in a manner to achieve left uterine displacement and optimal airway position.
4. De-nitrogenate with a high flow of oxygen for 3-5 minutes or 4 vital capacity breaths.
5. After the drapes are applied and the surgeon is ready, initiate a rapid-sequence induction with thiopental, 4.0-5.0 mg/kg, and succinylcholine, 1.0-1.5 mg/kg. Apply cricoid pressure and continue until correct position of the endotracheal tube is verified and the cuff is inflated. In hypotensive crises, ketamine, 1.0-1.5 mg/kg, should be substituted for thiopental. A defasciculating dose of muscle relaxant is not necessary.
6. Ventilate with 50% oxygen and 50% nitrous oxide and a volatile anesthetic as necessary. Maintain normocarbia and use muscle relaxation as necessary with either a nondepolarizing muscle relaxant or succinylcholine infusion.
7. After delivery, increase nitrous oxide to 70%, discontinue or reduce the volatile anesthetic, and administer an opioid and a benzodiazepine. Add oxytocin to intravenous fluids.
8. Insert an orogastric tube before completion of surgery.
9. Reverse neuromuscular blockade as necessary at completion of surgery.
10. Extubate when the patient is awake, the anesthesia is adequately reversed, and the patient is following commands.

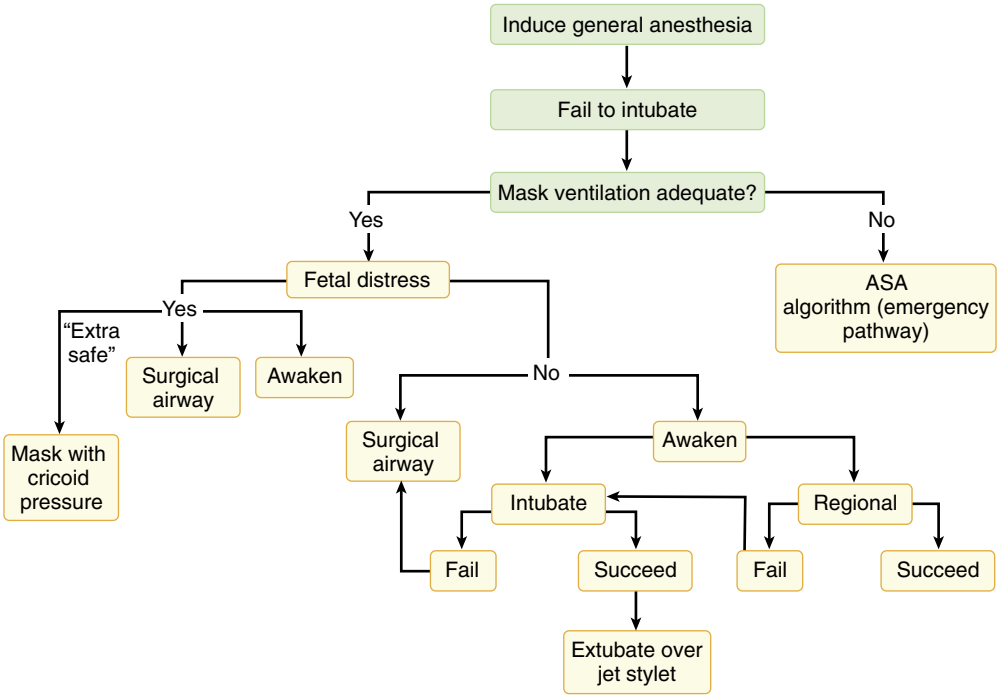

Figure 69-11 Management of failed intubation in pregnancy with reference to the presence or absence of fetal distress. ASA, American Society of Anesthesiologists. (*Redrawn from Reisner LS, Benumof JL, Cooper SD: The difficult airway: Risk, prophylaxis, and management. In Chestnut DH [ed]: Obstetric Anesthesia: Principles and Practice. St Louis, CV Mosby, 1999, p 607.*)

anesthesia was 16.7 times greater than that with regional anesthesia.[199] Most anesthesia-related deaths were due to hypoxemia when difficulty securing the airway was encountered. The most commonly occurring adverse respiratory events are failure to intubate, failure to recognize esophageal intubation, and failure to ventilate (see also Chapter 50). Physical changes associated with pregnancy, including weight gain, enlarged breasts, and oropharyngeal edema, can complicate endotracheal intubation. In addition, certain disease states such as preeclampsia may predispose to failed intubation. Central to decreasing the risk associated with general anesthesia is early assessment of the mother's airway. It has been reported that airway evaluation can often identify a parturient with a difficult airway, but it was not performed in upward of 10% of cases in which maternal mortality occurred.[200] Others have evaluated the risk factors associated with difficult intubation, and it has been suggested that the greatest risks are associated with a Mallampati class 4 airway, a short neck, protruding maxillary incisors, and mandibular recession.[201] From these data, an estimated prediction of a difficult airway has been calculated and highlighted in Figure 69-12. Regardless of the initial assessment, all patients must have a repeat airway examination performed before initiation of anesthesia for cesarean section because it has been demonstrated that labor may be associated with changes in the maternal airway.[202] A recent review of anesthesia-related maternal deaths over an 18-year period illustrated three key points: (1) anesthesia-related deaths from airway factors occurred during emergence and recovery and not during induction of general anesthesia; (2) system errors such as deficiencies in postoperative monitoring and in supervision of junior anesthesiologists contributed to fatalities; and (3) obesity and African American race were highlighted as risk factors for anesthesia-related maternal mortality.[203]

The series of triennial Confidential Enquiries into Maternal Deaths in the United Kingdom have documented numerous cases of maternal mortality associated with general anesthesia[204]; in particular, cases have been associated with difficult intubation and pulmonary aspiration. However, it has been suggested that the continuing downward trend of anesthetic mortality in the United Kingdom is associated with a stable number of general anesthetics.[205] Therefore, factors other than general anesthesia must also play a role.

Complications of Regional Anesthesia

Hypotension

Hypotension is present when systolic blood pressure decreases to less than 100 mm Hg or to more than 20% less than baseline readings, and it occurs in many patients after use of neuraxial anesthesia. The incidence and severity of hypotension depend on the height of the block, the position of the parturient, and whether prophylactic measures were taken to avoid such hypotension. Measures that decrease the risk of hypotension to varying degrees include intravenous administration of fluids, avoidance of aorto-

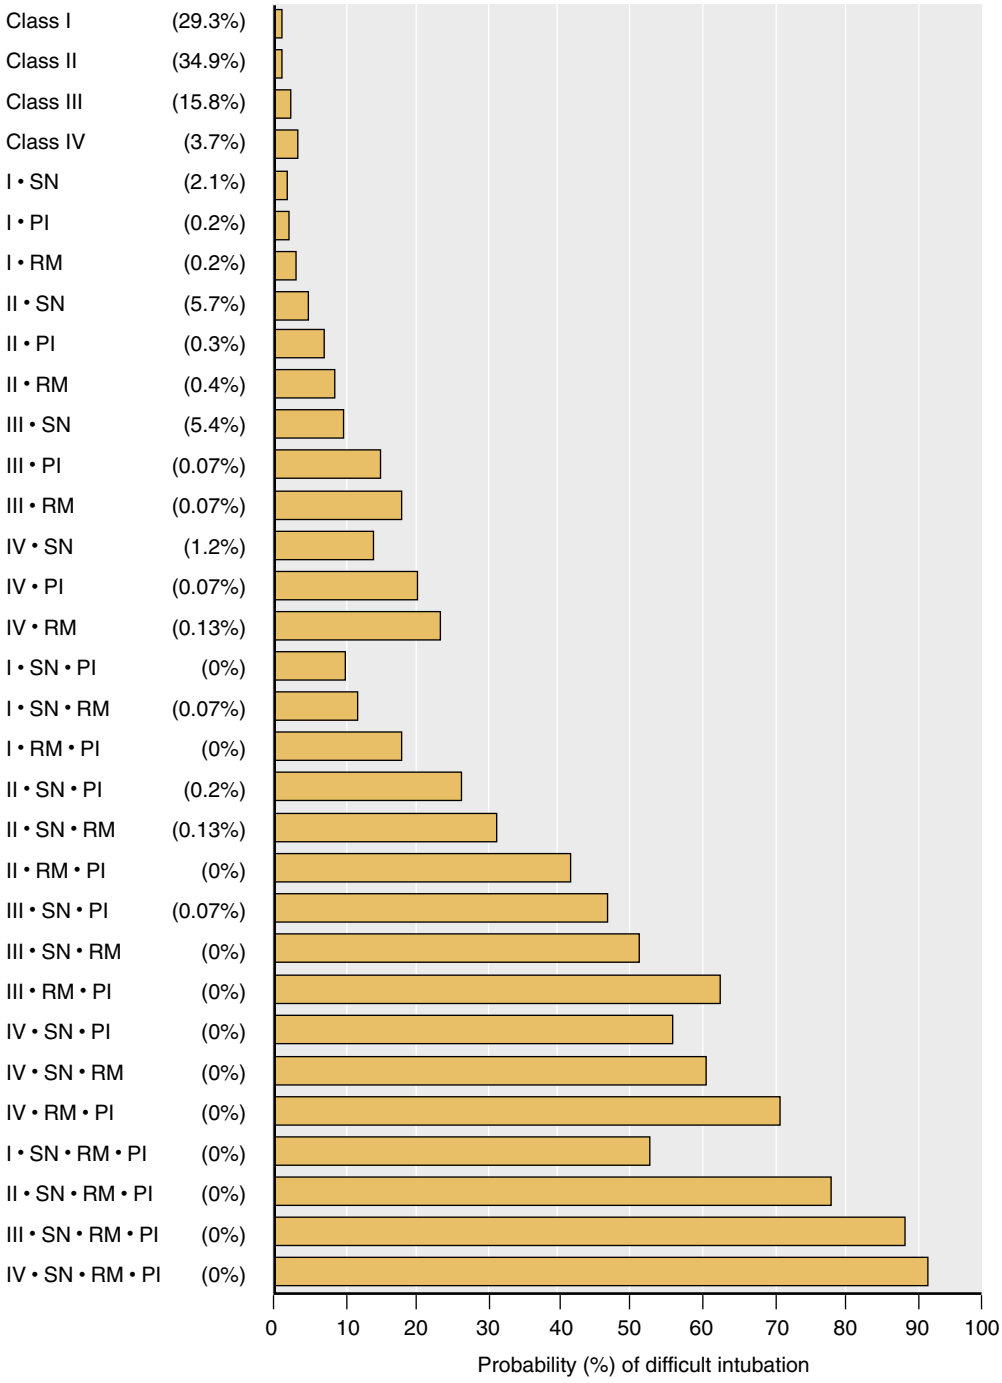

Figure 69-12 Graphic representation of the factors predictive of a difficult intubation. Such factors include Mallampati class, short neck (SN), protruding maxillary incisors (PI), and receding mandible (RM). Data were obtained from 1500 parturients undergoing cesarean section under general anesthesia. Values in parentheses represent observed incidences of risk factor combinations in the series. (*From Rocke DA, Murray WB, Rout CC, et al: Relative risk analysis of factors associated with difficult intubation in obstetric anesthesia. Anesthesiology 77:67, 1992.*)

caval compression (left uterine displacement), and vigilant monitoring of blood pressure at frequent intervals after placement of a regional anesthetic. In addition, FHR evaluation is helpful so that any adverse effects on the fetus can be corrected if possible. If recognized and treated promptly, transient maternal hypotension should not be associated with maternal or neonatal morbidity.[206] As previously discussed, although intravenous ephedrine in 5- to 10-mg increments remains the first-line treatment, recent evidence supports the use of phenylephrine.[41] The prophylactic administration of commonly used doses of ephedrine does not appear to be of benefit.[207,208]

Accidental Dural Puncture

A relatively common and problematic complication of epidural placement is accidental puncture of the dura ("wet tap"), which has an incidence of up to 3% (see also Chapter 51).[209] This complication can lead to the development of PDPH in up to 70% of cases.[210] The traditional management of accidental dural puncture is to reposition the epidural catheter at a different interspace. Recently, however, many anesthesiologists have advocated that the epidural catheter be passed into the spinal space to become a continuous spinal technique.[211] This technique establishes rapid and effective pain relief. Analysis of aggregate data from limited retrospective trials demonstrates a significant reduction in the incidence of PDPH and the need for an epidural blood patch in patients who receive continuous spinal analgesia after unintentional dural puncture.[120] In addition, the catheter provides excellent labor analgesia and a route toward almost instant onset of blockade for cesarean section. A recent review of seven cases in which epidural anesthesia was complicated by an unintentional dural puncture suggested that spinal headache could be reduced if five steps were followed: (1) injection of CSF from the epidural syringe back into the subarachnoid space through the epidural needle; (2) insertion of an epidural catheter into the subarachnoid space; (3) injection of preservative-free normal saline through the intrathecal catheter before its removal; (4) administration of continuous intrathecal labor analgesia; and (5) leaving the intrathecal catheter in situ for a total of 12 to 20 hours.[198]

Post–Dural Puncture Headache

As previously mentioned, PDPH will develop in 50% or more of patients after accidental dural puncture with an epidural needle. However, not all postpartum headaches occur as a result of dural puncture. A large analysis reported that headaches occurred in 15% of parturients who did not receive an epidural and in 12% of parturients who had an epidural but did not show evidence of dural puncture.[212] Other causes of headache in the postpartum period include nonspecific headache, migraine, hypertension, pneumocephalus, infection including sinusitis and meningitis, cortical vein thrombosis, and intracerebral pathology. In addition, because coffee and tea intake is so prevalent in our society, one should also consider caffeine withdrawal in the differential diagnosis. PDPH has the typical features of a postural headache that is worsened by standing or straining and relieved by lying down.

Generally, PDPH is initially treated conservatively with increased intake of both oral and intravenous caffeine and analgesics. No evidence, however, has shown that even dramatically increasing fluid intake will cause a greater production of CSF; recently, the use of intravenous fluid has been questioned.

Drugs that have been used to treat PDPH include caffeine, vasopressin, theophylline, sumatriptan, and adrenocorticotropic hormone (ACTH). Caffeine, a cerebral vasoconstrictor, has been used successfully, but the effects appear to be transient.[213] In addition, caffeine treatment seems to be more effective when headaches are the result of smaller rather than larger needles (e.g., spinal rather than wet-tap related). A negative aspect of caffeine treatment is that patients may feel anxious and unable to sleep. In addition, seizures and cardiac arrhythmias have been reported after caffeine administration.[214] Although some of the caffeine is present in breast milk, deleterious effects on the newborn have not been shown.[215] One recent study suggested that intravenous administration of caffeine may be effective for prophylaxis of PDPH.[216] Theophylline, which is also a cerebral vasoconstrictor and is available in long-acting formulations, may be useful in the pharmacologic treatment of PDPH. Unfortunately, the only study to evaluate this drug for PDPH has been published only in abstract form.[217] Sumatriptan, a serotonin agonist with cerebral vasoconstriction properties that is routinely used to treat migraine headaches, has also been used in the treatment of PDPH,[217] although not all studies support its use.[218]

ACTH has likewise been anecdotally reported as a treatment of PDPH.[219] If the symptoms are severe enough to limit a mother's activity or if evidence of cranial nerve involvement is noted, an epidural blood patch should be considered. The epidural blood patch was first described more than 40 years ago, and it continues to be the most effective treatment of PDPH. Although early reports suggested immediate and permanent cure of PDPH after an epidural blood patch, it has recently been suggested that complete success rates are approximately 75% and that the effectiveness of an epidural blood patch is decreased if the dural puncture was caused by a large-bore needle.[220] One study reported that although immediate relief occurred in almost all patients, permanent cure after an epidural blood patch was achieved in only 61%.[221] The success of an epidural blood patch is probably not as simple as the clotted blood obstructing the dural tear. CSF volume replacement is not rapid, yet the headache symptoms resolve almost immediately after injection of the blood. Other explanations for the effectiveness of an epidural blood patch include an increase in CSF pressure and cerebral vasoconstriction.[222] Some controversy has arisen regarding the optimal volume of blood to be injected; however, most practitioners use 15 to 25 mL and stop injection of the blood if severe back pain occurs. Although the incidence of complications (especially back pain) increases with increased volume, it appears that increased volume also increases the success rate.[223]

Radiologic studies using radiopaque dye while performing the blood patch have shown that blood inserted into the epidural space will travel one space below the level of insertion of the epidural needle and up to four spaces above the site.[224]

If inadvertent dural puncture occurs during epidural placement, there is growing evidence that placing a spinal catheter immediately and using continuous spinal analgesia may reduce the incidence of PDPH.[225]

Total Spinal Block

A total spinal block is a rare and life-threatening complication that occurs after excessive cephalic spread of the local anesthetic. It can occur during single-shot spinal anesthesia or as a result of inadvertent intrathecal spread of epidural medication after unintentional dural puncture or catheter migration.[226] Subdural spread of the local anesthetic can also cause a high block[227] characterized by a high sensory level, sacral sparing, and incomplete or absent motor block. Single-shot spinal anesthesia after a failed spinal or patchy epidural may also precipitate total spinal anesthesia.[228] There are several possible mechanisms for high spinal blocks when a spinal block is attempted after a failed epidural block. Expansion of the epidural space may compress the spinal canal and encourage cephalad spread of intrathecal drugs. Rapid transfer of local anesthetic from the epidural space across the dural hole may also occur. In addition, sufficient local anesthetic may be present in the nerve roots to decrease the dose requirements of subsequent spinal anesthesia.[229] In the case of a nonemergency cesarean section when a patchy block is present, several options are possible without resorting to a single-shot spinal block. An epidural catheter can be relocated and the drug titrated through the catheter. Alternatively, a CSE can be placed in which a fraction of the usual spinal dose can be administered; again, the catheter can be used to titrate to a desired level. Other options include repeating a spinal block after waiting for the original block to resolve or converting to general anesthesia.

Neurologic Complications

Neurologic complications after regional techniques in obstetric patients are fortunately rare, and often they are not due to the neuraxial block. They can be classified into three groups: (1) those relating directly to anesthesia, (2) those unrelated to anesthesia, and (3) those in which anesthesia is an incidental but possibly a contributory factor.[230] Neurologic examination of postpartum women has revealed transient postpartum sensory dysfunction in up to 21% of women who did not report any symptoms, and these symptoms were unrelated to regional anesthesia.[231] Neurologic complications are five times more common after childbirth itself than after regional blockade.[232] Most neurologic injuries after delivery that are obstetric in origin may be a result of the instrumentation, nonanatomic positioning during labor, or compression of sacral nerve roots by the fetal head during delivery.

Backache

Low back pain is common after delivery. Many patients believe that back pain is linked in some way to epidural analgesia administered for labor, and the alleged relationship between labor epidurals and postpartum backache has been suggested by two retrospective studies. One study reported new-onset long-term backache in 19% of women who delivered vaginally with labor epidural analgesia and in 10% of women who did not have an epidural catheter in situ.[233] A different group found an 18% incidence of new-onset postpartum back pain in women who delivered with epidural analgesia versus a 12% incidence in those who delivered without it.[234] More recently, however, prospective studies evaluating labor epidural analgesia and postpartum back pain failed to find a significant link between epidural analgesia and back pain. One study reported that the incidence of postpartum backache in women who received epidural anesthesia was equivalent to the incidence in those who did not (44% versus 45%). Further data analysis demonstrated an association of new-onset postpartum back pain with greater weight and shorter stature; postpartum back pain was also associated with a previous history of back pain, greater weight, and younger age.[235] Similarly, another study found no difference in the incidence of long-term low back pain in patients receiving epidural anesthesia for labor and controls who did not.[236]

Central Nervous System Infections

In routine anesthesia practice, the reported incidence of infection after regional anesthesia is extremely low. It is interesting to note that an epidural abscess may form spontaneously in up to 1 in 10,000 patients admitted to the hospital in the United States.[237] Typical signs and symptoms include fever, back pain, and localized infection at the level of the epidural site 2 to 3 days after the procedure.

Serious infectious complications after spinal/epidural analgesia and anesthesia are rare, but they can have devastating sequelae. Infection may be exogenous in origin and be caused by the contamination of equipment or pharmacologic agents or by colonization of the catheter. Endogenous spread may occur from a site of infection elsewhere in the body. There have also been reports of meningitis after spinal anesthesia in which the same phage type of organism (*Streptococcus viridans*) was isolated from the patient and the anesthesiologist who performed the procedure.[238] A recent comprehensive editorial by Reynolds highlights the risks and potential sources of infection associated with neuraxial techniques and discusses protective measures to reduce such potential complications.[239] Despite the lack of national guidelines on infection control precautions for neuraxial techniques in the U.S., most anesthesiologists believe that sterile precautions should be observed at all times.

Spinal and Epidural Hematoma

The incidence of neurologic injury resulting from hematoma associated with neuraxial anesthesia is very low, with estimates of 1 in 150,000 and 1 in 220,000 for epidural and spinal anesthesia, respectively.[240] A review of 61 cases of spinal hematoma associated with spinal or epidural anesthesia reported evidence of hemostatic abnormality in 68% of patients and difficult or bloody placement of needles and catheters in 25% of cases. In 15 of the reported cases the patients received spinal anesthesia, with the remaining 46 receiving epidural anesthesia.[241]

Another risk factor for the development of spinal hematoma is a high-risk parturient who is receiving low-molecular-weight heparin (LMWH). Recent guidelines by the American Society of Regional Anesthesia suggest that neuraxial techniques should be

deferred for 10 to 12 hours in a parturient who has received preoperative LMWH or 24 hours for parturients receiving higher doses of LMWH (e.g., enoxaparin, 1 mg/kg twice daily).[242]

Complicated Obstetric Conditions

Preeclampsia and Eclampsia

Preeclampsia complicates up to 8% of pregnancies.[243] It is the most common condition seen by obstetric anesthesiologists in which an otherwise healthy parturient can become critically ill. The classic triad of preeclampsia includes hypertension, proteinuria, and edema. Certain conditions predispose a woman to preeclampsia. In order of risk ratio, these conditions include homozygous angiotensin T-235, chronic renal disease, antiphospholipid syndrome, chronic hypertension, a family history of preeclampsia, multiple gestation, nulliparity, maternal age older than 40 years, diabetes, and African American race.[244] Preeclampsia has been defined as hypertension occurring after 20 weeks' gestation or in the early postpartum period and returning to normal within 3 months after delivery or onset after 20 weeks' gestation and at least one of the following[245]:

- Proteinuria higher than 300 mg/24 hr
- Oliguria or a serum-plasma creatinine ratio greater than 0.09 mmol/L
- Headaches with hyperreflexia, eclampsia, clonus, or visual disturbances
- Increased liver enzymes, plasma glutathione *S*-transferase-alpha 1-1, or serum alanine aminotransferase or right abdominal quadrant pain
- Thrombocytopenia, increased lactate dehydrogenase (LDH), hemolysis, disseminated intravascular coagulation (DIC)
- Intrauterine growth retardation

Preeclampsia may be classified as mild or severe according to the severity of symptoms and signs as illustrated in Table 69-8. It is misleading to assume a smooth progression from mild disease to severe preeclampsia to eclampsia, because 25% to 40% of patients will have normal blood pressure at the time of their first eclamptic seizure.[246]

In the most recent U.K. report "Why Mothers Die 2000-2002," hypertensive disease is now the fourth leading cause of direct deaths being surpassed by thromboembolic disease, hemorrhage, and deaths associated with early pregnancy, respectively. The report reiterates that "intra-cranial hemorrhage as the single largest cause of death indicates a failure of effective anti-hypertensive therapy."

Key recommendations from this report advocate the use of written guidelines for severe preeclampsia, effective treatment of severe life-threatening hypertension, and early involvement of senior obstetricians and intensive care specialists in the care of women with severe preeclampsia.[247]

Pathophysiology

Despite intensive research, the precise cause of preeclampsia remains unknown, thus making it "the disease of theories." Preeclampsia may be associated with abnormal placentation and failure of the normal invasion of trophoblast cells, thereby leading to maladaptation of maternal spiral arteries.[248] This aberration can result in abnormal villus development and potentially cause placental insufficiency. It has recently been proposed that the secondary pathology in preeclampsia is also linked to endothelial dysfunction and excessive activation of coagulation. This abnormality is accompanied by high circulating levels of fibronectin and endothelin, increased coagulation and fibrinolysis with increased platelet activation, and platelet consumption.[249] Figure 69-13 compares the balance in the biologic actions of prostacyclin and thromboxane in normal pregnancy with the imbalance of increased thromboxane and decreased prostacyclin in a preeclamptic patient. Based on this proposed mechanism, investigators have focused on various treatments to modulate this imbalance. The Collaborative Low-Dose Aspirin Study in Pregnancy (CLASP) trial involved pregnant women randomized to receive aspirin or placebo. Aspirin was not found to confer significant benefit in reducing the incidence of preeclampsia, but it did appear to delay the onset until a later gestational stage.[250]

Several studies have focused on the possible genetic basis of preeclampsia. It is thought that a single preeclampsia gene is unlikely, but that there are probably many modifier genes in conjunction with environmental factors.[251]

Clinical Features

The upper airway may become edematous in a preeclamptic woman and result in the potential for airway compromise or difficulty in intubation, which may be required for induction of general anesthesia, protection of the airway, or treatment of respiratory distress. Pulmonary edema occurs in up to 3% of these patients.[252] Its etiology is multifactorial, with high left atrial and

Table 69-8 Factors That Differentiate Mild from Severe Preeclampsia*

	Mild	Severe
Systolic arterial pressure	<160 mm Hg	≥160 mm Hg

(*Redrawn from Walsh SW: Preeclampsia: An imbalance in placental prostacyclin and thromboxane production. Am J Obstet Gynecol 152:335, 1985.*)

pulmonary capillary wedge pressure, low plasma colloid and osmotic pressure, and increased capillary permeability often seen.

The cardiovascular effects of preeclampsia may vary. Cotton and colleagues[253] described three subsets of cardiovascular changes in women with severe untreated preeclampsia:

1. Hyperdynamic circulation, high cardiac output, normal to increased systemic vascular resistance (SVR), and normal or slightly decreased blood volume and filling pressures
2. Normal cardiac output and lower filling pressures, but increased SVR
3. Highly elevated SVR, but reduced blood volume and decreased left ventricular function

Figure 69-14 illustrates these hemodynamic subsets in untreated severe preeclampsia.

In preeclampsia, increased uric acid results from decreased renal excretion and reflects tissue ischemia and oxidative stress. Acute renal failure is rare, but it may occur, especially with HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) and placental abruption. Hepatic impairment may also occur, but it is usually associated with HELLP syndrome. Liver rupture is a known, rare complication of preeclampsia. High levels of uric acid, LDH, or aminotransferases can be indicative of severe maternal disease.

HELLP Syndrome

As stated, this condition consists of hemolysis, elevated liver enzymes, and low platelets. Its severity ranges from a mild self-limiting condition to a fulminant process leading to multiorgan failure. Considerable debate, however, has centered around the definition, incidence, etiology, and management of this syndrome. Patients with HELLP syndrome may have various signs and symptoms, none of which is diagnostic and all of which may be found in patients with severe preeclampsia/eclampsia without HELLP syndrome.[254] Sibai, noting the lack of consensus regarding the diagnostic features of HELLP syndrome, recommended the following criteria: hemolysis (defined by an abnormal peripheral blood smear and an increased bilirubin level), increased liver enzymes (defined as an aspartate aminotransferase level ≥70 U/L and LDH >600 U/L), and a low platelet count (<100,000/mm^3).[255]

Assuming no other coagulopathy, hemostasis is typically not problematic unless the platelet count decreases below 40,000/mm^3.[256] The rate of fall in the platelet count is also of clinical significance, and regional anesthesia may be contraindicated if the platelet count has dramatically fallen over a short period. The

Table 69-9 Comparison of Properties of Hydralazine and Labetalol for Treatment of Hypertension

Drug	Hydralazine	Labetalol
Mode of action	Vasodilator	α- and β-blocker (1 : 3)
Speed of onset	Gradual	Quick
Dose	5-10 mg IV slowly	10-20 mg IV slowly
Interval	Repeat after 20 min	Titrate to effect
Infusion rate	2 mg/hr up to 20 mg/hr	20 mg/hr to maximum of 160 mg/hr
Effect on heart rate	Compensatory tachycardia	No effect

platelet count usually returns to normal within 72 hours of delivery, but thrombocytopenia may persist for longer periods.

Once preeclampsia is diagnosed, the goal of therapy is prevention and reduction of further complications by taking into account both maternal and fetal factors. Although the only definitive cure is delivery, management of maternal hemodynamics and prevention of the development of eclampsia are key to a favorable outcome for the mother and infant. There is now international consensus that magnesium is the treatment of choice for preeclampsia to prevent eclampsia, but the mechanism underlying its salutary effect remains debatable. Although magnesium is a direct smooth muscle relaxant at relatively high concentrations, it does not significantly reduce systemic blood pressure at the serum concentrations that are efficacious in treating preeclampsia.[257]

Treatment

The mainstay of therapy in preeclampsia is control of hypertension, prevention of seizures, and delivery of the fetus. Hydralazine and labetalol are commonly used as antihypertensives (Table 69-9). Other agents include nitroglycerin, nifedipine, and esmolol. Sodium nitroprusside may also be used, but only in the short term because of a risk of cyanide toxicity in the fetus.

Magnesium sulfate is the drug of choice for seizure control and prevention of recurrent eclamptic seizures.[258,259] The recently published Magpie trial demonstrated the efficacy of $MgSO_4$ in seizure prophylaxis. It reduced seizures by more than 50% and without any serious maternal morbidity.[260] A beneficial secondary effect in some patients may be vasodilatation and an increase in cardiac output by reducing SVR. Initial dosing is 4 g $MgSO_4$ given intravenously over a 10-minute period, followed by a maintenance infusion at 1 g/hr. In the presence of renal failure, the rate of infusion should be modified by evaluating serum magnesium levels. Magnesium has a narrow therapeutic index, with serum levels between 2 and 3.5 mmol/L being safe and effective. Levels should be monitored in conjunction with clinical signs to observe for toxicity (respiratory depression and reduced or absent tendon reflexes). If toxicity is present, 10 mL of 10% calcium gluconate given by slow intravenous injection should counteract its effects.

Anesthetic Considerations

Anesthetic management of a preeclamptic patient includes a detailed preanesthetic assessment that focuses on the severity of the condition, associated features and systemic involvement, evaluation of the airway, fluid status, and blood pressure control. Investigations should include a complete blood cell count, renal profile, and liver function tests. Routine coagulation screening is not recommended by all authors,[261] but if coagulopathy is suspected clinically, coagulation studies should be performed. However, before considering neuraxial analgesia or anesthesia, a recent platelet count should be evaluated. DIC may require the administration of whole blood, platelets, fresh frozen plasma, and cryoprecipitate. Initiation of neuraxial analgesia during DIC is contraindicated.

Although preeclampsia is accompanied by exaggerated retention of water and sodium, hypovolemia may be present because of a shift of fluids and proteins into the extravascular compartment. An inverse relationship between intravascular volume and the severity of hypertension has been demonstrated, and patients with very elevated diastolic pressure can be expected to have negative central venous pressure readings (Fig. 69-15).

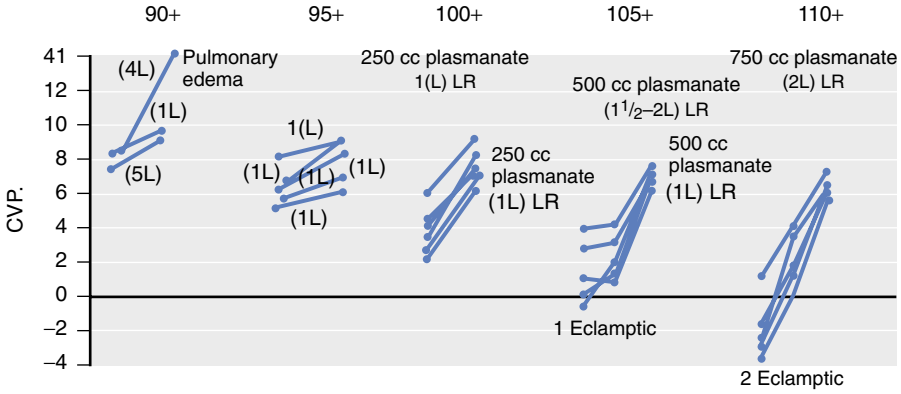

Figure 69-15 Initial central venous pressure (CVP.) readings (three or more recordings of maternal diastolic pressure) and intravascular volume replacement required to attain the range of 6 to 8 cm H_2O in five groups of women with preeclampsia classified according to the severity of the disease (by diastolic blood pressure). LR, lactated Ringer's solution. (*Redrawn from Joyce TH III, Debnath KS, Baker EA: Preeclampsia: Relationship of CVP and epidural analgesia. Anesthesiology 51[Suppl]:294, 1979.*)

Table 69-10 Hemodynamic Variables (Mean and Range) in Preeclamptic Patients and Control Subjects

Variable	Preeclamptic Patients (n = 10)					Control Subjects (n = 4)

From Groenendijk R, Trimbos MJ, Wallenberg HCS: Hemodynamic measurements in pre-eclampsia: Preliminary observations. Am J Obstet Gynecol 150:232, 1984.

Careful intravascular volume expansion may result in improved maternal tissue perfusion. As illustrated in Table 69-10, fluid administration is accompanied by a significant increase in pulmonary capillary wedge pressure and cardiac index and a decrease in SVR and maternal heart rate. In the presence of severe hypertension, central venous pressure may not be an acceptable measurement of right-sided preload.

Debate has been ongoing regarding the use of pulmonary artery catheters, and information about their use in the obstetric population is lacking. In 1997, the Pulmonary Artery Catheter Consensus recommended that the pulmonary artery catheter not be routinely used in the management of preeclampsia because of the lack of evidence supporting its use.[262] However, a retrospective study examining the safety and efficacy of pulmonary artery catheters in the management of severe preeclampsia and eclampsia reported a subjective benefit with their use in 93% of cases with a complication rate of 4%. The most common indications for insertion included renal failure (53%), pulmonary edema (30%), and eclampsia (17%).[263]

Epidural labor analgesia in a preeclamptic patient offers the advantage of a gradual onset of sympathetic blockade; it gives cardiovascular stability and avoids neonatal depression. The reduction in vasospasm and hypertension achieved potentially results in improved uteroplacental blood flow. Regional techniques also reduce the risk of airway complications and avoid the hemodynamic alterations associated with intubation. Ramanathan and coauthors reported the use of a CSE technique using 1.25 mg bupivacaine and 25 µg fentanyl in 39 severe preeclamptic parturients for labor analgesia. All patients had adequate analgesia, with a maximum decrease in mean arterial pressure of 16%. No correlation was found between low mean arterial pressure readings and umbilical artery pH values at birth.[264]

Although some authors have suggested that neuraxial anesthesia not be routinely performed in women with severe preeclampsia,[265] data suggest otherwise. A report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy from the National Heart, Lung, and Blood Institute has stated the following:

Neuraxial (epidural, spinal and combined spinal-epidural) techniques offer many advantages for labor analgesia and can be safely administered to the parturient with preeclampsia. Dilute epidural infusions of local anesthetic plus opioid produce adequate sensory block without motor block or clinically significant sympathectomy. When neuraxial techniques are used for cesarean delivery, however, there is a possibility of extensive sympatholysis with profound hypotension which may lead to decreased cardiac output and further diminished uteroplacental perfusion. This may be more likely with single shot spinal anesthesia, which although considered acceptable by some experts, is still considered by others to be relatively contraindicated for women with severe preeclampsia. A recent retrospective analysis, however, suggests that spinal anesthesia can be safely used in the patient with severe preeclampsia undergoing cesarean delivery because the magnitude of declines in maternal blood pressure after spinal and epidural anesthesia appear to be similar.[266] Newer prospective studies support the use of spinal anesthesia in severe pre-eclampsia demonstrating a lesser degree of hypotension when compared to healthy parturients for cesarean section using spinal anesthesia.[267,268] The incidence of hypotension can be reduced by meticulous attention to anesthetic technique and careful volume expansion. In one unblinded study of 80 women with severe preeclampsia randomly assigned to receive epidural, CSE, or general anesthesia, all three regimens appeared equally safe.[269] With general anesthesia, significant hypertension may occur at the time of laryngoscopy, at tracheal intubation, and again during emergence and extubation period. These responses can usually be blocked by appropriate pre-treatment with hydralazine, nitroglycerin, or labetalol. Remifentanil has also been safely used to modify such pressor responses in pre-eclamptic patients undergoing general anesthesia for cesarean section.[270]

Airway edema may be seen in the patient with preeclampsia and may increase the risks of a difficult airway situation, leading to failed intubation and ventilation. Because general anesthesia poses considerably greater risk to parturients than regional anesthesia, the risk of a failed endotracheal intubation

must be weighed against the risk of transient hypotension when deciding between general and regional anesthesia for cesarean delivery for the patients with severe preeclampsia-eclampsia. Although neuraxial techniques have become the preferred method to provide labor analgesia or anesthesia for cesarean delivery among women with severe preeclampsia-eclampsia, they are relatively contraindicated in the presence of coagulopathy. Early consultation with an anesthesiologist is suggested for parturients with severe preeclampsia.[271]

If general anesthesia becomes necessary in a preeclamptic patient receiving $MgSO_4$ therapy, the activity of succinylcholine will be enhanced; there is also enhanced sensitivity to nondepolarizing muscle relaxants. Magnesium offers another advantage in that it blunts the response to vasoconstrictors and inhibits catecholamine release after sympathetic stimulation.

Obesity (also see Chapter 64)

Obesity is an ever-increasing health problem in today's society. Recent data for the United States include prevalence rates for obesity and morbid obesity in nonpregnant women of childbearing age of 28.9% and 8%, respectively.[272] Both ACOG and the most recent Confidential Enquiries into Maternal Deaths (CEMD) report highlight the added risks of obesity and anesthesia.[247,273] Obesity is associated with comorbidities such as diabetes, hypertension, and obstructive sleep apnea. Obese parturients are at greater risk of developing gestational diabetes, preeclampsia, thromboembolic disease, and wound infections. Obesity is an independent risk factor for cesarean section, adverse neonatal outcome, and surgical and anesthetic risk. Exaggerated physiologic changes of pregnancy such as reduction in FRC, increased gastrointestinal reflux, and more pronounced aortocaval compression will have an impact on anesthesia care. Other factors such as difficult venous access, blood pressure monitoring, positioning of the patient, increased risk of cesarean section, and postpartum hemorrhage must also be considered.

Regional anesthesia techniques may prove difficult owing to inability to identify anatomic landmarks easily, and longer spinal or epidural needles may be necessary. ACOG practice guidelines encourage early placement of neuraxial catheters for high-risk patients (including twin pregnancy, difficult airway or obesity) even before a request for labor analgesia.[273] The presence of a "working catheter" may potentially reduce anesthetic and perinatal complications associated with provision of regional or general anesthesia in an emergency situation. Many obstetric anesthesiologists prefer a continuous spinal analgesia/anesthesia technique in obese patients. This can provide greater predictability and reliability, enabling titratable control of both level and duration of block. The incidence of PDPH is significantly decreased in morbidly obese parturients.[274] This may be due in part to the abdominal panniculus acting as an abdominal binder, elevating intra-abdominal pressures and thus reducing the degree of CSF leakage at the dural puncture site.

Many anesthesiologists use a reduced dose of local anesthetic in obese patients owing to a fear of unpredictable and exaggerated spread leading to possible high spinal block. The rationale for reduced local anesthetic dosing requirements includes a decrease in CSF volume with elevated abdominal pressure, thus decreasing the anesthetic solution. Hogan and associates observed a lower average CSF volume in subjects with higher body mass index.[275] A CSE technique for cesarean section may therefore be preferable over single-shot spinal anesthesia. CSE would allow a lower dose of local anesthetic and yet provide the quality of a spinal block with the flexibility of epidural supplementation of the block.

General anesthesia is associated with increased morbidity and mortality, [203,247] owing to factors such as rapid desaturation, increased risk of regurgitation, difficulty in maintaining mask ventilation, difficult intubation and difficulty in ventilating, intraoperative positioning, and prolonged surgery.

A multidisciplinary approach with effective communication and teamwork between obstetricians and anesthesiologists is vital for the care of obese patients. Early referral for anesthetic evaluation and adequate planning for labor and delivery can contribute to reducing anesthesia-related maternal morbidity and mortality.

Obstetric Hemorrhage

Although most patients tolerate the normal blood loss associated with delivery without hemodynamic consequences, occasionally blood loss may be excessive, leading to maternal and fetal compromise. The most common causes of third-trimester bleeding are abruptio placentae, placenta previa, and uterine rupture. Postpartum hemorrhage, which complicates approximately 10% of deliveries, is most often due to uterine atony, retained placenta, placenta accreta, or uterine inversion.

Placental Abruption

Placental abruption, a partial or complete separation of the placenta before delivery of the fetus, is estimated to occur in 1.3% to 1.6% of pregnancies. Figure 69-16 illustrates placental abrup-

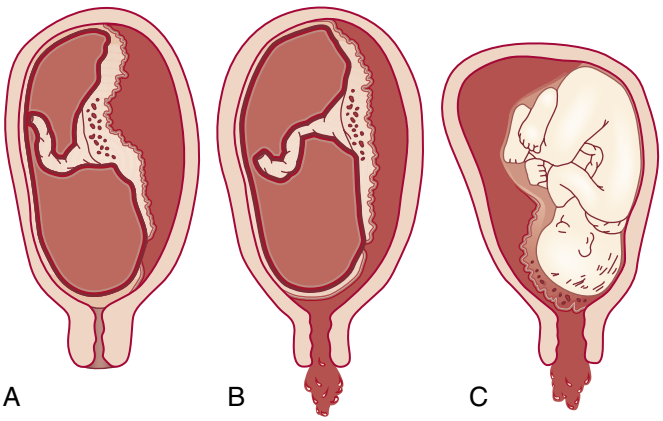

Figure 69-16 Illustration depicting degrees of abruptio placentae. **A,** Concealed hemorrhage. **B,** External hemorrhage. **C,** Complete placental separation. (*Redrawn from Bonica JJ, Johnson WL: Placenta previa, abruptio placentae or rupture of the uterus. In Bonica JJ [ed]: Principles and Practice of Obstetric Analgesia and Anesthesia, vol 2, 1st ed. Philadelphia, FA Davis, 1969, p 1164.*)

tion in its various forms. Certain preexisting conditions such as chronic hypertension, pregnancy-induced hypertension, preeclampsia, maternal cocaine use, excessive alcohol intake, smoking, and a previous history of abruption are all risk factors associated with placental abruption.

Placental abruption may be manifested as vaginal bleeding and uterine tenderness. However, as shown in Figure 69-16, blood loss can often be underestimated because of the potential for substantial hemorrhage concealed behind the placenta. Abruption may be mild, moderate, or severe, depending on the degree of placental separation. DIC may occur with abruptio placentae, and its incidence may be as high as 30% with an abruption large enough to result in fetal death.[276]

Obstetric management depends on the severity of bleeding and fetal status. Large-bore intravenous access should be established on admission and blood samples drawn for baseline hematocrit, coagulation studies, blood typing, and crossmatching. Treatment of associated DIC involves delivery of the fetus and placenta, restoration of maternal blood volume, and correction of coagulation with the use of blood components. Despite the lack of randomized controlled trials of the use of recombinant factor VIIa in uncontrolled obstetric hemorrhage, published reports in the literature supports the growing body of anecdotal evidence of the beneficial role of its use in the treatment of both massive obstetric hemorrhage and amniotic fluid embolism–related coagulopathy.[277] Recent European guidelines stress every attempt should be made to control bleeding by conventional methods, including administration of traditional blood products and correction of factors known to interfere with coagulation. Recombinant factor VIIa should not replace these treatments but should be given as an adjunct in the management of the bleeding patient.[278]

If an operative procedure is considered necessary, general endotracheal anesthesia is preferable to regional anesthesia in women with hemodynamic instability or coagulopathy. Direct arterial blood pressure and central venous pressure monitoring is useful to guide volume resuscitation.

Placenta Previa

Placenta previa occurs when implantation of the placenta is low in the uterus; it is either overlying or encroaching on the cervical os. Placenta previa is present in approximately 0.6% of all pregnancies. It may be categorized as *total* if the placenta completely covers the os, *partial* if there is some encroachment on the os by the placenta, and *marginal* if the placenta is not covering but is close to the internal os (Fig. 69-17). The condition is more common in multiparous women, and it is especially common in women who have had a previous cesarean section. Typically, in contrast with placental abruption, placenta previa is characterized by painless vaginal bleeding in the third trimester. Bleeding may stop spontaneously, in which case conservative management is recommended. However, if bleeding persists, stabilization of the mother and delivery of the fetus may be required.

Placenta Accreta

On occasion, the placenta can be adherent to the implantation site with an absent decidua, an abnormality that produces an absence of the physiologic line of cleavage through the decidual layer. This condition is termed *placenta accreta* and may produce life-threatening challenges. As shown in Figure 69-18, placenta accreta may be classified according to the degree of placental penetration of the myometrium. The condition occurs when the placenta is adherent to the myometrium. Placenta increta occurs when the placenta invades the myometrium. Placenta percreta occurs when the placenta extends through the myometrium and may adhere to surrounding structures. Patients with one or more previous cesarean sections have an increased likelihood of placenta accreta, as highlighted in Figure 69-19. With recent improvements in ultrasonography, it is now possible to diagnose most cases of placenta accreta antenatally.[279] The extent of trophoblast invasion can also be evaluated with magnetic resonance imaging

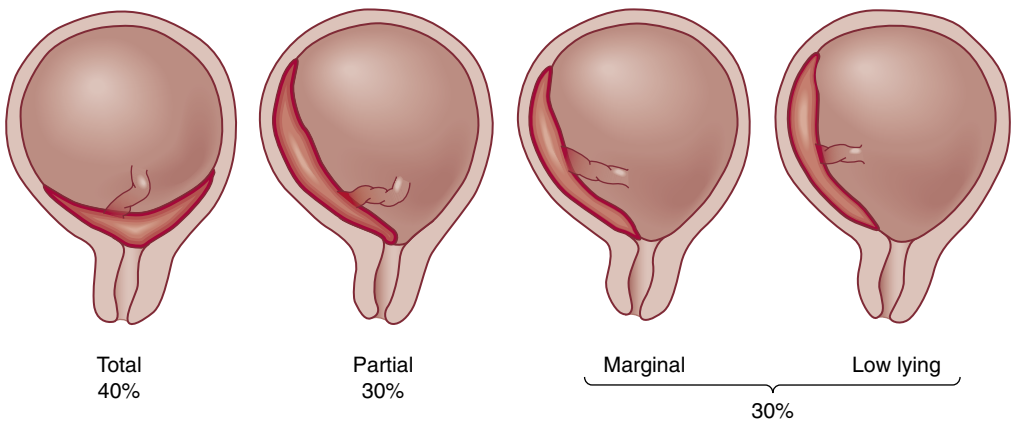

Figure 69-17 Types of placenta previa. (*Redrawn from Suresh MS, Belfort MA: Antepartum hemorrhage. In Datta S [ed]: Anesthetic and Obstetric Management of High Risk Pregnancy, 2nd ed. St. Louis, CV Mosby, 1996, p 93. Illustration copyright 1995. Baylor College of Medicine.*)

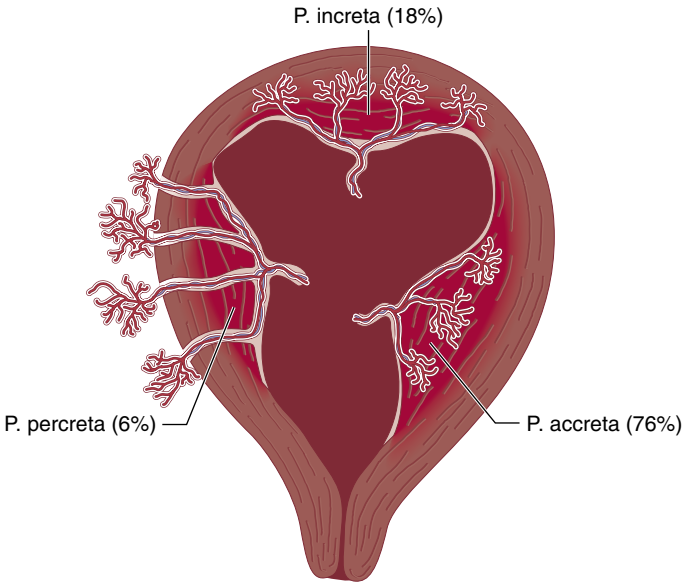

Figure 69-18 Classification of placenta accreta, increta, and percreta. (*From Birnbach DJ, Gatt SP, Datta S [eds]: Textbook of Obstetric Anesthesia. New York, Churchill Livingstone, 2000, p 406. Originally from Kamani AAS, Gambling DR, Christilaw J, et al: Anesthetic management of patients with placenta accreta. Can J Anaesth 34:613, 1987. (MRI).[280] If detected by radiologic studies, techniques such as arterial embolization under radiologic guidance may be used to decrease the extent of bleeding before or during cesarean hysterectomy.[281,282] Although controversy exists with regard to the use of cell salvage techniques during cesarean section, blood loss may be so massive in these cases that the benefits outweigh the potential risks of introduction of amniotic components into the maternal circulation. Two reports have described successful use of the cell salvage technique during cesarean hysterectomy.[283] This technique may also be of benefit to a Jehovah's Witness parturient, in whom a blood transfusion is not an alternative.

Optimal anesthetic management for cesarean hysterectomy is dependent on many factors, including the stability of the patient, the experience of the anesthesiologist, the availability of ancillary services, and patient wishes. In an early report by Chestnut and Redick, 7 of 25 patients undergoing cesarean hysterectomy required general anesthesia. Reasons for the use of general anesthesia included "patient discomfort" and "inadequate operating conditions."[284] A subsequent prospective multi-institutional study evaluated this subject and reported that continuous epidural anesthesia can be used safely for many cases of elective cesarean hysterectomy.[285] Because of the ever-present possibility that conversion to general anesthesia will be necessary, some anesthesiologists prefer to initially use general anesthesia in women with a high risk for placenta accreta. The timing of epidural catheter removal is controversial and warrants caution in cases in which massive hemorrhage and transfusion precipitate DIC.[286]

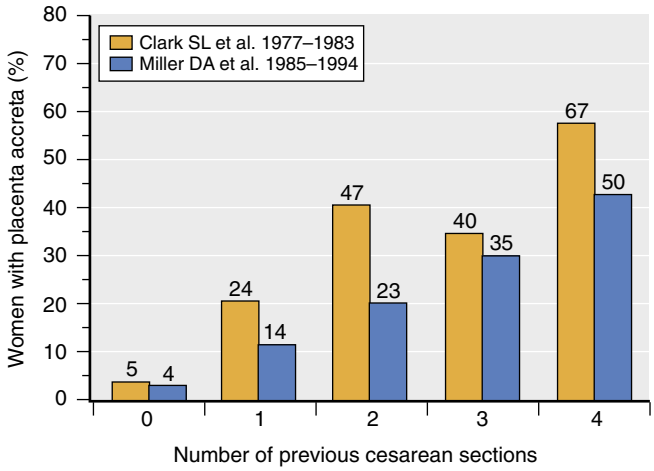

Figure 69-19 Relationship between the number of previous cesarean sections and the incidence of placenta accreta. (*Data from Clark SL, Koonings PP, Phelan JP, et al: Placenta previa/accreta and prior cesarean section. Obstet Gynecol 66:89, 1985; and Miller DA, Chollet JA, Goodwin TM: Clinical risk factors for placenta previa-placenta accreta. Am J Obstet Gynecol 177:210, 1997.*)

Vasa Previa

Vasa previa is an uncommon placental condition that carries with it high fetal mortality.[287] It occurs in pregnancies with a velamentous insertion of the umbilical vessels so that they run through amniotic membranes traversing between the fetal presenting part and the cervical os. These vessels have little support and are very susceptible to trauma during labor. A diagnosis of vasa previa is suspected when vaginal bleeding occurs immediately on rupture of the amniotic membranes and is accompanied by FHR abnormalities. The bleeding in vasa previa is fetal rather than maternal in origin; only a small amount of blood loss may result in fetal demise unless the problem is recognized quickly and an emergency cesarean section can be performed immediately.[288] Because this condition constitutes a true emergency, the fastest anesthetic technique should be used for cesarean section. For most patients (and most anesthesiologists), this would be general anesthesia.

Postpartum Hemorrhage

Postpartum hemorrhage remains a major contributor to maternal morbidity and mortality worldwide. The causes of postpartum hemorrhage can be divided into uterine and nonuterine causes. The most frequent uterine causes are atony and retention of pla-

cental products. Other uterine causes include uterine rupture and uterine inversion. Nonuterine causes include vaginal tears, perineal hematoma, and maternal coagulopathy.

Uterine Atony

Uterine atony is the most common cause of postpartum hemorrhage, and it is caused by ineffective uterine muscle contraction in the postpartum period. Risk factors include prolonged labor, an overdistended uterus (macrosomia or multiple births), infection, grand multiparity, and administration of drugs that relax the uterus (halogenated anesthetics, β-sympathomimetic agonists, and magnesium sulfate). Treatment includes oxytocin; however, boluses of this drug may precipitate hypotension, so continuous infusions are preferable.[289] Carboprost tromethamine (Hemabate), a 15-methyl analog of prostaglandin-$F_2\alpha$, is also a potent uterotonic that can be used. Side effects include nausea, vomiting, and bronchoconstriction. This drug is given intramuscularly either by the anesthesiologist or directly into the uterus by the obstetrician.[290] In addition, the ergot derivatives (ergonovine and methylergonovine) are also potent uterotonic agents that are given intramuscularly. Because profound hypertension may occur, this drug should be avoided in patients with severe hypertensive disease. Surgical compression suturing ("B-Lynch suture") is an important technique for treating postpartum hemorrhage associated with uterine atony and may avoid the need for cesarean hysterectomy.[291]

Other Complications

Umbilical Cord Prolapse

Cord prolapse is rare; it occurs in only 0.4% of cephalic term pregnancies. Abnormal presentations such as a complete breech or transverse lie carry a higher risk with an incidence of up to 6% or greater than 20%, respectively. The diagnosis may be suspected when there is a sudden fall in FHR, especially on rupturing the membranes in a patient with a known abnormal fetal lie or a patient with polyhydramnios. The diagnosis is confirmed by palpation of the umbilical cord on vaginal examination, with or without an associated fetal bradycardia. Management consists of manual replacement of the cord and avoidance of cord compression by the presenting fetal part against the pelvic rim. Urgent cesarean section should be performed. A regional technique may be considered if an epidural catheter is already in situ or if a spinal technique can be expeditiously performed in the lateral position. In the event that fetal compromise is noted, general anesthesia is usually chosen.

Multiple Births

The incidence of multiple gestations has increased with the increasing frequency of assisted reproduction. The frequency of higher-order multiple gestation has also increased significantly. Both perinatal and maternal morbidity and mortality are increased in these patients. These pregnancies are associated with a higher incidence of premature labor and delivery, abnormal presentation, preeclampsia, cord prolapse, need for operative delivery, uterine atony, and postpartum hemorrhage. Many of the maternal physiologic changes of pregnancy are exaggerated, which has significance for the anesthesiologist. FRC is greatly reduced because of the larger uterine size, and the reduced FRC results in a more rapid onset of hypoxemia during apnea or hypoventilation. In addition, aortocaval compression is more dramatic because of greater uterine weight and size. Uterine atony and the risk of postpartum hemorrhage are also greater than in singleton pregnancies. Depending on the fetal presentation, twins may be delivered vaginally; however, most obstetricians require vertex presentation of the presenting twin. If twin B has a nonvertex presentation, the obstetrician will perform either external cephalic version, breech extraction, or cesarean delivery. Epidural analgesia is useful in these situations because it can provide the necessary analgesia and be rapidly converted for use in an urgent cesarean section.

Uterine Rupture

Uterine rupture is a potentially life-threatening complication that is increasing in incidence. It may occur in a previously scarred uterus, or it may result from uterine manipulation, trauma, or overaggressive use of oxytocin. Of note, the incidence of rupture associated with vaginal birth after cesarean section (VBAC) appears to be higher than was once thought. The incidence of uterine rupture in VBAC labor is approximately 1%.[292] Among these ruptures, the rate of serious maternal or fetal morbidity or mortality is 10% to 25%. On the basis of this observation, the ACOG has recommended that for a trial of labor after cesarean section to occur, a physician capable of monitoring labor and performing an emergency cesarean section be immediately available throughout active labor. The ACOG recommendations also dictated that an anesthesiologist be immediately available.[293] The anesthesiologist for patients attempting VBAC should be aware of the signs and symptoms of uterine rupture. Symptoms can be nonspecific, but they almost always include fetal bradycardia. In addition, maternal hypotension along with loss of function of uterine pressure monitors often occurs. Treatment requires emergency laparotomy, and general anesthesia is usually indicated.

Uterine Inversion

Uterine inversion is a rare cause of postpartum hemorrhage in which the uterine fundus inverts through the cervix into the vagina.[294] Hypotension usually results before significant blood loss has occurred. Treatment of uterine inversion should include fluid therapy for the mother and restoration of the uterus to its normal position. Uterine relaxation may be necessary to replace the uterus; β-sympathomimetic agents, magnesium, and nitroglycerin all have been used to achieve this goal. The choice of agent may be dependent on the mother's hemodynamic stability. For example, in the case of profound maternal hypotension, magnesium sulfate may be a better choice than nitroglycerin. Should initial efforts to replace the uterus prove unsuccessful, rapid-sequence induction with cricoid pressure and endotracheal intubation should be undertaken. The use of volatile agents will also cause uterine relaxation, thereby assisting the obstetrician in replacing the uterus.

Anesthesia for Nonobstetric Surgery During Pregnancy

It is estimated that approximately 2% of pregnant women undergo nonobstetric surgery in the United States annually. Most of these

Table 69-11 Most Common Surgical Procedures Performed in Pregnant Women during Each Trimester of Pregnancy

Type of Operation	1st Trimester (%)	2nd Trimester (%)	3rd Trimester (%)
Central nervous system	6.7	5.4	5.6
Ear, nose, throat	7.6	6.4	9.5
Abdominal	19.9	30.1	22.6
Genitourinary-gynecologic	10.6	23.3	24.3
Laparoscopy	34.1	1.5	5.6
Orthopedic	8.9	9.3	13.7
Endoscopy	3.6	11	8.6
Skin	3.8	3.2	4.1

Adapted from Mazze RL, Kallen B: Reproductive outcome after anesthesia and operation during pregnancy: A registry study of 5,405 cases. Am J Obstet Gynecol 161:1178-1185, 1989.

procedures are nonelective and sometimes they are done for life-threatening reasons. Such situations are challenging to both the anesthesiologist and the surgeon. Anesthetic issues to be considered include maternal risk factors resulting from the physiologic and anatomic changes of pregnancy, the teratogenic potential of anesthetic agents, maintenance of adequate uteroplacental blood flow, and the direct and indirect effects of maternally administered agents on the fetus. Surgical management of such patients is also more complicated than in the nonpregnant state. The diagnosis of abdominal pathology is compounded by anatomic displacement of abdominal organs by the gravid uterus. Abdominal tenderness and leukocytosis are often normal findings during pregnancy.

A review of combined data from three Swedish health care registries from 1973 to 1981 by Mazze and Kallen detailed the types and rates of surgery during each trimester.[295] The most common abdominal procedures included appendectomy, cholecystectomy, and adnexal surgery (Table 69-11). Other, less frequent but more challenging situations include laparoscopic surgery, neurosurgery, cardiac surgery requiring cardiopulmonary techniques, and, more recently, fetal surgery.

Specific risks for the mother and fetus undergoing surgery include fetal loss, fetal asphyxia, premature labor, premature rupture of membranes, the potential for failed intubation, and thromboembolic phenomena. Surgery for obstetric indications is associated with a higher risk of perinatal mortality.

Trauma (also see Chapter 72)

Injury related to trauma occurs in up to 6% to 7% of all pregnancies and is perhaps the most common cause of nonobstetric maternal mortality. Motor vehicle accidents are responsible for most injuries, followed by domestic abuse and, to a lesser extent, falls. In contrast with nonpregnant women, abdominal injury during pregnancy is more likely than head injury.[296]

Rapid assessment, hemodynamic stabilization, and treatment of maternal injuries are essential for fetal survival. It is important to remember that the anatomic and physiologic changes associated with pregnancy may cause the clinician to underestimate the true extent of hypovolemia. For instance, shock in a pregnant patient may not be clinically evident until 25% to 30% of maternal blood volume is lost; at this point, the fetus may already be in jeopardy. In hemorrhagic shock, maternal blood is shunted away from the uterus to preserve perfusion to vital maternal organs at the expense of the fetus; such a physiologic response causes fetal hypoxemia and even death.[297]

Regardless of the clinical situation, a preoperative assessment that includes airway evaluation should be performed. The choice of regional or general anesthesia techniques should be based on the clinical status, surgical procedure, experience of the anesthesiologist, and the psychological condition of the patient.

Aspiration prophylaxis should be administered to all pregnant patients beyond 14 weeks' gestation because physiologic changes at the lower esophageal sphincter enhance the risk of aspiration. An H_2 antagonist should be given 1 hour before surgery if possible and a nonparticulate antacid such as sodium citrate given just before induction of anesthesia. Use of a prokinetic agent such as metoclopramide, 10 mg intravenously, may also enhance gastric emptying. It is imperative to position the patient correctly after the second trimester to avoid aortocaval compression by the gravid uterus; correct positioning may be accomplished by placing a wedge under the right hip.

Monitoring of the fetus perioperatively is important, but not always feasible, especially during abdominal surgery. External FHR monitoring is usually possible from 18 weeks onward. Whether intraoperative FHR monitoring can affect fetal outcome remains controversial. A literature review questioned the need to monitor FHR changes during surgery because of the lack of alterations in fetal outcome.[298] However, alterations in FHR may indicate adverse maternal conditions before they become apparent with standard monitoring. Such alterations should therefore encourage evaluation of maternal oxygenation, hemodynamics, acid-base status, and activities at the surgical field for compromise of uterine perfusion. It is advisable to document FHR before and after institution of both regional and general anesthesia and on completion of surgery. The decision to perform fetal monitoring should be individualized and may be based on gestational age, the type of surgery, and the facilities available.

If general anesthesia is necessary, a rapid-sequence technique with adequate preoxygenation, cricoid pressure, and endotracheal intubation should be used to minimize the risk of aspiration for any pregnant woman after 14 to 16 weeks' gestation. Drugs administered should be chosen for their known safety in pregnancy. Such agents include thiopental, depolarizing and nondepolarizing muscle relaxants, opioids (fentanyl, morphine, and meperidine), inhaled agents, and 50:50 O_2/N_2O mixtures. Maternal $Paco_2$ should be maintained in the normal range for pregnancy (30 mm Hg) because maternal hyperventilation may reduce placental blood flow. The patient should not be extubated until awake because there is still a risk of aspiration at the end of the procedure. Uterine activity should be monitored into the postoperative period, and tocolytic drugs may be required.

It has been suggested that nonsteroidal anti-inflammatory drugs should be avoided after the first trimester, because some of

these agents may constrict or close the fetal ductus arteriosus in the later stages of pregnancy.[299]

Cardiac Arrest in Pregnancy

Cardiac arrest in pregnancy is rare and carries a poor prognosis (see Chapter 97). Almost 10% of overall maternal deaths reported in the United Kingdom result from cardiac arrest.[247] Health care workers must be familiar with the physiologic changes of pregnancy that can make the diagnosis and treatment of cardiac arrest difficult in this population. Successful resuscitation of the mother requires prompt and effective CPR with some alterations in basic life support (BLS) and advanced cardiac life support (ACLS) principles. After 20 weeks' gestation, the gravid uterus may compress the inferior vena cava and impede venous return when in the supine position. The effects of aortocaval compression must be minimized by left lateral uterine tilt using manual uterine displacement or insertion of a wedge under the right hip.

Modification of Basic Life Support

Continuous cricoid pressure should be applied during positive-pressure ventilation for any unconscious pregnant patient to minimize the risk of regurgitation. As the diaphragm and abdominal contents are elevated by the gravid uterus, chest compressions should be performed higher than usual, slightly above the midpoint of the sternum.

Defibrillation should be performed as directed by standard ACLS guidelines. There is no evidence that shocks have adverse fetal cardiac effects. Fetal and maternal monitors should be removed before delivering any electric shocks.

Modification of Advanced Cardiovascular Life Support

The airway should be secured as early as possible in a cardiac arrest in order to minimize risk of regurgitation (see also Chapter 97). The airway may be edematous, and a smaller endotracheal tube may be required (0.5-1.0 mm smaller).

Pregnant patients can develop hypoxemia at a quicker rate than nonpregnant women owing to reduced FRC and increased oxygen requirements. The tidal volume of breaths delivered may need to be reduced because of elevation of the diaphragm.

There is a paucity of information in the literature on the use of resuscitative drugs. Current recommendations advise following standard ACLS guidelines regarding drugs and doses.[300]

Differential Diagnosis

One must consider standard causes of cardiac arrest and those specific to pregnancy. These may include amniotic fluid embolism, massive blood loss, complications of preeclampsia, acute coronary syndromes, aortic dissection, life-threatening pulmonary embolism, iatrogenic drug overdose (e.g., magnesium sulfate), or local anesthetic toxicity. Calcium gluconate, 1 g intravenously, is the drug of choice for magnesium toxicity. Cardiac arrest due to local anesthetic toxicity includes standard ACLS measures, and one should consider the use of 20% lipid emulsion therapy.[301]

Perimortem Cesarean Section

The best chance of fetal survival at 24 weeks' gestation and beyond is when delivery occurs no more than 5 minutes after the onset of maternal cardiac arrest. Therefore, the decision to perform an emergency cesarean section must be made early. There is little chance of maternal resuscitation until the uterus is emptied, which will restore venous return and cardiac output. Emptying of the uterus will also improve thoracic compliance and thus ability to improve maternal ventilation.[302]

Laparoscopic Surgery

Case series of successful diagnostic and operative laparoscopic procedures performed during pregnancy have been published (see Chapter 68).[303] A retrospective study of laparoscopic procedures versus open procedures during the first two trimesters of pregnancy demonstrated a significant reduction in opiate requirements and length of stay.[304] Certain physiologic changes of pregnancy may have an impact on anesthetic management during laparoscopic surgery. Mechanical ventilation of a pregnant patient can be difficult because of upward displacement of the diaphragm before abdominal insufflation. Capnography may be used to guide ventilation during CO_2 pneumoperitoneum with no increased risk of respiratory acidosis if the end-tidal CO_2 is maintained at 32 mm Hg.[305] The extent of Trendelenburg positioning may also be limited. Pneumoperitoneum pressure should be limited to 15 mm Hg.[306]

Analgesia for External Cephalic Version

Obstetricians have shown renewed interest in external cephalic version (ECV) in an attempt to decrease the cesarean section rate because of breech presentation. Recent published studies have demonstrated increased success rates for ECV, versus those in matched historical controls, when epidural or CSE analgesia is provided.[307,308] Provision of maternal analgesia with CSE creates a suitable environment for ECV; unlike older regional anesthesia techniques, it limits the use of excessive force by the obstetrician. If a serious complication occurs during ECV, the epidural catheter may be used to provide anesthesia for emergency cesarean section and avoid the complications of general anesthesia.

Fetal Surgery

Advances in prenatal diagnosis with the use of modern technology (ultrasonography, fetal echocardiography, fetal MRI, amniocentesis, umbilical blood sampling, and chorionic villus sampling) and the development of open fetal surgical techniques now permit the treatment of fetal conditions that would otherwise have caused progressive, irreversible damage and possible intrauterine fetal demise if left untreated.[309] Such abnormalities include congenital diaphragmatic hernia, hydronephrosis, twin-twin transfusion syndrome, and hydrothorax.

It is important for the anesthesiologist to understand the fetal lesion and the surgical approach because they determine the type of anesthetic care offered to the mother. Key issues for

the anesthesiologist include maternal safety, uterine relaxation, fetal immobility, and anesthesia. Intensive monitoring of uterine activity and the use of tocolytic agents (e.g., the volatile agents terbutaline and nitroglycerin) are often necessary to prevent the associated high risk of premature labor. The patient has an increased risk of pulmonary edema in the postoperative period as a result of aggressive tocolytic therapy; thus, close attention to fluid balance is warranted.

70 Anesthesia for Orthopedic Surgery

Key Points

1. Older age is a significant risk factor for poor outcome after orthopedic surgery. Elderly patients presenting for orthopedic surgery often have multiple comorbid conditions that must be considered in the perioperative anesthetic plan.
2. Patients with arthritis (osteoarthritis, rheumatoid arthritis, ankylosing spondylitis) have special problems that must be addressed in an anesthetic plan.
3. For many orthopedic procedures, regional anesthesia may reduce perioperative complications compared with general anesthesia, and may provide superior analgesia.
4. Fat embolism syndrome is a well-recognized complication of orthopedic trauma and major joint replacement. Early intervention and stabilization of these patients may avoid significant morbidity.
5. Corrective surgery for spinal deformities (scoliosis, kyphosis, kyphoscoliosis) presents a significant challenge to the anesthesiologist. These patients are at risk for large blood loss, pulmonary complications, neurologic deficits, and postoperative loss of vision. Changes in anesthetic management may reduce the incidence of some of these complications.

Orthopedic patients can be particularly challenging for anesthesiologists. These patients represent a broad scope of problems, ranging from an elderly patient with multiple comorbid conditions to a young, deceptively healthy trauma patient who may have associated injuries that can have a significant impact on the type of anesthetic administered. It is imperative that the anesthesiologist examine the entire patient and not just focus on the area of surgery. In this regard, a complete medical history also is important because it may reveal chronic connective tissue diseases that may alter the anesthetic plan.

The field of orthopedics also is changing in many ways that affect the anesthetic care of these patients. There is increasing demand for joint replacements in the active aging population with the expectation of regional anesthesia, a postoperative pain management plan, and early hospital discharge. More orthopedic procedures are now performed as ambulatory surgery, and the anesthesiologist becomes responsible for which patients can be discharged and how their pain is to be managed. Adult spinal surgery also is dramatically increasing. These procedures can be the most challenging to the anesthesiologist because of difficult airways, hours in the prone position, large blood loss, and significant postoperative pain.

This chapter discusses the perioperative factors that potentially alter outcome after orthopedic surgery. Complications associated with specific procedures are emphasized with regard to recognition of such complications, avoidance when possible, and management. Choice of the best anesthetic based on current evidence for a given orthopedic procedure also is discussed. In many cases, the pros and cons of regional versus general anesthesia are presented, but this chapter does not concentrate on the technical aspects of regional anesthesia. This chapter provides guidance for anesthesia for patients undergoing common orthopedic procedures.

Preoperative Evaluation

All patients presenting for orthopedic surgery warrant a thorough preoperative medical evaluation. Any orthopedic patient could represent an anesthetic challenge. There are specific types of patients, however, who are more likely to have orthopedic surgery and are more likely to have perioperative complications.

Geriatric Orthopedic Patients

The population of the United States older than 65 years in 2006 was 37.3 million (1 in 8 of the population), and at least 16 million of these individuals had "advanced" osteoarthritis (see Chapter 71). In the same year, more than 300,000 hip replacements and 500,000 knee replacements were done. By 2030, the number of U.S. citizens older than 65 years is expected to almost double to 71.5 million (U.S. Department of Health and Human Services,

www.cdc.gov/aging). This means that older patients with multiple comorbid conditions will be having increasingly more orthopedic procedures, including total joint replacements.

Postmenopausal and age-associated osteoporosis affect older individuals, increasing their risk of fractures. Age-associated osteoporosis may be the result of increased circulating parathyroid hormone and decreased vitamin D, growth hormone, and insulin-like growth factors.[1] With osteoporosis, there is a disproportionate loss of trabecular (structural) bone, placing the patient at risk for stress fractures. Although all bones are theoretically at risk, the thoracic and lumbar spine, the proximal femur, the proximal humerus, and the wrist are at the highest risk.[2] Compression fractures of the thoracic and lumbar spine also are common and may require surgical intervention. Osteoporosis also compromises the incidence and quality of postoperative fusions. The National Osteoporosis Foundation recommends measuring bone mineral density in patients at risk and postmenopausal women. Osteoporosis can be treated with increased dietary calcium intake and weight-bearing exercises.

The mortality after hip and knee arthroplasty surgery ranges from 0.4% to 4.6%, depending on primary versus revision replacement.[3-6] The in-hospital mortality after repair of hip fractures is 4.8%, and mortality increases to 30% after the first year following hospitalization. The major risk factor for perioperative mortality in all of these studies was advanced age, and the most frequent perioperative complications involved cardiac problems. In their review of 1636 consecutive hip and knee replacements, Parviz and colleagues[5] reported a 6.4% incidence of serious postoperative complications, with the most frequent complication relating to cardiac problems. The reported incidence of a perioperative myocardial infarction at an orthopedic hospital was 0.6% of all nonambulatory procedures (approximately 8000), and 6.5% of those patients were at risk for myocardial ischemia.[8]

Postoperative Complications

Cardiac Complications. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend preoperative cardiac testing in patients at increased cardiac risk on the basis of clinical risk profile, functional capacity, and type of surgery.[9] The ACC/AHA classifies orthopedic surgery as intermediate-risk surgery, which in most cases involves intermediate-risk patients. Older patients have an increased risk of perioperative myocardial morbidity and mortality after orthopedic surgery (see Chapter 71). The possible reasons for this increased risk are as follows: (1) Many elderly patients have multiple medical comorbid conditions,[10] (2) elderly patients have limited functional capacity, (3) some orthopedic procedures initiate a systemic inflammatory response syndrome, (4) some orthopedic procedures are associated with significant blood loss and fluid shifts, and (5) postoperative pain is a major management problem after orthopedic surgery[11] (see Chapters 55 and 87). All of these factors can trigger a stress response leading to tachycardia, hypertension, increased oxygen demand, and myocardial ischemia.

Because there is a significant incidence of postoperative cardiac complications after orthopedic surgery, and it is difficult to assess the functional status of these patients owing to the limitations imposed by their orthopedic disease, many of these patients are subjected to preoperative cardiac testing. Data for orthopedic surgery showing that preoperative risk stratification or coronary revascularization, or both, has an effect on outcome are limited, however (see Chapters 33 and 34). A report by Salerno and associates[7] suggested that preoperative abnormal noninvasive cardiac testing rarely changed medical management before orthopedic surgery. The Decrease-II study questioned the value of preoperative cardiac testing in patients of intermediate risk before noncardiac surgery.[12] In the CASS registry, Eagle and colleagues[13] reported that coronary artery bypass graft surgery offered no advantage before orthopedic surgery in reducing cardiac mortality. Similar results have been obtained using percutaneous coronary intervention. Postoperative myocardial infarction and death have not been reduced for noncardiac surgery in patients at cardiac risk when preceded by percutaneous coronary intervention.[14,15] In patients in whom percutaneous coronary intervention involved the placement of stents, there are the added risks of restenosis and thrombosis if antiplatelet therapy has to be discontinued before surgery, and increased perioperative bleeding if these medications are not discontinued.[16]

If preoperative cardiac testing and revascularization does not decrease postoperative cardiac morbidity, hemodynamic stress reduction might be the answer. Numerous studies have indicated that the use of perioperative adrenergic β-blockers can reduce myocardial ischemia and postoperative myocardial infarctions.[12,17,18] Several more recent reports have questioned the efficacy of β-blockers in preventing postoperative cardiac complications, particularly in patients at intermediate risk.[19,20] In elderly patients undergoing orthopedic procedures, β-blockers should be continued perioperatively in the patients taking long-term β-blockers and initiated in the patients at the highest risk, with a target heart rate less than 80 beats/min.[17,21]

Orthopedic patients at risk for perioperative cardiac complications should be assessed postoperatively for myocardial ischemia. The diagnosis of a postoperative myocardial infarction is important because these events can be associated with significant cardiac morbidity and mortality if not treated appropriately. In addition, the decision to initiate postoperative physical therapy and rehabilitation, activities that are imperative for optimal mobility in orthopedic patients, depends on whether there has been a diagnosis of a postoperative myocardial infarction. The introduction of plasma cardiac troponin I analysis has markedly increased the ability to detect myocardial damage. Increases in the plasma concentrations of cardiac troponin I are highly specific for cardiac injury and are a more specific marker for a myocardial infarction after orthopedic surgery than the creatine kinase MB isoenzyme.[22,23]

Respiratory Complications. The changes in the respiratory system secondary to age may predispose elderly patients to increased postoperative pulmonary complications. These changes include a progressive decrease in arterial oxygen tension, an increase in closing volumes, and a decrease of approximately 10% in the forced expiratory volume in 1 second with each decade of life. Many of these changes are the result of alterations in chest wall mechanics, which are exacerbated in elderly patients with arthritis. Elderly patients who have sustained hip fracture have significantly lower P_{AO_2} values than other surgical patients of comparable ages.[24] The hypoxia in these patients may reflect the above-noted respiratory changes caused by age, and embolization of bone marrow debris to the lungs in these patients.

Neurologic Complications. After cardiac and pulmonary complications, confusion or delirium is the third most common

complication seen in elderly patients after orthopedic surgery. In 2004, $69 billion from Medicare was spent on the treatment of hospital-acquired delirium. Delirium is associated with an increased length of hospital stay, poor functional recovery, progression to dementia, and increased mortality.[24,25] Postoperative delirium manifests as attention and awareness deficits, including acute confusion, reduced ability to focus, change in cognition, irritability, anxiety, paranoia, and hallucinations. Delirium develops acutely, but generally has a fluctuating course over several days (see Chapter 71).[26] Some patients manifest a hypoactive form of delirium, confused but quiet and nondisruptive, which can be difficult to diagnose. The major risk factors for postoperative delirium are advanced age, alcohol use, preoperative dementia or cognitive impairment, psychotropic medications, and multiple medical comorbid conditions. Perioperative events that may trigger delirium include hypoxemia, hypotension, hypervolemia, abnormal electrolytes, infection, sleep deprivation, pain, and administration of benzodiazepines and anticholinergic medications.

Aging alters the pharmacokinetics and pharmacodynamics of most medications, including anesthetics and analgesics. The "usual" adult doses of these medications may have longer and more profound central nervous system (CNS) effects on elderly patients. Strategies used to reduce the incidence of postoperative delirium include identifying risk factors, and vulnerable and affected patients early; preserving orientation; early mobilization; adequate pain control; maintenance of normal sleep cycles; and avoidance of psychotropic medications.

Fat Embolism Syndrome

Fat embolization is a well-known complication of skeletal trauma and surgery involving instrumentation of the femoral medullary canal.[28] Fat embolism syndrome (FES) is a physiologic response to fat within the systemic circulation. Fat embolization and FES are not synonymous. The embolization of fat can be detected in almost all patients who sustain a pelvic or femoral fracture, but the incidence of FES is less than 1%.

The clinical manifestations of FES include respiratory, neurologic, hematologic, and cutaneous signs and symptoms. The presentation of FES can be gradual, developing over 12 to 72 hours, or fulminant leading to acute respiratory distress and cardiac arrest. Gurd and Wilson[29] in 1974 suggested major and minor criteria to be used for the diagnosis of FES (Table 70-1). The presence of any one major finding plus four minor criteria and evidence of fat macroglobulinemia was required for the diagnosis of FES. The requirement for fat droplets in the circulation has been criticized, however, because fat droplets can be detected in the blood of healthy volunteers, and their presence in trauma patients is not always associated with FES. In addition, Gurd and Wilson[29] recommended the daily assessment of fat droplets in blood, hypothesizing that a change in the quantity of fat would correlate with symptoms. More recent investigations have indicated that the quantity of fat in the circulation does *not* correlate with the severity of FES symptoms or the development of acute respiratory distress syndrome.[30]

A petechial rash is pathognomonic of FES, with the rash usually present on the conjunctiva, oral mucosa, and skin folds of the neck and axillae. This is reflected in the Schonfeld FES index, which ranks signs and symptoms of FES in relation to their incidence of presentation (Table 70-2).[31] Respiratory signs also are common in FES; approximately 75% of patients present with mild hypoxemia and radiologic evidence of bilateral alveolar infiltrates, but less than 10% progress to acute respiratory distress syndrome. Neurologic manifestations of FES range from drowsiness and confusion to obtundation and coma. CNS symptoms have developed in the absence of significant pulmonary complications and may represent the passage of fat droplets across an atrial septal defect or other atrioventricular shunt.[32] Magnetic resonance imaging of the brain of these patients has revealed characteristic lesions of fat embolization (Fig. 70-1).

The pathophysiology of FES is unclear, but it probably involves two processes: the embolization of fat and "bone marrow debris," which can mechanically obstruct the capillaries of end organs, and the triggering of a systemic inflammatory response.[28] Using transesophageal echocardiography during total hip arthroplasty (THA), embolization of bone marrow debris has been detected in the right heart at the time of insertion of the cemented femoral prosthesis (Fig. 70-2).[33,34] In some patients, this embolization resulted in segmental wall motion abnormalities, elevated pulmonary arterial pressures, decreased right ventricular function, and, in one case, cardiac arrest and death.[34,35]

In most cases, the embolic events during THA were clinically benign, but some patients still progressed to FES. The fat

emboli lodged in the microvasculature of the lung and other end organs were metabolized to free fatty acids, which triggered a systemic inflammatory response. This inflammatory response involves the invasion of inflammatory cells, the release of cytokines, and in the lung, pulmonary endothelial damage and acute respiratory distress syndrome.[36]

The treatment of FES is supportive with early resuscitation and stabilization to minimize the stress response to hypoxemia, hypotension, and diminished end-organ perfusion. Patients at risk for developing FES should be monitored with pulse oximetry, and tracheal intubation and mechanical ventilation should be instituted before respiratory failure. Although 10% of patients with FES may require mechanical ventilation, in most of these patients the symptoms resolve within 3 to 7 days. Corticosteroids have been studied extensively in the management of FES, with many investigators reporting beneficial effects, but other reports contradicting these results.[37] Well-controlled studies with defined outcomes are required before corticosteroids can be recommended in the treatment of FES.

Special Considerations in Conditions Leading to Orthopedic Surgery

Osteoarthritis

Approximately 22% of the U.S. population (46 million) have been diagnosed as having arthritis, and 8% (17 million) have limitations in physical activity because of arthritis.[38] Osteoarthritis is the most common type of arthritis and involves the loss of articular cartilage and associated inflammation. In most cases, osteoarthritis is a disease of aging with radiographic evidence in 90% of women and 85% of men of loss of articular cartilage after age 65 years.[39] Clinical manifestations include pain, crepitance, reduced mobility, and deformity of involved joints. Physical examination of the hands may reveal spurring and swelling of the distal interphalangeal joints (Heberden's nodes) and proximal interphalangeal joints (Bouchard's nodes).

Although there are no systemic manifestations of osteoarthritis, the anesthesiologist should be cognizant of previous orthopedic surgeries (including joint replacements) and which joints are painful and have limited mobility. This information is important for surgical positioning and the choice of an appropriate anesthetic. An axillary block of the brachial plexus for forearm

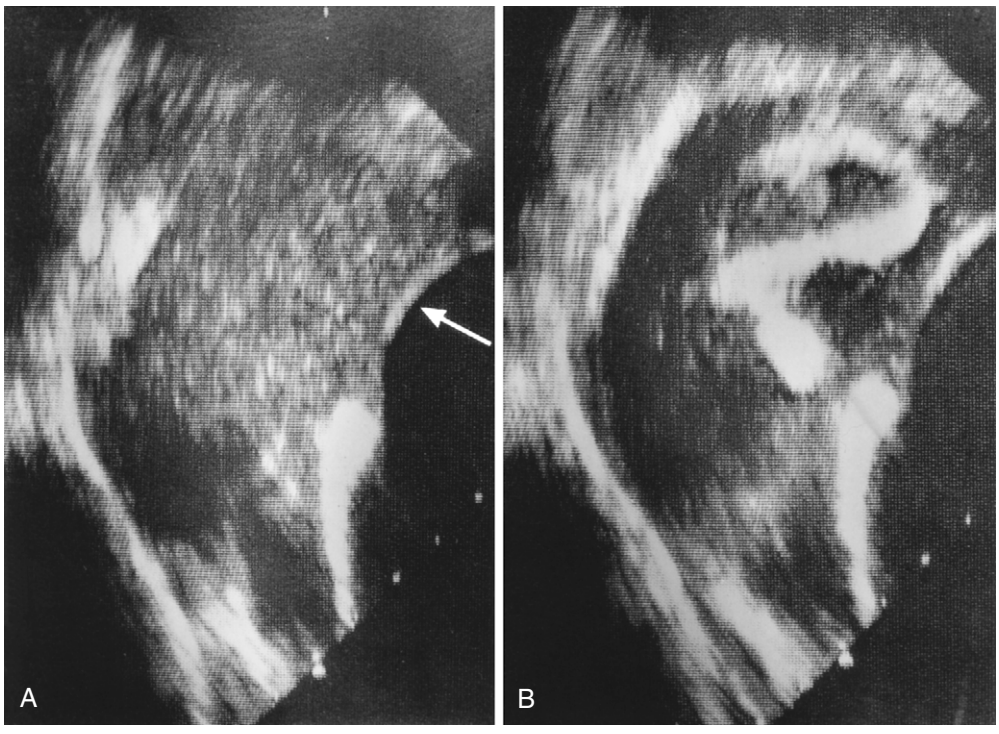

Figure 70-2 Right atrium during echocardiography. **A,** Multiple, small emboli (*arrow*) in the right atrium. **B,** Large embolus (7 cm long), which is probably a cast of the femoral vein. *(Adapted from Christie J, Burnett R, Potts HR, et al: Echocardiography of transatrial embolism during cemented and uncemented hemiarthroplasty of the hip. J Bone Joint Surg Br 76:409-412, 1994.)*

surgery is inappropriate in a patient with significant ipsilateral shoulder arthritis. Although the operative site would be completely anesthetized, the patient may complain of painful shoulder movement during the procedure. The appropriate regional anesthetic would include the arthritic shoulder; an appropriate anesthetic might be an interscalene block.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory form of arthritis, which affects about 1% of adults, with a prevalence two to three times higher in women than in men. RA is characterized by persistent joint synovial tissue inflammation leading to bone erosion, destruction of cartilage, and loss of joint integrity. RA also is a systemic disease, affecting multiple organ systems.[40] It often progresses through multiple exacerbations and remissions, but 20% to 30% of affected individuals become permanently disabled within 3 years of diagnosis.

The diagnosis of RA is primarily clinical. Patients commonly present with pain and stiffness in multiple joints. RA is characterized by morning stiffness often lasting more than 1 hour after initiating activity. Usually the wrists and metacarpophalangeal joints are involved; this distinguishes RA from osteoarthritis, which often affects distal interphalangeal joints. The symptoms may emerge over weeks and months, progressing from one joint to multiple joints, and may be accompanied by symptoms of anorexia, fatigue, and weakness. The rheumatoid joints are usually boggy, tender to the touch, and warm. Patients may have prominent epitrochlear, axillary, and cervical lymph node enlargement. Subcutaneous nodules (rheumatoid nodules) may surround joints, extensor surfaces, and bony prominences.

No single diagnostic laboratory test confirms the diagnosis of RA, but rheumatoid factor, an anti-immunoglobulin antibody, is elevated in 90% of patients with RA. In addition, C-reactive protein and erythrocyte sedimentation rate are elevated in patients with RA and are often used to monitor the course of the disease. RA also must be differentiated from other diseases that manifest as polyarthropathies, including seronegative spondylarthropathies, connective tissue diseases (scleroderma, lupus), fibromyalgia, hemochromatosis, polyarticular gout, polymyalgia rheumatica, and sarcoidosis.

Because joint destruction begins early with RA, disease-modifying antirheumatic drugs should be initiated immediately with the therapeutic goal of preservation of function and qualify of life. The most commonly used disease-modifying antirheumatic drugs include methotrexate, hydroxychloroquine, sulfasalazine, leflunomide, infliximab (Remicade), and etanercept (Enbrel). All of these medications are associated with an increased risk of infection, which is a significant concern in patients with joint replacements. Pharmacotherapy also usually involves a nonsteroidal anti-inflammatory drug (NSAID) and oral or intra-articular glucocorticoids. RA patients taking NSAIDs should be assessed for gastrointestinal side effects and renal complications. Glucocorticoids, although highly effective at relieving symptoms, should be used at low doses and sparingly because of their side effects, which include osteoporosis, cataracts, cushingoid symptoms, and hyperglycemia. Patients taking significant quantities of glucocorticoids need stress-dose steroids for their operations.

Because of the myriad systemic problems associated with RA and the side effects of the medications administered to manage RA, the anesthetic considerations can be complex (Table 70-3). Airway management can be particularly challenging in RA patients and requires pre-planning even in patients receiving regional anesthesia because of the complexity of their airways (see later). Synovitis of the temporomandibular joint may significantly limit mandibular motion and mouth opening in these patients. Arthritic damage to the cricoarytenoid joints may result in diminished movement of the vocal cords, resulting in a narrowed glottic opening; this is manifested preoperatively as hoarseness and stridor. During laryngoscopy, the vocal cords may appear erythematous and edematous, and the reduced glottic opening may interfere with passage of the endotracheal tube.[41] There also is an increased risk of cricoarytenoid dislocation with traumatic endotracheal intubations.

Table 70-3 Anesthetic Considerations for Patients with Rheumatoid Arthritis

Airway	Limited TMJ movement Narrow glottic opening
Cervical spine	Atlantoaxial instability
Cardiac	Pericarditis Cardiac tamponade
Eyes	Sjögren's syndrome
Gastrointestinal	Gastric ulcers secondary to ASA, steroids
Pulmonary	Diffuse interstitial fibrosis
Renal	Renal insufficiency secondary to NSAIDs

ASA, acetylsalicylic acid; NSAIDs, nonsteroidal anti-inflammatory drugs; TMJ, temporomandibular joint.

Arthritis of the cervical spine is common in patients with RA. Anterior subluxation of C1 on C2 (atlantoaxial subluxation) may occur in 40% of patients with RA, with symptoms of progressive neck pain, headaches, and myelopathy (Fig. 70-3). Posterior and vertical migration of the odontoid process is less common. Flexion of the head in the presence of atlantoaxial instability could result in the displacement of the odontoid process into the cervical spine and medulla and compression of the vertebral arteries (Fig. 70-4). This may precipitate quadriparesis, spinal shock, and death. Preoperative cervical flexion-extension radiographs should be evaluated in RA patients with limited neck movement and neurologic symptoms. If the distance from the anterior arch of the atlas to the odontoid process exceeds 3 mm, the patient should undergo an awake fiberoptic tracheal intubation, and the cervical spine should be protected with a cervical collar during the procedure. These patients require postoperative monitoring with pulse oximetry and judicious administration of narcotic analgesics because emergent airway management, including tracheotomy, is extremely difficult.

The anesthesiologist also should be aware of several extra-articular manifestations of RA, which could potentially result in significant perioperative morbidity. RA patients frequently are affected with acute pericarditis. Restrictive pericarditis is characterized by dyspnea, right heart failure, fever, chest pain, pericardial friction rub, and pulsus paradoxus. RA patients with these symptoms should be evaluated by echocardiography. Pleural disease and intrapulmonary nodules can occur in RA, but are usually symptomatic. Some RA patients may have diffuse interstitial fibrosis with pneumonitis, producing symptoms of progressive dyspnea and a chronic cough. Pulmonary function tests show a restrictive ventilatory pattern. This pattern can progress to respiratory insufficiency, pulmonary hypertension, and right heart

Figure 70-3 MR image of a patient with advanced rheumatoid arthritis shows invagination of the odontoid process of C2 (*arrow*) through the foramen magnum, compressing the brainstem. Notice the degeneration of C4 and C5, a common problem in rheumatoid arthritis.

failure. These patients would be at higher risk for any orthopedic procedure.

Overlapping connective tissue syndromes also occur. RA patients can develop Sjögren's syndrome, which is associated with drying of the eyes and with corneal and conjunctival lesions. It is usually treated with artificial tears and ophthalmic ointments, which should be continued perioperatively. RA patients with chronic constitutional systems may develop Felty's syndrome, which includes splenomegaly, lymphadenopathy, anemia, thrombocytopenia, and leukopenia involving the neutrophils.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic inflammatory arthritic disease that results in fusion of the axial skeleton. Ankylosing spondylitis involves ossification of the axial ligaments progressing from the sacral lumbar region cranially, resulting in a significant loss of spinal mobility (Fig. 70-5). These patients are a significant challenge to the anesthesiologist with regard to airway management because of the reduced movement of their cervical spines and their temporomandibular joints. In most cases, awake fiberoptic endotracheal intubation is required for general anesthesia. The increased rigidity of the thoracic spine in most cases also necessitates intraoperative controlled mechanical ventilation. Although sometimes neuraxial anesthesia can be an attractive alternative to general anesthesia, in these patients, the ossification of the spinal ligaments closes the intervertebral spaces, which may block access to the epidural space and prevent successful spinal anesthesia. In some cases, caudal epidural anesthesia may be a feasible alternative approach.

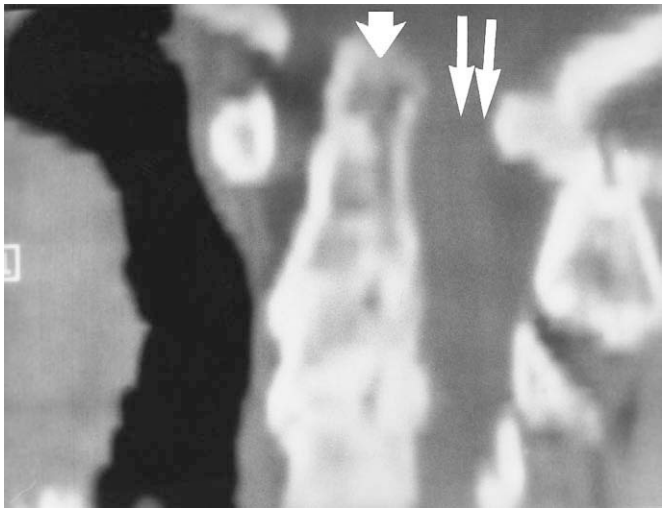

Figure 70-4 CT scan of the neck shows moderate subluxation of C1 and C2. The odontoid (*single arrow*) tends to compress the spinal cord (*double arrow*) against the posterior arch of C1, especially during neck flexion.

Extraskeletal manifestations of ankylosing spondylitis include aortic insufficiency, cardiac conduction abnormalities, iritis, upper lobe fibrobullous disease, and pleural effusions. Strict attention to intraoperative positioning is needed to avoid fracture of the fused spine with concomitant spinal cord trauma.

Achondroplasia

Achondroplasia is the most common cause of dwarfism, with short stature, short trunk, and disproportionate development. The estimated incidence is 1 in 26,000. Achondroplasia is transmitted by an autosomal dominant gene. Affected individuals are of normal intelligence and can lead a full and productive life. Their associated medical problems often require orthopedic surgical intervention, however, with the risk of perioperative complications.[42-44] The most serious complication of achondroplasia is premature fusion of the base of the skull resulting in a narrowed cervical canal or foramen magnum stenosis or both. Kyphoscoliosis with potential neurologic symptoms is another common complication associated with this genetic condition. These affected

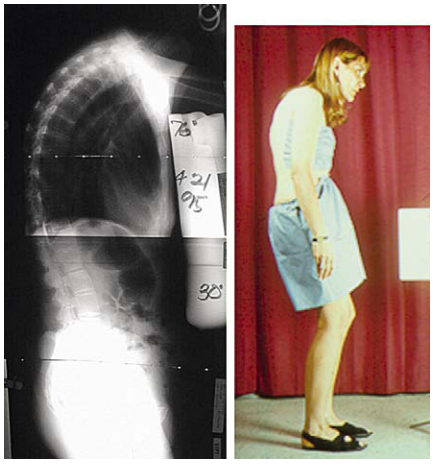

Figure 70-5 Patient with ankylosing spondylitis, exhibiting significant kyphosis of the spine. Note significant kyphosis in the lateral x-ray.

individuals undergo numerous orthopedic (spinal) procedures, including suboccipital craniotomy for foramen magnum stenosis, correction or stabilization of kyphoscoliosis, and laminectomies for spinal nerve root compressions.

Conventional laryngoscopy and tracheal intubation can be difficult and dangerous in achondroplastic dwarfs. Laryngeal exposure via direct visualization may be difficult in dwarfs with cervical kyphosis, and neck flexion should be avoided in dwarfs with atlantoaxial instability or foramen magnum stenosis. Awake fiberoptic tracheal intubation is the safest approach to securing the airway in these patients. Intravenous sedation should be administered judiciously during the preparation of the airway because many of these patients experience central sleep apnea owing to brainstem compression. Severe episodes of sleep apnea also can occur in these patients without any other clinical evidence of cord compression.

When the airway is secured, dwarfs can still represent an anesthetic challenge because of restrictive lung disease and pulmonary hypertension. Pulmonary hypertension develops from chronic hypoxemia and hypercarbia secondary to airway obstruction, sleep apnea, and thoracic kyphoscoliosis. Preoperative spirometry can be difficult to interpret in a dwarf, with successive changes in measurements more useful than absolute values.[45] An echocardiogram should be obtained before major surgery to assess the degree of pulmonary hypertension and intracardiac shunts. Pulmonary hypertension leading to cor pulmonale is the most common and devastating cardiovascular complication that develops in dwarfs. In these patients, the anesthetic must avoid aggravating pulmonary hypertension (hypoxemia and acidosis) and ensure adequate cardiac output and end-organ perfusion. In many cases, it is safer to allow the patient to remain intubated and monitored in the intensive care unit (ICU) until fully awake and spontaneously ventilating.

Orthopedic Procedures in Children with Special Conditions

The anesthetic management of pediatric patients undergoing orthopedic surgery is beyond the scope of this chapter (see Chapters 81 and 82). In most cases, care of pediatric patients would be similar as for other surgical procedures except that in many cases regional anesthesia might be a preferred alternative to general anesthesia. There are, however, a few pediatric diseases that predispose children to multiple orthopedic procedures.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is inflammation of the synovium of the joints that occurs before 16 years of age. JIA is classified into five types, as follows: (1) Oligoarthritis accounts for 50% of JIA and involves fewer than five joints; often these patients also have uveitis. (2) Polyarthritis involves arthritis in five or more joints. (3) Systemic arthritis accounts for 10% to 20% of JIA and is characterized by associated high fevers, rash, and nonarticular organ involvement. (4) Enthesitis-related arthritis affects the spine, hips, and attachment points of tendons to bones. (5) Psoriatic arthritis includes psoriasis and arthritis.

As in adult RA, the disease is chronic with quiescent periods interspersed with acute exacerbations. Also as in adult RA, airway issues can make tracheal intubation difficult and potentially dangerous. In most cases, fiberoptic intubation should be performed, and this can be done after the child has been anesthetized and is breathing spontaneously. Muscle relaxants should be reserved until the airway is secured. In contrast to adult RA, pulmonary disease is uncommon, but JIA patients can have associated pleuritis, pleural effusions, and pneumonitis. Pericarditis is common in patients with JIA, and it responds to steroid therapy. Some JIA patients also have myocarditis and conducting system abnormalities. In addition, vascular access in JIA patients can be extremely difficult because of fragile veins and a tendency to bruise and bleed easily. As with adult RA, JIA patients are managed with similar groups of medications with similar potential complications.

Osteogenesis Imperfecta

Osteogenesis imperfecta is a rare autosomal dominant inherited disease that results in extremely brittle bones because of a defect or deficiency in type I collagen production.[46,47] Repeated and multiple bone fractures are the most significant clinical manifestation of this disease (Table 70-4). In the most extreme form, multiple fractures occur during delivery, which are often fatal. In the milder variations, the individual is affected by multiple fractures produced with seemingly inconsequential force or trauma. Fractures are more common in the lower extremity, with the femur being the most commonly broken bone. Fracture deformities of the pelvis can lead to acetabular protrusions into the abdomen. Kyphoscoliosis is common secondary to decreased ligamentous stability. Affected children usually have a blue sclera because of defective collagen production. Impaired platelet function with increased perioperative bleeding also occurs.

Although osteogenesis imperfecta has been associated with malignant hyperthermia, this has not been verified by muscle biopsy (see Chapter 37).[48] Hyperthermia and metabolic acidosis can, however, be common intraoperative clinical manifestations of osteogenesis imperfecta. Associated cardiac abnormalities include patent ductus arteriosus, septal defects, and acquired aortic regurgitation and cystic degeneration of the proximal aorta (see Chapters 82 and 83).

The fragility of connective tissue and bones in osteogenesis imperfecta demands extreme care in positioning and padding during anesthesia. The area under the blood pressure cuff must be padded, and for longer procedures insertion of an arterial catheter avoids the repeated inflation of the cuff and the risk of a

Table 70-4 Anesthetic Considerations for Patients with Osteogenesis Imperfecta

Airway	Risk of fractures of the mandible, maxillary surface, and cervical spine
Bleeding	Platelet abnormalities
Cardiac	Congenital and valvular heart disease; cystic degeneration of proximal aorta
Eyes	Exophthalmos—prone positioning
Hyperthermia	Malignant hyperthermia; hydration; possible cooling
Positioning	Risk of repeated fractures
Pulmonary	Kyphoscoliosis—restrictive lung disease
Regional anesthesia	Fractures; intraosseous injections

humeral fracture. Because patients with osteogenesis imperfecta often have reduced mobility of the cervical spine, tracheal intubation must be achieved with minimal neck manipulation. Awake fiberoptic intubation in many cases would be the prudent approach. The administration of succinylcholine should be avoided for the induction of anesthesia because of the theoretical risk of malignant hyperthermia, and because muscle fasciculations may produce bony fractures. Osteogenesis imperfecta patients should have a preoperative echocardiogram and any abnormal findings should be managed accordingly.

The bleeding status of patients with osteogenesis imperfecta should be evaluated preoperatively to prepare for the perioperative transfusion of platelets. In some cases, desmopressin (DDAVP) may reverse the platelet abnormality. Because there is a risk of intraoperative hyperthermia and metabolic acidosis, osteogenesis imperfecta patients should be aggressively hydrated, and if necessary active cooling should be instituted. Regional anesthesia is an attractive alternative to general anesthesia, but must be approached with caution to avoid bone punctures and intraosseous injections (see Chapters 52 and 53).

Cerebral Palsy

Cerebral palsy is a nonprogressive motor impairment arising from lesions in the brain that occurred during the early stages of development—in utero (75%), at birth (10%), and soon after birth (15%) (see Chapter 82). The cause of cerebral palsy remains unclear; however, intrapartum asphyxia, which was originally thought to be the major etiology of the disease, may be responsible for only 10% of the cases. Perioperative infections and low birth weight may play a much more important role. Cerebral palsy is divided into four major classifications to describe the different movement impairments: spastic, athetoid/dyskinetic, ataxic, and mixed. Spastic cerebral palsy, which is the most common type, results from damage to the corticospinal tract, motor cortex, or pyramidal tract. Many of these affected children also have epilepsy and cognitive disorders.[49]

Although the neurologic deficit in cerebral palsy is nonprogressive, the secondary orthopedic consequences of the disease lead these patients to multiple surgical procedures. Normal skeletal developmental requires stress from the musculature to attain their proper shape and size. Without these stresses or with abnormal stresses as in cerebral palsy, various angular joint deformities and gracile (thin) shafts and abnormal articular joints develop. Orthopedic surgeries often involve loosening of tight muscles (hip adductor and iliopsoas release), releasing fixed joints, straightening abnormal twists (derotational osteotomy of the femur), rhizotomies to reduce spasm, and spinal surgery to correct kyphoscoliosis.

Cerebral palsy patients have significant gastroesophageal reflux and poor laryngeal reflexes. In most cases, surgical procedures on cerebral palsy patients require general anesthesia with tracheal intubation, even if also accompanied by regional anesthesia to reduce the need for systemic anesthetics and to provide postoperative analgesia. Postoperative epidural analgesia with local anesthetic alone eliminates the potential complications of narcotics, and permits continued dosing with diazepam to relieve spasms. Regional anesthesia also may shorten emergence from general anesthesia, which can be prolonged because of inherent cerebral damage and the effects of antiseizure medications. Postoperative pulmonary complications are common owing to multiple causes, including aspiration, poor respiratory effort, and thoracic compliance. After major surgical procedures, cerebral palsy patients should be observed in a monitored setting for several hours.

Regional Versus General Anesthesia

Many orthopedic procedures are well suited for regional anesthetic techniques (see Chapters 52 and 81). The controversy as to whether regional anesthesia has an advantage over general anesthesia has been debated for decades without clear evidence documenting superiority of one method. Regional anesthesia may reduce the incidence of major perioperative complications with certain surgical procedures, however, including deep vein thrombosis (DVT), pulmonary embolism (PE), blood loss, respiratory complications, and death.[50,51] In addition, postoperative pain management, a significant problem after orthopedic procedures with regional anesthetic techniques, leads to superior pain relief.[52] Peripheral nerve blocks employing long-acting anesthetics or catheters may provide excellent intraoperative anesthesia and superior postoperative analgesia.[53,54] Regional anesthesia may provide preemptive analgesia. In addition, severe acute pain after orthopedic surgery can develop into a chronic pain syndrome, which may be ameliorated by aggressive perioperative analgesia.[55]

As stated earlier, orthopedic patients often pose difficult airway management problems. Regional anesthesia avoids manipulation of the airway, and conscious patients can aid in the safest and most comfortable positioning for surgery. It is prudent, however, to recognize the warnings of Benumof: "Use of regional anesthesia in the patient with a recognized difficult airway does not solve the problem of the difficult airway; it is still there."[56] A well-defined plan must be devised for these patients for management of the airway in the event of a regional anesthetic failure or the need to secure the airway during an emergency.

A further advantage to the use of regional anesthetic techniques for orthopedic surgery has been the suggestion of decreased intraoperative blood loss. Since 1966, 17 randomized trials of patients undergoing THA have shown diminished blood loss with regional anesthesia compared with the same procedure performed under general anesthesia.[57] Modig[58] compared blood loss in THA patients randomly assigned to epidural anesthesia, general anesthesia with spontaneous ventilation, and general anesthesia with positive-pressure ventilation. The epidural group showed the smallest blood loss, but no significant relationship between arterial blood pressure and blood loss. The authors suggested that epidural anesthesia reduces venous blood pressure (measured in the operative wound), and this is the significant factor in determining surgical bleeding.

Perioperative Management of Orthopedic Patients

Thromboprophylaxis in Orthopedic Surgery

Thromboembolic complications remain one of the leading causes of morbidity and mortality after orthopedic surgery.[59,60] THA,

total knee arthroplasty (TKA), and hip and pelvic fracture surgery have the highest incidence of venous thromboembolism, including DVT and PE. Patients with DVT and PE are at risk for short-term and long-term morbidity and mortality. Patients with symptomatic PE have an 18-fold higher risk of death than patients with a DVT alone. The short-term complications of survivors of acute DVT and PE include prolonged hospitalization, bleeding complications related to DVT and PE treatments, local extension of DVT, and further embolization. Long-term complications include post-thrombotic syndrome, pulmonary hypertension, and recurrent DVT.

Because venous thrombi consist of fibrin polymers, anticoagulants should be administered for the prevention and treatment of DVT. Thrombolytics should be administered only in the event of a severe, possibly fatal PE. Treatment guidelines are based on the Seventh American College of Chest Physicians Conference document on DVT and PE.[61] Low-molecular-weight heparin (LMWH) is recommended over unfractionated heparin (intravenous or subcutaneous) for initial therapy of DVT and PE. LMWHs do not require monitoring of coagulation. Although DVT prophylaxis may be more efficient when started preoperatively, the risk of surgical bleeding also increases. Administration of LMWH 6 hours postoperatively was effective in DVT prophylaxis and did not increase bleeding; delaying prophylaxis until 24 hours was less effective.[62] Although the optimal duration of therapy is unknown, LMWH should be continued for at least 10 days in routine orthopedic procedures and in patients not considered high risk. Extended prophylaxis to 28 to 35 days would be supported in patients with evidence of a DVT or at higher risk for DVT. Risk factors for the development of PE after surgery are advanced age, obesity, previous PE and DVT, cancer, and prolonged bed rest. Factor V Leiden is the most common hereditary blood disorder associated with DVT. Warfarin is usually employed in the long-term treatment of DVT, with a target international normalized ratio (INR) of 2.5 maintained for the duration of therapy. In the United States, LMWH (enoxaparin) is administered at 30 mg every 12 hours; in Europe, it is administered at 40 mg daily. An alternative to LMWH is fondaparinux, a synthetic pentasaccharide that is a selective inhibitor of factor Xa and has a prolonged half-life of 18 hours. When administered once daily, fondaparinux produces a predictable anticoagulant response.[63] The American College of Chest Physicians guidelines do not recommend the sole use of aspirin for DVT prophylaxis after THA, TKA, and hip fracture surgery. More recent reports, however, have supported the use of aspirin, pneumatic compression, and early mobilization as effective prophylaxis for DVT after THA and TKA.[64]

The use of perioperative anticoagulants has a significant impact on the use of regional anesthesia, in particular neuraxial anesthesia with the potential risk of an epidural hematoma. The American Society of Regional Anesthesia (ASRA) has published and updated consensus conference recommendations with regard to the use of anticoagulants and regional anesthesia.[65] Full anticoagulation is a contraindication to regional techniques. The risk of an epidural hematoma is significantly increased with the use of LMWH, so the following recommendations have been made:

1. An interval of 12 hours should be observed after administration of the usual dose of LMWH and placement of a neuraxial block.
2. In patients receiving larger doses of LMWH (enoxaparin 1 mg/kg every 12 hours), the delay should be extended to 24 hours.
3. Epidural catheter removal should occur at least 8 to 12 hours after the last LMWH administration, or 1 to 2 hours before the next administration of LMWH.

Aspirin and NSAIDs do not seem to increase the risk of an epidural hematoma after neuraxial anesthesia. The American Society of Regional Anesthesia also recommends that for patients receiving warfarin, the prothrombin time and INR should be checked before neuraxial anesthesia, and an epidural catheter should not be removed if the INR is greater than 1.5. In a retrospective review of more than 12,000 TKAs in which warfarin was administered postoperatively, and an epidural catheter was maintained for analgesia, there were no reported epidural hematomas despite patients having an INR greater than 1.5.[66]

Lower Extremity Surgery

Arthroscopy

Arthroscopic procedures for the knee, hip, and ankle are increasingly performed as ambulatory procedures (see Chapter 78). These cases can be particularly challenging for the anesthesiologist who must decide on the appropriateness of the patient and procedure for outpatient surgery and an anesthetic that is adequate for the procedure, but provides the patient's expectation of an uncomplicated postoperative recovery with minimal pain.

Limited data are available to determine which patients are inappropriate adult ambulatory patients. In most centers, morbidly obese patients and patients with sleep apnea require monitored observation overnight after procedures in which systemic anesthetics and analgesics have been administered. The presence of stable preexisting diseases does not increase the incidence of postoperative complications in ambulatory patients, but American Society of Anesthesiologists grade 3 and 4 patients should have a medical clearance that documents the stability of their medical conditions. It follows then that medically unstable patients are not outpatient surgical candidates.

In a prospective study of 1088 patients for ambulatory surgery, Pavlin and coworkers[67] reported that the most important factors in determining discharge time were pain, nausea and vomiting, unresolved neuraxial blocks, and urinary retention. This study emphasizes the role of anesthesia in prolonging ambulatory surgical stay. General anesthesia is a safe and effective anesthetic for arthroscopic surgery, but it has been associated with increased postoperative nausea and vomiting and pain. A properly designed regional anesthetic may reduce the importance of some of these factors.

Arthroscopic knee surgery can be performed with a combination of extra-articular and intra-articular injections of local anesthetics. Short-duration local anesthetics are often combined with longer acting local anesthetics (bupivacaine) and morphine to provide postoperative analgesia. Intra-articular morphine probably does provide significantly additional analgesia after arthroscopic knee surgery. For more involved arthroscopic procedures, such as an anterior cruciate ligament repair, surgical relaxation is also required. Spinal anesthesia with pencil-point

atraumatic needles to prevent postdural puncture headaches provides excellent operating conditions for these procedures.

Problems related to neuraxial anesthesia for ambulatory surgery include unpredictable onset and regression of the spinal blockade, urinary retention, and transient neurologic symptoms. A dose of 45 mg of isobaric spinal mepivacaine results in a mean motor block of 142 ± 37 minutes. Using 30 to 40 mg of spinal chloroprocaine, Yoos and Kopacz[68] reported 155 ± 34 minutes to ambulation in outpatient surgical patients. Transient neurologic symptoms (TNS) are symptoms of pain in the gluteal region that can radiate down both legs and appear within a few hours to 24 hours after an uneventful spinal anesthetic.[69,70] The incidence of TNS is more frequent after outpatient surgery in the lithotomy position and in patients undergoing knee arthroscopy. The pain can vary from mild to severe, lasts 2 to 5 days, and is best treated with NSAIDs. TNS is more common after a spinal anesthetic with lidocaine (approximately 14%) than with mepivacaine (6.5%) and bupivacaine (<1%). For ambulatory patients, the benefit of short-acting spinal anesthetic must be weighed against the risk of developing transient neurologic symptoms. For postoperative analgesia after anterior cruciate ligament repairs, a femoral nerve block with a long-acting local anesthetic is superior to intra-articular injections. Because the quadriceps muscle is blocked, it is important for the patient to be fitted with a knee brace before ambulation.

Hip arthroscopy has become a common outpatient procedure for the diagnosis and treatment of hip pathology. The patient can be placed in either the supine or the lateral position (operative side up) with 50 to 75 lb of traction applied to the operative limb to gain access to the joint with the arthroscope. In positioning the patient, the anesthesiologist must ensure that the peroneal post is padded and not compressing the pudendal nerve, and that excessive traction for prolonged periods is not applied (see Chapter 36). Because complete muscle relaxation is required for the procedure, the patient must have either a general anesthetic or a neuraxial block. A lumbar-plexus block can be performed for postoperative analgesia.

Hip Fractures

Hip fractures in elderly individuals are common (1 in 50 individuals >60 years old), and as previously stated are associated with significant morbidity and mortality (1-year mortality of 30%).[4] The high perioperative complication rate is related to many factors, including cardiac conditions, pulmonary conditions, DVT, and delirium. Postoperative confusion and delirium is common, reported in 50% of elderly patients after the repair of hip fractures, and it is associated with increased mortality.[25-27] In many cases, dehydration and electrolyte abnormalities contributed to this delirium. In one study, the incidence of hyponatremia was 4%, and it was associated with a sevenfold increase in hospital mortality.[71]

These patients often arrive in the hospital in pain, under considerable stress, and possibly exhibiting signs and symptoms of myocardial ischemia. Although preoperative preparation is essential, delaying surgery may exacerbate these problems and increase the incidence of complications. Early surgery (<12 hours) has resulted in lower pain scores, decreased length of hospital stay, and reduced perioperative complications.[72] Compared with delayed surgery, however, early surgery has not been associated with increased overall survival. Early surgery for hip fractures should still be the goal for stable patients, combined with early mobilization, rehabilitation, and aggressive medical care.

Patients with hip fracture are often dehydrated and anemic because the fracture site can accommodate considerable extravasated blood. Blood hematocrit values are often normal because of this constricted blood volume in a dehydrated patient. A normal intravascular blood volume should be restored before anesthesia and surgery; this is best achieved with central venous catheter monitoring. Central venous catheter monitoring also may prevent overhydration, which can precipitate congestive heart failure. Placement of an arterial catheter permits accurate blood pressure monitoring during surgery and the ability to follow serial arterial blood gases. Hypoxemia, possibly owing to fat embolization, has been a major determinant of mortality in these patients.

Several studies have reported improved outcome with regional anesthesia compared with general anesthesia in these patients.[51] Patients undergoing hip fracture surgery have the greatest risk of death from a PE.[59] In a meta-analysis of patients undergoing the repair of femoral neck fractures, the incidence of DVT was almost four times greater in the patients who received general versus regional anesthesia.[73] A spinal anesthetic with isobaric 0.5% bupivacaine provides a stable regional anesthetic of sufficient duration to complete the surgical repair. Epidural anesthesia with postoperative analgesia is usually not indicated because in most cases aggressive postoperative anticoagulation is instituted.[61] Intravenous sedation during the procedure must be coupled with the ability of the patient to remain adequately oxygenated. Long-acting benzodiazepines should be avoided because of their association with postoperative confusion. In many cases, these patients require postoperative monitoring in an ICU-like setting.

Pelvic Fractures

Pelvic fractures are usually caused by significant trauma to the lower trunk and are often accompanied by chest (21%), head (16%), and liver and spleen (8%) injuries.[74] The 3-month mortality for pelvic fractures is almost 14%. Pelvic fractures also can result in fatal retroperitoneal bleeding. Hypotension and an increase in abdominal girth is an indication for emergent exploratory surgery. Injuries to the bladder and urethra also are often associated with pelvic fractures; urology clearance is usually indicated before inserting a Foley catheter. Because there is a significant risk of DVT and PE, many of these patients require a temporary inferior vena cava filter before surgery.

Most reports suggest that the optimal time for stabilization of pelvic fractures is within the first week of trauma, but associated injuries often delay the operation. Because iatrogenic sciatic nerve injury is the most frequent surgical complication (approximately 18%), many trauma surgeons advocate the use of neuromuscular monitoring during the operation. An optimal anesthetic may be the combination of a general anesthetic with the placement of an epidural catheter for postoperative analgesia after the preservation of lower extremity movement and sensation has been confirmed. In most cases, these patients require monitoring with arterial and central venous catheters, and the placement of large-gauge venous catheters in the event of sudden surgical hemorrhage.

Hip and Knee Arthroplasties

With the aging of the population, major orthopedic joint replacement procedures are becoming increasingly more common. The rate of major adverse events after hip and knee arthroplasties is 6.4%, and as stated earlier, the most important risk factor is advanced age (see Chapter 71).[3,5] The most common complications after THA and TKA are cardiac events, PE, pneumonia and respiratory failure, and infection.[3,75,76] Elderly patients with major comorbid conditions, including cardiac conditions, pulmonary conditions, and diabetes, should have a complete preoperative medical evaluation. In addition, obesity, particularly in a TKA patient, can be a problem anesthetically, and postoperatively with regard to obstructive sleep apnea and infections.[77] Many of these patients require prolonged postoperative monitoring in the postanesthesia care unit or ICU (see Chapter 85).

THA may be performed via an anterior or lateral approach. The anterior approach offers the advantage of exposure without violation of the muscles, but restricts full access to the femur with the risk of lateral femoral cutaneous nerve injury. The lateral posterior approach provides excellent exposure to the femur and the acetabulum with minimal muscle damage, but increases the risk of posterior dislocation. Most surgeons prefer the lateral posterior approach, which places the patient in the lateral decubitus position, surgical side up, for the operation. The anesthesiologist must be aware that this position may compromise oxygenation, particularly in obese and severely arthritic patients, owing to ventilation-perfusion mismatch. In addition, to prevent excessive pressure on the axillary artery and brachial plexus by the dependent shoulder, an anterior roll or pad must be placed beneath the upper thorax.

The nerve supply to the hip joint includes the obturator, inferior gluteal, and superior gluteal nerves. Regional anesthesia for THA is best achieved with a spinal or epidural anesthetic. Although most studies suggest decreased postoperative complications, particularly DVT and PE and respiratory problems, with regional anesthesia compared with general anesthesia, some controversy still remains.[51] A lumbar paravertebral block may be used for postoperative analgesia when postoperative anticoagulation requires removal of the epidural catheter.[78]

Blood loss during THA can be significant, and with revision procedures the patient can lose 1 to 2 L of blood. Several studies have shown that controlled hypotensive epidural anesthesia with mean arterial blood pressures of 50 to 60 mm Hg can reduce intraoperative blood loss for primary THAs to approximately 200 mL.[79] Elderly patients (mean age 72 years) were able to tolerate this degree of blood pressure reduction without cognitive, cardiac, or renal complications.[80] In addition to reduced overall blood loss during THA, hypotensive anesthesia may improve the cement prosthesis to bone fixation by limiting bleeding in the femoral canal.[81]

The femoral prosthesis can be fixed to the femoral canal through methyl methacrylate cement or bony ingrowth. Cemented fixation of the femoral prosthesis has been complicated by the "bone-cement implantation syndrome," which may result in intraoperative hypotension, hypoxia, and cardiac arrest and FES postoperatively (Fig. 70-6; see Fig. 70-2).[33-35] Several mechanisms have been suggested for these events, including embolization to the circulation of bone marrow debris during pressurization of the femoral canal, toxic effects of circulating methyl methacrylate monomer, and the release of cytokines during reaming of the femoral canal that promote microthrombus formation and pulmonary vasoconstriction. The cement monomer induces systemic hypotension, but not myocardial depression when intravenously injected in dogs.[82] The embolization of intramedullary debris is the most likely explanation because this debris can be visualized in the right heart using transesophageal echocardiography (see Fig. 70-2).

During THA, the hip is dislocated, and the femoral vein is probably obstructed. With hip relocation, embolic material generated during the insertion of the femoral prosthesis is released into the circulation after the relocation of the hip and unkinking of

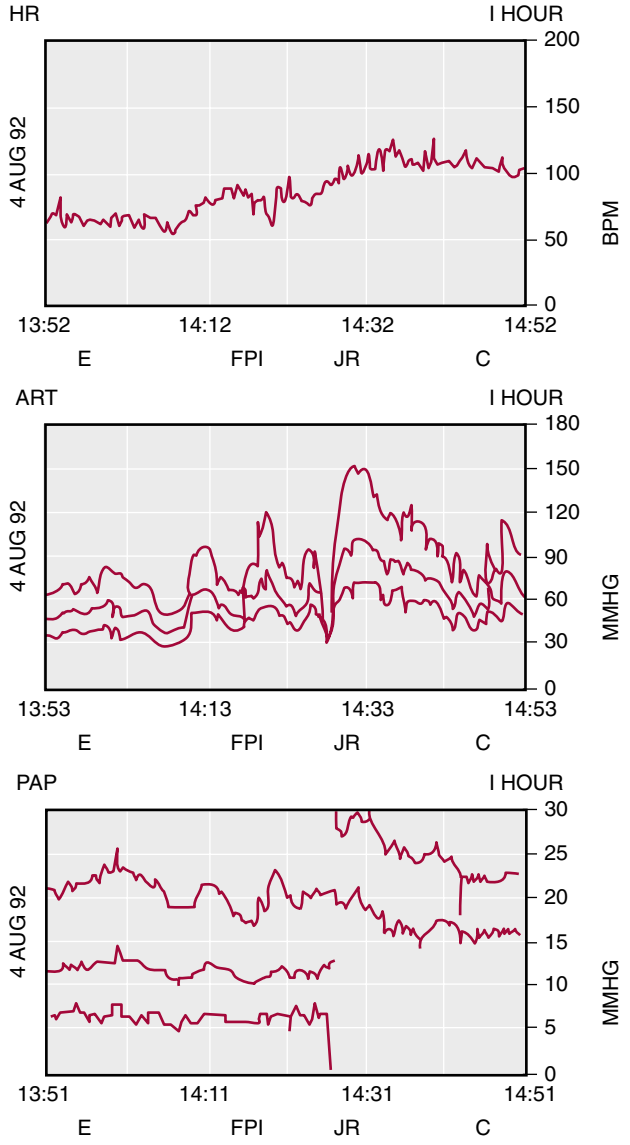

Figure 70-6 Intraoperative heart rate (HR), systemic arterial blood pressure (ART), and pulmonary arterial pressure (PAP) tracings of a patient undergoing revision total hip arthroplasty. Anesth Analg 82:1225-1229, 1996.)*

the femoral vein. The hypotensive events that follow should be treated with epinephrine. Some of these hemodynamic consequences can be ameliorated through high-pressure pulsatile lavage of the femoral canal and drilling a vent hole in the femur before prosthesis insertion. Risk factors for this complication include revision surgery, a long-stem femoral prosthesis, THA for a pathologic fracture, preexisting pulmonary hypertension, and the quantity of cement used. These patients should be monitored with arterial and central venous catheters.

TKA also is becoming a major orthopedic procedure in the aging population, and these patients require the same preoperative medical evaluation as outlined for THA patients. The innervation of the knee includes the tibial nerve, the common peroneal nerve, the posterior branch of the obturator nerve, and the femoral nerve. Although general anesthesia can be safely provided for TKA, a prospective case-controlled study found general anesthesia and endotracheal intubation to be a major risk for nonsurgical complications after TKA.[50] Regional anesthesia in the form of a neuraxial block (spinal or epidural) or a combination of a femoral and sciatic block can be provided for the surgery. Sciatic nerve blocks may be a particular problem, however, in valgus knee deformities, where early detection of sciatic and peroneal nerve palsies is desired.

TKA patients have severe postoperative pain, and several studies have shown that management of this pain with regional analgesia has reduced complications and improved outcome.[83-85] Single-injection femoral nerve blocks in combination with intravenous and epidural patient-controlled analgesia have been employed to manage postoperative pain and improve functional recovery. When LMWH has been instituted for the prevention of DVT, patient-controlled epidural anesthesia cannot be continued postoperatively, and instead continuous femoral nerve catheters are used.

A pneumatic tourniquet is routinely inflated over the thigh during TKA to reduce intraoperative blood loss and provide a "bloodless" field for cement fixation of the femoral and tibial components. When the tourniquet is deflated, however, blood loss usually continues for the next 24 hours. Tourniquets are usually inflated to a pressure 100 mm Hg above the patient's systolic blood pressure for 1 to 3 hours. Nerve injury after extended tourniquet inflation (>120 minutes) has been attributed to the combined effects of ischemia and mechanical trauma. Peroneal nerve palsy, which is a recognized complication of TKA (incidence of 0.3% to 10%), may be caused by the combination of tourniquet ischemia and surgical traction.[86] Horlocker and colleagues[86] reported a combined tibial and peroneal nerve dysfunction of 7% of TKA patients associated with younger age, the presence of preoperative flexion deformities, and longer total tourniquet time. When prolonged tourniquet inflations are required, deflating the tourniquet for 30 minutes of reperfusion may reduce neural ischemia.

Pain related only to tourniquet inflation also may occur after 60 minutes, despite the presence of a regional anesthetic that is adequate for the surgery. It has been postulated that tourniquet pain is caused by the unblocking of unmyelinated C fibers during recession of a neuraxial block. The addition of narcotics to spinal or epidural anesthesia may ameliorate tourniquet pain. After tourniquet release, mean arterial blood pressure decreases significantly, partly owing to the release of metabolites from the ischemic limb into the circulation and the decrease in peripheral vascular resistance. In patients with known preexisting sciatic neuropraxias, neuropathic pain, and vascular disease in the operative leg, the operation can be performed without a tourniquet.

Many patients have symptomatic arthritis of both knees and require bilateral TKA to achieve functional improvement in pain and lifestyle. Controversy still exists as to whether both knees should be replaced sequentially in a single operation (simultaneous bilateral total knee arthroplasty [SBTKA]) or as a two-staged procedure, usually separated by several months. The advantages of SBTKA include exposure to the risks of one anesthetic, one postoperative course of pain, reduced rehabilitation and hospitalization, and an earlier return to baseline function. SBTKA has been associated, however, with a higher incidence of serious perioperative complications, including myocardial infarction, fat embolization, and thromboembolic events. Serious postoperative complications are more prevalent in elderly patients with cardiovascular disease.[87,88] SBTKA patients also require increased numbers of blood transfusions, are more likely to be transferred to a rehabilitation center, and have a higher incidence of postoperative ICU admissions.

Two more recent reports suggest that SBTKA can be performed without major complications.[89,90] Urban and associates[89] reported that with regional anesthesia and aggressive clinical management, which included 24-hour postoperative monitoring in an ICU, SBTKA patients had a major complication rate similar to matched control unilateral TKA patients. SBTKA patients exhibited a significantly higher incidence of FES and cardiac arrhythmias, however, than unilateral TKA patients did. Using published reports of SBTKA patients at risk for postoperative complications, Urban and associates[89] published guidelines for the exclusion of patients from SBTKA (Table 70-5).

Foot and Ankle Surgeries

Regional anesthesia that combines sciatic and femoral nerve blocks is sufficient for all surgical procedures below the knee that do not require a thigh tourniquet. The femoral nerve innervates the medial leg to the medial malleolus, and the remainder of the leg below the knee, including the foot, is innervated by the

common peroneal nerve and tibial nerve, both branches of the sciatic nerve. The sciatic nerve is usually blocked high in the popliteal fossa to ensure anesthesia to the tibial and peroneal nerves. The nerves are identified through the use of a nerve-stimulating needle with foot inversion as the motor response or with ultrasound guidance. For procedures that also involve the medial aspect of the leg, the femoral nerve (saphenous nerve) can be blocked on the medial aspect of the leg, just below the knee. The popliteal sciatic nerve block also has been shown to reduce postoperative pain and narcotic requirements after foot and ankle surgery, when performed as a single preoperative injection or as a continuous catheter infusion.[91,92]

The acute compartment syndrome exists when edema and blood accumulate within a confined osseofascial space compromising the circulation and tissues within that space.[93,94] If not treated promptly, the pressure in the compartment leads to muscle and nerve ischemia and death, with potential loss of limb. Compartment syndrome occurs after fractures of the tibia, followed by the femur and ankle. Delay in diagnosis and treatment (surgical decompression) is the most common cause of serious complications. Pain out of proportion to the clinical situation is the usual early symptom. After the surgical repair of tibial and ankle fractures, a discussion with the surgeon with regard to the risk of compartment syndrome should occur before administering long-acting sciatic nerve blocks.

The ankle block is used for surgical procedures on the foot that do not require the use of a thigh tourniquet, although an ankle-level Esmarch tourniquet may be used. Because the block is primarily an infiltrative block, it usually is not performed by eliciting a paresthesia.

Five terminal nerves are usually blocked to provide complete anesthesia to the foot: (1) posterior tibial nerve, which provides sensation to the plantar surface; (2) saphenous nerve, which innervates the medial malleolus; (3) deep peroneal nerve, which supplies the interspace between the great and second toes; (4) superficial saphenous nerve, which supplies the dorsum of the foot and the second through the fifth toes; and (5) sural nerve, which supplies the lateral foot and lateral fifth toe (Fig. 70-7). Mineo and Sharrock[95] reported that the ankle block performed at the midtarsal level with 30 mL of 0.75% bupivacaine provided a mean duration of 17 hours of analgesia with safe blood levels of local anesthetic.

Upper Extremity Surgeries

Surgery for the upper extremity, from the shoulder to the hand, can be performed successfully by blocking the brachial plexus at several points until it branches into peripheral nerves (Table 70-6). Several methods are used to document the optimal location for neural blockade of the brachial plexus, including eliciting a paresthesia, motor nerve stimulation, ultrasound guidance, and perivascular infiltration. Regional anesthesia for the upper extremity also can provide postoperative analgesia using long-acting local anesthetics or continuous catheter techniques.

Regional anesthesia for shoulder surgery (see Chapters 52 and 53) has not gained wide acceptance because of the belief by anesthesiologists and surgeons that it is often inadequate for surgical anesthesia and the concern for postoperative neurologic symptoms (PONS). Several studies have reported 97% or greater successful surgical anesthesia using the interscalene block (ISB) approach to the brachial plexus with documentation of a paresthesia or the use of a nerve stimulator to locate the optimal site of injection.[96-98] The brachial plexus is formed from the ventral rami of C5-T1 nerve roots. After these roots pass between the anterior and middle scalene muscles, they fuse into three trunks (superior C5-6, middle C7, inferior C8-T1). During performance of the ISB, local anesthetic is injected between the scalene muscles at the level of the cricothyroid notch (C6) (Fig. 70-8).

The major acute complications and side effects associated with ISB are respiratory depression, intravascular injection with seizures and cardiac arrest, pneumothorax, epidural and spinal anesthesia, Horner's syndrome, hoarseness, and dysphagia. The ipsilateral phrenic nerve is blocked in all patients undergoing ISB, resulting in hemidiaphragmatic paresis.[99] Because hemidiaphragmatic paresis may result in a 25% reduction in pulmonary function, patients with severe respiratory disease may not tolerate an ISB without the addition of mechanical ventilation. An ISB would be contraindicated in patients after pneumonectomy on the contralateral side and for bilateral operative procedures. The

Table 70-6 Brachial Plexus Anesthesia

Site of Block	Simulated Brachial Plexus	Response

At the level of the cricoid cartilage (C6), the anesthesiologist's finger is rolled laterally from the posterior border of the sternocleidomastoid muscle (S) into the interscalene grove (I) between the anterior and middle scalene muscles (Sc). The needle is inserted at point I and directed 45 degrees caudad and perpendicular to all planes. *(From Urban MK: The interscalene block for shoulder surgery. Tech Shoulder Elbow Surg 5:61-65, 2004.)*

supraclavicular block performed with ultrasound guidance may provide effective shoulder anesthesia without complete ipsilateral paresis of the phrenic nerve.

Because of the proximity to major vascular structures (vertebral artery, carotid artery, jugular vein), CNS toxicity is usually cited as a major risk of ISB. The reported incidence of CNS effects has been very low, however. Conn and associates[100] reported that ISB resulted in 3 of 100 patients experiencing CNS symptoms and one seizure. Urban and Urquhart[96] reported that 2 of 266 patients had CNS symptoms and no seizures.

PONS related directly to brachial plexus anesthesia is often cited as the reason to avoid regional anesthesia for shoulder and hand surgery. The few large studies that have attempted to ascertain the extent of nerve injury associated with ISB have concluded that although some patients may have neurologic complaints after surgery, many of them cannot be attributed to the anesthetic, and most of them resolve (Table 70-7). In the retrospective study by Conn and associates,[100] 2 of 100 patients had PONS, which persisted for 7 months and 18 months, respectively. In the prospective analysis of 266 patients by Urban and Urquhart,[96] 9% complained of paresthesias on the day after surgery, two thirds of which resolved after 2 weeks, and one persisted beyond 6 weeks. Liguori and colleagues[97] reported the incidence of PONS after ISB performed with either the documentation of a paresthesia (10 of 108) or the use of a nerve stimulator (11 of 109), with a median duration of 2 months and resolution of all cases of PONS within 1 year.

Arthroscopic shoulder surgery is often performed in the sitting (beach chair) position. Numerous hypotensive and bradycardic events, some progressing to asystolic arrest, have been associated with shoulder surgery in the sitting position under regional anesthesia.[102] There is some evidence that these events are the result of a cardiac inhibitory reflex, Bezold-Jarisch reflex, which occurs in response to diminished ventricular volume (venous pooling in the sitting position) and a hypercontractile ventricle. Prophylactic administration of β-blockers, anxiolytics, and intravenous fluids reduces the incidence of these events.[103]

For surgery from the elbow to the hand, the brachial plexus can be blocked via either the infraclavicular block approach or the axillary approach. Blockade of the nerves to the arm at the axilla can be achieved by a transarterial technique or the stimulation of a single nerve or multiple nerves. Advocates of the multiple paresthesia technique cite the report by Thompson and Rorie,[104] which states that within the axillary sheath the nerves are separated by discrete septa. Using a transarterial approach, Urban and Urquhart[96] reported a success rate of 93%. Advocates of the paresthesia or nerve stimulator technique for the axillary block argue that the transarterial approach may result in a hematoma with ischemic damage to the brachial plexus. Using the transarterial axillary block in 242 patients for forearm and hand surgery, 23% of the patients complained of tenderness and bruising at the axilla, and 19% had acute PONS.[96]

The infraclavicular block to the brachial plexus may be the best approach for elbow surgery, and it may result in less patient discomfort and PONS when used for forearm and hand surgery compared with the axillary approach, although objective evidence is still lacking.[105,106] Using the nerve stimulator technique, two large series of infraclavicular blocks reported 90% to 94% success with only posterior cord stimulation, whereas other reports still recommend a double stimulation technique. Performing the infraclavicular block with ultrasound guidance may avoid the need for multiple needle passes and the complications of vascular puncture and pneumothorax.[107]

Forearm and hand surgery also can be done under intravenous regional anesthesia. Intravenous regional anesthesia is a simple technique that involves exsanguinating the arm by wrapping it with a tight band, inflating an upper arm tourniquet to about 250 mm Hg, and injecting in a hand vein about 50 mL of a short-acting local anesthetic (0.5% lidocaine). A second tourniquet, proximal to the first, is often inflated 15 minutes later with subsequent deflation of the first, to minimize tourniquet pain. This technique is limited to short surgical procedures (approximately 1 hour). Complications occur when the tourniquet fails during initial anesthetic injection or the tourniquet is deflated early (<30 minutes), risking systemic local anesthetic toxicity.

Spinal Surgeries

In the United States with an active, aging population, 4.6 million individuals require spinal surgery at some time during their life. Spinal surgery includes a wide variety of procedures ranging from microdiskectomies for a herniated disk to complex reconstructive surgery for spinal deformities. These procedures can be simple or involve fusions at multiple levels, anterior or posterior approaches, and considerable blood loss. A few procedures, such as diskectomies, can be done under regional anesthesia.[108]

Table 70-7 Interscalene Block Complications: Postoperative Neurologic Symptoms

Reference	Acute Symptoms (%)	Chronic Symptoms (%)

DVT, deep vein thrombosis; ETT, endotracheal tube.

Most spinal surgeries require general anesthesia. In this patient population with preexisting arthritic conditions, tracheal intubation often poses a challenge (Table 70-8). Awake, sedated fiberoptic intubation of many of these patients is the safest approach to general anesthesia. This is the standard of care in a patient with cervical spinal instability who requires posterior stabilization. These patients should be intubated first with a flexible fiberoptic bronchoscope, then positioned prone for surgery sedated but awake (if possible), and assessed for movements of upper and lower extremities before the induction of general anesthesia.

The careful positioning of patients for spinal surgery is an important shared responsibility of the anesthesiologist and surgeon (see Chapter 36). As stated previously, patients at risk for spinal cord compression should be positioned under light sedation, then observed for upper and lower extremity movement before inducing general anesthesia. Because some posterior cervical spine decompressions are done in the sitting position, preparations must be made for the possibility of a venous air embolism. Complex spinal deformity procedures often require anterior and posterior approaches to the spine. For a low lumbosacral approach, the patient is supine with the legs spread wide. Because pelvic retraction during this procedure may compromise blood flow to the legs, a pulse oximeter should be placed on a toe. Patients undergoing anterior thoracolumbar procedures are usually positioned in the lateral decubitus position where attention must be focused on the dependent arm and leg and the position of the neck. Table 70-9 outlines possible complications from prone positioning for these spinal procedures.

Complex corrective surgery of the spine includes patients with scoliosis, kyphosis, kyphoscoliosis, and revision surgery on patients with previous thoracolumbar fusions. Kyphosis is an exaggerated anterior flexion of the spine, as seen in ankylosing spondylitis. Scoliosis is defined as a lateral rotation of the spine greater than 10 degrees accompanied by vertebral rotation. Scoliosis is classified as idiopathic, congenital, or neuromuscular. Congenital scoliosis is the result of early embryonic errors in vertebral column formation, and half of the cases are associated with other organ system anomalies. Adolescent idiopathic scoliosis is common—present in 2% to 4% of children 10 to 16 years old. Only 10% of these adolescents have curves that require some type of medical intervention. Surgical intervention occurs when the curve magnitude estimated by the Cobb method is more than 40 degrees (Fig. 70-9), and there is a strong likelihood of curve progression. Most idiopathic scoliosis curves are right-sided; a left thoracic curve is more likely to be associated with other thoracic anomalies.

Thoracic scoliosis results in a narrowed chest cavity producing a decrease in chest wall compliance and restrictive lung disease. Cobb angles of greater than 65 degrees usually cause significant decreases in lung volumes. Although exercise tolerance is an important determinant of the effects of the severity of the curve on respiratory function, formal pulmonary function studies should be obtained before surgery. This information guides decisions regarding the extent of surgery permitted at one time and the requirement for postoperative ventilatory support. A vital capacity of less than 40% of the normal range is predictive of the requirement for postoperative ventilation. The major abnormality in arterial blood gases is hypoxemia, secondary to ventilation-perfusion inequalities caused by alveolar hypoventilation. Chronic hypoxemia produces elevated pulmonary vascular resist-

Figure 70-9 X-ray of a patient with scoliosis. Cobb angle is an angle formed by a line drawn perpendicular to the top of the superior vertebrae of the scoliotic curve and a similar perpendicular line drawn along the bottom of the inferior vertebrae. The Cobb angle in this patient is 62 degrees. *(From Reamy BV, Slakey JB: Adolescent idiopathic scoliosis: Review and current concepts. Am Fam Med 64:1-10, 2001.)*

ance, which ultimately leads to cor pulmonale. An echocardiogram should be assessed for pulmonary hypertension and right ventricular hypertrophy. In patients with pulmonary hypertension, the electrocardiogram may reveal evidence of right ventricular hypertrophy and right atrial enlargement.

Surgical spinal corrections involving high anterior thoracic levels or video-assisted thoracoscopic surgery require the isolation of one lung. One-lung ventilation traditionally has been achieved with a double-lumen endotracheal tube. In single-staged anterior then posterior spinal fusions and for postoperative ventilation, the double-lumen endotracheal tube must be replaced with a single-lumen endotracheal tube. A single-lumen endotracheal tube with an enclosed bronchial blocker also can provide one-lung ventilation, but has the advantage of being left in place as a single-lumen endotracheal tube with the blocker deflated at the end of the anterior procedure.[109] In patients with restrictive lung disease, adequate oxygenation may be difficult during one-lung ventilation and may require continuous positive airway pressure to the nonventilated lung and positive end-expiratory pressure to the ventilated lung.

Surgery for the correction of spinal deformities is usually associated with large blood losses. Multiple factors have been suggested to influence the magnitude of this blood loss, including: surgical technique, operative time, number of vertebral levels fused, anesthetics, mean arterial blood pressure, platelet abnormalities, dilutional coagulopathy, and primary fibrinolysis.[110] Several techniques have been employed to reduce this blood loss and limit the need for homologous blood transfusions, including proper positioning of the patient to reduce intra-abdominal pressure, surgical hemostasis, deliberate controlled hypotensive anesthesia, reinfusion of salvaged blood, intraoperative normovolemic hemodilution, use of pharmacologic agents that promote clot formation, and preoperative donation of autologous blood.

Controlled hypotensive anesthesia has been used commonly in limiting blood loss during idiopathic scoliosis corrections in adolescents, but must be used with caution in older patients.[111] In a young healthy patient, a mean arterial pressure of 50 to 60 mm Hg is well tolerated, but higher pressures may be required in adult patients with cardiovascular disease. In addition, perfusion of the spinal cord during deformity-correcting surgery may be exquisitely sensitive to low perfusion pressures. The adequacy of end-organ perfusion can be estimated with invasive monitoring, a urine output of 0.5 to 1 mL/kg/hr, and periodic blood gas analysis looking for evidence of metabolic acidosis.[112] In addition, central venous oxygen saturation analysis aids as an indicator of the patient's oxygen use. Although the increased heart rate associated with hypotensive anesthesia also may indicate anemia, hypovolemia, or "light" anesthesia, the use of a combined α/β-blocker for hypotensive anesthesia reduces the risk of myocardial ischemia and ameliorates rennin release with concomitant pressure rebound when the surgery has ended. Synthetic lysine analogs, such as aminocaproic acid and aprotinin, a polypeptide with serine protease inhibitor activity, also have been used to limit blood loss during these procedures by reducing fibrinolysis, but there may be concern because of more recent findings in postoperative cardiac cases.[113]

A postoperative neurologic deficit is one of the most feared complications of complex spinal reconstructive surgery. In a large survey of 97,586 spinal surgeries, neurologic deficits occurred in 0.55% of the cases.[114] To reduce this complication, Vauzelle and colleagues[115] introduced the concept of waking the patient up during surgery to determine the functional integrity of the spinal cord. This test is limited to gross motor movements of the lower extremities and can be influenced by anesthetics and the cognitive integrity of the patient. In addition, complications related to the test include inadvertent extubation of the patient during movement in the prone position, air embolism during a deep inspiration, and dislodgment of the instrumentation during violent movements.

Multimodal intraoperative monitoring has become the standard of care for complex reconstructive spinal surgery.[116] This monitoring includes somatosensory evoked potential (SSEP), motor evoked potential (MEP), and electromyogram monitoring. Electromyograms are used to monitor nerve root injury during pedicle screw placement and nerve decompressions (see Chapter 46). The posterior—sensory—portion of the spinal cord is evaluated using SSEP monitoring. MEPs assess the integrity of the anterior—motor—spinal cord. There are several potential adverse effects of MEP monitoring, including cognitive deficits, seizures, bite injuries, intraoperative awareness, scalp burns, and cardiac arrhythmias. It is advisable to employ a soft bite block during MEP monitoring to prevent tongue biting and dental damage. MEP monitoring should be avoided in patients with active seizures, vascular clips in the brain, and cochlear implants. In SSEPs, an impulse is sent from a peripheral nerve and measured centrally. In MEPs, an impulse is triggered in the brain and monitored as movement of a specific muscle group. SSEPs and MEPs are evaluated with regard to amplitude—strength—of the signal and latency—time it takes the signal to travel through the spinal cord—compared with the patient's nonsurgical control values.

Numerous physiologic factors attenuate SSEP and MEP monitoring, including hypotension, hypothermia, hypocarbia, hypoxemia, anemia, and anesthetics. The potent inhaled agents reduce the amplitude of the signal and increase latency in a dose-dependent manner. If a volatile anesthetic is used for the anesthetic, the concentration should be kept at about half minimum alveolar concentration and not varied throughout the procedure. Nitrous oxide produces a decrease in the amplitude of the signal and may have to be eliminated during MEP monitoring. Total intravenous anesthesia has been used successfully for MEP and SSEP monitoring. MEPs are the least affected by narcotics, midazolam, and ketamine, but are depressed by propofol. The depressant effect of propofol is diminished, however, with ketamine, such that the best total intravenous anesthetic may be an infusion of narcotic, ketamine (at low doses), and propofol.[117,118] Muscle relaxants cannot be administered during MEP monitoring.

Postoperative visual loss (POVL) is another devastating complication of spinal surgery (see Chapter 90). POVL is rare after spinal surgery (≤0.1%) and may be caused by ischemic optic neuropathy (ION), retinal artery or vein occlusion, and cortical brain ischemia. In an attempt to delineate the etiology of POVL, the American Society of Anesthesiologists Committee on Professional Liability established a POVL registry to collect detailed information on these cases.[119] Most patients with central retinal artery occlusion had evidence of unilateral ocular trauma, suggesting that improper positioning may have played a role. ION was the most common cause of POVL after spinal surgery. ION can be divided into anterior ION and posterior ION depending on the visual field cut, and whether edema to the optic disk is present early (anterior ION) or later (posterior ION). Both types are the result of reduced blood flow or oxygen delivery from end-arteriole branches of the ophthalmic artery.

The registry of 93 POVL cases after spinal surgery reported that most patients were relatively healthy and that blood loss greater than 1000 mL and duration in the prone position greater than 6 hours were present in 96% of the cases. ION occurs in the absence of direct pressure on the eye. Because ION occurred in the absence of vascular injury to other critical organs and in cases where neither hypotension nor anemia was reported, optic nerve blood supply may be uniquely vulnerable to hemodynamic perturbations in the prone position.

Patients experience considerable pain after multilevel spinal fusions with instrumentation (see Chapter 87). Most of these patients are initially treated with intravenous narcotics, but because of their multiple side effects, a multimodality approach with other agents has been recommended. For lumbar fusions, an epidural catheter placed at a level above the incision can be used for patient-controlled epidural anesthesia infusions of local anesthetics and narcotics. For procedures involving more extensive spinal levels, intrathecal morphine administered during surgery has been shown to provide reliable postoperative pain control.[120] NSAIDs may have a negative influence on the success of spinal fusions, however. For narcotic-tolerant patients, subanesthetic doses (0.2 mg bolus, then 2 μg/kg/hr) of ketamine reduced postoperative pain after posterior spine fusions.[121]

71 Geriatric Anesthesia

Key Points

1. Two important principles must be kept in mind when discussing the physiology of aging. First, aging is associated with a progressive loss of functional reserve in all organ systems. Second, the extent and onset of these changes vary from individual to individual.
2. Generally, elderly patients are more sensitive to anesthetic agents. Less medication is usually required to achieve a desired clinical effect, and drug effect is often prolonged.
3. The greatest concern of the elderly patient is to maintain independence. The most important outcome and overall objective of perioperative care of geriatric patients is to speed recovery and avoid functional decline.
4. Surgical risk and outcome in patients 65 years old and older depend primarily on four factors: age, the patient's physiologic status and coexisting disease (American Society of Anesthesiologists class), whether the surgery is elective or urgent, and the type of procedure.
5. When performing preoperative evaluation of a geriatric patient, one should have a high index of suspicion for disease processes commonly associated with aging, and one should assess the degree of functional reserve of specific, pertinent organ systems, and the patient as a whole, before surgery.
6. Important issues of special concern in caring for elderly patients are cognitive dysfunction and perioperative delirium.
7. Current data suggest that routine testing on the basis of age alone is not indicated. Instead, selective testing should be done on the basis of the history and physical examination and the specific surgical procedure.
8. Preoperative comorbid disease is a greater determinant of postoperative complications than anesthetic management. Perioperative care should be tailored to comorbid disease and requirements of the surgical procedure.
9. Preoperative and postoperative management of pulmonary problems in elderly patients is of particular importance in the prevention of morbidity and mortality.

Although understanding anesthetic care for older patients can be related to the description of fundamental alterations in physiology and changes in the pharmacokinetics and pharmacodynamics of anesthetic medications, these issues are only starting points for defining the myriad factors influencing perioperative care of this heterogeneous population. This chapter reviews the relevant basics and discusses special considerations for optimizing care of elderly surgical patients.

Defining and implementing optimal perioperative care for elderly patients is of increasing importance to all stakeholders in health care, including consumers, insurers, and government agencies. The emphasis on cost containment and pay for performance initiatives is likely to drive many aspects of care in this arena. The demographic considerations alone are staggering. As of 2003, the number of individuals older than 65 years in the United States had increased to 35.9 million with 18.3 million 65 to 74 years old and 12.9 million 74 to 84 years old. In 2003, 4.7 million were older than age 85. In 2000, the average life expectancy was 76.5 years. In the United States, the first of the "baby boomers" will reach age 65 in 2011. It is estimated that by 2030, 72 million (20%) U.S. citizens will be older than 65 years. Worldwide, 974 million people will be older than 65 years with 70% residing in developing countries.[1]

Elderly individuals frequently access health care. In 2004, elderly patients represented roughly 12% of the health care population, accounted for 38% of discharges, and used 44% of all hospital days while receiving approximately one third of all surgical procedures in acute care hospitals in the United States.[2] Fifty percent of all individuals older than 65 years are estimated to have a surgical procedure.

Core Concepts in the Anesthetic Management of Elderly Patients

Two important principles must be kept in mind when discussing the physiology of aging. First, aging is associated with a progressive loss of functional reserve in all organ systems. Second, the

extent and onset of these changes vary from person to person. In most older patients, physiologic compensation for age-related changes is adequate, but the resultant limitation in physiologic reserve may become evident only during times of physiologic stress, including exercise, illness, and surgery. Anticipating the interaction of underlying disease, limited end-organ reserve, and the stress of the perioperative period should aid the perioperative physician in providing the best care possible.

Mechanisms of Aging

Aging is a universal and progressive physiologic process characterized by declining end-organ reserve, decreased functional capacity, increasing imbalance of homeostatic mechanisms, and an increasing incidence of pathologic processes.[3] Aging is now viewed as an extremely complex multifactorial process with interaction of various pathways to differing degrees and effect.[4] Theories of aging may be grouped into broad categories including evolutionary and physiologic mechanisms. These mechanisms also may be defined according to "programmed" or biologic clock theory, in which genetic mechanisms program declining function, and "error" theories, in which environmental damage leads to impaired function and progressive decline. These processes of aging overlap and may be defined further by the organizational level of an organism where a given process occurs. Changes at one level influence processes at another level. Molecular effects influence cellular function, which causes alterations in major organ systems and ultimately may exert evolutionary pressure by influencing survival and reproduction. Weinert and Timiras[3] recently reviewed major theories of aging. These are summarized in Table 71-1.

Table 71-1 Classification and Brief Description of Theories of Aging

Biologic Level/Theory	Description
Evolutionary	
Mutation accumulation	Mutations that affect health at older ages are not selected against
Disposable soma	Somatic cells are maintained only to ensure continued reproductive success; after reproduction, soma becomes disposable
Antagonistic pleiotropy	Genes beneficial at younger age become deleterious at older age
Molecular	
Gene regulation	Aging is caused by changes in the expression of genes regulating development and aging
Codon restriction	Fidelity/accuracy of mRNA is impaired owing to inability to decode codons in mRNA
Error catastrophe	Decline in fidelity of gene expression with aging results in increased fraction of abnormal proteins
Somatic mutation	Molecular damage accumulates primarily to DNA/genetic material
Dysdifferentiation	Gradual accumulation of random molecular damage impairs regulation of gene expression
Cellular	
Senescence-telomere theory	Phenotypes of aging are caused by an increase in frequency of senescent cells owing to telomere loss or cell stress
Free radical	Damage caused by free radical production from oxidative metabolism
Wear-and-tear	Accumulation of normal injury
Apoptosis	Programmed cell death
System	
Neuroendocrine	Alterations in neuroendocrine control of homeostasis leads to physiologic change
Immunologic	Decline in immune function leads to altered incidence of infection and autoimmunity
Rate-of-living	Assumes a fixed amount of metabolic potential for every living organism (live fast, die young)

Nervous System

With aging, several important processes occur that are of interest to the anesthesiologist.[5] These changes may be modified further by other underlying pathologic or age-related processes.[6] Memory decline occurs in greater than 40% of individuals older than age 60 years.[7] Memory decline in aging is not inevitable, however. Age-related memory decline is important because it can dramatically affect performance of the activities of daily living (ADL).

Structurally, cerebral atrophy occurs with aging in a selective and differential manner. There is a decrease in the volume of gray and white matter.[8] The decrease in gray matter volume is thought to be secondary to neuronal shrinkage as opposed to neuronal loss. More recent studies focusing on the effects of normal aging on the human cerebral cortex suggest that there is a small overall loss of neurons from the neocortex.[9] This decrease in neuron number is nowhere near as massive as older studies had indicated. Some neocortical areas do not lose any neurons with aging. There may be 15% loss, however, of white matter with aging.[9] Such loss results in gyral atrophy and increased ventricular size. Shrinkage in the subcortical white matter and the hippocampus may be accelerated by hypertension and vascular disease.

It is controversial whether the aging process alters the number of synapses present in the cortex. Data from nonhuman primates suggest significant regional reductions in the neurotransmitters dopamine, acetylcholine, norepinephrine, and serotonin with aging.[9] Levels of glutamate, the primary neurotransmitter in cortex, do not seem to be affected. Coupling of cerebral electric activity, cerebral metabolic rate, and cerebral blood flow remains intact in elderly individuals.

Although biochemical and anatomic changes have been described in the aging brain, the exact mechanisms causing changes in functional reserve are unclear. Decreases in brain reserve are manifested by decreases in functional ADL, increased sensitivity to anesthetic medications, increased risk for perioperative delirium, and increased risk for postoperative cognitive dysfunction.

Neuraxial changes include a reduction of the area of the epidural space, increased permeability of the dura, and decreased

volume of cerebrospinal fluid. The diameter and number of myelinated fibers in the dorsal and ventral nerve roots are decreased in elderly individuals. In peripheral nerves, inter–Schwann cell distance is decreased, as is conduction velocity. These changes tend to make elderly individuals more sensitive to neuraxial and peripheral nerve block.[10]

Cardiovascular System

The aging process is associated with primary and secondary changes in the heart, primary changes in the blood vessels, and alterations in autonomic control. As the heart ages, changes in morphology occur. Myocyte number decreases, left ventricular wall thickening occurs, and conduction fiber density and sinus node cell number decrease.[11] Functionally, these changes translate to decreased contractility, increased myocardial stiffness and ventricular filling pressures, and decreased β-adrenergic sensitivity.[11] Vascular stiffness increases with advancing age related to breakdown of elastin and collagen. Alterations in nitric oxide–induced vasodilation also contribute.[12]

Morphologically, one sees an increase in the diameter and stiffness of large elastic arteries. Functionally, these changes are readily observed in terms of an elevated mean arterial pressure and increased pulse pressure.[13] Increased vascular stiffness leads to important secondary responses in the heart. In youth, the cardiac pump and the blood vessels are optimally coupled to maximize efficiency. With increased resistance in the blood vessels, the velocity of conduction of pulse waves down the vascular tree increases. Increased pulse wave velocity results in earlier reflection of pulse waves from the periphery. In younger humans, wave reflection occurs later because of slower propagation, such that reflected waves reach the heart after aortic valve closure. In the setting of increased pulse wave velocity with early wave reflection, reflected pulse waves reach the heart during the latter phases of ejection, imposing an increased cardiac load.[11] Alterations in left ventricular afterload can lead to left ventricular wall thickening, hypertrophy, and impaired diastolic filling.[14]

Hypertrophy is not necessary for alterations in ventricular stiffness to occur.[15] Decreased ventricular compliance and increased afterload combine to cause a compensatory prolongation of myocardial contraction. This occurs at the expense of a decreased early diastolic filling time. Under these conditions, the contribution of atrial contraction to late ventricular filling becomes more important and explains why cardiac rhythm other than sinus is often poorly tolerated in elderly individuals.

Changes in the autonomic system with aging include a decrease in response to β-receptor stimulation and an increase in sympathetic nervous system activity.[16] Decreased β-receptor responsiveness is secondary to decreased receptor affinity and alterations in signal transduction.[17] Decreased β-receptor responsiveness assumes functional importance when increased flow demands are placed on the heart. Normally, β-receptor–mediated mechanisms act to increase heart rate, venous return, and systolic arterial pressure, while preserving preload reserve. In contrast, the attenuated β-receptor response in elderly individuals during exercise or stress is associated with decreased maximal heart rate and decreased peak ejection fraction. This response causes the increased peripheral flow demand to be met primarily by preload reserve, making the heart more susceptible to cardiac failure.[11]

It is well known that sympathetic nervous system activity increases with aging. Although changes in β-receptor responsiveness are well defined, it is controversial whether the aging process alters the α-receptor response. Clinically, these autonomic changes lead to a greater likelihood of intraoperative hemodynamic lability and decreased ability to meet the metabolic demands of surgery.

Although the age-related changes in cardiovascular physiology are generally well tolerated, several pathophysiologic states warrant mention. Impairment of diastolic relaxation leads to diastolic dysfunction in the aging heart. In its severest form, diastolic dysfunction may manifest as diastolic heart failure. Predisposing disease states for this condition include hypertension with left ventricular hypertrophy, ischemic heart disease, hypertrophic cardiomyopathies, and valvular heart disease. More recent population-based studies suggest that diastolic dysfunction is common and associated with an increase in all-cause mortality.[18] In patients with clinically evident heart failure, ejection fraction is preserved in more than half, with 40% manifesting overt diastolic failure. Mortality in the cohort with preserved ejection fraction is similar to patients with impaired ejection fraction.[19]

Clinically, diastolic failure occurs when decreased left ventricular compliance results in greatly increased left ventricular diastolic pressure. If this pressure is conducted retrograde to the pulmonary circulation, it results in pulmonary venous congestion and pulmonary edema. Diastolic dysfunction or failure is often related to systemic blood pressure and does not imply volume overload. Diagnosis can be difficult because the clinical picture appears identical to left ventricular systolic failure. Making the correct diagnosis is important because interventions commonly employed in systolic failure, such as diuretics and inotropes, may exacerbate diastolic dysfunction.[20] Echocardiography is the diagnostic modality of choice (see Chapter 34).[21] Classically, echocardiography shows preserved or hyperdynamic left ventricular systolic function and characteristic changes of flow velocity at the mitral valve.

Aortic valve sclerosis and mitral annular calcification are common echocardiographic findings in elderly patients. These represent non–flow-limiting calcifications around the aortic and mitral valves. Otto and colleagues[22] showed that aortic valve sclerosis is common in elderly patients and is associated with a 50% increase in the risk of cardiovascular death. It has been suggested that aortic valve sclerosis may represent a marker for coronary artery disease. A similar association has been postulated for mitral annular calcification.[23]

Respiratory System

Alterations in control of respiration, lung structure, mechanics, and pulmonary blood flow place elderly patients at increased risk for perioperative pulmonary complications. Ventilatory responses to hypoxia, hypercapnia, and mechanical stress are impaired secondary to reduced central nervous system activity.[24] In addition, the respiratory depressant effects of benzodiazepines, opioids, and volatile anesthetics are exaggerated.[24,25] These changes compromise the usual protective responses against hypoxemia after anesthesia and surgery in elderly patients.

Structural changes in the lung with aging include the loss of elastic recoil after reorganization of collagen and elastin in lung parenchyma. This loss of elastic recoil combined with altered

surfactant production leads to an increase in lung compliance. Increased compliance leads to limited maximal expiratory flow and a decreased ventilatory response to exercise.[26] Loss of elastic elements within the lung is associated with enlargement of the respiratory bronchioles and alveolar ducts, and a tendency for early collapse of the small airways on exhalation. There also is a progressive loss of alveolar surface area secondary to increases in size of the interalveolar pores of Kohn. The functional results of these pulmonary changes are increased anatomic dead space, decreased diffusing capacity, and increased closing capacity all leading to impaired gas exchange.

Loss of height and calcification of the vertebral column and rib cage lead to a typical barrel chest appearance with diaphragmatic flattening. The flattened diaphragm is mechanically less efficient, and function is impaired further by a significant loss of muscle mass associated with aging. Functionally, the chest wall becomes less compliant, and work of breathing is increased.

Although there are alterations in lung volumes with aging, total lung capacity is relatively unchanged. Residual volume increases by 5% to 10% per decade. Vital capacity decreases. Closing capacity increases with age. Change in the relationship between functional residual capacity and closing capacity cause an increased ventilation-perfusion mismatch and represent the most important mechanism for the increase in alveolar-arterial gradient for oxygen observed in aging (Table 71-2).[27] In younger individuals, closing capacity is below functional residual capacity. At 44 years of age, closing capacity equals functional residual capacity in the supine position, and at 66 years of age, closing capacity equals functional residual capacity in the upright position.[27] When closing capacity encroaches on tidal breathing, ventilation-perfusion mismatch occurs. When functional residual capacity is below closing capacity, shunt increases, and arterial oxygenation decreases. This results in impairment of preoxygenation. Increased closing capacity in concert with depletion of muscle mass causes a progressive decrease in forced expiratory volume in 1 second by 6% to 8% per decade.

Increases in pulmonary vascular resistance and pulmonary arterial pressure occur with age and may be secondary to decreases in cross-sectional area of the pulmonary capillary bed.[28] Hypoxic pulmonary vasoconstriction is blunted in elderly individuals and may cause difficulty with one-lung ventilation.

Renal and Volume Regulation

Renal mass may decrease 30% by age 80 years.[29] Loss of mass is most prominent in the renal cortex. This loss correlates with a decrease in the number of functioning glomeruli. Many confounders exist, however, in interpreting the data of older morphologic studies. Lower numbers of glomeruli have been associated with low birth weight, and rates of attrition are accelerated in hypertension.[30] Renal blood flow seems to decrease about 10% per decade. There is a progressive decline in creatinine clearance with age, yet with normal aging, serum creatinine remains relatively unchanged. This occurs because muscle mass also decreases with aging. Serum creatinine is a poor predictor of renal function in elderly patients. This concept is important in proper dosage adjustment for medications that are excreted by the kidneys.

Functional changes in the kidneys with aging include alterations in electrolyte handling and the ability to concentrate and dilute urine. Renal capacity to conserve sodium is decreased. Overall, older patients have a tendency to lose sodium in the setting of inadequate salt intake. This tendency, paired with a decreased thirst response, may place an elderly patient at risk for dehydration and sodium depletion. The elderly patient also has a diminished ability to handle a salt load, as evidenced by increased sodium retention and expansion of the extracellular volume during the perioperative period.[31] These changes assume particular importance under conditions of limited fluid intake.

Table 71-2 Normal Values for Arterial Po_2

Age (yr)	Mean; Range (mm Hg)
20-29	94; 84-104
30-39	91; 81-101
40-49	88; 78-98
50-59	84; 74-94
60-69	81; 71-91

From Nunn J: Nunn's Applied Respiratory Physiology, 4th ed. Oxford, Butterworth-Heinemann, 1995, p 269.

Hepatic Changes

Liver volume decreases approximately 20% to 40% with aging. Hepatic blood flow decreases about 10% per decade.[32] There also is a variable decrease in the liver's intrinsic capacity to metabolize drugs. Effects on phase I reactions predominate. Decreases in hepatic blood flow may decrease maintenance dose requirements in drugs that are rapidly metabolized. The pharmacokinetics of drugs that are slowly metabolized are more affected by innate liver capacity than by blood flow.[33]

Preventable Hazards and Special Perioperative Considerations for Elderly Patients

The greatest concern of the elderly patient is to maintain independence. The most important outcome and overall objective of perioperative care of the geriatric population is to speed recovery and avoid functional decline. Many factors must be considered in the preoperative planning that affect anesthetic management and recovery from surgery.

Consent, Surrogate Decision Makers, and Advance Directives

Autonomy is the most important principle in health care decision making with the elderly.[34] Autonomy implies mental competence, however. The legal standards for competence include the abilities to communicate a choice, understand relevant information, appreciate the current situation and its consequences, and manipulate information rationally.[35] Cognitive and sensory difficulties

frequently jeopardize informed consent in frail elderly patients. Dementia, depression, hearing difficulties, and stroke all may interfere with the ability to make independent decisions.

If one's ability to make decisions becomes severely impaired, a surrogate must give consent. Caution must be exercised in this situation. A low rate of agreement has been shown when comparing the health care decisions made by surrogates with the desires of the elderly patients involved.[36] Advance directives, when available, can be extremely helpful, but even with them difficult problems remain. Issues of consent and end-of-life decisions in elderly patients are complex and familiar to the practicing anesthesiologist. Addressing the specific desires of a patient who presents to the operating room with "do not resuscitate" orders is a common problem. Often there are no easy answers to these ethical dilemmas (see Chapter 9).[37]

Age and Age-Related Disease

It is well appreciated that aging is associated with an increased incidence of chronic systemic disease processes, such as hypertension, diabetes mellitus, ischemic heart disease, and malignancy. Some specific diseases, such as dementia and Parkinson's disease, have a significantly higher incidence in elderly individuals. It is often difficult to separate the effects of aging alone from the effects caused by concurrent disease. Acute and chronic pathologic insults occur in the setting of a decreased physiologic reserve that can have profound effects on the usual compensatory mechanisms and dramatically alter clinical presentation. These factors become especially confusing in considering perioperative risk in elderly patients.

Atypical Presentation of Disease

Recognizing acute illness and exacerbation of chronic disease in elderly patients can be challenging. Frequently, acute illness may have an atypical presentation.[38] The appearance of pneumonia in elderly patients may be heralded by uncharacteristic features such as confusion, lethargy, and general deterioration of condition.[39,40] There may be significant differences in the presentation of disease in demented versus nondemented patients. Studies suggest that the nonspecific presentation of disease in older individuals is primarily linked to the presence of dementia rather than a characteristic feature of the aging process.[41]

Dementia

Dementia is common in the geriatric population. Alzheimer's disease is present in 6% to 8% of patients 65 years old and older. Hospitalization and surgery represent a challenge to the demented patient. Agitation, in particular, is an issue in these patients.

It is important to determine the presence of cognitive deficit during the preoperative evaluation. Preoperative cognitive deficit has a direct bearing on postoperative emergence and perioperative morbidity. Cognitive deficits are associated with poorer rehabilitation outcomes and higher surgical mortality.[42,43] In terms of choice of anesthetic technique, it is controversial whether the administration of general anesthesia accelerates the progression of senile dementia because not all studies support this view.[44,45] Perhaps most important, dementia is a predictor of postoperative delirium.[46] Accurate diagnosis of dementia is not always easy. For the purposes of preoperative evaluation, the mini-mental status examination allows for quick screening of baseline cognitive status.[47] In addition, insight may be gained by speaking with the patient's family concerning baseline function and ADL.

Parkinson's Disease

The etiology of Parkinson's disease is unknown. Parkinson's disease is present in about 3% of the population older than age 66.[48] The classic triad of resting tremor, muscle rigidity, and bradykinesia results from destruction of dopaminergic neurons in the pars compacta of the substantia nigra. Patients may present for procedures related to treatment of Parkinson's disease or for treatment of common surgical diseases. More recent reviews emphasize the complexity of tailoring anesthetic care for patients with Parkinson's disease.[49] Parkinson's patients are at increased risk for postoperative pharyngeal dysfunction, leading to difficulty handling secretions and risk of aspiration. Autonomic instability may result from Parkinson's disease, as a complication of therapy, or as a combination of the two. Exacerbation of disease can lead to complications related to muscle dysfunction, including respiratory embarrassment and increases in tremor, akinesia, confusion, or frank hallucination.

Generally, the antiparkinsonian regimen should be continued up to the time of surgery. The commonly used agent levodopa has a short half-life, and therapeutic effects may wane by the end of the proposed surgery. Other agents frequently used in treatment of Parkinson's disease include monoamine oxidase inhibitors with well-known adverse interactions with opiates. Opiates may exacerbate muscle rigidity. Phenothiazines, butyrophenones, and metoclopramide all have potential to worsen symptoms and should be avoided. Propofol may have unpredictable effects on motor function and is best avoided during stereotactic procedures.

Polypharmacy

It has been estimated that the average patient older than age 65 takes eight different medications each day.[50] The number of medications used is directly proportional to the likelihood of having an adverse drug reaction with an incidence of 5% to 35% in outpatients older than age 65.[51] An expert panel identified risk factors for adverse drug reactions, including 12 medication-related factors and 9 specific patient characteristics.[51] Many of these adverse drug reactions represent classes of medications used in the perioperative period and common characteristics of elderly surgical patients. There is significant risk for interaction with medications introduced in the perioperative period.

Functional Status and Assessment of Functional Reserve

One end point in determining the success of surgical interventions in geriatric patients should be to return the patient to his or her previous level of activity and independence. Evidence suggests that current level of function is helpful in predicting long-term outcomes in medical patients.[52] Few studies in the surgical literature have attempted to address how preoperative level of function predicts postoperative quality of life (Table 71-3). Preop-

Table 71-3 Effect of Preoperative Level of Function on Postoperative Quality of Life

Study	Patient Population	Comment
Eisler et al*	Hip fracture	Low preoperative functional status predicts functional independence at 3 mo and 6 mo postoperatively
Falcoz et al†	Open heart surgery	Preoperative quality-of-life assessment is predictive of 1-yr cardiac functional status
Bo et al‡	General surgical patients	Functional measures are predictive of 30-day mortality in urgent procedures

*Eisler J, Cornwall R, Strauss E, et al: Outcomes of elderly patients with nondisplaced femoral neck fractures: 2002. J Orthop Trauma 17:S31-S37, 2003.
†Falcoz PE, Chocron S, Stoica L, et al: Open heart surgery: One-year self-assessment of quality of life and functional outcome. Ann Thorac Surg 76:1598-1604, 2003.

erative functional assessment provides a baseline to determine whether quality of life has been maintained by surgical intervention. Ideally, surgical decision making incorporates outcomes research on quality of life to an ever greater extent.

Various instruments are available to evaluate functional activity[53] and heath-related quality of life.[54] A commonly used screening tool for determining independence and functional level for the preoperative assessment is to question the patient concerning ADL and instrumental activities of daily living (IADL). ADL represent activities involved in physical day-to-day self-care, whereas IADL represent more complex tasks. These instruments are useful for indicating specifically how an individual is performing at the present time. When these instruments are used longitudinally over time, they serve as documentation of an individual's functional improvement or deterioration. IADL and ADL assessments are important for their predictive ability. Any ADL impairment is associated with a relative risk of 1.9 (1.2 to 2.9; 95% confidence interval) for 90-day mortality in medical patients. Any IADL impairment is associated with a relative risk of 2.4 (1.4 to 4.2; 95% confidence interval) for 90-day mortality in medical patients.[52] Any impairment of one to two ADL is associated with a relative risk of 1.47 (1.08 to 2.01; 95% confidence interval) hazard ratio of recovering independent function from a disability.[55]

For some anesthesiologists, a complete functional assessment can be an onerous task. Some data suggest that the entire battery of ADL and IADL questions is unnecessary, and the preoperative examination may entail a more focused approach. Self-reported walking ability may be the best predictor of overall mobility in community-dwelling older adults, even if they have existing difficulties with ADL and mobility.[56] Self-reported walking ability is important to assess because data suggest that walking-related items are predictive of mortality and nursing home admission.[57]

Frailty

Frailty refers to a loss of physiologic reserve that makes a person more vulnerable to disability during and after stress. The components of the frailty syndrome include mobility; muscle weakness; poor exercise tolerance; unstable balance; and factors related to body composition such as weight loss, malnutrition, and muscle wasting (Table 71-4).[58] It is estimated that the incidence of frailty in the community-dwelling population older than 65 years is 6.9%.[59] Patients who are frail are more likely than their peers to be hospitalized, fall, develop disability, and die. When followed over 3 years, frailty is predictive of disability, hospitalization, and death.[59] Data are scant concerning the effect of frailty on surgical outcomes. The concept of frailty assumes greater importance in assessment of surgical outcomes research.

Delirium

The incidence of postoperative delirium in elderly patients varies widely depending on the type of surgery. The incidence of delirium has been estimated to approximate 10% in elderly patients after major elective surgery, but to be higher after cardiac surgery and hip fracture repair.[60] In a review of 26 primary data collection studies conducted between 1966 and 1992, the incidence of postoperative delirium for all types of surgery was found to be 36.8% (range 0% to 73.5%).[46]

Incidence, but not prevalence, of delirium is an important predictor of longer hospital stay and increased costs.[61] Overall, 2 million to 3 million elderly patients per year experience delirium during their hospital stay, involving more than 17.5 million inpatient days and accounting for more than $4 billion in Medicare expenditures.[62] Milbrandt and associates[63] projected the yearly

Table 71-4 Criteria Used to Define Frailty*

Weight Loss Criterion
The patient is asked the question, "In the last year, have you lost more than 10 lb unintentionally (i.e., not due to dieting or exercise)?"
Patients answering yes are categorized as frail by the weight loss criterion.
Exhaustion Criterion
The patient is read the following two statements: (1) I felt that everything I did was an effort; (2) I could not get going. The question is asked, "How often in the last week did you feel this way?" The patient's response is rated as follows: 0 = rarely or none of the time (<1 day); 1 = some or little of the time (1-2 days); 2 = a moderate amount of the time (3-4 days); or 3 = most of the time.
Patients answering "2" or "3" are categorized as frail by the exhaustion criterion.
Physical Activity Criterion
The patient is asked about weekly physical activity.
Patients with low physical activity are categorized as frail by the physical activity criterion.
Walk Time Criterion
The patient is asked to walk a short distance and timed.
Patients who are slow walkers are categorized as frail by the walk time criterion.
Grip Strength Criterion
The patient's grip strength is measured.
Patients with decreased grip strength are categorized as frail by the grip strength criterion.

*Frailty is defined as a clinical syndrome in which three or more of the above frailty criteria are met.
Adapted from Fried LP, Tangen CM, Walston J, et al: Frailty in older adults: Evidence for a phenotype. J Gerontol A Biol Sci Med Sci 56:M146-M156, 2001.

costs associated with delirium in a medical intensive care unit (ICU) patient to be $6.5 billion to $20.4 billion. Whether these costs apply to surgical ICU patients is yet to be determined. In a study cohort of 500 elective surgical patients at the Cleveland Clinic, the incidence of postoperative delirium was 11.4%, and average costs per patient were increased by $908, $1400, and $400 for nursing, technical services, and professional consultative fees, respectively. These individual increases accounted for a greater than $2500 cost increase per surgical patient experiencing delirium.[64]

Delirium is a syndrome characterized by acute onset of variable and fluctuating changes in level of consciousness accompanied by a range of other mental symptoms. By convention, the presence or absence of delirium is based on application of diagnostic criteria articulated in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV): "The essential feature of a delirium is a disturbance in consciousness that is accompanied by a change in cognition that cannot be better accounted for by a preexisting or evolving dementia" (Table 71-5).[65]

The Confusion Assessment Method (CAM)[66] is a bedside rating scale developed to assist non–psychiatrically trained clinicians in the rapid and accurate diagnosis of delirium in clinical settings. The CAM follows DSM-III-R criteria for delirium, but can be easily adapted to approximate DSM-IV criteria, which are similar. The CAM is designed to be administered by any clinician, including physicians or nurses, and may be administered by trained lay interviewers. Data suggest that geriatricians, nurses, and trained lay interviewers perform as well as psychiatrists in rating the CAM.[67] The sensitivity of the CAM versus psychiatric diagnosis is 94% to 100%, and specificity is 90% to 95%.[66]

There are many possible pathophysiologic mechanisms for delirium.[68] Although we do not yet fully understand the basic mechanisms of delirium, in the geriatrics paradigm, delirium epitomizes an atypical presentation of disease[69] in which acute illness is manifested in the most vulnerable organ system, or "the weakest link"—in this case, the brain. This theory holds that the normal aging process can be characterized as "homeostenosis," the progressive constriction of each organ system's ability to respond to stress.[70] In addition, the aging brain is more likely to be affected by diseases and drugs that cloud the sensorium. The sum of these effects leads some elderly to be teetering on the brink of neurodysfunction. Add any stressor, and these individuals develop acute worsening of their mental status. Based on the concept that "lack of brain reserve" predisposes elderly patients to delirium when exposed to stress, investigators have examined what preexisting vulnerability factors predispose elderly patients to delirium.

In medical patients, Inouye and Charpentier[71] developed a risk model for delirium that showed that the greater the number of preexisting vulnerability factors, the less acute the stressors required to invoke delirium. The important preexisting vulnerability factors defined in the medical model of delirium are visual impairment, severe illness, cognitive impairment, and dehydration. Kalisvaart and associates[72] attempted to validate the medical risk factor model of delirium in elderly hip surgery patients. Their study showed the usefulness of the medical risk factor model in predicting postoperative delirium in surgery patients and supports the concept that when more preexisting vulnerability factors are present, there is a higher risk for postoperative delirium.

A cornerstone of management of delirium is the recognition and treatment of any predisposing or precipitating factors for delirium (Table 71-6). More recent studies have shown that interventions consisting of standardized protocols for the management of known risk factors for delirium (e.g., cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration) result in significant reductions in the number and duration of episodes of delirium in hospitalized older patients.[73] Anesthetic-specific interventions include correction of metabolic and electrolyte disorders and perioperative continuation of pharmacologic therapy for neuropsychiatric disorders. Other interventions may be aimed at removing any triggering agents, such as drugs (e.g., anticholinergics) or inadequately controlled pain.[74] Type of anesthesia (regional versus general) and intraoperative hemodynamic complications have not been associated with delirium.[75] Alterations in blood transfusion practice may affect incidence because delirium has been associated with greater intraoperative blood loss, more postoperative blood transfusions, and postoperative hematocrit less than 30%.[75] Algorithms for pharmacologic treatment of delirium have been outlined in several more recent reviews.[76]

Table 71-5 DSM-IV Diagnostic Criteria for 293.0 Delirium

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention
B. A change in cognition (e.g., memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia
C. The disturbance develops over a short time (usually hours to days) and tends to fluctuate during the course of the day
D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiologic consequences of a general medical condition

Table 71-6 Predisposing and Precipitating Factors for Postoperative Delirium

Demographic characteristics—age >65 yr and male
Cognitive impairment or depression
Functional impairment
Sensory impairment, especially visual and hearing
Decreased oral intake
Drugs—polypharmacy, alcoholism, psychoactive, sedatives, narcotics, anticholinergic
Comorbidity—severe illness and neurologic disease
Some types of surgery—high-risk surgery (American Heart Association guidelines) and orthopedic
Intensive care unit admission
Pain
Sleep deprivation
Immobility/poor physical condition

Adapted from Inouye SK: Delirium in older persons. N Engl J Med 354:1157-1165, 2006.

Nutrition

In the community-dwelling elderly population, malnutrition has been reported to occur in 16.9% of women and 11.4% of men.[77] Among hospitalized elderly patients, the prevalence of malnutrition ranges from 15% to 26%.[78,79] Surgical patients who are malnourished have increased morbidity and mortality[80] and increased length of stay.[81] The diagnosis of malnutrition should be made on the basis of preoperative history and physical examination and laboratory tests (see Chapter 95).

Depression

Depression is estimated to occur in 10% of the community-dwelling population older than age 65 years.[82] Depression is an important issue because its presence may influence the occurrence of delirium[83] and length of stay,[84] and have a significant impact on postoperative quality of life.[85] Patients with baseline depression are at increased risk of death after coronary artery bypass graft (CABG) procedures.[86] Depression is easily treated with medications and psychological therapy. If possible, antidepressants should be continued during the perioperative period. Discontinuing antidepressants may increase symptoms of depression and confusion.[87]

Immobility

Bed rest leads to ventricular atrophy, hypovolemia, and orthostatic intolerance.[88] Prolonged bed rest causes decreases in muscle mass, which may influence ADL and pulmonary function.[89]

Dehydration

Dehydration accounts for approximately 6.7% of Medicare admissions.[90] Dehydration is often associated with hypernatremia and is accompanied by infection, such as pneumonia and urinary tract infection.

Alcoholism

Alcoholism is a common problem among elderly individuals.[91] Alcohol-related problems in elderly individuals often manifest as physical problems in the form of accidents or falls.[92] Alcoholism is an important predictor of postoperative pneumonia in noncardiac surgery patients.[93]

Hypothermia

Maintaining body temperature is important because unintentional hypothermia has been associated with myocardial ischemia, angina, and hypoxemia during the early postoperative period, particularly in high-risk patients undergoing lower extremity vascular surgery.[94] In patients with cardiac risk factors who are undergoing noncardiac surgery, the perioperative maintenance of normothermia is associated with a reduced incidence of morbid cardiac events and ventricular tachycardia.[95] Advanced age and general anesthesia are associated with hypothermia. During spinal anesthesia, a higher level of blockade is associated with a greater magnitude of core hypothermia.[96]

Trauma

Traumatic injury is an increasing problem for older adults and the individuals who care for them (see Chapter 72). Aside from the dramatic increase in the population at risk, in many circumstances older adults are enjoying a more active lifestyle that places them at risk for traumatic injury. There are important differences in patterns of injury and presentation of trauma in elderly patients.[97] In addition, evidence exists that elderly patients are often undertriaged. They are not initially transported to trauma centers even when appropriate criteria exist. This situation may occur because of inaccuracy of standard criteria in elderly patients or an age bias in referral patterns.

Age has been associated with increased mortality with various traumatic injuries. Cervical spine trauma is twice as likely in elderly patients with a greater likelihood of falls from sitting or standing height, multiple-level involvement, C1-2 involvement, and cervical instability compared with younger patients. Mortality and functional outcome after head injury is considerably worse in elderly patients, with preinjury anticoagulation or antiplatelet therapy dramatically worsening outcome.[98,99] Substance abuse is an often underappreciated factor.[100]

Falls are a common problem in and out of the hospital. As with any traumatic injury, prevention is the primary goal. Simple interventions, including identifying patients at risk, physical therapy, modification of the environment, and avoiding medications associated with orthostatic hypotension, may mitigate risk.[101]

Iatrogenic Complications

There are numerous hazards of hospitalization for elderly surgical patients. Iatrogenic complications are common and of increased severity in elderly patients.[102] The iatrogenic complications important to the anesthesiologist include adverse drug events, dehydration, delirium, and functional decline. Adverse drug events have a reported prevalence of 14.6% in hospitalized patients 70 years old and older, and are associated with the number of new inpatient medications and admission cognitive status. Patients experiencing an adverse drug event often incur a longer length of stay and a functional decline.[103]

Chronic Pain

The assessment of pain in elderly patients is often complicated by social, emotional, cognitive, and subjective issues (see Chapter 58).[104] At some time after age 65, 80% to 85% of individuals experience a significant health problem that predisposes them to pain. Chronic pain is frequently undetected, and it is important to evaluate the current use of pain medication.[105] Surveys of nursing home residents show arthritis is the most prevalent indication for analgesics (41.7% of residents), followed by bone fracture (12.4%) and other musculoskeletal conditions (9.7%). More residents

(76.8%) are reported to have chronic pain than acute pain (19.9%), and 3% have chronic and acute pain.[106]

Expected Outcomes

The successful end point of surgical intervention should be, at the very least, to return the patient to his or her previous level of activity and independence. Studies of certain high-risk patients reveal, however, that return to baseline function may be the exception rather than the norm. Thirty-nine percent of patients undergoing vascular surgery show a decline in capacity for independent function.[107] These types of findings suggest that physicians must begin to think about modification of treatment strategies in hopes of improving independent living status after vascular surgery. When achievement of return of function after major surgery and illness recovery is prolonged, many patients require extended assistance with ADL. This has important implications for discharge planning and rehabilitative care.

Disposition and Posthospital Care

Numerous factors are considered in determining the need for postacute care in a rehabilitation facility, including age, postoperative functional status, and home social situation.[108] Additionally, the availability of postacute care facility beds may drive the willingness to refer patients after discharge.[109] The decisions regarding disposition and the skill level required for care after discharge from the acute care hospital are complex. The effect of such care on overall outcome is largely unknown, however.[110]

Risk Assessment

Increased life expectancy, safer anesthesia, and less invasive surgical techniques have made it possible for a greater number of geriatric patients to be considered for surgical intervention. The decision to operate should not be based on age alone, but should reflect an assessment of the risk-to-benefit ratio of individual cases. Surgical risk and outcome in patients 65 years old and older depend primarily on four factors: (1) age, (2) the patient's physiologic status and coexisting disease (American Society of Anesthesiologists [ASA] class), (3) whether the surgery is elective or urgent, and (4) type of procedure (see Chapter 34).

Earlier studies suggest that anesthetic complications are related to age.[111] Surgical mortality increases with age.[112,113] Age also is an independent predictor of any serious adverse perioperative event.[114,115] These data emphasize that extremes of age do incur additional risk. The perioperative mortality in nonagenarians ranges from 0% to 20% depending on the type of procedure.[116,117] Compared with younger patients, patients 90 years old or older are more likely to die during hospitalization after hip fracture repair.[118] Age alone should not be a deterrent from surgery, however.

Prospective survival studies in surgical patients older than 75 years show that following an initial high mortality rate, the survival of this group as a whole approaches that of an age-matched population.[119] When surgical morbidity and mortality rates for nonagenarians are compared with age-matched, sex-matched, and calendar year of birth–matched peers from the general population, there is a decrease in patient survival at 1 year that reverses by 2 years, with observed survival at 5 years comparable to the rate expected.[120] In surgical patients 100 years old and older, the reported 48-hour, 30-day, and 1-year mortality rates are 0%, 16.1%, and 35.5%, respectively. Compared with survival rates for age-matched, sex-matched, and calendar year of birth–matched peers from the general population, the survival rate for centenarians who undergo surgery and anesthesia is comparable to the rate expected for nonsurgical patients.[121]

Although age has been shown to be a predictor of poor operative risk, the effect of age cannot be separated from ASA status or underlying comorbidity.[114] In carotid endarterectomy, mortality is greater in patients older than age 80 years. Illness severity has a greater impact on mortality after extracranial vascular surgery, however, than octogenarian status per se.[122] It is hard to pinpoint how aging alters surgical risk. It is likely that the association between age and surgical risk is related to the aging process and its ongoing decrease in functional organ reserve.

Emergency surgery is an independent predictor of adverse postoperative outcomes in older surgical patients undergoing noncardiac surgery.[120,123] Poorer preoperative physiology and preparation has a large influence on these results. Emergent care presents special problems, such as atypical presentations, impaired cardiopulmonary function, and fluid and electrolyte imbalance in the setting of decreased physiologic reserve.

Surgical mortality in elderly patients varies widely according to procedure.[113,124] The fact that risk varies widely depending on the type of surgery is well recognized. The current guidelines for cardiovascular evaluation of patients undergoing noncardiac surgery provide a useful means of categorizing procedures into low, intermediate, and high risk.[125]

Preoperative Evaluation

Two principles should be kept in mind when performing preoperative evaluation of a geriatric patient (see Chapter 34). First, one should have a high index of suspicion for disease processes commonly associated with aging. Common diseases of elderly patients may have a major impact on anesthetic management and require special care and diagnosis. Cardiovascular disease and diabetes are particularly prominent in this population. Pulmonary complications have an incidence of 5.5% and are the third leading cause of postoperative morbidity in elderly patients undergoing noncardiac surgery.[123] Pulmonary diagnosis and optimization cannot be overemphasized preoperatively. Management of cardiovascular disease, diabetes, and pulmonary disorders are discussed elsewhere in this textbook.

Second, one should assess the degree of functional reserve of specific, pertinent organ systems and the patient as a whole before surgery. Laboratory and diagnostic studies, history, physical examination, and determination of functional capacity should attempt to evaluate the patient's physiologic reserve. Laboratory testing should be guided by the patient's history, physical examination, and proposed surgical procedure, and should not be based on age alone. A prospective study of laboratory abnormalities in elderly patients failed to show any specific laboratory value as

predictive of adverse outcome. Only ASA physical status and surgical risk were significant.[126] Although electrocardiogram abnormalities are frequent, they also fail to predict postoperative cardiac complications.[127]

Although many questions remain, current evidence suggests cardiovascular risk may be mitigated by judicious perioperative β-blockade for patients with known coronary artery disease, particularly if begun at least weeks before surgery.[128] For elderly patients on long-term β-blocker therapy, long-acting β-blockers seem to be more effective than short-acting β-blockers in reducing risk of perioperative myocardial infarction.[129] A protocol involving acutely administering β-blockers beginning the day of surgery and continued perioperatively has been associated with an increased incidence of stroke and all-cause mortality.[129a]

Anesthetic Management

Clinical Pharmacology

Factors that affect the pharmacologic responses of elderly patients are well described and include changes in (1) plasma protein binding, (2) body content, (3) drug metabolism, and (4) pharmacodynamics.[130,131] The main plasma binding protein for acidic drugs is albumin and for basic drugs is α_1-acid glycoprotein. The circulating level of albumin decreases with age, whereas α_1-acid glycoprotein levels increase. The effect of alterations in plasma binding protein on drug effect depend on which protein the drug is bound to, and the resulting change in fraction of unbound drug. The relationship is complex, and generally changes in plasma binding protein levels are not a predominant factor in determining how pharmacokinetics are modified with aging.

Changes in body composition with aging reflect a decrease in lean body mass, an increase in body fat, and a decrease in total body water. We might infer that a decrease in total body water could lead to a smaller central compartment and increased serum concentrations after bolus administration of a drug. In addition, the increase in body fat might result in a greater volume of distribution, with the potential to prolong the clinical effect of a given medication.[33]

As discussed previously, alterations in hepatic and renal clearance occur with aging. Depending on the degradation pathway, decreases in liver and kidney reserve can affect a drug's pharmacokinetics profile.

The clinical response to anesthetic medications in elderly patients may be the result of alterations in sensitivity of the target organs (pharmacodynamics). A given agent's physical properties and alterations in receptor numbers or sensitivity determine the relative influence of pharmacodynamics alterations on anesthetic effect in elderly patients. Generally, elderly patients are more sensitive to anesthetic agents. Less medication is usually required to achieve a desired clinical effect, and drug effect is often prolonged. Undesired hemodynamic perturbations also tend to occur more frequently and in greater magnitude. Hemodynamic responses to intravenous anesthetics may be exaggerated because of interactions with the aging heart and vasculature. Expected compensatory or reflex responses are often blunted or absent because of physiologic changes associated with normal aging and age-related disease. Whatever the cause of altered pharmacologic effect, an elderly patient usually requires a downward adjustment in medication dose.

Clinical Pharmacology of Specific Anesthetic Drugs

Table 71-7 summarizes the clinical pharmacology of anesthetic agents in elderly patients.

Inhaled Anesthetics

The minimum alveolar concentration (MAC) decreases approximately 6% per decade for most inhaled anesthetics (see Chapter 21). A similar pattern is observed for MAC-awake.[132] The mechanism of action of inhaled anesthetics is related to altered activity of neuronal ion channels associated with nicotinic, acetylcholine, $GABA_A$, and glutamate receptors. Perhaps with aging alterations in ion channels, synaptic activity, or receptor sensitivity may occur to account for these changes in pharmacodynamics.

Intravenous Anesthetics and Benzodiazepines

There is no change in brain sensitivity to thiopental with age (see Chapter 26).[133] The dose of thiopental required to achieve anesthesia decreases with age, however. The age-related decrease in thiopental dose is related to an age-related decrease in the initial distribution volume of the drug. The decrease in initial distribution volume results in higher serum drug levels after a given dose of thiopental in elderly patients.[133] Likewise, in the case of etomi-

Table 71-7 Clinical Pharmacology of Anesthetic Agents in Elderly Patients

Drug	Brain Sensitivity	Pharmacokinetics	Dose
Inhaled agents	↑	—	↓
Thiopental	—	↓ Initial distribution volume	↓

Atracurium	NA	—	—
Cisatracurium	NA	—	—
Vecuronium	NA	↓ Clearance	↓

*See text. NA, not applicable.

date, age-dependent changes in pharmacokinetics (decreased clearance and initial volume of distribution), rather than altered brain responsiveness, account for the decrease in etomidate dose requirement in elderly patients.[134] The brain becomes more sensitive to the effects of propofol with age.[135] In addition, clearance of propofol is reduced. These additive effects are associated with a 30% to 50% increased sensitivity to propofol in elderly patients.[33]

The dose requirement of midazolam to produce sedation during upper gastrointestinal endoscopy is decreased approximately 75% in elderly patients.[136] These changes are related to increased brain sensitivity and decreased drug clearance.[137]

Opiates

Age is an important predictor of postoperative morphine requirements, with elderly patients needing less drug for pain relief (see Chapter 27).[138] Morphine and its metabolite morphine-6-glucuronide have analgesic properties. Morphine clearance is decreased in elderly patients.[139] Morphine-6-glucuronide depends on renal excretion.[140] Patients with renal insufficiency may have impaired elimination of morphine glucuronides, and this may account for some of the enhanced analgesia from a given dose of morphine in an elderly patient.[141]

Shafer[33] provided a comprehensive review of the pharmacology of sufentanil, alfentanil, and fentanyl in elderly patients. Sufentanil, alfentanil, and fentanyl are approximately twice as potent in elderly patients. These findings are primarily related to an increase in brain sensitivity to opioids with age, rather than alterations in pharmacokinetics.

Aging is associated with changes in the pharmacokinetics and pharmacodynamics of remifentanil. There is an increase in brain sensitivity to remifentanil with age. Remifentanil is approximately twice as potent in elderly patients, and one half the bolus dose is required.[142] The volume of the central compartment, V1, and clearance decrease with age,[143] and approximately one third the infusion rate is required in elderly patients.[142]

Muscle Relaxants

Generally, age does not significantly affect the pharmacodynamics of muscle relaxants (see Chapter 29). Duration of action may be prolonged, however, if the drug depends on liver or renal metabolism. One would expect that pancuronium clearance would decrease in elderly patients because of its dependence on renal excretion. Changes in pancuronium clearance with aging are controversial.[144,145] Atracurium depends to a small extent on hepatic metabolism and excretion, and elimination half-life is prolonged in elderly patients. Clearance is unchanged with age, however, suggesting that alternative pathways of elimination (ester hydrolysis and Hofmann elimination) assume importance in elderly patients.[146] Cisatracurium undergoes Hofmann degradation and is unaffected by age. Plasma clearance of vecuronium is lower in elderly patients.[145] The age-related prolonged duration of action of vecuronium may reflect decreases in renal or hepatic reserve.[147]

Neuraxial Anesthesia and Peripheral Nerve Blocks

Age has no effect on duration of motor blockade with bupivacaine spinal anesthesia (see Chapters 33 and 51).[148] The time of onset is decreased, however, and spread is more extensive with hyperbaric bupivacaine solution.[148,149] Effects of age on duration of epidural anesthesia have not been shown with 0.5% bupivacaine. Time of onset is shorter, however, and extent of block is greater.[150] A reduced plasma clearance of local anesthetics is observed in elderly patients. This can become a factor during repeated dosing and continuous infusion techniques prompting a reduction in top-up doses and infusion rates.[10] When using 0.75% ropivacaine for brachial plexus block, age is a major factor in determining duration of motor and sensory blockade.[151]

Anesthetic Technique

Advantages of Specific Drugs in Elderly Patients

Data suggest that preoperative comorbid disease is a greater determinant of postoperative complications than anesthetic management.[152] Perioperative care should be tailored to comorbid disease and requirements of the surgical procedure. Several comments concerning pharmacologic and physiologic management are in order, however. There may be a role for shorter acting anesthetics in caring for elderly patients. A more predictable method of opioid titration may be to use a shorter acting opioid such as remifentanil. By adjusting the bolus and infusion doses, the variability in remifentanil pharmacokinetics is considerably less than for other intravenous opioids.[153] Similarly, it may be prudent to use shorter acting muscle relaxants. Studies show that there is an increased incidence of postoperative residual block and pulmonary complications in patients receiving pancuronium compared with atracurium or vecuronium.[154] The use of sugammadex as a reversal drug for rocuronium should improve muscle relaxant use in elderly patients (see Chapter 29). When comparing inhaled anesthetics, there does not seem to be a significant difference in recovery profile of cognitive function. Desflurane is associated with the most rapid emergence.[155]

Generally, it is unclear what constitutes the optimal physiologic management to produce the best surgical outcomes. What is optimal blood pressure during surgery? This issue has been addressed during cardiopulmonary bypass where the question concerning most favorable perfusion pressure remains unresolved.[156,157] Similarly, it is uncertain whether deliberate hypotension in elderly patients is detrimental. Studies have shown that elderly patients can safely receive controlled hypotensive anesthesia (mean arterial blood pressure range 45 to 55 mm Hg) during orthopedic procedures without increased risk.[158] Even more controversy surrounds the question of whether better outcomes are obtained when invasive hemodynamic monitoring is used to optimize hemodynamics and fluid therapy. The use of pulmonary artery catheters in high-risk patients has been called into question because large prospective randomized studies analyzing in-hospital mortality have found no benefit to therapy directed by pulmonary artery catheter over standard care in elderly, high-risk surgical patients requiring ICU care.[159]

Regional versus General Anesthesia

Most evidence suggests little, if any, difference in outcome between regional and general anesthesia in elderly patients (see Chapters 33 and 51).[160] These results have been reported in many types of surgery, including major vascular and orthopedic procedures.[161,162] Use of regional anesthesia does not seem to decrease the incidence of postoperative cognitive dysfunction compared with general anesthesia.[163]

Specific effects of regional anesthesia may provide some benefit. First, regional anesthesia affects the coagulation system

by preventing postoperative inhibition of fibrinolysis.[164] Deep vein thrombosis or pulmonary embolism may occur in 2.5% of patients after certain high risk procedures.[165] Regional anesthesia may decrease the incidence of deep vein thrombosis after total hip arthroplasty.[166] These findings are controversial, however, because similar results have not been reported with total knee arthroplasty.[167] In lower extremity revascularization, regional anesthesia is associated with a decreased incidence of postoperative graft thrombosis compared with general anesthesia.[168] Second, the hemodynamic effects of regional anesthesia may be associated with decreased blood loss in pelvic and lower extremity surgery.[169] Third, regional anesthesia does not require instrumentation of the airway and may allow patients to maintain their own airway and level of pulmonary function. Data suggest that elderly patients are more susceptible to hypoxemic episodes in the recovery room. Patients who undergo regional anesthesia may have a lower risk of hypoxemia.[170] It is unclear, however, whether fewer pulmonary complications occur with regional versus general anesthesia.

Postoperative Considerations

Common Problems in the Postanesthesia Care Unit

Preoperative and postoperative management of pulmonary problems is of particular importance (see Chapters 35 and 93). In general surgical patients 65 years old and older, the incidence of common postoperative morbidities is 17% for atelectasis, 12% for acute bronchitis, 10% for pneumonia, 6% for heart failure or myocardial infarction (or both), 7% for delirium, and 1% for new focal neurologic signs.[171] In higher risk procedures, such as vascular surgery, the incidence of major postoperative pulmonary complications is 15.2%.[172] Numerous predictors of postoperative pulmonary complications in elective noncardiac surgery have been identified,[173,174] and risk indices have been developed to forecast the development of postoperative pneumonia.[93] Elderly patients may be at higher risk for aspiration secondary to the progressive decrease in laryngopharyngeal sensory discrimination that occurs with aging.[175] In addition, dysfunctional swallowing predisposes elderly patients to aspiration. After cardiac operations, dysfunctional swallowing occurs in 4% of patients and is more common in older patients. Swallowing dysfunction after cardiac surgery is closely associated with the intraoperative use of transesophageal echocardiography and carries with it a 90% rate of pulmonary aspiration and pneumonia.[103]

Treatment of Acute Postoperative Pain

Experimental and clinical studies provide support for the notion of an age-related decrease in pain perception (see Chapter 87).[176,177] It is unclear, however, whether the observed changes are caused by the aging process or reflect other age-associated effects, such as an increased presence of comorbid disease.[178] A greater problem occurs in patients with cognitive impairment. Evidence suggests that evaluation of pain, especially in a severely cognitively impaired individual, is difficult even for a geriatrician.[179] Nonetheless, the basic principles of evaluation of pain in elderly patients are similar to those in other age groups. Verbal pain scales are superior to nonverbal methods in elderly patients.[180]

As discussed earlier in this chapter, aging alters functional organ reserve and pharmacokinetics. The combination of pain assessment and drug dose adjustment provides challenges in the management of postoperative pain in elderly patients. Several general principles should be kept in mind when managing frail elderly patients. First, it is important to try to incorporate multiple modalities of analgesia, such as intravenous patient-controlled analgesia and regional nerve blocks, to enhance analgesia and reduce narcotic toxicity. This principle is especially important in frail elderly patients, who often tolerate systemic narcotics poorly. Second, the use of site-specific analgesia is a helpful adjunct. Certain operative sites, such as the upper extremity, are especially amenable to local nerve blocks. Others, such as thoracotomy, are especially painful, and techniques such as neuraxial analgesia or intercostal nerve block might be considered. Third, whenever possible, nonsteroidal anti-inflammatory drugs should be used to spare narcotics, enhance analgesia, and decrease inflammatory mediators. Unless the patient has a contraindication, or there is a strong concern about hemostasis or peptic ulceration, nonsteroidal anti-inflammatory drugs should generally be administered.[181] Opioid-based postoperative pain management may be used in elderly patients. It is imperative to keep in mind, however, the alterations in dose requirements that occur with age.[138]

Postoperative Cognitive Dysfunction

Short-term changes in cognitive test performance during the first days to weeks after surgery are well documented and typically involve multiple cognitive domains, such as attention, memory, and psychomotor speed (see Chapter 89). Early cognitive decline after surgery is largely reversible by 3 months.[182] Cardiac surgery is associated with a 36% incidence of cognitive decline at 6 weeks postoperatively.[183] The reported incidence of cognitive dysfunction after major noncardiac surgery in patients older than 65 years is 26% at 1 week and 10% at 3 months.[184] Predictors of early postoperative cognitive decline include age, low educational level, preoperative cognitive impairment, depression, and surgical procedure.[185,186] Short-term cognitive dysfunction after surgery may be attributed to multiple etiologies, including microemboli (especially with cardiac surgery), hypoperfusion, systemic inflammatory response (cardiopulmonary bypass), anesthesia, depression, and genetic factors (E4 allele).

Whether or not anesthesia contributes to long-term postoperative cognitive dysfunction is controversial and an area of intense investigation. In noncardiac procedures, anesthesia has a modest impact on long-term cognitive decline, although this effect may be more robust with increasing age.[44] Postoperative cognitive decline after major noncardiac surgery is reversible in most cases, but may persist in approximately 1% of patients.[187]

In patients undergoing CABG procedures, Newman and colleagues[188] reported a 42% incidence of cognitive decline at 5 years postoperatively (see Chapter 60). In addition, lower 5-year overall cognitive function scores were associated with poorer general health and less productive working status. Newman's study did not contain a nonsurgical control group. Other investigations addressing the issue of neurocognition and CABG procedures using nonsurgical control groups suggest that long-term postoperative cognitive dysfunction may result from factors other than anesthesia and surgery. First, patients with underlying coronary artery disease have lower baseline cognitive test scores compared with controls without coronary artery disease.[189] Second, long-term cognitive outcome of on-pump and off-pump CABG procedures is similar.[190] Third, long-term neurocognitive per-

formance in patients undergoing CABG procedures and nonsurgical controls with comparable coronary artery disease is similar.[191] These data suggest that the etiology of long-term cognitive changes after anesthesia and surgery may be related to underlying cerebrovascular disease risk factors. Management of risk factors, such as blood pressure, cholesterol, and diabetes, may be important in attenuating long-term cognitive decline. In addition, the role of interim medical events, such as new stroke, surgery with general anesthesia, or cardiac catheterization, in long-term cognitive decline has yet to be defined.

Intensive Care Outcomes

A growing number of studies have examined long-term outcome after critical care in elderly patients (see Chapters 91 and 92).[192,193] Survival to discharge from an ICU seems to be most closely related to severity of illness at the time of admission, whereas age and prehospital functional status correlate most closely with long-term survival. Recovery is often a long process with many elders requiring assistance with IADL 1 year after discharge.

Future Directions

Future trends are toward less invasive surgery with shorter hospital stays, as evidenced in many surgical subspecialties. Video-assisted muscle-sparing minithoracotomy for major lung resection has been used to decrease mean length of hospital stay for elderly patients to 1 day.[194] Early extubation and critical pathways for accelerated discharge have been used successfully in elderly patients undergoing isolated CABG procedures.[195] Endovascular repair of abdominal aortic aneurysm is now being used in high-risk patients with good results.[196] Laparoscopic surgical approaches have been shown to provide benefits to elderly patients in the form of smaller scars, decreased postoperative pain, and more rapid return to normal activity.[197] In addition, there is a major thrust toward ambulatory surgery in elderly patients. Studies report, however, that with ambulatory surgery, elderly patients have higher rates of intraoperative events, in particular, events of a cardiovascular nature.[198] Although the ideal model for perioperative care for older patients is unknown, studies suggest multidisciplinary teams including geriatricians can influence outcome.[199] More outcome studies are needed across a wide range of perioperative issues including ambulatory surgery. The challenge of the future will be managing perioperative care of elderly patients with their associated comorbid diseases and increased risk in a cost-conscious environment.

72 Anesthesia for Trauma

Key Points

1. Trauma anesthesiology is a unique subspecialty of our profession. Optimal anesthetic care of trauma patients depends on an understanding of trauma system design and surgical priorities.
2. Successful emergency airway management is based on having a clear plan, such as the American Society of Anesthesiologists algorithm for difficult airways. In general, rapid-sequence induction of anesthesia accompanied by cricoid pressure and in-line cervical stabilization, followed by direct laryngoscopy, is the safest and most effective approach.
3. Recognition of hemorrhagic shock is at the center of advanced trauma life support. Hemorrhagic shock indicates the need for rapid operative treatment, with the possibility of a "damage control" approach.
4. Resuscitation during acute hemorrhagic shock is controversial, but current recommendations are to maintain deliberate hypotension during active bleeding by limitation of crystalloid infusion and to emphasize maintenance of blood composition by early transfusion of red blood cells, plasma, and platelets.
5. Management of patients with severe traumatic brain injury poses unique challenges for the anesthesiologist. Monitoring and maintenance of cerebral perfusion are the keys to operative and intensive care of these patients.
6. Trauma anesthesiology includes a substantial component of critical care practice. Operating room use of advanced ventilator strategies, including permissive hypercapnia and facilitated spontaneous ventilation (bilevel or airway pressure release ventilation), may improve outcomes.
7. Prehospital, interhospital, and intrahospital transport of critically injured patients is the province of the trauma anesthesiology team and requires planning and attention to detail.

Injury is the leading cause of death between the ages of 1 and 45 years in the United States and the third leading cause of death overall.[1] Because it affects primarily the young, trauma is *the* leading cause of years of life lost before the age of 75. The World Health Organization (WHO) estimates that injury is the leading cause of death worldwide for both men and women from the age of 15 to 44 years, and by 2020, injuries will be the third leading cause of death and disability in all age groups.[2] Unlike in developed nations, where road traffic deaths are predicted to decrease by 2020, annual road traffic mortality is expected to rise by 80% in low- and middle-income countries.[3]

Globally, about 16,000 people die of injuries every day and about 5.8 million people every year, which corresponds to an annual mortality rate of 97.9 per 100,000 population. Mortality from injury under-represents the true burden of disease inasmuch as hundreds of people require hospital treatment for every death. According to the 2002 *World Report on Violence and Health*, injury accounts for 12.2% of the total burden of disease.[4] In comparison with other disease and health conditions, morbidity and disability as a result of injury account for a disproportionate number of deaths in children and young adults. This leads to a major burden on health sector and social welfare services, and the economic consequences include both the cost of care and a substantial amount of lost productivity.

A comprehensive review published by the WHO showed that more than 1.6 million people worldwide lost their lives to violence in the year 2000. About half the deaths were caused by suicide, nearly a third were homicides, and about a fifth were casualties of armed conflict.[5] In the post–Cold War period 1990 to 2001 there were 57 different major armed conflicts in 45 different locations. Terrorism, either transnational or domestic, is not new. In addition to the increasing global incidence of trauma, other major trends in trauma and its management include a growing emphasis on prevention and public health aspects of trauma, globalization of trauma practices because of rapid dissemination of new information, a critical emphasis on organizational aspects of trauma care and education, and the prominent role of efficacious and cost-effective management practices.[6]

Management of trauma patients presents unique challenges to the health care system because they require resource-intensive care, they have multiple injuries to multiple body systems, and their acute injuries overlie and interact with a variety of chronic medical conditions. Anesthesiologists in practice at designated

trauma centers are involved in the care of trauma patients beginning with airway and resuscitation management in the emergency department (ED) and proceeding through the operating room (OR) to the intensive care unit (ICU). Trauma patients represent a significant proportion of all OR cases handled during night and weekend shifts. Critical care and pain management specialists see trauma patients as a large fraction of their practice. Even practitioners at outpatient surgery centers will encounter trauma patients in need of reconstructive, orthopedic, or plastic surgery.

At the same time, very few anesthesiologists in the United States consider trauma their primary specialty. This is distinct from European practice, where it is not unusual to find an anesthesiologist working in the prehospital environment, as an ED director, or as leader of a hospital's trauma team. The U.S. model, in which all anesthesiologists treat trauma patients but few do so exclusively, has led to a relative dearth of research, publication, and education in this field. This situation is unfortunate because trauma is a rapidly evolving field of study that presents unique challenges to the clinician and one in which improvements in care can have a dramatic impact on society as a whole.

Anesthesia for trauma patients is different from routine OR practice. Most urgent cases occur during off-hours, when the most experienced OR and anesthesia personnel may not be available. In small hospitals and military and humanitarian practice, austere conditions may influence the resources available. Patient information may be limited, and allergies, genetic abnormalities, and previous surgeries may create sudden crises. Patients are frequently intoxicated, with full stomachs and the potential for cervical spine instability. Simple operations may become complicated, and specialty surgical and anesthesia equipment may be required on short notice. Patients often have multiple injuries requiring complex positioning, multiple procedures, and the need to consider priorities in management. Occult injuries, such as tension pneumothorax, can be manifested at unexpected times. Successful perioperative care of these patients requires a good understanding of the basics, supplemented by preparation, flexibility, and the ability to react quickly to changing circumstances.

As with other endemic diseases, successful treatment of trauma extends well beyond the boundaries of an individual hospital. Community-based prevention has included efforts to incorporate airbags in motor vehicles, mandate helmet use on motorcycles, encourage citizens to wear seat belts, punish intoxicated drivers, and promote responsible handgun ownership.[7] All of these measures have had an impact on the demographics of injury in much the fashion that smoking cessation, dietary modification, and routine mammography have affected the incidence of heart disease and cancer. When prevention fails, outcomes after injury are heavily influenced by the community's commitment to an organized system of trauma care.[8]

A "systems" approach to the delivery of trauma care has been shown to improve outcome. Trauma care systems represent a continuum of integrated care that is a coordinated effort between out-of-hospital and hospital providers with close cooperation of medical specialists in each phase of care. In 1998, the first Academic Symposium to Evaluate Evidence Regarding the Efficacy of Trauma Systems (the Skamania Conference) systematically reviewed the published literature in an effort to quantify the understanding of trauma system effectiveness at that time and to chart a course to outline future research endeavors.[9,10] The Skamania Symposium concluded that treatment at a trauma center versus a nontrauma center is associated with fewer inappropriate deaths and less disability. This conclusion was substantiated in 2006 by a *New England Journal of Medicine* study showing that mortality is reduced when care is provided at a trauma center versus a nontrauma center.[11] Studies in the United States have shown that a reduction in unnecessary deaths from greater than 30% to less than 5% occurred in trauma centers as compared with general hospitals and that a regionalized system with triage criteria and dedicated trauma centers also reduces the potentially preventable mortality rate to a low of 1% to 3%. However, based on a U.S. study evaluating rates of mortality after implementation of a statewide trauma system program, a mean of *9 years* elapsed after passage of enabling legislation before a significant benefit in survival was achieved.[12]

The degree to which the trauma system is organized and regulated varies widely from state to state across the United States. States such as Maryland, Pennsylvania, Connecticut, and Illinois have established protocols for the care of trauma patients that begin at the moment of first contact with the emergency medical system. In other states the system may be more fragmentary, and care may vary widely between one jurisdiction and another. Mature trauma systems include protocols for patient triage and transport, standards for hospitals providing trauma care, and data collection systems that facilitate benchmarking. Although some states have written their own standards for certifying trauma hospitals, the most influential national document is *Resources for Optimal Care of the Injured Patient*, published by the American College of Surgeons Committee on Trauma in 2006.[13] This reference offers standards for accreditation of trauma hospitals based on the availability of key resources, the volume of trauma patients treated, and the institutional commitment to prevention and education. The presence of an experienced anesthesiologist and the immediate availability of an open OR are both core resource standards for accreditation of a "level 1" trauma center. Prospective studies have demonstrated improved patient outcomes when a hospital pursues and attains designation as a trauma center.[14]

The need for ongoing education of providers is brought home by the numerous innovations in trauma care witnessed in just the past decade, including technologies for rapid volume resuscitation; "damage control" surgical techniques; diagnostic modalities such as high-speed computed tomography (CT), angiography, and focused abdominal ultrasound; and perfusion-focused strategies for managing traumatic brain injury (TBI). The coming decades will see new pharmacologic therapies for shock and reperfusion, new strategies for achieving hemostasis, and better patient monitoring. Improving patient outcomes requires a commitment to continuing education on the part of the anesthesiologist and every member of the trauma team.

This chapter provides an overview of important areas of trauma care for the anesthesiologist. We begin with a description of the initial approach to an injured patient, followed by discussions of emergency airway management, fluid volume resuscitation, and care of patients with central nervous system (CNS) injuries. We briefly cover the needs of orthopedic and reconstructive surgery patients and then conclude with a discussion of postoperative and critical care issues for the trauma anesthesiologist. New to this edition is a discussion of the anesthesiologist's role in battlefield medicine, including combat casualty assessment, stabilization, and transfer.

Prioritizing Trauma Care

The advanced trauma life support (ATLS) (see Chapter 97) course of the American College of Surgeons is the most widely recognized training program for trauma physicians of all disciplines.[15] Though not comprehensive in subspecialty areas, the ATLS curriculum nonetheless provides a framework and a common language for the care of injured patients. ATLS is based on a "primary survey" that includes simultaneous efforts to identify and treat life- and limb-threatening injuries, beginning with the most immediate. This focus on urgent problems first is captured by the "golden hour" catchphrase and is the most important lesson of ATLS. Put simply, better outcomes are achieved with faster diagnosis and treatment. Resolution of urgent needs is followed by a meticulous secondary survey and further diagnostic studies designed to reduce the incidence of missed injuries. Knowing the basics of ATLS is essential for *any* physician who interacts with trauma patients. Figure 72-1 is a simplified representation of the ATLS protocol.

ATLS emphasizes the ABCDE mnemonic: airway, breathing, circulation, disability, and exposure. Verification of an open airway and acceptable respiratory mechanics is of primary importance because hypoxia is the most immediate threat to life. Inability to oxygenate the patient will lead to permanent brain injury and death within 5 to 10 minutes. Trauma patients are at risk for airway obstruction and inadequate respiration for the reasons listed in Box 72-1. Endotracheal intubation, whether performed in the prehospital environment or in the ED, must be confirmed immediately by capnometry. Esophageal intubation or endotracheal tube dislodgement are common and devastating if not promptly corrected. Patients in cardiac arrest may have very low end-tidal CO_2 values; direct laryngoscopy should be performed if there is any question about the location of the endotracheal tube (see also Chapter 50).

If establishment of a secure airway and adequate ventilation requires a surgical procedure such as a tracheostomy, tube thoracostomy, or open thoracotomy, this procedure must precede all others. Indeed, these procedures are commonly performed in the ED, often before the arrival of an anesthesiologist. Subsequent surgery to convert a cricothyroidotomy to a tracheostomy or close an emergency thoracotomy may then follow in the OR.

Hemorrhage is the next most pressing concern inasmuch as ongoing blood loss is inevitably fatal. The symptoms of shock are presented in Box 72-2. Shock is presumed to result from hemorrhage until proved otherwise. Assessment of the circulation consists of an early phase, during active hemorrhage, and a late phase, which begins when hemostasis is achieved and continues until normal physiology is restored. In the early phase, diagnostic efforts focus on the five sites of bleeding detailed in Table 72-1, the only areas in which exsanguinating hemorrhage can occur. Any surgical procedure to diagnose or control active hemorrhage is an emergency case that must be brought to the OR as soon as possible. This includes exploration of the neck or pericardium to rule out hemorrhage in sensitive compartments. In the OR, the trauma surgeon focuses on anatomic control of hemorrhage, whereas the anesthesiologist is responsible for restoring the patient's physiology. Goals for early and late resuscitation are discussed in more detail later.

After management of the circulation is assessment of the patient's neurologic status by calculation of the Glasgow Coma Scale (GCS) score (Box 72-3)[16]; examination of the pupils for size, reactivity, and symmetry; and determination of sensation and motor function in each of the extremities. Significant abnormalities on the neurologic examination are an indication for immediate cranial CT. A majority of trauma patients with a diminished GCS score will have nonoperative conditions, but for the few who require operative evacuation of an epidural or subdural hematoma, timeliness of treatment has a strong influence on outcome. Patients with unstable spinal canal injuries and incomplete neurologic deficits will also benefit from early surgical stabilization.

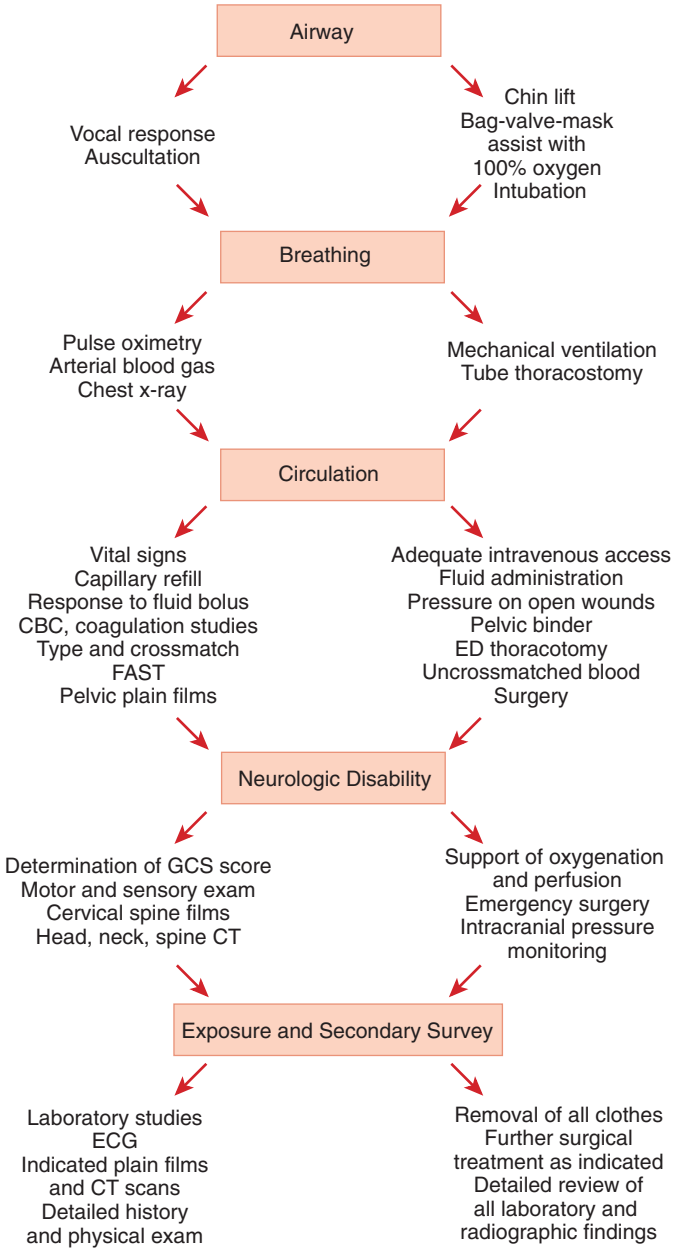

Figure 72-1 Simplified assessment and management of a trauma patient. Box 72-1 Causes of Obstructed Airway or Inadequate Ventilation in A Trauma Patient

Airway Obstruction
Direct injury to the face, mandible, or neck
Hemorrhage in the nasopharynx, sinuses, mouth, or upper airway
Diminished consciousness secondary to traumatic brain injury, intoxication, or analgesic medications
Aspiration of gastric contents or a foreign body (e.g., dentures)
Misapplication of an oral airway or endotracheal tube (esophageal intubation)

Inadequate Ventilation
Diminished respiratory drive secondary to traumatic brain injury, shock, intoxication, hypothermia, or oversedation
Direct injury to the trachea or bronchi
Pneumothorax or hemothorax
Chest wall injury
Aspiration
Pulmonary contusion
Cervical spine injury
Bronchospasm secondary to inhalation of smoke or toxic gas

The final step in the primary survey is complete exposure of the patient and a head-to-toe search for visible injuries or deformities, including deformities of bones or joints, soft tissue bruising, and any breaks in the skin. The anesthesiologist can assist in this procedure by support of the head and neck, maintenance of the airway, and care in manipulating the spine.

After the primary survey a more deliberate secondary examination is undertaken that includes a thorough history and physical examination, diagnostic studies, and subspecialty consultation. Any remaining injuries are diagnosed at this time and treatment plans established. Indications for urgent or emergency surgery may also arise during the secondary survey. The presence of a limb-threatening injury as a result of either vascular compromise, compartment syndrome, or a severely comminuted fracture is one such indication. Although the ABCDE issues must be addressed first, a pulseless extremity, compartment syndrome, near-amputation, or massively fractured extremity must go to the OR as soon as the patient is otherwise stable.

Another category of urgency arises in patients with a time-dependent potential for systemic infection. Because sepsis is a leading cause of complications and death in trauma patients, open injuries should be thoroughly débrided—and closed if appropriate—at the earliest opportunity (see Chapters 91 and 92). Other

Box 72-2 Symptoms of Shock

Pallor
Diaphoresis
Agitation or obtundation
Hypotension
Tachycardia
Prolonged capillary refill
Diminished urine output
Narrowed pulse pressure

4 = Withdraws from painful stimuli
3 = Abnormal flexion (decorticate posturing)
2 = Abnormal extension (decerebrate posturing)
1 = None

*The Glasgow Coma Scale score is the sum of the best scores in each of three categories.

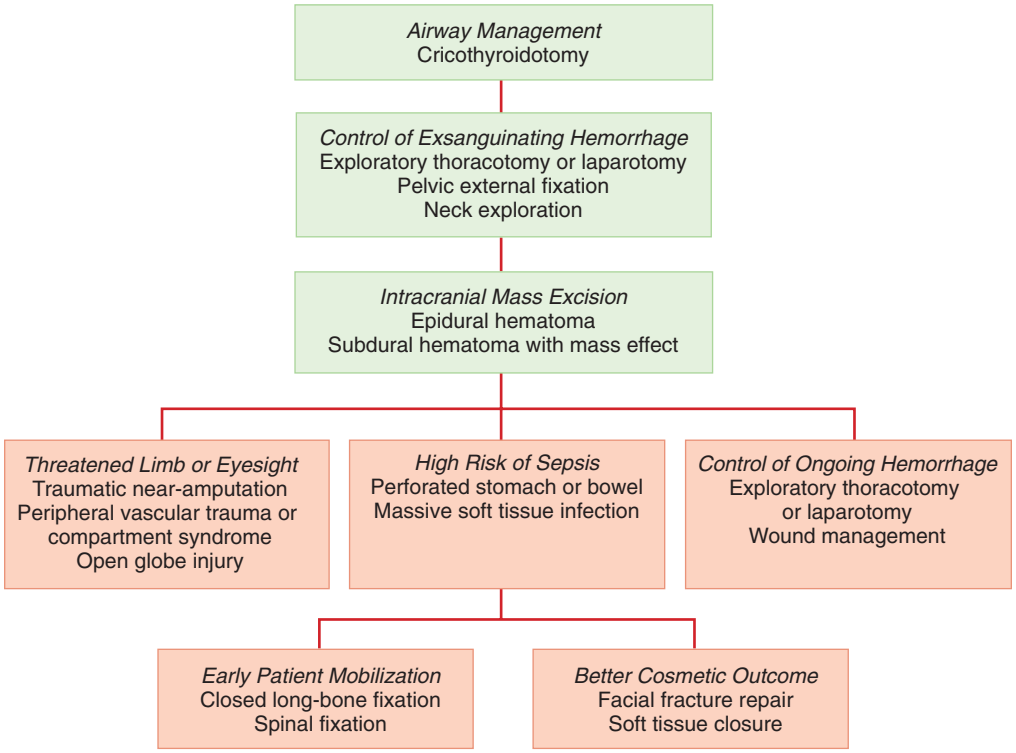

Figure 72-2 Surgical priorities in a trauma patient. *(Reprinted with permission from Dutton RP, Scalea TM, Aarabi B: Prioritizing surgical needs in the patient with multiple injuries. Probl Anesth 13:311, 2001.)*

urgent indications for surgery include perforation of the bowel, open fracture, and extensive soft tissue wounds. The frequency of infectious complications of open fractures increases in a linear fashion with time from the moment of injury until operative débridement[17]; the anesthesiologist must balance the need for early surgery against the need for diagnostic studies and adequate preoperative resuscitation and may be required to determine the priority of this procedure relative to other cases.

Figure 72-2, an algorithm for prioritizing surgical management in trauma patients, is presented with the understanding that individual situations will vary according to available resources and the patient's response to therapy. A trauma patient will often arrive at the OR with the need for more than one surgical procedure by more than one surgical service. A trauma patient may have injuries requiring emergency surgery coexisting with injuries that can be repaired at any time. The anesthesiologist plays an important role in determining which procedures to perform, in which order, and which procedures should be postponed until the patient is more stable.

Anesthesia in War and Austere Conditions

"While it is evident that the general principles of anesthesia are not affected by the circumstances of war, it is equally evident that it is our duty to assiduously seek those means in anesthesia which are especially suited to the exigencies of battle."[18]

Though written in 1942, these words are still true today and many of the principles developed from earlier wars still apply on the modern battlefield or in a large-scale disaster (see Chapter 74). Recent conflicts and events have allowed anesthesiologists, nurse anesthetists, and other providers to help improve management of traumatically injured patients in the areas of anesthesia, resuscitation, and damage control surgery. Management of battlefield casualties typically follows the same flow as outlined earlier, but with special consideration in the areas of prehospital interventions, resuscitation, technologic and logistic support, patient movement, mass casualty management, and surgical interventions.[19]

Modern advancements in battle armor, prehospital interventions, provision of forward surgical support, and resuscitative strategies have had an impact on survival from combat injuries. During the most recent conflicts in Iraq and Afghanistan, the killed-in-action rate has dropped to 13.9% from 20.2% in Vietnam and World War II.[20] This is mirrored by a similar reduction in the case fatality rate. Paradoxically, the ability to get many of the severely wounded patients to a hospital has led to an increase in the "died-of-wounds" rate. Most likely this rate would be even higher if not for improvements in surgical management such as damage control techniques, improved ICU care, earlier recognition of abdominal compartment syndrome, liberal use of fresh whole blood, and institution of a theater-wide trauma system approach.

One of the major advances in battlefield medical support has been the rapid movement of patients out of the theater of operations to more comprehensive medical facilities. In the most recent conflict, the time from injury in the Middle East until return to the United States is frequently less than 72 hours for even the most seriously injured patients.[21] This may include initial in-theater damage control surgery followed by one or two aeromedical evacuation missions lasting up to 12 hours with a critical care air transport team (CCATT). In preparation for such rapid movement, the anesthesiologist must ensure that perioperative

interventions such as airway management, pain control, and adequacy of resuscitation are addressed before transfer. In addition, anesthesiologists are frequently assigned to a CCATT as the physician team member based on their overall skill set and ability to provide en route support to critically ill or injured patients. Beyond the support provided during wartime, the CCATT has also proved useful for the movement of critical patients during large-scale disasters such as occurred after Hurricane Katrina in 2005.[22]

Mass casualty situations are not uncommon in wartime conditions, although the role of the anesthesiologist will vary depending on the number of patients and requirements for urgent surgical interventions. Given the limited number of anesthesia providers in most combat-related scenarios, it is unlikely that they will be directly involved in the triage process. If available, however, emergency airway management, establishment of venous access, and supervision of resuscitative efforts would be augmented by anesthesia support. Only 10% to 20% of arriving casualties require immediate lifesaving interventions, although a much larger percentage will ultimately require surgical procedures.[23] As a theater matures, a well-developed trauma system will evolve and management of mass casualty scenarios will become routine.[24]

Overall anesthetic management of battlefield casualties is similar to that for patients in a civilian trauma setting; however, a number of factors must be considered in the perioperative plan for a combat casualty.[25] Environmental considerations such as extremes of temperature, availability of water, contamination with sand, lack of consistent electricity, and other aspects may have to be taken into consideration. Logistic support chains may be long and not keep up with use of supplies in the early phases of a conflict. Deployable equipment, such as draw-over vaporizer systems or portable ventilators, may be different from those used during peacetime, so predeployment training is vital (Fig. 72-3).[26]

In addition, techniques such as total intravenous anesthesia and regional anesthesia/analgesia will frequently be used and thus require familiarity with their management and associated equipment (see Chapters 51 and 52).[25]

Optimal care of wartime casualties or victims of large disasters requires not only familiarity with a broad range of anesthetic principles and techniques but also the ability to be flexible in the face of a rapidly changing environment. With special training in airway management, provision of anesthesia and sedation, resuscitation, and pain management, anesthesiologists may find themselves involved in triage, emergency management, and perioperative and critical care.

Emergency Airway Management

The American Society of Anesthesiologists (ASA) algorithm for management of difficult airways (see Fig. 50-2) is a useful starting point for the trauma anesthesiologist, whether in the ED or the OR.[27] Although the options included will vary from institution to institution and provider to provider, the concept of the algorithm is an important one. The anesthesiologist should have a plan for the initial approach to the airway and for coping with any difficulties that might develop. Figure 72-4 is a typical algorithm for emergency intubation of an unstable trauma patient. Note that it differs from the ASA algorithm in that reawakening the patient is seldom an option because the need for emergency airway control will presumably remain. Once the decision to obtain a definitive airway is made, efforts will continue until a cuffed tube is in position in the trachea, whether by conventional intubation or via a surgical approach. Failure to commit to a surgical airway soon enough results in bad outcomes more commonly

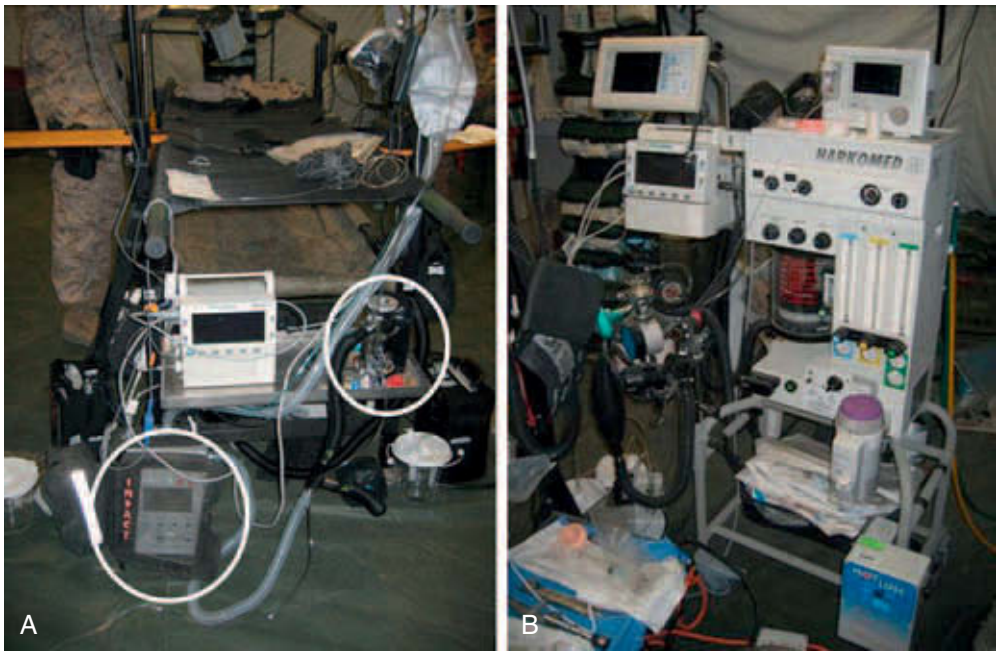

Figure 72-3 Deployable military anesthesia equipment. **A,** Draw-over vaporizer and portable ventilator (*circled*) in a field hospital. **B,** Portable anesthesia machine. *(Used with permission from CPT Bruce Baker, M.D., USN.)*

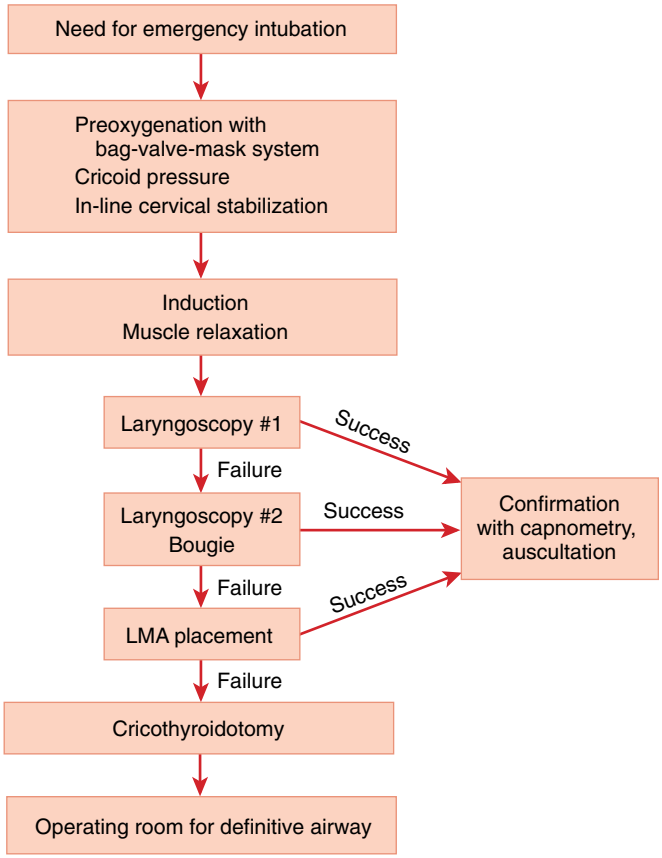

Figure 72-4 Emergency airway management algorithm used at the R Adams Cowley Shock Trauma Center, presented as an example. Individual practitioners and trauma hospitals should determine their own algorithm based on available skills and resources. LMA, laryngeal mask airway.

than do complications of a procedure that might have been unnecessary.

Indications

The goal of emergency airway management is to ensure adequate oxygenation and ventilation while protecting the patient from the risks of aspiration. Endotracheal intubation is commonly required and is specifically indicated in the following conditions:

- Cardiac or respiratory arrest
- Respiratory insufficiency (see Box 72-1)
- Airway protection
- The need for deep sedation or analgesia, up to and including general anesthesia
- Transient hyperventilation of patients with space-occupying intracranial lesions and evidence of increased intracranial pressure (ICP)
- Delivery of a 100% fraction of inspired oxygen (Fio_2) to patients with carbon monoxide poisoning
- Facilitation of the diagnostic workup in uncooperative or intoxicated patients

Approach to Endotracheal Intubation

In general, the anesthesiologist should insist on the same monitoring standards for airway management in the ED as in the OR, including an electrocardiogram (ECG), blood pressure, oximetry, and capnometry. Appropriate equipment, including an oxygen source, bag-valve-mask ventilating system, mechanical ventilator, suction, and a selection of laryngoscope blades, endotracheal tubes, and devices for managing difficult intubations, should be available in any location where emergency intubation is likely, including the ED.

Endotracheal intubation is best accomplished in almost all cases with a modified rapid-sequence approach by an operator with experience in this practice. Although concern may exist that the use of neuromuscular blocking drugs and potent anesthetics outside the OR will be associated with a higher complication rate,[28] in fact the opposite is more likely correct. Anesthesia and neuromuscular blockade allow the best intubating conditions on the first approach to the patient's airway, which is advantageous in an uncooperative, hypoxic, or aspirating patient. Attempts to secure the airway in an awake or lightly sedated patient increase the risk for airway trauma, pain, aspiration, hypertension, laryngospasm, and combative behavior. Experienced providers, supported by appropriate monitoring and equipment, have achieved results of medication-assisted intubation outside the OR that are equivalent to those for emergency intubation within the OR (Table 72-2).[29-31]

Prophylaxis Against Aspiration of Gastric Contents

A trauma patient is always considered to have a full stomach and to be at risk for aspiration during induction of anesthesia. Reasons include ingestion of food or liquids before the injury, swallowed blood from oral or nasal injuries, delayed gastric emptying associated with the stress of trauma, and administration of liquid contrast medium for abdominal CT scanning. As with obstetric anesthesia (see Chapter 69), it is reasonable to administer nonparticulate antacids to a trauma patient before induction if time and patient cooperation allow.

Cricoid pressure—the Sellick maneuver—should be applied continuously during emergency airway management from the time that the patient loses protective airway reflexes until

Table 72-2 Drug-Assisted Intubation outside the Operating Room (OR)

Author(s)	Number of Patients	Problems
Rotondo et al.[29]	204	No difference from the OR
Stene et al.[30]	>3000	None noted
Talucci et al.[31]	260	No hemodynamic or neurologic complications
Karlin*	647	No difference from the OR

endotracheal tube placement and cuff inflation are confirmed. The Sellick maneuver consists of elevating the patient's chin (without displacing the cervical spine) and then pushing the cricoid cartilage posteriorly to close the esophagus. Although the value of cricoid pressure in occluding the esophagus is debatable, it costs nothing to perform and may offer secondary benefits.[32,33] Posterior displacement of the larynx may improve the view for the intubator, whereas palpation of the larynx during intubation can provide a clue to anatomic distortions and an early suggestion that the endotracheal tube has been placed correctly. Some recent evidence, however, suggests that cricoid pressure may worsen the laryngoscopic grade of view in up to 30% of patients.[34] It is appropriate for the intubator to request that cricoid pressure be released if this problem is suspected.

In the traditionally defined rapid-sequence induction of anesthesia, any attempt at ventilation between administration of medication and intubation is avoided, presumably because positive-pressure ventilation may force gas into the patient's stomach, leading to regurgitation and aspiration. The reasoning for this is unclear inasmuch as appropriate application of cricoid pressure should prevent any entry of air into the esophagus. Indeed, Sellick's original paper described ventilation during cricoid pressure in patients with full stomachs.[35] Furthermore, the increase in oxygen consumption in trauma patients necessitates preoxygenation whenever possible, and because preoxygenation may be difficult in a trauma patient—as a result of facial trauma, decreased respiratory effort, or agitation—rapid desaturation is a possibility. Positive-pressure ventilation during all phases of induction provides the largest possible oxygen reserve during emergency airway management and will help mitigate hypoxia if intubation proves difficult.

Protection of the Cervical Spine

Standard practice dictates that all blunt trauma victims be assumed to have an unstable cervical spine until this condition is ruled out.[15] The airway management of these patients receives much attention from anesthesiologists because direct laryngoscopy causes cervical motion, with the potential to exacerbate spinal cord injury (SCI).[36] Stabilization of the cervical spine will generally occur in the prehospital environment, with the patient already having a rigid cervical collar in place. This collar may be kept in place for several days before the complete gamut of tests to rule out cervical spine instability have been completed (see later). The presence of an "uncleared" cervical spine mandates the use of in-line manual stabilization (not traction) throughout any attempt at intubation.[15] This approach allows removal of the front of the cervical collar to facilitate wider mouth opening and jaw displacement. In-line stabilization has been tested through considerable clinical experience and is the standard of care in the ATLS curriculum. Emergency awake fiberoptic intubation, though requiring less manipulation of the neck, is generally very difficult because of airway secretions and hemorrhage, rapid desaturation, and lack of patient cooperation and is best reserved for cooperative patients with known cervical instability under controlled conditions. Indirect video laryngoscopy with systems such as the Bullard laryngoscope[37] or GlideScope[38,39] offer the potential to enjoy the best of both worlds: an anesthetized patient and minimal cervical motion. However, it will require years of clinical experience to verify this hypothesis.

Figure 72-5 Emergency intubation of a trauma patient immobilized on a long spine board. The front of the cervical collar is removed once in-line manual stabilization of the spine is established to allow cricoid pressure and greater excursion of the mandible. *(Reprinted with permission from Dutton RP: Spinal cord injury. Int Anesthesiol Clin 40:111, 2002.)*

Personnel

Emergency intubation requires more assistance than an intubation performed under controlled conditions (see Chapter 6). Three providers are required to ventilate the patient, hold cricoid pressure, and provide in-line cervical stabilization; a fourth provider to administer anesthetic medications allows the intubating physician to maintain uninterrupted focus on the patient's airway. Figure 72-5 is an illustration of this approach. Additional assistance may be required to restrain a patient who is combative as a result of intoxication or TBI.

The immediate presence of a surgeon or other physician who can expeditiously perform a cricothyroidotomy is desirable. Even if a surgical airway is not required, additional experienced hands may prove useful during difficult intubations. The surgeon may also wish to inspect the upper airway during laryngoscopy if there has been trauma to the face or neck. Urgent tube thoracostomy may prove necessary in some trauma patients to treat the tension pneumothorax that develops with the onset of positive-pressure ventilation.

Anesthetics and Induction of Anesthesia

Any intravenous anesthetic administered to a trauma patient in hemorrhagic shock may potentiate profound hypotension and even cardiac arrest as a result of inhibition of circulating catecholamines. Although propofol and sodium thiopental are the mainstays of intravenous induction in the OR, their use in trauma patients is especially problematic because both drugs are vasodilators and both have a negative inotropic effect. Moreover, the effects of hemorrhagic shock on the brain appear to potentiate the effects of these anesthetics, with propofol doses as small as one tenth of normal producing deep anesthesia in animals in shock.[40] Etomidate is a frequently espoused alternative because of its cardiovascular stability in comparison with other intravenous

hypnotic drugs in the trauma population,[41-43] although its inhibition of catecholamine release may still produce profound hypotension.

Ketamine continues to be popular for induction of anesthesia in trauma patients because it is a CNS stimulant.[44] However, it is also a direct myocardial depressant.[45,46] In normal patients the effect of catecholamine release masks cardiac depression and results in hypertension and tachycardia. In hemodynamically stressed patients the cardiac depression may be unmasked and lead to cardiovascular collapse.[47]

Hypotension will develop in hypovolemic patients with the administration of any anesthetic because of interruption of compensatory sympathetic outflow and the sudden change to positive-pressure ventilation. Previously healthy young patients can lose up to 40% of their blood volume before experiencing a decrease in blood pressure, thereby leading to potentially catastrophic circulatory collapse with induction of anesthesia, regardless of the anesthetic chosen. The dose of anesthetic must be decreased in the presence of hemorrhage, down to none at all in patients with life-threatening hypovolemia. Rapid-sequence induction of anesthesia and endotracheal intubation may proceed with muscle relaxants alone, although onset time may be prolonged in a patient with circulatory impairment. Subsequent patient recall of intubation and emergency procedures is highly variable and affected by the presence of coexisting TBI, intoxication, and the depth of hemorrhagic shock (see Chapter 11). Decreased cerebral perfusion appears to inhibit memory formation but cannot be reliably associated with any particular blood pressure or chemical marker. Administration of 0.2 mg of scopolamine (a tertiary ammonium vagolytic) has been advocated to inhibit memory formation in the absence of anesthetic drugs in this situation, but it may interfere with subsequent neurologic examination because of its long half-life. Small doses of midazolam will reduce the incidence of patient awareness but can also contribute to hypotension. Although recall of ED and OR events is not unusual in this circumstance, anesthesia provider liability appears to be limited; a recent analysis of intraoperative awareness lawsuits in the ASA Closed Claims Database revealed no claims related to surgery in trauma patients.[48]

Neuromuscular Blocking Drugs

Succinylcholine remains the neuromuscular blocker with fastest onset—less than 1 minute—and shortest duration of action—5 to 10 minutes (see Chapter 29). These properties make it popular for rapid-sequence induction of anesthesia. Although the use of succinylcholine may allow return of spontaneous respiration before the development of significant hypoxia in the "cannot intubate, cannot ventilate" situation, this is unlikely to be of benefit in an emergency intubation in a trauma patient. The anesthesiologist should not rely on return of spontaneous breathing in time to salvage a difficult airway management problem but should instead proceed with efforts to obtain a definitive airway, including cricothyroidotomy if other possibilities have been exhausted.

Administration of succinylcholine is associated with several adverse consequences. Increases in serum potassium of 0.5 to 1.0 mEq/L are expected, but in certain patients potassium may increase by more than 5 mEq/L.[49] A hyperkalemic response is typically seen in burn victims and those with muscle pathology secondary to direct trauma, denervation (as with SCI), or immobilization. Hyperkalemia is not seen in the first 24 hours after these injuries, and succinylcholine may be used safely for acute airway management. Patients at risk are those with underlying pathology before their traumatic event or those undergoing subsequent surgery in the weeks to months after injury.

Succinylcholine causes an increase in intraocular pressure and should be used cautiously in patients with ocular trauma.[50] Succinylcholine may also increase ICP,[51] so its use in brain trauma victims is controversial. In both these cases, however, hypoxia and hypercapnia may be as damaging as the transient increase in pressure caused by the drug. If the use of succinylcholine will lead to faster intubation, its benefits may outweigh its risks. The provider must weigh the use of succinylcholine in each individual situation based on the acuity of CNS injury, the anticipated speed with which intubation can be accomplished, and the likelihood that hypoxia will develop.

Alternatives to succinylcholine include rocuronium (0.9 to 1.2 mg/kg) and vecuronium (0.1 to 0.2 mg/kg). Because these drugs have no significant cardiovascular toxicity, large doses can be administered to achieve rapid (1- to 2-minute) systemic relaxation. Unfortunately, at this dose the duration of action of either rocuronium or vecuronium will be 1 to 2 hours, which may be of significance if inadequate sedation leads to patient awareness of paralysis or if it prevents ongoing neurologic assessment. An exciting different approach could come about with the introduction of sugammadex as an antagonist of rocuronium-induced neuromuscular blockage. Specifically, instead of succinylcholine for rapid-sequence induction of anesthesia, rocuronium, 0.9 to 1.2 mg/kg, would be given, the trachea intubated, and then the profound block immediately reversed by sugammadex (see Chapter 29 for details).

There will always be specific situations in which maintaining spontaneous ventilation during intubation is the preferred manner in which to proceed. If patients are able to maintain their airway temporarily but have clear indications for an artificial airway (e.g., penetrating trauma to the trachea), slow induction with ketamine or inhaled sevoflurane through cricoid pressure will enable placement of an endotracheal tube without compromising patient safety.

Adjuncts to Endotracheal Intubation

Equipment to facilitate difficult intubation should be readily available wherever emergency airway management is performed. The particular equipment available depends on the preferences of the anesthesiologist; the usefulness of most special equipment depends more on previous experience than on any intrinsic properties of the device. Certain items deserve mention, however, because of their frequent citation as aids to management of a difficult airway.

The *gum elastic bougie*, or intubating stylet, is an inexpensive and easily mastered adjunct for management of a difficult airway. The stylet is placed through the vocal cords via direct laryngoscopy, and the endotracheal tube is then advanced over the stylet into the trachea. Placement of the bougie is easier than direct placement of an endotracheal tube because of both its smaller diameter and the ability of an experienced operator to feel it enter the trachea even when the glottic opening cannot be visualized. The bougie is passed under the epiglottis and gently advanced; if resistance is met, it is withdrawn, rotated slightly, and

advanced again. In this fashion the anesthesiologist can blindly "palpate" the larynx until the bougie advances into the trachea. The bougie can also be used with indirect video laryngoscopy systems such as the GlideScope and is especially useful in the ED when the sniffing position cannot be used because of uncertainty about the cervical spine. The GlideScope may provide improved visualization (based on the Cormack score) and facilitate safe intubation in patients wearing a cervical collar.[52]

The *esophageal Combitube* may be used by paramedics as a backup for failed intubation in the prehospital environment; in many jurisdictions it is the sanctioned airway rescue device for failed rapid-sequence intubation (RSI). Because placement of the Combitube has been associated with esophageal injury, its use should be reserved for emergency situations.[53-55]

The *laryngeal mask airway* (LMA) (LMA North America, San Diego, CA) is recommended in the ASA algorithm for management of a patient with a difficult airway. The LMA can be used as a guide for intubation when an unsuspected difficult intubation is encountered in a trauma patient; an endotracheal tube may be placed blindly through the lumen of the LMA and into the trachea, or a fiberoptic bronchoscope may be used to guide the tube through the LMA. The LMA is an appropriate rescue device for a difficult airway situation in trauma, provided that there is no major anatomic injury or hemorrhage in the mouth and larynx. In our practice the LMA has most commonly been used as a bridge to emergency tracheostomy because it allows more controlled conditions than a cricothyroidotomy does.

Oral Versus Nasotracheal Intubation

The most recent ATLS guidelines suggest that practitioners providing emergency airway management should proceed with the method of intubation with which they are most proficient.[15] In general, oral intubation is preferable to nasal intubation in the emergency setting because of the risk of injury to the brain from nasal instrumentation in the presence of a basilar skull or cribriform plate fracture. Furthermore, nasal intubation poses a risk for sinusitis in a patient who will be mechanically ventilated for longer than 24 hours, and use of a smaller-diameter tube will also increase the difficulty of subsequent airway suctioning and fiberoptic bronchoscopy. If nasal intubation is most likely to be successful in a given situation, however, this is the route that should be used. Change to an oral tube with a larger internal diameter can occur once the patient's condition has stabilized.

Facial and Pharyngeal Trauma

Trauma to the face and upper airway poses particular difficulties for the anesthesiologist. Serious skeletal derangements may be masked by apparently minor soft tissue damage. Failure to identify an injury to the face or neck can lead to acute airway obstruction secondary to swelling and hematoma. Laryngeal edema is also a risk in patients who have suffered chemical or thermal injury to the pharyngeal mucosa. Intraoral hemorrhage, pharyngeal erythema, and change in voice are all indications for early intubation.

In general, both maxillary and mandibular fractures will make ventilation by mask more difficult, whereas mandibular fractures will make endotracheal intubation easier. Palpation of the facial bones before manipulation of the airway will alert the anesthetist to these possibilities. Patients with injuries to the jaw and zygomatic arch often have trismus. Although the trismus will resolve with the administration of neuromuscular blocking agents, preinduction assessment of airway anatomy may be difficult. Bilateral mandibular fractures and pharyngeal hemorrhage may lead to upper airway obstruction, particularly in a supine patient, although intubation may be easier because of loss of skeletal resistance to direct laryngoscopy. A patient arriving at the ED in the sitting or prone position because of airway compromise is best left in that position until the moment of anesthetic induction and intubation.

Resuscitation from Hemorrhagic Shock

Resuscitation refers to restoration of normal physiology after injury. Resuscitation from hemorrhagic shock refers specifically to restoration of normal circulating blood volume, normal vascular tone, and normal tissue perfusion. Resuscitation begins immediately after injury, via the patient's own compensatory mechanisms, and continues through the prehospital, ED, OR, and ICU phases of care.

Pathophysiology of Hemorrhagic Shock

The initial response to hemorrhage takes place on the macrocirculatory level and is mediated by the neuroendocrine system. Decreased blood pressure leads to vasoconstriction and release of catecholamines. Heart, kidney, and brain blood flow is preserved, whereas other regional beds are constricted. Pain, hemorrhage, and cortical perception of traumatic injuries lead to the release of hormones and other inflammatory mediators, including renin, angiotensin, vasopressin, antidiuretic hormone, growth hormone, glucagon, cortisol, epinephrine, and norepinephrine.[56] This response sets the stage for the microcirculatory response that follows.

Individual ischemic cells respond to hemorrhage by taking up interstitial fluid, thus further depleting intravascular fluid.[57] Cellular edema may choke off adjacent capillaries and result in the "no-reflow" phenomenon, which prevents reversal of ischemia, even in the presence of adequate macroperfusion.[58] Ischemic cells produce lactate and free radicals, which accumulate in the circulation if perfusion is diminished. These compounds cause direct damage to the cell and form the bulk of the toxic load that washes back to the central circulation when flow is reestablished. Ischemic cells also produce and release inflammatory factors: prostacyclin, thromboxane, prostaglandins, leukotrienes, endothelin, complement, interleukins, tumor necrosis factor, and others.[59] Figure 72-6 shows the inflammatory response to shock, with an emphasis on immune system amplification. This inflammatory response, once begun, becomes a disease process independent of its origin. This is why a patient may die of multiple organ failure after traumatic hemorrhage even when bleeding has been controlled and fluid volume restored.

Specific organ systems respond to traumatic shock in specific ways. The *central nervous system* is the prime trigger of the

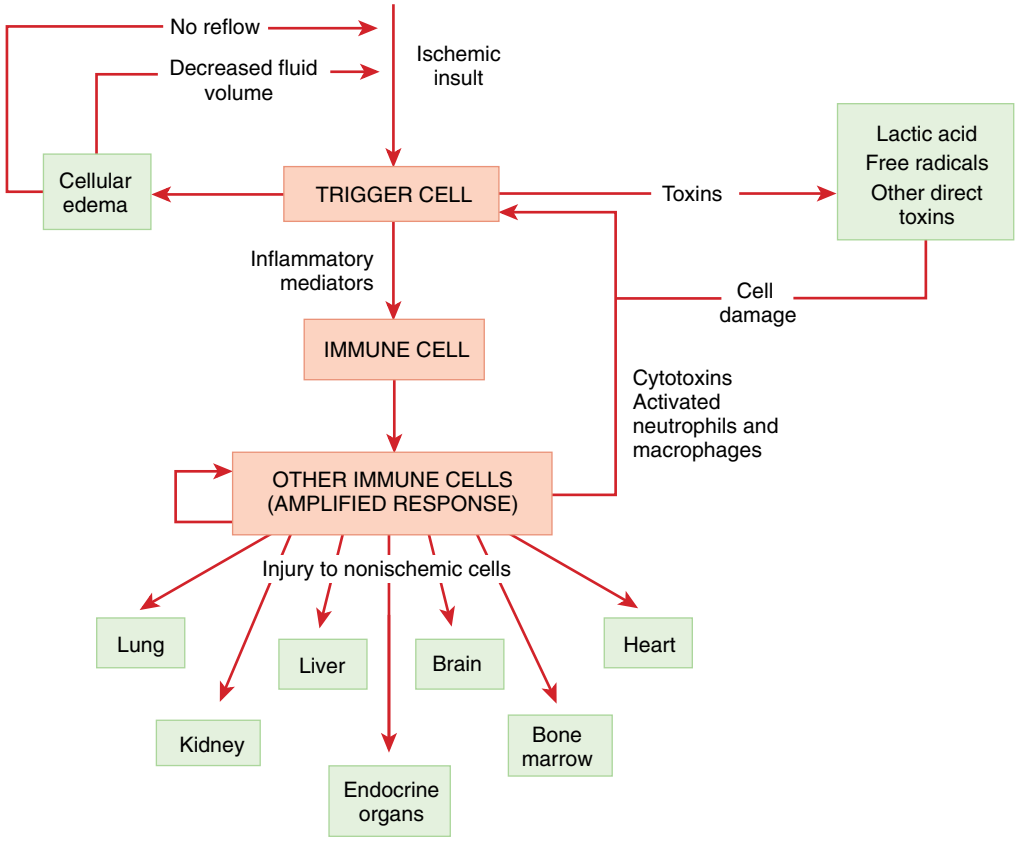

Figure 72-6 The "shock cascade." Ischemia of any given region of the body will trigger an inflammatory response that will have an impact on nonischemic organs even after adequate systemic perfusion has been restored. *(Reprinted with permission from Dutton RP: Shock and trauma anesthesia. In Grande CM, Smith CE [eds]: Anesthesiology Clinics of North America: Trauma. Philadelphia, WB Saunders, 1999, pp 83-95.)*

neuroendocrine response to shock, which maintains perfusion to the heart, kidney, and brain at the expense of other tissues.[60] Regional glucose uptake in the brain changes during shock.[61] Reflexes and cortical electrical activity are both depressed during hypotension; these changes are reversible with mild hypoperfusion but become permanent with prolonged ischemia. Failure to recover preinjury neurologic function is a marker for a poor prognosis, even when normal vital signs are restored.[62]

The *kidney* and *adrenal glands* are prime responders to the neuroendocrine changes associated with shock and produce renin, angiotensin, aldosterone, cortisol, erythropoietin, and catecholamines.[63] The kidney maintains glomerular filtration in the face of hypotension by selective vasoconstriction and concentration of blood flow in the medulla and deep cortical area. Prolonged hypotension leads to decreased cellular energy and an inability to concentrate urine (renal cell hibernation), followed by patchy cell death, tubular epithelial necrosis, and renal failure.[64]

The *heart* is preserved from ischemia during shock because of maintenance of or even an increase in nutrient blood flow, and cardiac function is well preserved until the late stages. Lactate, free radicals, and other humoral factors released by ischemic cells all act as negative inotropes and, in a bleeding patient, may produce cardiac dysfunction as the terminal event in the shock spiral.[65] A patient with cardiac disease or direct cardiac trauma is at great risk for decompensation because a fixed stroke volume inhibits the body's ability to increase blood flow in response to hypovolemia and anemia. Tachycardia is the patient's only option, with potentially disastrous consequences on the oxygen supply-demand balance in the heart itself. Shock in the elderly may therefore be rapidly progressive and not respond predictably to fluid administration.[66]

The *lung* is the filter for the inflammatory by-products of the ischemic body. Immune complex and cellular factors accumulate in pulmonary capillaries and lead to neutrophil and platelet aggregation, increased capillary permeability, destruction of lung architecture, and acute respiratory distress syndrome (ARDS).[67,68] The lung is the sentinel organ for the development of multiple organ system failure (MOSF) in a traumatic shock patient.[69,70] Pure hemorrhage, in the absence of hypoperfusion, does not produce pulmonary dysfunction.[71] This is evidence that traumatic shock is more than just a hemodynamic disorder.

The *gut* is one of the earliest organs affected by hypoperfusion and may be the prime trigger of MOSF. Intense vasoconstriction occurs early and frequently leads to a "no-reflow" phenomenon, even when the macrocirculation is restored.[72] Intestinal cell death causes a breakdown in the barrier function of the gut that results in increased translocation of bacteria to the liver and lung, thereby potentiating ARDS.[73]

The *liver* has a complex microcirculation and may experience reperfusion injury during recovery from shock.[74] Hepatic cells are also metabolically active and contribute to the ischemic inflammatory response and to irregularities in blood glucose.[75] Failure of synthetic function of the liver after shock is almost always lethal.

Skeletal muscle is not metabolically active during shock and tolerates ischemia better than other organs do. The large mass of skeletal muscle, though, makes it important in the generation of lactic acid and free radicals from ischemic cells. Sustained ischemia of muscle cells leads to an increase in intracellular sodium and free water, with an aggravated depletion of fluid in the vascular and interstitial compartments.[76]

Early Resuscitation

Fluid administration is the cornerstone of resuscitation (see Chapters 88 and 97). Intravascular volume is lost to hemorrhage, to uptake by ischemic cells, and to extravasation into the interstitial space. Administration of intravenous fluids will predictably increase cardiac output and blood pressure in a hypovolemic trauma patient. The ATLS curriculum advocates rapid infusion of up to 2 L of warmed isotonic crystalloid solution in any hypotensive patient with the goal of restoring normal blood pressure.[15]

This approach has been questioned in recent years because of a growing awareness that fluid administration during active hemorrhage may be counterproductive. Dilution of red cell mass reduces oxygen delivery and contributes to hypothermia and coagulopathy. Elevation of blood pressure leads to increased bleeding as a result of disruption of clots and reversal of compensatory vasoconstriction.[77] The result of aggressive fluid administration is often a transient rise in blood pressure, followed by increased bleeding, another episode of hypotension, and the need for more volume administration. This vicious circle has been recognized since the First World War and remains a complication of resuscitation therapy today. The ATLS manual characterizes such patients as "transient responders" with active, ongoing hemorrhage.[15] Resuscitation of these patients should be considered in two phases:

- *Early*, while active bleeding is still ongoing
- *Late*, once all hemorrhage has been controlled

Managing late resuscitation is driven by end-point targets and consists of giving enough fluid to maximize oxygen delivery. Early resuscitation is much more complex because the risks associated with aggressive volume replacement (see Box 72-4), including the potential for exacerbating hemorrhage and thus prolonging the crisis, must be weighed against the risk of hypoperfusion and ischemia.

Box 72-4 Risks Associated with Aggressive Volume Replacement during Early Resuscitation*

Increased blood pressure
Decreased blood viscosity
Decreased hematocrit
Decreased clotting factor concentration
Greater transfusion requirement
Disruption of electrolyte balance
Direct immune suppression
Premature reperfusion
Increased risk for hypothermia

*Most complications of volume resuscitation arise from increased hemorrhage volume or excessive hemodilution.

Deliberate hypotensive management is an accepted standard of anesthetic care for elective surgical procedures such as total joint replacement, spinal fusion, radical neck dissection, reconstructive facial surgery, and major pelvic or abdominal procedures.[78] Application of this technique to the initial management of hemorrhage is controversial and has been the focus of numerous laboratory and clinical research efforts. In 1965 Shaftan and colleagues published the results of a study of coagulation in dogs in which it was demonstrated that the formation of a soft extraluminal clot limits bleeding after arterial trauma.[79] This study compared the quantity of blood lost from a standardized arterial injury under a variety of conditions. The least blood loss occurred in hypotensive animals (whether hypotensive from hemorrhage or from administration of a vasodilator), followed by the control group and then vasoconstricted animals. The largest amount of blood was lost in animals that underwent vigorous reinfusion during the period of hemorrhage.

Laboratory data have shown the benefits of limiting intravascular fluid volumes and blood pressure in actively hemorrhaging animals.[80-83] In the most sophisticated models, direct assessment of cardiac output and regional perfusion showed no difference between moderate- or large-volume resuscitation in terms of cardiac output, arterial blood pressure, or regional perfusion of the heart, kidneys, and intestines. Moderate resuscitation (to a lower than normal blood pressure) improved perfusion of the liver.[84] Burris and coworkers studied both conventional resuscitation fluids and various combinations of hypertonic saline and dextran and found that rebleeding was correlated with higher mean arterial pressure (MAP) and that survival was best in groups resuscitated to lower than normal MAP. The optimum target blood pressure for resuscitation varied with the composition of the fluid used.[85] A 1994 consensus panel on resuscitation from hemorrhagic shock noted that mammalian species are capable of sustaining MAP as low as 40 mm Hg for periods as long as 2 hours without deleterious effects. The panel concluded that spontaneous hemostasis and long-term survival were maximized by reduced administration of resuscitation fluids during the period of active bleeding in an attempt to keep perfusion only just above the threshold for ischemia.[86]

To date there have been two published prospective studies of deliberate hypotensive resuscitation in trauma patients. The first was that of Bickell and colleagues in 1994.[87,88] The investigators randomized victims of penetrating torso trauma to one of two treatment groups: standard of care (up to 2 L of crystalloid infused in the prehospital setting) or delayed resuscitation (no fluid until the patient reached the OR). This well-managed 37-month study eventually included 598 patients. Average times of transport and care were 30 minutes from injury to the ED and then 50 minutes before reaching the OR; the fluid-restricted group received an average of about 800 mL of fluid during this time. The immediate-resuscitation group received an average of 2500 mL of crystalloid and 130 mL of blood over this same period. Though substantially different during the period of study, blood pressure on arrival at the OR was similar in both groups, which the authors took as evidence that the unresuscitated group had achieved spontaneous hemostasis. Survival to hospital discharge in the delayed-resuscitation group was significantly improved over the immediate-resuscitation group (70% versus 62% [$P = .04$]). No

Table 72-3 Results of a Randomized Trial of Deliberate Hypotensive Resuscitation*

	Conventional	Hypotensive	Total
Patients enrolled	55	55	110
Male	46	41	87
Blunt trauma	22	31	53
Penetrating trauma	33	24	57
Injury severity score	19.65	23.62 ($P = .11$)	
Predicted survival	0.94	0.90 ($P = .19$)	
Systolic blood pressure during study period	114	100 ($P < .001$)	
Survived to discharge	51	51	
Died	4	4	

*The probability of survival was calculated from published historical data.

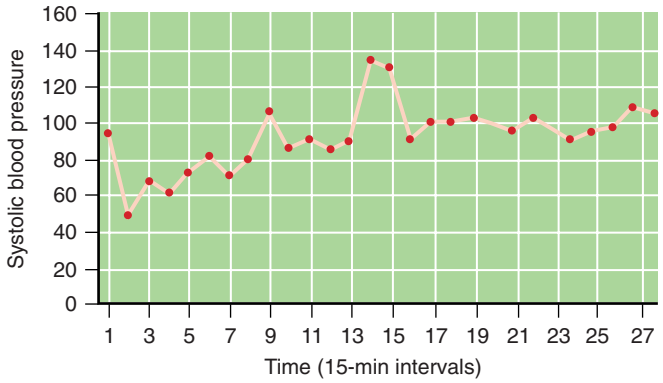

Figure 72-7 Typical systolic blood pressure measurements of a patient undergoing damage control surgery for a grade V liver injury during deliberate hypotensive management. Oscillations in blood pressure are common during early resuscitation because of ongoing hemorrhage and bolus fluid administration. Once hemorrhage is controlled, blood pressure will stabilize.

data were presented on the conduct of anesthesia after arrival at the OR but before control of hemorrhage or on the incidence of rebleeding after volume loading and induction of anesthesia in patients who had achieved hemostasis preoperatively.

A retrospective review of trauma admissions to the Los Angeles Medical Center published in 1996 supported these findings. Patients brought to the hospital by private conveyance fared substantially better than those delivered by paramedics, even with high levels of injury severity.[89] Further corroboration was provided by retrospective examination of outcomes in a population of hemorrhaging trauma patients who received fluids via a commercial rapid infusion system (RIS) (Haemonetics, Inc.) during initial resuscitation.[90] The survival rate of this group was compared with that predicted by the institution's trauma registry. RIS patients, when compared with case-matched controls, had a survival rate of only 56.8% versus 71.2% for patients of similar age with similar injuries ($P < .001$).

This retrospective review was followed in 2002 by the second prospective trial of delayed resuscitation in trauma patients.[91] Patients with systolic blood pressure lower than 90 mm Hg and clinical evidence of blood loss were randomized to fluid resuscitation titrated to a systolic blood pressure of 100 mm Hg (normal group) or 70 mm Hg (study group) until the end of surgical interventions to control hemorrhage. The results of this study are summarized in Table 72-3. As in the Bickell study, hypotension allowed spontaneous resolution of hemorrhage and autoresuscitation; blood pressure would increase without exogenous fluid administration once hemostasis was achieved. The typical patient began with a low initial pressure, followed by recovery to the vicinity of the target, overshoots and undershoots as bleeding and fluid administration continued, and an eventual rise above the target when the hemorrhage resolved, even in the absence of further fluid administration (Fig. 72-7). The 93% overall survival rate in this study was more frequent than predicted from historical data and substantially higher than seen in Bickell's group. This reflects the exclusion of patients who died in the prehospital phase or arrived at the trauma resuscitation unit in a moribund condition. It may also reflect improvements in overall care, an observation effect (i.e., patients in both groups received better care than patients not in the study did), or a bias in subject recruitment. Over the first 24 hours, lactate and base deficit cleared to normal in both groups and required similar amounts of fluid and blood products, thus suggesting that both groups were reaching an equivalent resuscitation end point. The authors concluded that administration of fluids to an actively hemorrhaging patient should be titrated to specific physiologic end points, with the anesthesiologist navigating a course between the Scylla of increased hemorrhage and the Charybdis of hypoperfusion.

The effect of anesthetic drugs on the body's response to hemorrhage is an important difference between deliberate hypotension occurring in the elective operative setting and hemorrhagic shock occurring in the ED. Hypotensive trauma patients receive a minimum of anesthetics, even for induction, because of the obvious effect of these drugs on arterial blood pressure. A hypotensive trauma patient is thus in a state of profound vasoconstriction, as opposed to a patient undergoing elective intraoperative hypotension, who is vasodilated by general anesthesia before any blood loss. Table 72-4 summarizes the physiologic contrasts between these two states. It should be noted that blood loss without shock does not produce systemic complications such

Table 72-4 Differences in Clinical Findings Between Surgical Patients Undergoing Elective Deliberate Hypotension and Emergency Trauma Cases*

Aspect	Elective	Trauma
Intravascular volume	Euvolemic	Hypovolemic
Temperature	Normal	Probably hypothermic
Capillary beds	Dilated	Constricted
Level of general anesthesia	Deep	Usually light
Preexisting mental status	Normal	May be impaired
Coexisting injuries	None	May be significant
Comorbid conditions	Known and managed	Unknown

*Each of these factors produces a real or perceived contraindication to the use of deliberate hypotensive technique in trauma patients.

Box 72-5 Goals for Early Resuscitation*

- Maintain systolic blood pressure at 80 to 100 mm Hg
- Maintain hematocrit at 25% to 30%
- Maintain the prothrombin time and partial thromboplastin time in normal ranges
- Maintain the platelet count at greater than 50,000 per high-power field
- Maintain normal serum ionized calcium
- Maintain core temperature higher than 35°C
- Maintain function of the pulse oximeter
- Prevent an increase in serum lactate
- Prevent acidosis from worsening
- Achieve adequate anesthesia and analgesia

*Fluid administration to limit hypoperfusion is balanced against an undesirable increase in blood pressure and thus bleeding.

as ARDS in experimental models.[71] Based on this physiology, the recommended goals for early resuscitation are expressed in Box 72-5, and an algorithm for management is presented in Figure 72-8. The emphasis in this situation must be on rapid diagnosis and control of ongoing hemorrhage; the anesthesiologist should attempt to restore vascular volume and provide anesthesia in equal measure by moving the patient from a vasoconstricted state to a vasodilated one while facilitating hemostasis by maintenance of lower than normal blood pressure.

Vulnerable Patient Populations

Clinical trials of deliberate hypotensive resuscitation have avoided the application of this technique to populations perceived to be at greater risk for ischemic complications,[87,91] including patients with known ischemic coronary disease, elderly patients, and those with injuries to the brain or spinal cord (see Chapters 35, 63, and 71). The prohibition against hypotension in patients with TBI is especially well established because of the observed disparity in outcome between TBI patients who experience hypotension and those who do not.[92,93] Older trauma patients suffer worse outcomes from similar injuries compared with younger patients, presumably because of their reduced physiologic reserve.[94] Clinical care of these patients is focused on avoidance of ischemic stress and rapid correction of hypovolemia. It may well develop, however, that deliberate hypotensive management to enable rapid control of hemorrhage is equally beneficial in vulnerable populations. There have been no clinical trials to date on this subject, but a laboratory study did find a benefit of deliberate hypotension in animals with both TBI and hemorrhagic shock.[95] Absent convincing human evidence, deliberate hypotension in older or brain-injured patients should generally be avoided.

Resuscitation Fluids

Isotonic crystalloids (normal saline, lactated Ringer's solution [LR], Plasma-Lyte A) are the initial resuscitative fluids administered to any trauma patient (see Chapter 88). They have the advantage of being inexpensive, readily available, nonallergenic, noninfectious, and efficacious in restoring total-body fluid. They are easy to store and administer, they mix well with infused medications, and they can be rapidly warmed to body temperature. Disadvantages of crystalloids include their lack of oxygen-carrying capacity, their lack of coagulation capability, and their limited intravascular half-life. More recent laboratory data have implicated specific crystalloid solutions as immunosuppressants and triggers of cellular apoptosis.[96] Unlike necrosis, apoptosis is highly regulated and involves gene modulation and complex pathways of signal transduction. It seems clear that apoptosis is an important element of reperfusion injury. In a rat model of controlled hemorrhage, animals receiving LR showed an immediate increase in apoptosis in the liver and small intestine after resuscitation.[97] Neither whole blood nor hypertonic saline increased the amount of apoptosis.

Hypertonic saline solutions, with or without the addition of polymerized dextran (HS or HSD), have been extensively studied in resuscitation from hemorrhagic shock.[98] In theory, HS will draw fluid into the vascular space from the interstitium and thereby reverse some of the nonhemorrhagic fluid loss caused by shock and ischemia. A given amount of HS will thus have an enhanced ability to restore intravascular volume when compared with an equivalent volume of an isotonic solution. This has made HS a popular choice for fluid resuscitation under austere conditions. HSD is licensed for prehospital use in a number of European countries and is used for resuscitation by units of the U.S. military. Multiple studies of otherwise lethal hemorrhage in animals have demonstrated improved survival after resuscitation with HSD versus either normal saline solution or the components of HSD alone. Studies of the efficacy of HSD in trauma patients have been inconclusive[99]; the most obvious benefit occurred in a subset of polytraumatized patients with both hemorrhage and TBI, in whom improved neurologic status was demonstrated in those who received HSD as a resuscitation fluid. Indeed, HS is commonly used as an osmotic agent in the management of TBI with elevated ICP.[100]

Colloids, including starch solutions and albumin, have been advocated for rapid plasma volume expansion. Like crystalloids, colloids are readily available, easily stored and administered, and relatively inexpensive. As with hypertonic solutions, colloids will increase intravascular volume by drawing free water back into the vascular space. When intravenous access is limited, colloid resuscitation will restore intravascular volume more rapidly than crystalloid infusion will and at a lower volume of administered fluid. Colloids do not transport oxygen or facilitate clotting; their dilutional effect will be similar to that of crystalloids. Recent studies have demonstrated no great benefit of colloids over crystalloids in a variety of resuscitation models.[101,102]

Many of the risks of aggressive intravascular fluid administration just summarized are related to dilution of the circulating blood volume. Recognition of this fact and continued improvement in the safety of donated blood have led to increased use of *blood products* in the management of early hemorrhagic shock (see Chapter 55). The risk of systemic ischemia is decreased by the maintenance of an adequate hematocrit, and the potential for dilutional coagulopathy can be avoided by the early administration of plasma. The composition of resuscitation fluids may be as important as the rate and timing of administration. A 4-year retrospective review of a cohort of critically injured patients who underwent emergency surgery examined the outcomes of

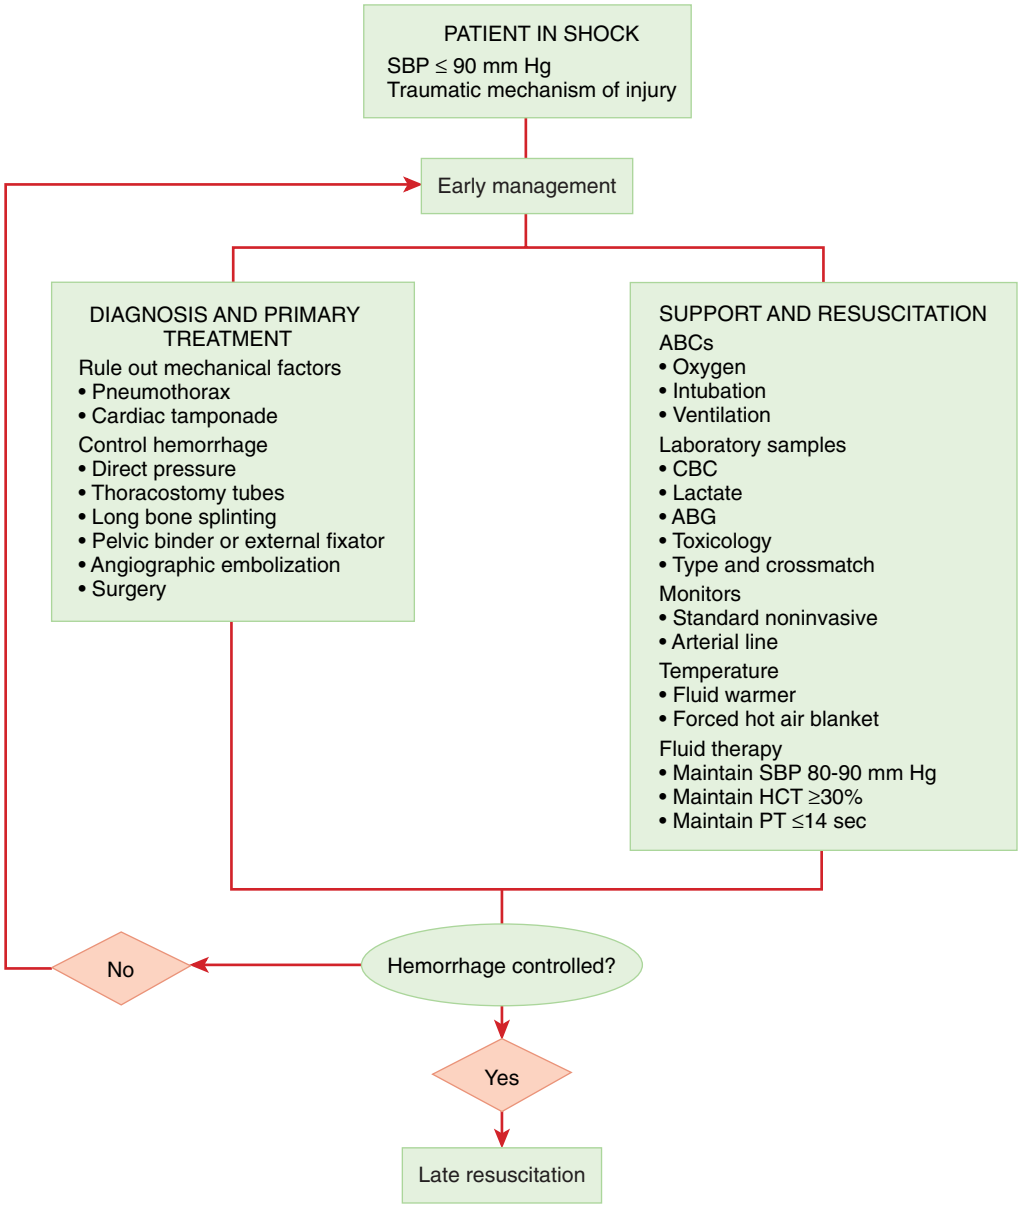

Figure 72-8 Algorithm for the management of early hemorrhagic shock. ABCs, airway, breathing, circulation; ABG, arterial blood gases; CBC, complete blood count; HCT, hematocrit; PT, prothrombin time; SBP, systolic blood pressure.

short-term care based on the number of units of blood transfused.[103] One hundred forty-one patients received massive blood transfusions (20 or more units of red blood cells [RBCs]) during preoperative and intraoperative resuscitation. The number of blood units did not differ between survivors (30%) and nonsurvivors (70%). Eleven variables were significantly different: aortic clamping for control of blood pressure, use of inotropic agents, time with a systolic blood pressure higher than 90 mm Hg, time in the OR, temperature lower than 34°C, urine output, pH lower than 7.0, Pao_2/Fio_2 ratio less than 150, $Paco_2$ greater than 50 mm Hg, potassium greater than 6 mM/L and calcium lower than 2 mM/L. Of these, the presence of the first three variables in the face of transfusion of more than 30 units of packed RBCs was invariably fatal. Total blood loss and the amount of transfused blood were less critical than the depth and duration of shock. These concerns led to the concept of damage control surgery, which emphasizes rapid control of active hemorrhage.[104]

Red blood cells are the mainstay of treatment of hemorrhagic shock. With an average hematocrit of 50% to 60%, a unit of RBCs will predictably restore oxygen-carrying capacity and expand intravascular volume *as well as any colloid solution.* RBCs of blood type A, B, or AB carry major incompatibility antigens that may precipitate a lethal transfusion reaction if given to a patient with the opposite blood type. Because RBCs also carry dozens of minor antigens that can cause reactions in susceptible patients, crossmatching is desirable when time allows (typically about 1 hour from the time that a sample reaches the blood bank until the RBCs reach the patient). Type-specific blood requires less time for delivery from the blood bank (usually about 30 minutes) and may be an appropriate alternative in some

situations. Type O blood—the "universal donor" type—can be given to patients of any blood type with little risk of a major reaction.[105] This is the preferred approach for patients who arrive at the ED in hemorrhagic shock. If O-positive blood is given to a Rhesus-negative woman who survives, prophylactic administration of anti-Rh_0 antibody is indicated.

Risks of RBC administration include transfusion reaction, transmission of infectious agents, and hypothermia (see Chapter 55 for details.) For example, RBCs are stored at 4°C and will decrease the patient's temperature rapidly if not infused through a warming device or mixed with warmed isotonic crystalloid at the time of administration.

Plasma requires blood typing but not crossmatching; delay in availability of plasma is caused by the need to thaw frozen units before they can be administered. Busy trauma hospitals will often maintain a supply of pre-thawed plasma (thawed fresh plasma [TFP] as opposed to fresh frozen plasma [FFP]) that can be issued quickly in response to an emergency need; in smaller hospitals it is important to request plasma early in resuscitation if it is likely to be needed. Very busy centers are experimenting with keeping 2 to 4 units of pre-thawed type AB (universal donor) plasma available in the trauma resuscitation unit. Units are kept ready in this way for 2 days at a time; if not used on an emergency basis, the units are returned to the blood bank and released to the next patient needing plasma. Whether this approach improves outcomes has not yet been studied.

Platelet transfusion should normally be reserved for clinically coagulopathic patients with a documented low serum level (<50,000 per high-power field). When the patient is in shock, however, and blood loss is likely to be substantial, platelets should be empirically administered in proportion to RBCs and plasma (1:1:1). Transfused platelets have a very short serum half-life and should be administered only to patients with active coagulopathic bleeding. Platelets should not be administered through filters, warmers, or rapid infusion systems because they will bond to the inner surfaces of these devices, thereby reducing the quantity of platelets actually reaching the circulation.

Rapid transfusion of banked blood carries the risk of inducing "citrate intoxication" in the recipient. Harvested blood units are treated with citrate to bind free calcium and thus inhibit the clotting cascade. Consecutive administration of multiple units of banked blood leads to a correspondingly large dose of citrate, which may overwhelm the body's ability to mobilize free calcium and have a profound negative inotropic effect on the heart. Unrecognized hypocalcemia is a cause of hypotension in patients after massive transfusion and persists despite an adequate volume of resuscitation. Ionized calcium levels should be measured at regular intervals in a hemorrhaging patient, and calcium should be administered as needed (in a separate intravenous line from transfusion products) to maintain serum levels in the normal range.

Resuscitation Equipment

Intravascular fluid resuscitation of any kind is impossible in the absence of intravenous access. Immediate placement of at least two large-bore catheters (16 gauge or larger) is recommended during the primary assessment of any trauma patient.[15] Practitioners should have a low threshold for placement of a large-caliber central line in any patient in whom antecubital or other peripheral placement attempts have been unsuccessful. Potential sites for central line placement include the internal jugular, subclavian, and femoral veins, each of which has its own benefits and potential risks. The internal jugular approach, though familiar to most anesthesiologists, will require removal of the cervical collar and manipulation of the patient's neck and is not recommended in the acute setting unless other options have been exhausted. The femoral vein is easily and rapidly accessed and is an appropriate choice in patients without apparent pelvic or thigh trauma who require urgent drug or fluid administration. Caution should be used in patients with penetrating trauma to the abdomen because fluids infused via the femoral vein may contribute to hemorrhage from an injury to the inferior vena cava or iliac vein; these patients should have intravenous access placed above the diaphragm if possible. Femoral vein catheterization carries a high risk for the formation of deep venous thrombosis,[106] thus limiting use of this approach to the acute setting. Femoral lines should be removed as soon as possible after the patient's condition stabilizes. The subclavian vein is the most common site for early and ongoing central access in a trauma patient because the subclavian region is easily visible and seldom directly traumatized. This approach carries the highest risk for the development of pneumothorax, although many patients will already have indications for tube thoracostomy in one or both chest cavities; when possible, this is the preferred side for placement of a subclavian line. Placement of an arterial line facilitates frequent laboratory analysis and allows close monitoring of blood pressure; this should be undertaken as soon as possible but should not impede other diagnostic or therapeutic maneuvers.

The anesthesiologist should work to maintain thermal equilibrium (see Chapter 48) in any trauma patient. Although deliberate hypothermia has been suggested as a management strategy for both hemorrhagic shock[107] and TBI,[108] there is insufficient evidence to support this approach. Hypothermia will potentiate dilutional coagulopathy and systemic acidosis, and shivering and vasoconstriction in response to cold will demand an additional metabolic effort that may predispose the patient to myocardial ischemia. Hypothermia also greatly increases the subsequent risk for sepsis. Because many trauma patients arrive at the ED cold from exposure to the elements, early active warming measures are required. All intravenous fluids should be prewarmed or infused through a warming device. The patient should be kept covered with warmed blankets whenever possible, and the environment should be kept warm enough to make the patient comfortable. If hypothermia has already developed, the use of forced hot air warming is strongly indicated to restore normothermia. Even though all these measures are routine and obvious in the OR, the anesthesiologist can perform a valuable service by ensuring that they are available and applied in the ED, CT scanner, and angiography suite as well.

Commercial rapid-infusion devices are of great benefit in trauma care, particularly in the presence of hemorrhagic shock. These machines offer a number of benefits whenever large quantities of fluid resuscitation are likely (Box 72-6). Early experience with these devices demonstrated higher patient temperature and reduced acidosis at the conclusion of the initial surgery,[109] although others have suggested that rapid infusers might contribute to overinfusion of fluids, inappropriately elevate blood pressure, and contribute to rebleeding.[90] Application of the principles described earlier can prevent this complication; basal fluid administration should be kept low (200 to 500 mL/hr), with small fluid

Box 72-6 Benefits of a Fluid Infusion System in Resuscitation from Hemorrhagic Shock

- An active mechanical pump enables fluid administration rates of up to 1500 mL/min
- Compatible with crystalloid, colloid, packed red blood cells, washed salvaged blood, and plasma (*not* platelets)
- The reservoir allows mixing of products in preparation for rapid blood loss
- Fluids infused at a controlled temperature (38°C to 40°C)
- Able to pump simultaneously through multiple intravenous lines
- Fail-safe detection systems to prevent infusion of air
- Accurate recording of fluid volume administered
- Portable enough to travel with the patient between units

boluses given in response to measured systolic blood pressure below 80 to 90 mm Hg. In practice, fluid boluses are given alternately with anesthetic agents, with the goal of reaching a normal depth of anesthesia without increasing systolic blood pressure.

Late Resuscitation

Box 72-7 summarizes end points for late resuscitation, and Figure 72-9 presents an algorithm for management. Fluid administration is an integral, mandatory component. The adequacy of resuscitation should not be judged by the presence of normal vital signs, but by normalization of organ and tissue perfusion. The role of the anesthesiologist-intensivist is to recognize the presence of ongoing shock after traumatic hemorrhage and to resuscitate the patient with the appropriate fluid, in the appropriate amount, at the appropriate time.

Late resuscitation begins once bleeding is definitively controlled by surgery, angiography, or the passage of time. The practitioner's goal at this time is to restore normal perfusion to all organ systems while continuing to support vital functions. Hypoperfusion caused by hemorrhagic shock triggers a predictable cascade of biochemical events that will cause physiologic derangements persisting long after adequate blood flow is restored. The extent of hypoperfusion—the depth and duration of shock—is highly correlated with the development of subsequent organ system failure. Unfortunately, traditional vital sign markers such as blood pressure, heart rate, and urine output are insensitive to the adequacy of resuscitation. Occult hypoperfusion syndrome is common in postoperative trauma patients, particularly young ones.[110] This syndrome is characterized by a normal blood pressure maintained by systemic vasoconstriction; intravascular volume is low, cardiac output is low, and organ system ischemia persists. The patient will be at high risk for MOSF if the hypoperfusion is not promptly corrected.

The search for the optimal end point of resuscitation has led to several different hemodynamic, acid-base, and regional perfusion targets. Table 72-5 summarizes modalities that are available to gauge the adequacy of resuscitation, along with the shortcomings of each technique. Although the flow of blood to tissue beds is a determinant of tissue perfusion, pressure should also be an important consideration. The left ventricular stroke work index is a variable that accounts for both flow and pressure. Furthermore, left ventricular power output has been used to quantify left ventricular performance. These indices were compared with purely flow-derived hemodynamic and oxygen transport variables as markers of perfusion and outcome in critically injured patients during resuscitation.[111] A consecutive series of 111 patients were monitored with a volumetric pulmonary artery catheter during the first 48 hours of resuscitation. The ability to clear lactate in less than 24 hours and survival were studied. Survivors exhibited significantly higher stroke work and left ventricular power output than nonsurvivors did. In addition to heart rate, these were the only variables that were significantly related to lactate clearance and survival. The higher stroke work and left ventricular power output in survivors were related to better ventricular-arterial coupling and therefore more efficient cardiac function.

Box 72-7 Goals of Late Resuscitation*

- Maintain systolic blood pressure higher than 100 mm Hg
- Maintain hematocrit above individual transfusion threshold
- Normalize coagulation status
- Normalize electrolyte balance
- Normalize body temperature
- Restore normal urine output
- Maximize cardiac output by invasive or noninvasive measurement
- Reverse systemic acidosis
- Document decrease in lactate to normal range

*Fluid administration should be continued until adequate systemic perfusion is restored.

Table 72-5 Modalities for Assessment of Systemic Perfusion

Technique	Shortcomings
Vital signs	Will not indicate occult hypoperfusion
Urine output	May be confounded by intoxication, diuretic therapy, circadian variation, or renal injury
Systemic acid-base status	Confounded by respiratory status
Lactate clearance	Requires time to obtain laboratory result
Cardiac output	Requires placement of a pulmonary artery catheter or use of noninvasive technology
Mixed venous oxygenation	Difficult to obtain, but a very accurate marker
Gastric tonometry	Requires time to equilibrate, subject to artifact
Tissue oxygenation	Emerging technology, appears beneficial
Stroke volume variation	Emerging technology, requires an arterial line
Acoustic blood flow	Investigational technology, unproven

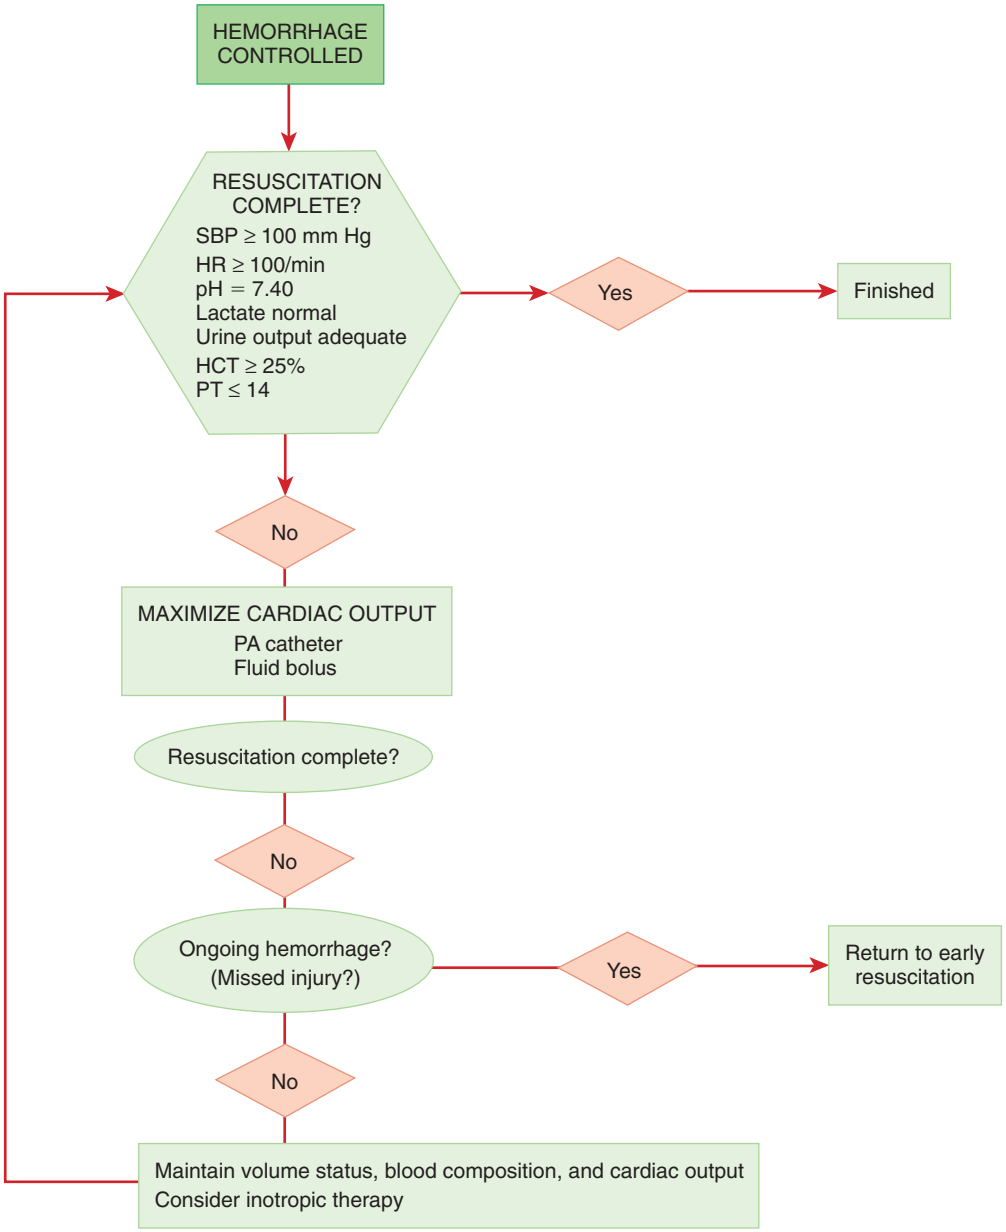

Figure 72-9 Algorithm for the management of late hemorrhagic shock. HCT, hematocrit; HR, heart rate; PT, prothrombin time; PA, pulmonary artery; SBP, systolic blood pressure.

Monitoring resuscitation with invasive monitors is changing at present to noninvasive approaches that assess the return of adequate metabolism, respiration, and oxygen transport in peripheral tissue beds. One such technique is tissue oxygen monitoring (skin, subcutaneous tissue, or skeletal muscle). Skeletal muscle blood flow decreases early in the course of shock and is restored late during resuscitation, thus making the skeletal partial pressure of oxygen a sensitive indicator of low flow.[112,113] Early "goal-directed" treatment of septic shock,[114] with an emphasis on measurement of mixed-venous oxygen saturation, has influenced the care of trauma patients, and many ICUs are now using continuously measured venous oxygenation to guide resuscitation. Stroke volume variation, the change in arterial pressure driven by the respiratory cycle, is emerging as another less invasive measure of fluid volume status; increased variation in arterial pressure during positive-pressure ventilation is a reliable predictor of decreased intravascular volume.[115]

Tissue hypercapnia has been suggested as a universal indicator of critically reduced perfusion. Measurement of gastric P_{CO_2} by gastric tonometry has been used in trauma patients as an indicator of restoration of splanchnic blood flow, and distal gut pH has shown promise as a reliable indicator.[116] The most proximal area of the gastrointestinal tract, the sublingual mucosa, is a useful site for measurement of P_{CO_2} (P_{SLCO_2}).[117] When P_{SLCO_2} exceeded a threshold of 70 mm Hg (normal, 45.2 ± 0.7 mm Hg), its positive predictive value for circulatory shock was 100%.[118] Inadequate tissue perfusion, as indicated by these specific monitors or by the traditional systemic markers of serum lactate, base deficit, and decreased pH, must be treated promptly once ongoing hemorrhage is controlled. The rate at which lactate returns to

normal after shock is strongly correlated with outcome; failure to normalize within 24 hours is associated with a greater risk for MOSF and eventual death.[110,119]

Future Developments in Resuscitation

Because resuscitation from hemorrhagic shock begins with control of bleeding, improvements in the ability to diagnose and treat hemorrhage are likely to prove beneficial after trauma. The past decade has seen the development and widespread use of focused assessment by sonography for trauma (FAST)[120] and high-resolution CT to improve the diagnosis of hemorrhage and of damage control surgery and angiographic embolization to correct it. Two different classes of prothrombotic agents have become increasingly popular adjuvants for use in hemorrhaging patients: topical clotting agents and systemic procoagulants.

Topical preparations are applied to open wound surfaces (such as a lacerated liver) to induce the immediate formation of clot. The ones that have seen the longest use are preparations of thrombin and fibrin. These "fibrin glues" will not work in the presence of brisk hemorrhage because they are rapidly washed away, but they are advantageous in the management of oozing surfaces and organs that are difficult to suture or cauterize, such as lung or liver.[121] Fibrin glue is assembled from recombinant or highly purified thrombin; it carries no risk of transmission of viral disease, although there have been reports of antibodies developing to bovine thrombin administered topically. Systemic uptake is also limited, which means that inappropriate coagulation remote from the site of application is unlikely. Formulations of thrombin and fibrinogen layered on collagen-based dressings, intended for rapid control of large-area injuries to solid visceral organs or the musculoskeletal system, have been developed and are in use by the military in Iraq and Afghanistan.[122] Also in use by the military are several newer topical hemostatics consisting of small hydrophilic particles (zeolite or chitosan) that rapidly absorb free water from injured tissue, thereby greatly concentrating clotting factors and platelets and thus enhancing the rate of clot formation.[123] At present, none of these compounds are licensed for internal use, although this is a probable future development.

Recombinant activated human coagulation factor VII (rFVIIa) is licensed for the treatment of hemophiliacs with active or anticipated hemorrhage and known antibodies to factor VIII (see Chapters 54 and 55). The observation of rapid hemostasis in this population led to the anecdotal use of rFVIIa in other congenital and acquired coagulopathies, including the dilutional coagulopathy of traumatic hemorrhage. Factor VIIa in pharmacologic doses works by triggering a burst of thrombin on the surface of platelets activated by exposed tissue factor, which produces rapid clot formation. Because tissue factor is required, coagulation is limited to the site of vascular injury, and inappropriate clotting of uninjured organs or vessels, though an acknowledged risk, occurs at only low frequency.[124] Prospective trials of rFVIIa have demonstrated decreased blood loss in patients undergoing elective open prostate surgery[125] and rapid reversal of coagulopathy in patients taking warfarin.[126] Retrospective reports have suggested a role for rFVIIa in the management of acute traumatic hemorrhage,[127] gastrointestinal hemorrhage secondary to cirrhosis,[128] hemorrhage after cardiovascular surgery[129] and liver transplantation,[130] and intracranial hemorrhage in both neonates[131] and the elderly.[132] One small placebo-controlled trial of rFVIIa in hemorrhaging trauma patients has demonstrated decreased blood loss, decreased transfusion requirements, and improved outcome.[133] A larger international trial is currently under way.

Other anticipated developments in the field of resuscitation include more specific management strategies for the consequences of shock and reperfusion (see Chapters 91 and 92). Hemorrhagic shock followed by resuscitation can be viewed as an ischemia-reperfusion injury involving the entire body. Prevention of organ ischemia or damage may be possible in the future through the administration of agents that regulate cellular function and humoral signaling. Possibilities include manipulation of shock-related pathophysiologic alterations such as complement and granulocyte activation, endothelial activation, leukostasis, and edema formation with resultant organ injury.[134] Modification of outcome may be possible through the use of oxygen carriers (fluorocarbons and modified hemoglobins), antioxidants, nitric oxide scavengers, and antiendotoxin compounds. Even more exciting is the possibility of tailoring treatment to the patient's individual genetic make-up, with controlled manipulation of a wide variety of proinflammatory and anti-inflammatory agents used to maintain optimal serum chemistry during recovery from injury. Though a distant possibility at present, the first steps in this approach are being taken with the recent recognition that patterns of genetic expression can predict outcome after major injury.[135]

Trauma to the Central Nervous System

CNS trauma accounts for almost half of all trauma deaths examined post mortem in population-based analyses[136] or after trauma center admission (see Chapter 63).[137] In addition, more than 90,000 Americans are disabled by TBI[138] and 8000 to 10,000 by SCI[139] each year. As with hemorrhagic shock, CNS trauma consists of both the primary injury, in which tissue is disrupted by mechanical force, and a secondary response, in which the body's reaction to the injury plays an important role. Mitigation of secondary CNS injury depends on prompt diagnosis and early, goal-directed therapy. Although there is no way to minimize primary CNS injury other than with preventive strategies, secondary brain injury accounts for much of the death and disability that follows trauma. The initial management of these patients can significantly affect outcome. Attention to the ABCDE approach is paramount to successful resuscitation, and the trauma anesthesiologist should be intimately involved in this process. Critical care management of TBI patients is covered elsewhere in this volume (see Chapter 94). What follows is a brief discussion of the early management of these patients.

Trauma produces shear forces that result in primary damage to neuronal cell bodies and axons and to the vasculature. The pathophysiology of secondary injury includes metabolic failure, oxidative stress, and a cascade of biochemical and molecular events leading to both delayed necrotic and apoptotic cell death.[140] Secondary injury is often exacerbated by tissue hypoxia/ischemia and by inflammatory responses, and outcomes from TBI are influenced by a large number of interacting factors. Individual

drugs such as free radical scavengers, anti-inflammatory agents, and ion channel blockers have been effective in animals but have had little impact or yielded disappointing results in human trials.

Patients with mild TBI (GCS score of 13 to 15) who maintain a stable GCS score for 24 hours after injury are very unlikely to deteriorate further, although they are at risk for a number of "postconcussive" effects, including headache, memory loss, emotional lability, and sleep disturbance.[141] Moderate TBI (GCS score of 9 to 12) may be accompanied by intracranial lesions that require surgical evacuation, and early CT is strongly indicated. Early intubation, mechanical ventilation, and close observation may be required in the management of patients with moderate TBI because of combative or agitated behavior and the potentially catastrophic consequences of respiratory depression or pulmonary aspiration occurring during diagnostic evaluation. Extubation of the trachea can be undertaken if the patient is hemodynamically stable and appropriately responsive after the diagnostic workup. Treatment of secondary brain injury is accomplished by early correction and subsequent avoidance of hypoxia, prompt fluid resuscitation, and management of associated injuries. The timing of indicated noncranial surgery in these patients is highly controversial in that early surgery has been associated with an increase in episodes of hypoxia and hypotension.[142] Whereas some studies have demonstrated a decrement in neurologic outcomes after early surgery,[143,144] others have shown an increased incidence of pulmonary and septic complications when orthopedic and soft tissue surgeries are delayed.[145,146] Recent reviews of surgical timing have not substantiated an increased risk with early surgery, although a definitive prospective trial has not yet been reported.

Neurologic monitoring of patients with moderate TBI consists of serial assessment of consciousness and motor and sensory function. Deterioration of the GCS score is an indication for urgent CT to establish the need for craniotomy or invasive monitoring of ICP. If frequent neurologic monitoring is not possible because of general anesthesia continuing longer than 2 hours, the need for aggressive analgesia, or prophylaxis against delirium tremens, invasive ICP monitoring is indicated.[93] Although mortality from moderate TBI is low, almost all patients will suffer significant long-term morbidity.

Severe TBI is classified as a GCS score of 8 or less at the time of admission and carries a significant risk for mortality. Early, rapid management focused on restoration of systemic homeostasis and perfusion-directed care of the injured brain will produce the best possible outcomes in this difficult population. Guidelines for all aspects of the management of patients with severe TBI have been published by the American Association of Neurological Surgeons, now in the third edition. The clinical pathway in place at our institution appears in Figure 72-10.

A single episode of hypoxemia (Pao_2 <60 mm Hg) occurring in a patient with severe TBI is associated with nearly a doubling of mortality.[147] The data on prehospital intubation are controversial. In the past it was thought that field intubation, by providing a "definitive" airway and adequate oxygen delivery to the brain, would benefit patients. However, there are no prospective data evaluating the impact of prehospital intubation in adult trauma patients, and two retrospective studies have shown worsened neurologic outcomes.[148,149] An expert panel examining this question concluded that (1) the existing literature regarding paramedic RSI is inconclusive and apparent differences in outcome can be explained by the use of different methodologies and variability in comparison groups; (2) use of the GCS score alone to identify TBI patients requiring RSI is limited, with additional research needed to refine screening criteria; (3) suboptimal RSI technique, as well as subsequent hyperventilation, may account for some of the increase in mortality reported with the procedure; (4) initial and ongoing training, as well as experience with RSI, appears to affect performance; and (5) the success of a paramedic RSI program is dependent on the particular characteristics of the emergency medical service and trauma system. The patient should be transported as rapidly as possible to a facility capable of managing severe TBI or to the nearest facility capable of intubating the patient and initiating systemic resuscitation. The sine qua non is adequacy of systemic oxygenation, by whatever means that this can best be accomplished.

Patients with isolated head injuries can be managed with traditional ventilatory strategies, but those with chest trauma, aspiration, or massive resuscitation after shock are at high risk for the development of acute lung injury. The classic teaching of no or low-level positive end-expiratory pressure (PEEP) to prevent elevated ICP is inappropriate because it may fail to correct hypoxemia. With adequate volume resuscitation, PEEP does not increase ICP or lower cerebral perfusion pressure (CPP)[150] and may actually decrease ICP as a result of improved cerebral oxygenation.[151] Hyperventilation therapy (e.g., at a $Paco_2$ of 25 mm Hg), long a mainstay in the management of patients with TBI, is no longer recommended as a prophylactic treatment. Current guidelines imply a range of $Paco_2$ between 30 and 35 mm Hg, with hyperventilation to 30 mm Hg only for episodes of elevated ICP that cannot be controlled with sedatives, drainage of cerebrospinal fluid, neuromuscular blockade, osmotic agents, or barbiturate coma.[92] Hyperventilation during the first 24 hours is of particular concern because of the critical reductions in perfusion during this timeframe. However, these recommendations should be taken in context and modified in the face of unstable clinical circumstances such as an expanding mass lesion or signs of imminent herniation.[152]

The most challenging of all trauma patients are those with severe TBI and coexisting hemorrhagic shock. A single episode of hypotension, defined as systolic blood pressure lower than 90 mm Hg, is associated with an increase in morbidity and doubled mortality after severe TBI.[147] Hypotension together with hypoxia is associated with a threefold increase in mortality. Systolic blood pressure less than 90 mm Hg should be avoided, with a goal of greater than 70 mm Hg MAP until ICP monitoring is instituted and CPP can be directly targeted. Contrary to practices in the past, current recommendations are to maintain a patient with severe TBI in a euvolemic state. Therefore, *fluid resuscitation is the mainstay of therapy*, followed by vasoactive infusions as needed. The ideal fluid has not yet been identified, but increasing evidence suggests that hypertonic saline solutions are optimal. Correction of anemia from blood loss is the first priority, with a goal of maintaining the hematocrit at greater than 30%. After the initial ABCDE management of a patient with severe TBI, a stepwise approach to maintenance of CPP is initiated, with a currently recommended goal range of 50 to 70 mm Hg, as discussed in Chapter 63.

Decompressive craniectomy is a surgical procedure used to control severely elevated ICP and prevent herniation after stroke, and it is now more widely used for the same indications after severe TBI.[153] Decompressive craniectomy is indicated for selected anatomic patterns of TBI, such as when CPP cannot be

Critical Pathway for Treatment of Cerebral Perfusion Pressure in Patients with Severe Traumatic Brain Injury

General parameters for ALL patients

- Maintain systolic BP > 90 mm Hg with transducer leveled at the phlebostatic axis
- Keep Hct 30%-33%
- Maintain serum sodium at 140-145 unless patient has ICP elevations
- Encourage use of P_{ETCO_2} monitoring
- Initiate DVT prophylaxis
- Initiate nutrition as soon as medically appropriate with full caloric replacement by 7 days after injury
- Initiate anticonvulsants for the first 7 days after injury; phenytoin is the agent of choice

Initial interventions

- Establish airway, breathing, and circulaton
- Ventilate to maintain $Paco_2$ to 35 mm Hg
- Provide supplemental O_2 to keep Pao_2 >70 mm Hg or Spo_2 >94%
- Maintain normothermia
- Maintain head of bed to optimize CPP and minimize ICP
- Ensure good head and neck alignment
- Reduce unnecessary noxious stimuli
- See sedation algorithm

Insert camino or IVC ICP monitor: Pbro2 monitor

Maintain CPP > 60 mm Hg

* When patient has an unexplained ICP elevation or there is a change in mental status:
– Check the ABG to ensure Pao_2 and $Paco_2$ are in the desired range
– Ensure that the patient's position is not limiting ventilation or causing increased ICP

Intracranial hypertension? ≥20 mm Hg or*

No

Yes

*>25 mm Hg after decompressive craniectomy

- Ensure all initial interventions are in place*
- Administer sedation (see algorithm)
- Consider repeating a brain CT scan

Carefully remove treatment for ICP

Intracranial hypertension? ≥20 mm Hg or*

No

Yes

- Ensure all initial interventions are in place*
- Insert IVC and drain CSF
- Consider repeating a brain CT scan

Intracranial hypertension? ≥20 mm Hg or*

No

Figure 72-10 Clinical pathway for the management of severe traumatic brain injury. The goal of therapy is to maintain cerebral perfusion pressure above 60 mm Hg by support of the circulation and control of intracranial pressure. Progressively more intensive therapies are added until this goal is achieved. ABG, arterial blood gases; BP, blood pressure; CBF, cerebral blood flow; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography; DVT, deep venous thrombosis; Hct, hematocrit; ICP, intracranial pressure; IVC, intraventricular catheter.

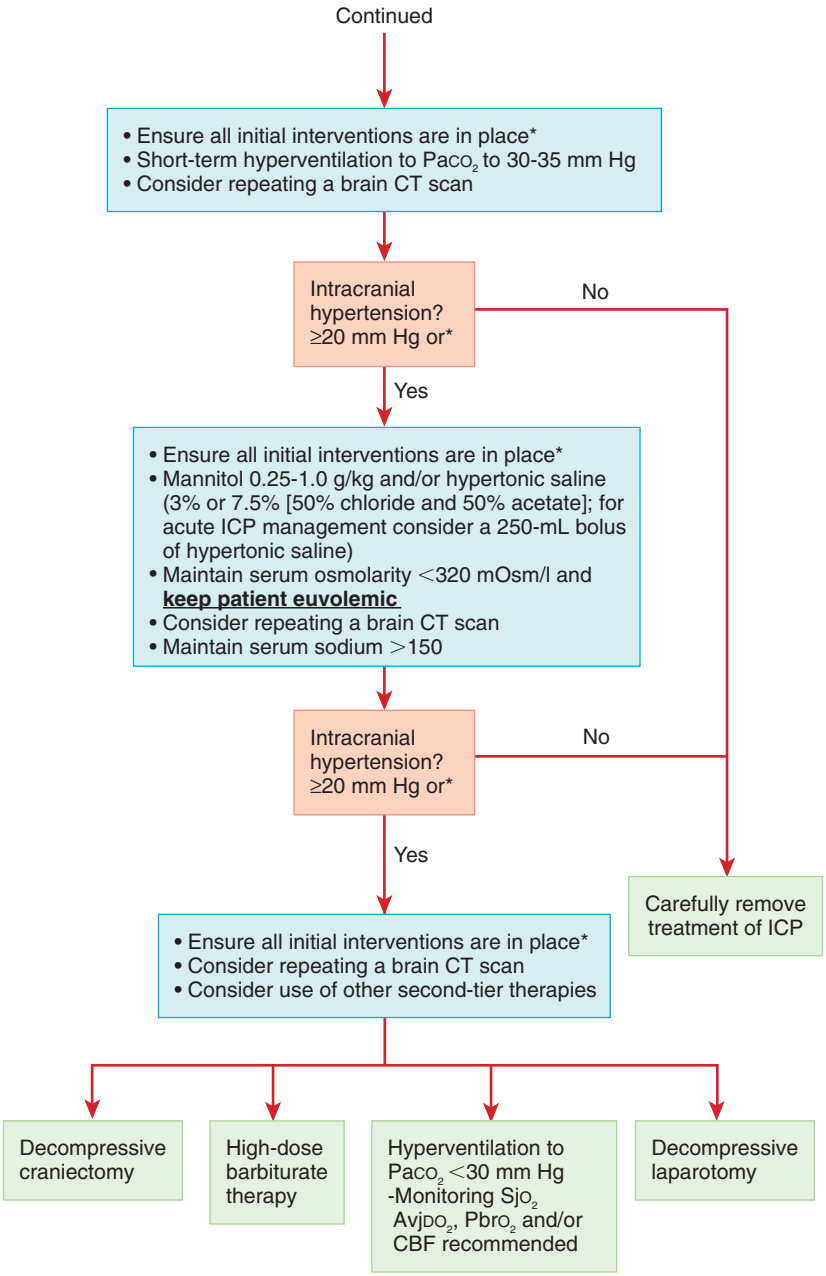

Figure 72-10, cont'd

maintained despite vigorous application of the previously described therapies, including barbiturate coma. Recent evidence suggests that relieving ICP by removal of a piece of cranium and use of a dural patch may improve mortality and morbidity in patients who might not otherwise survive.[154] Decompressive laparotomy may be also be indicated in patients with severe TBI if coexisting injuries or vigorous volume infusion have increased intra-abdominal compartment pressure to greater than 20 mm Hg. Elevated abdominal pressure worsens pulmonary mechanics, thus necessitating higher MAP to maintain arterial oxygen saturation. This increase in ventilating pressure will increase intrathoracic pressure and impair venous drainage from the head and consequently decrease CPP. The use of decompressive celiotomy as a therapy to reduce ICP was recently described.[155] More recently, a new concept of "multiple compartment syndrome" in patients with severe TBI has been proposed.[156] Fluid therapy or acute lung injury (or both) may increase intra-abdominal pressure and intrathoracic pressure, thereby increasing ICP. Further fluid

administration to support cerebral perfusion or increasing ventilatory support to treat acute lung injury further exacerbates this problem. This can create a cycle that ultimately produces multiple compartment syndrome and necessitates opening of the abdomen, even in the absence of primary abdominal trauma. Isolated TBI can thus become a multisystem disease.

Like hyperventilation therapy, there has been a progressive change in the use of hypothermia to treat severe TBI. Early studies demonstrated that moderate, systemic hypothermia reduces both the rate of cerebral edema and mortality after cortical injury in laboratory animals.[157,158] Small, clinical series in humans also suggested improved outcome in patients suffering TBI when hypothermia was maintained for 24 or 48 hours.[159,160] However, a recently published multicenter, randomized trial of hypothermia (33°C) versus normothermia demonstrated no improvement in outcome in a population of patients with severe TBI.[161] Of note, patients who were hypothermic on admission and then were randomized to the normothermia group had a worse outcome than those who were left hypothermic, thus leading to the recommendation that patients with severe TBI who are hypothermic on admission not undergo active rewarming.

Management of Intracranial Pressure in the Operating Room

Although most interventions for management of a patient with severe TBI will occur in the ICU, urgent cranial or noncranial surgery is frequently indicated.

All of the previously described therapies should be continued throughout the perioperative period, including positional therapy (when possible), aggressive hemodynamic monitoring and resuscitation, administration of osmotic agents (with attention to maintaining euvolemia), and deep levels of analgesia and sedation. Appropriate anesthetic choices include narcotics and low concentrations of volatile anesthetics.

Spinal Cord Injury

SCI after trauma affects some 10,000 Americans each year.[139] Blunt trauma accounts for the majority of SCI: 40% from motor vehicle collisions, 20% from falls, and the remainder as a result of penetrating trauma (14%).[162] Complete neurologic deficit occurs in approximately 3500 patients a year and partial deficit in an additional 4500.[163] The health care cost of SCI is staggering: $5.6 billion in direct and indirect costs to the government each year for medical care, rehabilitation, and lost wages.[164] Cervical spine injuries occur in 1.5% to 3% of all major trauma.

Most spinal injuries are found in the lower cervical spine, just above the thorax, or in the upper lumbar region, just below the thorax. Blunt SCI is most common in the regions of the cord that are most flexible, especially at the junctions between flexible and inflexible segments. SCI at midthoracic levels is less common because of the rotational stabilization provided by the rib cage and intercostal musculature.

SCI is commonly accompanied by radiographically visible injury to the bony spine and concomitant disruption of the muscles, ligaments, and soft tissues that support it. However, clinically significant injury to the cervical spinal cord can occur in the absence of visible skeletal injury. This entity, known as SCIWORA (spinal cord injury without radiographic abnormality) is more common in children and is presumably the result of temporary hyperdistraction or torsion of the neck insufficient to disrupt the bony skeleton.[165]

Primary injury to the spinal cord sustained at the moment of trauma may be exacerbated by a number of secondary factors (Fig. 72-11). SCI includes sensory deficits, motor deficits, or both. Incomplete deficits may be worse on one side than the other and may improve rapidly in the first minutes after injury. Complete deficits—representing total disruption of the spinal cord at one level—are much more ominous, with generally little improvement seen over time. Cervical spine injuries causing quadriplegia are accompanied by significant hypotension because of inappropriate vasodilatation and loss of cardiac inotropy (neurogenic shock). Functioning of the lower cord will gradually return, along with restoration of normal vascular tone. Diagnosing cervical spine instability can be difficult. The Eastern Association for the Surgery of Trauma has published guidelines regarding which patients require cervical spine radiographs, which views and studies should be obtained, and how to determine the absence of significant ligamentous injury in an unconscious patient.[166]

Evaluation of the ABCs (airway, breathing, circulation) is often followed by a glucocorticoid steroid bolus in patients with blunt SCI and complete or partial deficit. A bolus dose of 30 mg/kg of methylprednisolone, followed by a maintenance infusion of 5.4 mg/kg/hr, is given if the patient is less than 8 hours removed from the time of injury. This infusion is continued for 24 hours if started within 3 hours of injury and for 48 hours if started 3 to 8 hours after injury. High-dose glucocorticoid therapy has resulted in a small, but statistically significant improvement in neurologic level after SCI in two large multicenter trials: the National Acute Spinal Cord Injury Study (NASCIS) II and III.[167,168] Methylprednisolone has been shown to improve spinal cord blood flow, reduce intracellular calcium influx, and mitigate the formation of free radicals in ischemic spinal cord tissue. The NASCIS results have been challenged for several reasons.[169-171] The positive benefits seen with high-dose steroid administration were driven by results in a few subpopulations and were not present in a majority of patients. The improvement in spinal level seen after steroid administration has not been shown to lead to increased survival or improved quality of life, and the results have not been reproducible in other studies of acute SCI.

Patients with bony injury to the spinal cord will require surgery based on their neurologic symptoms and the anatomic stability of the injury. Magnetic resonance imaging is indicated to assess ligamentous and soft tissue injury in any patient with bony fracture or neurologic deficit. Surgery is more commonly required for cervical lesions, whereas supportive bracing or extension casting of the torso may be used for thoracic and lumbar fractures.

Early intubation is almost universally required for patients with cervical spine fracture and quadriplegia. Ventilatory support is absolutely required for patients with a deficit above C4 because they will lack diaphragmatic function. Patients with levels from C6 to C7 may still need support because of lost chest wall innervation, paradoxical respiratory motion, and an inability to clear secretions. Early intubation is recommended and can often be accomplished by awake fiberoptic bronchoscopy or use of the GlideScope before hypoxia renders the patient anxious and uncooperative.[172,173] Spontaneous ventilation and extubation are possible after surgical stabilization and resolution of neurogenic shock, although pneumonia is a common and recurrent

complication that frequently necessitates tracheostomy to facilitate pulmonary toilet.

Intraoperative Management of Spinal Cord Injury

A patient about to undergo surgical reduction and fixation of a spinal column fracture presents a number of challenges for the anesthesiologist. First and foremost is the need for intubation of the trachea in a patient with a known injury to the cervical spine. Direct laryngoscopy with in-line stabilization is appropriate in the emergency setting and in unconscious, combative, or hypoxemic patients when the status of the spine is not known.[174] In the OR, an awake, alert, and cooperative patient can be intubated by a number of different methods known to produce less displacement of the cervical spine, presumably with less risk of worsening an unstable SCI. A common technique in current clinical practice is awake fiberoptic intubation. Although the nasal route is associated with an easier path to intubation in most patients, it can lead to an increased risk for sinusitis in the ICU if the patient is not extubated at the end of the procedure. Oral intubation is likely to be more challenging technically but will be of greater value if the patient remains mechanically ventilated. Blind nasal intubation, transillumination with a lighted stylet, and use of an intubating LMA, GlideScope or Bullard laryngoscope, and any of a variety of other instrument systems for indirect laryngoscopy are acceptable. The clinician is advised to use the equipment and techniques that are most familiar. The important concept is to successfully achieve tracheal intubation while minimizing motion of the cervical spine and preserving the ability to assess neurologic function after positioning.

Orthopedic and Soft Tissue Trauma

Musculoskeletal injuries are the most frequent indication for operative management in most trauma centers (see Chapter 70). Because many procedures can be appropriately managed under regional anesthesia, familiarity with these techniques is essential. The length of many procedures, particularly in patients with multiple extremity injuries, necessitates attention to body positioning, maintenance of normothermia, fluid balance, and preservation of peripheral blood flow.

For the last 15 years the emphasis in trauma management of a multiply injured patient has included early stabilization of long-bone, spine, pelvic, and acetabular fractures. Failure to do so results in increased morbidity, pulmonary complications, and length of hospital stay.[175,176] In one study, only 2% of patients with femoral shaft fractures stabilized within the first 24 hours of injury had pulmonary complications, as compared with 38% of patients in whom fracture stabilization was delayed for more than 48 hours.[176]

Specific Conditions

Dislocation of the hip is common after high-energy trauma and is frequently accompanied by fracture of the acetabulum. Whereas the fracture itself can be safely managed on a delayed basis, the

dislocation is a medical emergency that must be promptly addressed if the patient is to have a good functional outcome. Failure to promptly diagnose and reduce a dislocated hip joint is a significant risk factor for avascular necrosis of the femoral head. Reduction typically requires a very deep level of sedation, which may be facilitated by nondepolarizing neuromuscular blockade. For this reason the anesthesiologist is commonly involved.[177] Although it is possible to reduce a dislocated hip in a spontaneously breathing patient sedated with fentanyl, midazolam, ketamine, propofol, or a combination of two or more agents, an acutely injured patient is at high risk for aspiration. Any patient who will be undergoing surgery in the near future (as for an open long-bone fracture or exploratory laparotomy) should be intubated at the time of reduction and maintained with appropriate sedation and analgesia until reaching the OR. Other patients who may require intubation even for uncomplicated reductions include those who are inebriated or uncooperative, hemodynamically unstable, or suffering from pulmonary dysfunction.

Unlike acetabular fractures, fracture of the pelvic ring requires immediate recognition and management by the trauma team. Hemorrhage, even exsanguination, is common after a major pelvic ring fracture and is a leading contributor to early death after motor vehicle collisions. Bleeding occurs from multiply disrupted venous beds in the posterior pelvic bowl; if the pelvis as a whole is unstable, there is no anatomic barrier to continued expansion of this retroperitoneal bleeding. Surgical exploration by way of the peritoneum is usually unrewarding because the bleeding vessels are not easily accessed.[178] Therapy consists of supportive volume resuscitation, external fixation of the unstable pelvis, and angiography. Intubation is usually undertaken on an emergency basis in a hypotensive patient, and the anesthesiologist may remain with the patient throughout the initial hours of stabilization to manage sedation, analgesia, transport, and fluid resuscitation. In the absence of an orthopedic specialist, temporary stabilization and tamponade of some pelvic fractures can be accomplished with use of a specially made pelvic binder, the pelvic portion of military antishock trousers, or a bed sheet knotted tightly around the bony pelvis.[179]

Open fractures should be pulse-lavaged and débrided as soon as possible after injury to minimize the risk of infectious complications. If ongoing resuscitation or unstable TBI precludes the patient from early management in the OR, this procedure should be performed at the bedside.

The advantages and disadvantages of regional and general anesthesia are summarized in Boxes 72-8 and 72-9. For many orthopedic trauma cases a combined approach will provide an optimal solution by incorporating the hemodynamic and analgesic benefits of a regional anesthetic with the flexibility and increased anxiolysis of a general anesthetic.

One prevalent concern in the management of an orthopedic trauma patient is the concomitant use of regional anesthesia/analgesia and prophylaxis for venous thromboembolism, as discussed in Chapter 70.

Intraoperative transesophageal echocardiography (TEE) has shown that most patients undergoing long-bone fracture manipulation experience microembolism of fat and marrow.[180] Most patients suffer no discernible clinical impact from this phenomenon, but some will experience a significant acute inflammatory response. After long-bone fractures, some lung dysfunction occurs in almost all patients ranging from minor laboratory abnormalities to full-blown fat embolism syndrome (FES). A lack of universally accepted diagnostic criteria combined with concomitant pulmonary and cardiovascular dysfunction accounts for the varying incidence reported in the literature. Most studies suggest that clinically significant FES occurs in 3% to 10% of patients, although the presence of multiple long-bone fractures is associated with a higher incidence. Patients with coexisting lung injury are at additional risk for FES. Signs include hypoxia, tachycardia, mental status changes, and a petechial rash on the upper portions of the body, including the axillae, upper arms and shoulders, chest, neck, and conjunctivae. FES should be considered whenever the alveolar-arterial oxygen gradient deteriorates in conjunction with decreased pulmonary compliance and CNS deterioration. Under general anesthesia, the CNS changes will not be apparent but may be manifested as failure to awaken after

Box 72-8 Advantages and Disadvantages of Regional Anesthesia for Trauma Patients

Advantages
- Allows continued assessment of mental status
- Increased vascular flow
- Avoidance of airway instrumentation
- Improved postoperative mental status
- Decreased blood loss
- Decreased incidence of deep venous thrombosis
- Improved postoperative analgesia
- Better pulmonary toilet
- Earlier mobilization

Disadvantages
- Peripheral nerve function difficult to assess
- Patient refusal common
- Requirement for sedation
- Hemodynamic instability with placement
- Longer time to achieve anesthesia
- Not suitable for multiple body regions
- May wear off before procedure(s) conclude

Box 72-9 Advantages and Disadvantages of General Anesthesia for Trauma Patients

Advantages
- Speed of onset
- Duration—can be maintained as long as needed
- Allows multiple procedures for multiple injuries
- Greater patient acceptance
- Allows positive-pressure ventilation

Disadvantages
- Impairment of global neurologic examination
- Requirement for airway instrumentation
- Hemodynamic management more complex
- Increased potential for barotrauma

Acute exertion

surgery. If central hemodynamic monitoring is available, pulmonary artery pressure is elevated, often accompanied by decreases in the cardiac index. Diagnosis in the OR is largely based on the clinical findings after ruling out other causes of hypoxemia. Fat globules in urine are nondiagnostic, but lung infiltrates seen on chest radiography confirm the presence of lung injury and the need for appropriate ventilatory management with oxygen, higher PEEP, and possible longer-term mechanical ventilatory support.[181,182] Treatment includes early recognition, administration of oxygen, and judicious fluid management. A change in the orthopedic procedure may be indicated, such as converting intramedullary nailing of the femur to external fixation.

Acute compartment syndrome of the extremities is defined as a "condition in which increased pressure within a limited space compromises the circulation and function of the tissues within that space."[183] With orthopedic trauma the most common cause of compartment syndrome is edema secondary to muscle injury and associated hematoma formation. Though most commonly associated with traumatic injuries, compartment syndrome can also occur as a result of a number of causes associated with trauma, including reperfusion injury, burns, drug overdose, and prolonged limb compression (Box 72-10). The most common fractures associated with the development of compartment syndrome are those of the tibial shaft (40%) and forearm (18%).[184,185] A further 23% are caused by soft tissue injuries without fracture.[185]

The classic hallmarks of compartment syndrome have been described as pulselessness, pallor, paralysis, paresthesia, and pain—the "five P's." The presence of these findings, however, is associated with an established syndrome of ischemic injury, and fasciotomy at this stage is associated with a poor outcome. The early presence of pain out of proportion to the injury can be the first clinical indication of compartment syndrome and may easily be confused with pain associated with the injury or operative repair. In addition, pain with passive stretching or paresthesia may be the initial complaint. An altered level of consciousness because of associated conditions may easily mask this finding.

Fasciotomy is usually indicated when compartment pressure approaches 20 to 30 mm Hg below diastolic pressure in any patient with a worsening clinical condition, a documented rising tissue pressure, major soft tissue injury, or a history of 4 to 6 hours of total ischemia of an extremity. Prophylactic fasciotomy may be indicated in patients with warm ischemic time in excess of 4 to 6 hours, ligation of the major veins in the popliteal region or distal part of the thigh, and crush injuries.

Crush syndrome is the general manifestation of crush injury caused by continuous prolonged pressure on one or more extremities[186] and is commonly found in patients who have been trapped in one position for an extended period. Muscle injury secondary to ischemia causes myoglobinuria, which can lead to acute renal failure and subsequent profound electrolyte disturbances. The most critical treatment consists of crystalloid fluid resuscitation; a total-body fluid deficit of 15 L may occur in severe rhabdomyolysis.[187] Osmotic diuresis with mannitol and alkalinization of urine with sodium bicarbonate to prevent precipitation of myoglobin in the renal tubules are controversial.[188,189] The preferred therapy for renal failure secondary to rhabdomyolysis at the Shock Trauma Center is continuous renal replacement therapy and hemofiltration.[190] A majority of these patients eventually have full recovery of native renal function.[191]

Soft Tissue Trauma

Assessment of soft tissue injury is critical in the management of a trauma patient. Muscular coverage is necessary for the viability of any orthopedic repair, but it may be jeopardized by avulsion at the time of injury, ischemia from elevated compartment pressure, and ongoing bacterial infection in open wounds. Acute surgical management of soft tissue injury is straightforward: all dead or devitalized tissue must be débrided away and the wound thoroughly irrigated to reduce the load of bacterial contaminants. When muscle or fascia involvement is significant, serial débridement at 1- to 3-day intervals is necessary to establish a margin of completely viable tissue. Vacuum dressings for large soft tissue wounds are gaining in popularity because continuous negative pressure over the wound surface removes contaminants and encourages blood flow.[192] When serial débridement establishes viable tissue at all margins of the wound, arrangements for definitive closure can be made. Closure may be as simple as a split-thickness skin graft or as complex as free tissue transfer of muscle and fascia from an uninjured portion of the body, with attendant arterial and venous anastomoses.

Superficial vacuum dressings can be changed at the bedside under light sedation, but patients with deep wound dressings will require general anesthesia. The need for repeated surgeries is an important consideration for the anesthetic technique. When otherwise appropriate, the use of a continuous epidural catheter for both analgesia and operative anesthesia can greatly facilitate the care of these complex patients. Anesthesia for free tissue transfer surgery requires meticulous attention to detail because these operations can be quite protracted. Every effort should be made

to facilitate perfusion of the grafted vessels, including keeping the patient warm, euvolemic, and comfortable and maintaining the hematocrit in the rheologically favorable range of 25% to 30%. The use of epidural anesthesia and analgesia is controversial, with some surgeons favoring it for its vasodilatory effects and others being concerned that it will induce a "steal" phenomenon that will actually limit flow in the denervated free tissue.[193]

Amputation is occasionally necessary for massive crush injury, vascular injury, or progressive soft tissue infection. Anesthetic management is notable for the strong emotional overlay that accompanies this operation. Although regional anesthesia is physiologically appropriate and has been shown to limit the subsequent development of phantom limb pain, very few patients will be accepting. General anesthesia is usually required, although combining it with epidural analgesia may confer the benefits of both techniques.

Other Traumatic Injuries

Head and Neck Surgery

With the exception of emergency exploration of penetrating trauma to zone II of the neck (from the clavicles up to the angle of the mandible), most surgical repair of head and neck trauma will occur in the subacute phase, after complete resuscitation and secondary diagnostic studies (see Chapter 75). Anesthetic management of these patients is not substantially different from that for similar elective procedures, although coexisting injuries may influence patient positioning and ventilator settings. Surgery on the mandible and maxilla will be facilitated by nasotracheal intubation, but the anesthesiologist should not jeopardize a secure airway by attempting to switch from an oral to a nasal tube in a patient in whom visualization of the larynx might be difficult because of traumatic swelling or body habitus. It is safer in these cases for the surgeon to either work around an oral tube secured behind the second molar (to allow dental occlusion) or to place a tracheostomy if the need for intubation and mechanical ventilation is likely to be protracted. Surgery on the zygoma and the nasal, orbital, and ethmoid bones will be possible with an oral endotracheal tube. Securing the endotracheal tube to the molar with a fine-gauge wire will help stabilize it through the operation. All of these surgeries will lead to significant soft tissue swelling in the immediate postoperative period, often necessitating several days of continued intubation and sedation until sufficient venous drainage has occurred to allow safe extubation. Though not by itself definitive, the presence of an air leak when the endotracheal tube cuff is deflated is suggestive that the airway will remain patent once the tube is removed.

Chest Injuries—Pulmonary

Injuries to the lung parenchyma that produce pneumothorax can be managed by tube thoracostomy to relieve tension, drain accumulated blood, and apply suction to the pleural space until the air leak spontaneously resolves (see Chapter 59). Bleeding from the low-pressure pulmonary circulation is usually self-limited. Thoracostomy is uncommon but becomes necessary when there is evidence of mediastinal injury, chest tube output exceeds 1500 mL in the first hours after injury, tracheal or bronchial injury and massive air leak are apparent, or the patient is hemodynamically unstable with evident thoracic pathology.[15] Blood collected from the pleural space is generally free of clotting factors and can be directly reinfused with any of several commercial systems.[194] Hemorrhage necessitating surgery may be from injured intracostal or internal mammary arteries, as well as from the lung parenchyma. Staple resection of injured lung or even anatomic lobectomy is not uncommon, particularly after penetrating trauma.

Although double-lumen endotracheal intubation is desirable during urgent thoracotomy, this should not be the initial approach. RSI with a large-caliber (at least 8.0 mm in internal diameter) conventional endotracheal tube will allow diagnostic bronchoscopy and protect the patient from aspiration until passage of a gastric tube can reduce the stomach contents. The change to a double-lumen tube can then be made under controlled conditions in the presence of adequate oxygenation, anesthesia, and muscle relaxation. Tolerance of single-lung ventilation is variable in the trauma population and depends in large part on the absence of significant pathology in the ventilated lung. Many patients with blunt thoracic injury have bilateral pulmonary contusions and will require increased Fio_2 and high levels of PEEP to maintain adequate oxygenation, even when both lungs are ventilated.

Although chest trauma requiring pneumonectomy has historically resulted in mortality approaching 100%, a recent multicenter retrospective review reported on a series of survivors of this surgery.[195] Intraoperative deaths are the result of uncontrollable hemorrhage, acute right ventricular failure, and air embolism. Patients who survive the initial procedure are at risk for early postoperative morbidity and mortality. Fluid management may be complicated by the need to weigh ongoing resuscitation against the treatment of right ventricular failure. Blunt thoracic trauma requiring pneumonectomy is often associated with abdominal and pelvic trauma. Volume replacement must be judicious, and the use of a pulmonary artery catheter (placed with care in a postpneumonectomy patient) or TEE may be beneficial. Echocardiography will also play an important role in assessing right ventricular function and pulmonary hypertension. Treatment of right ventricular failure after traumatic pneumonectomy is difficult.[196] During hypovolemic shock there is a disproportionate increase in pulmonary vascular resistance with respect to systemic vascular resistance,[197] as well as high mortality with combined hemorrhagic shock and pneumonectomy.[198] With severe right heart dysfunction it is desirable to maintain a higher preload than normal. Several therapeutic approaches have been used to treat right ventricular failure, including close monitoring of pulmonary artery pressure, the use of diuretics for volume overload, and administration of pulmonary vasodilators. Because this injury is rare and the number of patients reported in the literature is small, it is impossible to definitively state which treatment option is superior. A recent case report describes the use of nitric oxide to successfully treat pulmonary hypertension after posttraumatic pneumonectomy.[199] Extracorporeal support has also been used to sustain patients through the perioperative period, although the technical challenges are substantial and successful weaning may require days to weeks on bypass. Early initiation has been beneficial in our experience, with a recent survival rate of approximately 60%.

Tracheal-bronchial injury can result from either blunt force or penetrating trauma. Penetrating injuries are usually more promptly diagnosed and treated. *Blunt* trauma most commonly results in an injury to the tracheobronchial tree within 2.5 cm of the carina and may initially be unrecognized. The presence of subcutaneous emphysema, pneumomediastinum, pneumopericardium, or pneumoperitoneum, without apparent cause, should alert the practitioner to possible tracheobronchial injury.[200] Despite bronchoscopy and helical CT scanning, a small injury may never be delineated. If the resultant injury is an incomplete tear, it may heal with stenosis, subsequent atelectasis, pneumonia, pulmonary destruction, and sepsis. When surgery is required for a delayed, incomplete tracheobronchial injury, pulmonary resection may be required if there is significant tissue destruction, whereas complete transection may be amenable to reconstruction with preservation of pulmonary tissue. The level of injury dictates the surgical approach. Cervical injuries are approached through a transverse neck incision, left bronchial injuries via a left thoracotomy, and tracheal or right main bronchial injuries via a right thoracotomy. In the cervical region it is sometimes possible to access a longitudinal tear of the posterior membranous trachea by opening the anterior trachea and operating around the endotracheal tube.

Chest Injuries—Traumatic Aortic Injury

Traumatic aortic injury (TAI) must be ruled out in any patient suffering a high-energy injury, such as from a motor vehicle accident or fall from a height. The incidence of TAI has decreased in recent years because of the increased presence of airbags in motor vehicles; a majority of cases in the past decade have been caused by side-impact collisions.[201] Aortic injury occurs most commonly just distal to the left subclavian artery and is the result of sheer forces between the mobile heart and aortic arch and the immobile descending thoracic aorta. TAI is manifested as a continuum of injury from a small intimal flap to free transection contained by the surrounding mediastinum and pleura. The diagnosis is made by screening chest radiography, followed by definitive angiography, CT, or TEE. Surgical or endovascular repair is indicated for most patients with TAI because of the high risk of rupture in the hours and days after injury.[202] Various techniques have been described for this highly morbid surgery, with the best results attributed to partial bypass techniques using inflow from the left atrium, a centrifugal pump, and outflow to the descending aorta.[203] There have been reports of selective nonoperative management of high-risk patients with TAI in the recent literature.[204,205] Treatment is similar to that in patients with uncomplicated type B aortic dissection and consists of β-blockade to minimize the cardiac rate-pressure product. Endovascular repair is becoming more common at centers with experience in this technique and is likely to become the standard practice as stent-grafting hardware continues to improve.

Chest Injuries—Rib Fractures

Rib fractures are the most common injury resulting from blunt chest trauma. The fracture itself generally requires no specific treatment and will heal spontaneously over a period of several weeks. Therapy is directed at minimizing pulmonary complications secondary to these fractures, such as pain, splinting, atelectasis, hypoxemia, and pneumonia. Of particular concern are rib fractures in the elderly (age >55). Elderly patients with rib fractures have twice the mortality and thoracic morbidity of younger patients with similar injuries. Epidural anesthesia should be used liberally in patients with severe pain, the elderly, and patients with preexisting compromised pulmonary function. There are data to support a 6% decrease in morbidity and mortality in the elderly when epidural anesthesia is used.[206] Epidural analgesia may minimize or avoid complications of splinting and pain such as hypoxemia, hypoventilation, the need for tracheal intubation, and the possibility of pneumonia. Endotracheal intubation is reserved for patients who are unable to oxygenate or ventilate or who require protection of the airway.

Fracture of multiple neighboring ribs will result in the flail chest syndrome, characterized by paradoxical chest wall motion during spontaneous ventilation. Not all patients with a flail chest require positive-pressure ventilation, and endotracheal intubation should be reserved for those who meet the usual criteria. Patients who are not initially intubated should be observed closely in the ICU for signs of worsening respiratory function. There are increasing reports of the use of noninvasive positive-pressure ventilation (NIPPV) for lung injury secondary to trauma.[207] For these patients who subsequently require intubation for a surgical procedure, the anesthesiologist will need to determine the safety of extubation postoperatively. NIPPV is associated with fewer cases of pneumonia, which may lead to fewer tracheostomies and decreased ICU length of stay. A successful technique has been early extubation to a mask delivering continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP).[208] Concomitant pulmonary injury, especially lung contusion, is commonly associated with flail chest. Pulmonary contusion will cause shunting, which will lead to hypoxemia. This syndrome may progress rapidly in the hours and days after injury. An initially clear chest radiograph does not exclude the possibility of a pulmonary contusion, and again, close observation is warranted if signs of significant chest wall trauma are present. As with all patients after traumatic injury, a high degree of suspicion along with a continuous search for missed injuries is warranted. There is no specific therapy for a pulmonary contusion, and therapy is directed at the associated injuries or resultant hypoxemia. Early and aggressive implementation of a lung protective strategy is crucial in the treatment of patients with significant pulmonary contusion to minimize progression to ARDS or concomitant ventilator-associated lung injury.

Chest Injuries—Cardiac Injury

Blunt cardiac injury is a rare and poorly understood phenomenon that must be considered in any patient who has sustained a frontal impact to the chest. Bruising or edema of the myocardium is functionally indistinguishable from myocardial ischemia and may be causally related in that the pathophysiology of cardiac contusion may involve forcible dislodgement of unstable atherosclerotic plaque. If the patient is hemodynamically stable and the ECG does not demonstrate conduction disturbances or tachyarrhythmias, blunt cardiac injury can be safely excluded.[209] If either a new tachyarrhythmia or conduction disturbance subsequently develops or the patient has unexplained hypotension, other causes (hypovolemia, renal failure) should be ruled out first. If the

workup is negative, transthoracic echocardiography (TTE) should be performed. Right ventricular dysfunction resulting in hypotension may be overlooked while more common causes of hypotension in the trauma patient are being evaluated. TEE is superior to TTE in obese patients or those with injuries to the chest wall that make it difficult to obtain adequate acoustic windows, but it will generally require intubation and deep sedation to perform. Once diagnosed, blunt cardiac injury should be managed as ischemic cardiac injury, with completion of resuscitation and then careful control of fluid volumes, administration of coronary vasodilators, and monitoring and symptomatic treatment of rhythm disturbances. Anticoagulation with aspirin or heparin may be helpful but should be approached on a case-by-case basis as determined by the patient's other injuries. Cardiology consultation is appropriate if there is a possibility that the patient would benefit from coronary angiography followed by angioplasty or stenting of stenotic vessels.

Patients with penetrating cardiac trauma and blunt trauma causing rupture of one or more chambers (usually the atria) will infrequently be seen by the trauma center because of high prehospital mortality. Those who do not die immediately of free exsanguination into the thoracic cavity will have pericardial tamponade and can be extremely unstable in the first minutes after admission. This condition is diagnosed by clinical suspicion, by FAST, and by direct inspection during ED thoracotomy. Relief of the tamponade and clamp or suture control of the cardiac injury may allow restoration of spontaneous circulation and necessitate urgent transition to the OR for definitive hemostasis and chest closure. Cardiopulmonary bypass may be required for support during repair of cardiac injuries.

Abdominal Injury

The need for exploratory laparotomy, once the mainstay of the trauma surgeon, has declined significantly in recent years. FAST and high-resolution CT have reduced the incidence of negative abdominal explorations, whereas angiographic embolization of hemorrhaging vessels in the liver and spleen has reduced the need for open procedures. Urgent celiotomy, when it does occur, will typically follow the principles of damage control.[104] The abdomen is opened and packed tightly in all four quadrants. Systematic exploration is undertaken in each quadrant in turn, with time taken only for control of hemorrhage and rapid staple closure of open gastrointestinal injuries. The abdomen is packed open at the conclusion of the procedure, a sterile drape is used to cover exposed viscera, and the patient is moved to the ICU to complete resuscitation. Definitive treatment of nonlethal injuries and restoration of bowel continuity are deferred until a second operation 24 to 48 hours later.

Anesthetic management of emergency celiotomy should follow the principles of early resuscitation outlined earlier. Adequate intravenous access is required, as well as continuous arterial pressure monitoring. Cell salvage devices can be used to reduce the patient's exposure to banked blood, although reinfusion is generally deferred if there has been significant contamination by bowel contents. A rapid infusion system is advantageous for preservation of intravascular volume and normothermia during periods of heavy bleeding. Subsequent abdominal surgeries will be needed in hemodynamically stable patients and should not present unusual anesthetic challenges. Subsequent reconstructive procedures can become technically difficult as scarring and adhesions develop; the anesthesiologist should be prepared for a long anesthetic procedure with the potential for significant hemodynamic compromise.

Selected Patient Populations

Trauma and Pregnancy

Trauma to pregnant patients is associated with a high risk for spontaneous abortion, preterm labor, or premature delivery, depending on the location and magnitude of the mother's injury (see Chapter 69). Early consultation with an obstetrician is desirable for any pregnant trauma patient, both for immediate management and for long-term follow-up. The best treatment of the developing fetus consists of rapid and complete resuscitation of the mother. Trauma patients in the first trimester of gestation may not realize that they are pregnant; for this reason human chorionic gonadotropin testing is part of the initial laboratory studies for any injured woman of childbearing age. Serious trauma occurring during the period of fetal organogenesis may induce birth defects or miscarriage because of hemorrhagic shock with uterine ischemia, pelvic irradiation, or the effects of medications. Indicated radiologic tests should not be deferred, but shielding of the pelvis should be provided whenever possible. Patients who do not spontaneously miscarry should be advised of the potential risks related to trauma and anesthesia and be referred for counseling if desired. Dilatation plus curettage of the uterus is advisable after miscarriage to avoid toxicity arising from retained products of conception.[210]

Trauma occurring in the second or third trimester of pregnancy necessitates early ultrasonographic examination to determine fetal age, size, and viability. Monitoring of the fetal heart rate is indicated if the pregnancy is sufficiently advanced that the fetus would be viable if delivered. Preterm labor is very common in this population and should be treated with β-agonist agents or magnesium at the direction of the obstetrician; delivery should be delayed as long as the fetus is not an unacceptable metabolic stress on the mother. Delivery by cesarean section is indicated if the mother is in extremis, if the uterus itself is hemorrhaging, or if the gravid uterus is impairing surgical control of abdominal or pelvic hemorrhage.[211] Placental abruption can occur in response to substance abuse or abdominal trauma and can precipitate life-threatening uterine hemorrhage. Emergency cesarean section is indicated. The Kleihauer-Betke blood test can be used to determine if fetal blood has leaked into the maternal circulation[211]; if positive, administration of anti-Rh_0 immune globulin is recommended for any Rh-negative mother carrying an Rh-positive fetus. By the third trimester the uterus is sufficiently enlarged to compress the inferior vena cava when the patient is positioned supine, thereby impairing venous return to the heart and contributing to hypotension. Left lateral uterine displacement is indicated to treat this problem. If the patient is immobilized on a long spine board because of concern for a thoracic or lumbar spinal fracture, the whole board can be tipped to the left.

Elderly Trauma Patients

Equivalent traumatic injuries will have a markedly more serious outcome in the elderly than in younger victims (see Chapter 71).[212] Decreased cardiopulmonary reserves lead to a higher incidence of postoperative mechanical ventilation in older trauma patients and a much greater risk for MOSF after hemorrhagic shock. Greater care must be taken with intraoperative positioning to avoid pressure injuries. A higher hematocrit achieved by tighter control of administered fluid is generally recommended to maintain maximized tissue oxygen delivery. Post-traumatic myocardial dysfunction is a significant risk, particularly if the heart rate is elevated secondary to blood loss, pain, or anxiety. Complex operations or large blood loss should encourage the use of TEE or pulmonary artery catheterization to guide fluid and inotropic therapy.[94] Although prophylactic β-antagonist therapy has been recommended for older patients undergoing major elective surgery,[213] its role in the early management of older trauma patients is unknown. Older patients will have diminished requirements for postoperative analgesia and may respond to sedative medications with inappropriate agitation. Prophylaxis against deep venous thrombosis is important in patients who cannot be immediately mobilized in the postoperative period, as is aggressive pulmonary physiotherapy.

Jehovah's Witness Patients

A trauma patient who refuses blood products requires special management. Early identification and control of hemorrhage are obviously important; deliberate hypotension to limit bleeding may be helpful. Preoperative and intraoperative phlebotomy should be minimized, possibly by using pediatric blood collection tubes. The use of salvaged red cells (from intraoperative collection or from a chest drainage system) should be discussed with the patient because some Jehovah's Witness patients will allow the use of salvaged blood provided that the entire system remains in continuity with the vasculature.[214] The use of albumin and other substances derived from circulating proteins should be addressed. Early hemodynamic monitoring is indicated to help determine the role of colloid therapy, pressors, and inotropes in maintaining tissue oxygen delivery at the highest possible level. Case reports have described the successful use of rFVIIa and hemoglobin-based O_2 carriers in Jehovah's Witness patients to rapidly correct bleeding and support oxygen delivery, but these agents are not approved for these uses and large case series are not available.[215] The use of erythropoietin to promote red cell growth will shorten the period of relative anemia.[216]

Postoperative Care

Emergence and Tracheal Extubation

Initial surgery in a trauma patient is followed by a period of monitoring and ongoing treatment in which the anesthesiologist is closely involved, either in the postanesthesia care unit (PACU) or in the ICU (see Chapter 85). The adequacy of post-traumatic resuscitation must be confirmed, as outlined earlier, and diagnostic studies of the secondary survey completed. Rapid termination of general anesthesia is highly desirable, particularly in patients with an altered level of consciousness or other evidence of TBI before surgery. Change in mental status from the preoperative baseline is an indication for repeat cranial CT and a search for possible metabolic or toxic derangements.[15]

Although it is imperative that neurologic function be assessed postoperatively, early extubation of a trauma patient should not be taken for granted. Many patients will require continued ventilator support because of CNS trauma, direct pulmonary or chest wall trauma, massive transfusion, upper airway edema, or ongoing intoxication. Box 72-11 lists the criteria for extubation after urgent or emergency trauma surgery. If there is any doubt about the patient's ability to meet these criteria, it is appropriate that the patient be transported to the PACU or ICU with the endotracheal tube in place. Appropriate analgesic medication should be administered, with sedation if necessary. Twelve to 24 hours of support allows confirmation of successful resuscitation and surgical repair, hemodynamic equilibration, titration of appropriate analgesia, and resolution of intoxication. Many patients can be extubated easily and safely at this time; those who cannot are at high risk for the development of MOSF—heralded by the development of post-traumatic ARDS—and will usually require days to weeks of subsequent intensive care.

Box 72-11 Criteria for Operating Room or Postanesthesia Care Unit Extubation of Trauma Patients

Mental Status
Resolution of intoxication
Able to follow commands
Noncombative
Pain adequately controlled

Airway Anatomy and Reflexes
Appropriate cough and gag
Ability to protect the airway from aspiration
No excessive airway edema or instability

Respiratory Mechanics
Adequate tidal volume and respiratory rate
Normal motor strength
Required Fio_2 less than 0.50

Systemic Stability
Adequately resuscitated (see above)
Small likelihood of urgent return to the operating room
Normothermic, without signs of sepsis

Acute Pain Management

Trauma patients present significant pain management challenges to the clinician because of multiple sites of injury, protracted episodes of care, complicating psychological and emotional issues, and prior or ongoing substance abuse (see Chapter 87). As with pain management practice in other diseases, trauma patients are

frequently undertreated, thus creating a significant source of dissatisfaction. Because trauma patients run the gamut of physiology from healthy young athletes to the debilitated elderly, anesthesiologists providing pain management for trauma patients must be prepared for a wide range of needs.

Individual trauma patients will have widely varying requirements for pain medication, so induction of analgesia must be titrated carefully, ideally in a closely monitored environment such as the PACU. Administration of rapidly acting intravenous agents in small doses at frequent intervals until pain relief is achieved is recommended. This allows the practitioner to determine the patient's basal requirements before starting long-acting medications or patient-controlled analgesia. Hypotension in response to analgesics is most commonly indicative of hypovolemia and should prompt a search for occult hemorrhage while further resuscitation occurs.

The need for analgesic medication and the duration of requirement for analgesics will be minimized if a comprehensive emotional support system is available to the patient. Trauma, because of its unexpected nature, carries with it a strongly negative psychological overlay that can have a profound effect on how anatomically based pain is perceived by the brain[217] and on how the patient reacts. After an injury the patient may have legal, financial, and family-based concerns, without the ability to immediately address them. The availability of counselors—religious, financial, or legal—who can help the patient and family with these issues is of enormous benefit. The anesthesiologist can help by communicating to the patient a clear description of the patient's injuries, the probable time required for recovery, and the plan for managing pain throughout the patient's course. The anesthesiologist should refer the patient to counseling services as needed and should be alert to the potential for post-traumatic stress disorder (PTSD) in any traumatized patient.[218] Referral to an experienced psychiatrist or psychologist is appropriate if PTSD is hindering the patient's recovery.

The need for analgesic medication is also influenced by the schedule of physical therapy prescribed for the patient. In general, the more active a patient can be after traumatic injury, the lower the risk of pulmonary complications, venous thrombosis, and decubitus ulcers. Though painful in the short term, the sooner the patient is mobilized, the lower the analgesic requirements in the long term. Early mobilization demonstrates to the patient the "path to recovery" and contributes to an improved emotional state. One of the goals of analgesia, therefore, is provision of adequate medication to facilitate physical therapy without so sedating the patient that participation is impossible.

Neuropathic pain arises when there is direct injury to a major sensory nerve and is common after spinal cord trauma, traumatic amputations, and major crush injuries. Neuropathic pain is characterized by burning, intermittent electrical shocks, and dysesthesia in the affected dermatomal distribution. It is important to identify neuropathic pain because it responds poorly to the analgesics used for somatic pain. This diagnosis should be considered whenever pain control is poor or the patient has a rising requirement for medications unexplained by anatomic injuries. First-line therapy for neuropathic pain has been revolutionized by the widespread use of gabapentin, an antiepileptic drug with very strong specificity for this problem.[219] Gabapentin therapy is typically initiated at a dose of 200 mg three times daily, with daily titration upward to a maximum of 2 to 3 g/day. If neuropathic pain persists, selective regional anesthesia or analgesia may be indicated in an effort to "break the cycle" of spinal cord receptor recruitment.[220]

Regional analgesia provided through an epidural or brachial catheter should be considered for any trauma patient with a potential to benefit from this approach because it will spare the use of systemic narcotics and facilitate early mobilization. Epidural analgesia has been shown to produce high levels of patient satisfaction and improved pulmonary function after major thoracoabdominal and orthopedic surgery in elective populations[221]; this is very likely true for the trauma population as well. Regional techniques are less useful when the patient has multiple sites of injury or when fractures or open wounds make placement difficult. Although epidural placement in anesthetized patients is relatively contraindicated because of the potential for occult SCI, the risk-benefit ratio in many trauma patients favors placement during surgery, when general anesthesia facilitates appropriate positioning and patient cooperation.

Summary

Trauma touches all ages and classes of patients, from young and vigorous to elderly and frail. Because of its great prevalence, practicing anesthesiologists will encounter trauma patients throughout their careers. Increased public recognition of the consequences of injury has sparked interest in trauma research and education, with the result that diagnostic and therapeutic techniques have evolved rapidly in recent years. The anesthesiologist, as a perioperative physician, is in the ideal position to understand and apply these new techniques.

73 Anesthesia and Prehospital Emergency and Trauma Care

Key Points

1. Anesthesiology was instrumental in creating critical care and emergency medicine. In many countries, worldwide anesthesiology departments are responsible for prehospital emergency and trauma care. Physician-based emergency medical services (EMS) systems exist in many European countries, whereas paramedics are the mainstay of EMS in the United States.
2. The basics of prehospital care follow the general form of basic life support (BLS) and advanced life support (ALS), depending on the nature of the EMS system in place for a given region or country.
3. In major trauma, prehospital care must aim at limiting the time spent on the scene, controlling hemorrhage, and expediting transport to a trauma center, often ideally via rescue helicopter. Prehospital fluid resuscitation for major trauma is controversial and patients with penetrating torso injuries and hemorrhagic shock might benefit from limited fluid resuscitation, in particular in urban settings. Prevention of the lethal triad in trauma of hypothermia, acidosis, and coagulopathy is paramount.
4. In acute coronary syndrome (ACS), achieving rapid reperfusion of the ischemic myocardium is the main goal. Opioids (morphine), oxygen, nitrates, and aspirin (MONA) are the main components of prehospital therapy. Fibrinolysis for ACS has been used with much success in the prehospital setting but requires very close supervision by EMS physicians.
5. Prehospital endotracheal intubation and rapid-sequence induction (RSI) have been shown in more than 15 studies to be associated with increased mortality and poorer neurologic outcomes, in particular after traumatic brain injury. It appears that what anesthesiologists consider the standard of care in the operating room may not be the ideal approach for less experienced EMS providers. Perhaps reappraising intubation and RSI in favor of alternate airways such as the laryngeal mask airway or laryngeal tube can improve outcomes.
6. Medical simulation is rapidly becoming the future standard for teaching and training prehospital EMS personnel in the management of complex emergency scenarios.

Unbeknown to many current practitioners, anesthesiologists not only serve as the backbone of physician-staffed prehospital emergency medical services (EMS) in many countries[1-3] but also were instrumental in the creation of modern prehospital emergency medicine.[4,5] In several countries, emergency medicine is considered the fourth pillar of our specialty besides anesthesiology, critical care, and pain therapy.

After World War II, the inadequacy of the civilian ambulance service became all too apparent for wartime experienced physicians, as motor vehicle–related injuries and deaths increased sharply and ambulances provided only transport to the hospital. In Germany, this led to a call to "bring the doctor to the patient" rather than the more traditional converse arrangement.[1,5] As a consequence, the first surgeon-staffed ambulance, the "Klinomobil," was implemented in 1957 in Heidelberg and functioned as a mobile operating room,[5] a concept that was soon abandoned in favor of physician-staffed ambulances, sometimes referred to as mobile ICUs.[6] Similar developments occurred throughout Europe, for example, in Prague, Mainz, Munich, Moscow, and several Scandinavian countries where physicians began to staff ambulances to respond to motor vehicle crashes and other accidents.[3,4] In Belfast, Ireland, Frank Partridge was the first to implement a mobile coronary care unit (CCU) that brought a defibrillator to prehospital patients in cardiac arrest due to ventricular fibrillation.[7] Over the next decades, several European countries, such as France, Germany, Austria, and Norway, implemented nationwide physician-staffed ambulance services that were often complemented by physician-staffed helicopter

emergency medical services (HEMS).[1-3,8,9] Anesthesiology is currently the dominant medical specialty providing EMS physicians in Europe, and many anesthesiology departments are in charge of staffing ambulances and helicopters with physicians.[3,10]

In the United States, a different development took place. For various reasons, physician-staffed ambulances were not considered an option, so specifically trained emergency medical technicians (EMTs) and paramedics became the mainstay of EMS in North America. A landmark event for the creation of modern EMS systems was the publication of the report *Accidental Death and Disability: The Neglected Disease of Modern Society*, commonly referred to as *The White Paper*, published by the National Academy of Sciences in 1966.[11] Among several remarkable physicians, two anesthesiologists, Peter Safar, in Pittsburgh, the father of modern cardiopulmonary resuscitation (CPR), and Eugene Nagel, in Miami, were most influential in creating the first paramedic-based EMS system in the United States in the 1960s. Before emergency medicine became its own medical specialty, anesthesiologists were often involved in prehospital emergency care based on their unique expertise in resuscitation, airway management, and critical care. This involvement has dwindled over the past 2 decades, although it appears that anesthesiology could still play an important role in prehospital emergency care in the United States based on what the recent, widely cited Institute of Medicine report *Emergency Medical Services: At the Crossroads* identified as the major problems in prehospital care, such as prehospital airway management, fluid resuscitation, rapid-sequence induction (RSI), and pain therapy.[12]

In this chapter, we provide a concise overview of prehospital emergency and trauma care with a focus on the important role of anesthesiology.

Organizational Models of Prehospital Emergency Care

Levels of Care

Originally, the terms *basic* and *advanced life support* were only used to describe the two different levels of care for CPR (see Chapter 97) but were later expanded to all emergency situations, including trauma and pediatric emergencies. Currently, they denote the level of care in an organized EMS system and are usually divided into BLS and ALS. First responders, such as police officers and firefighters, are not part of an EMS system and they provide first aid, operating below the formal BLS level.

Basic Life Support

Prehospital care at the BLS level is usually provided by EMTs and does not include advanced and invasive techniques and skills.[13] BLS is focused on the classic ABCs (Airway, Breathing, Circulation) and includes simple airway maneuver, such as chin lift or jaw thrust, oral and nasal airways, bag-valve-mask ventilation, hemorrhage control, and administration of oxygen (Table 73-1). During CPR, the use of an automated external defibrillator is considered a BLS skill. BLS-only ambulances are often found

Table 73-1 Skill Set for BLS and ALS Providers and Prehospital Emergency Physicians

BLS
Basic patient evaluation
Vital signs and basic monitoring (noninvasive blood pressure, pulse oximetry, heart rate)
Hemorrhage control via direct pressure or pressure dressing
Cardiopulmonary resuscitation (BLS) with use of automatic external defibrillator
Bag-valve-mask ventilation
Oral and nasal airway
Oral suctioning
Administration of oxygen
Basic patient rescue, positioning, and transport skills
Cervical spine stabilization
Fracture splinting
Assisting a patient taking prescribed medication (e.g., albuterol inhaler)
ALS
Venous access and fluid therapy
Administration of select drugs*
Advanced monitoring (ECG, capnography)
Cardiopulmonary resuscitation (ACLS)
Manual defibrillation
Basic 12-lead ECG interpretation
External pacing
Endotracheal intubation* (without drugs; some EMS systems allow rapid-sequence induction)
Cricothyroidotomy
Sedation*
Needle decompression of tension pneumothorax
Knowledge of mass casualty incident management and triage
Knowledge of biological, chemical, and nuclear agents
Prehospital Emergency Physician
Unlimited administration of emergency drugs
Use of narcotics and controlled substances (e.g., fentanyl)
Prehospital rapid-sequence induction and anesthesia
Advanced airway management
Chest tube placement
Advanced 12-lead ECG interpretation
Advanced techniques (ultrasound, noninvasive ventilation)
Emergency surgery
Can assume role of medical incident commander in mass casualty event

*Not in all ALS-level EMS systems allowed.
ALS, advanced life support; BLS, basic life support.

in rural areas where the incidence of emergencies is low and volunteer EMTs frequently staff ambulances.

Advanced Life Support

ALS is usually provided by paramedics and flight nurses with a rigorous educational background and includes the use of advanced and invasive techniques (see Table 73-1). In many countries, ALS-level providers are allowed to work semi-independently with often only indirect physician control through the use of standing orders and protocols issued by the EMS medical director. The use of drugs is tightly regulated, and physician permission from the emergency department must be sought in cases where drugs outside the approved list are to be administered. Most urban EMS systems use ALS units to provide prehospital care. In EMS systems without EMS physicians responding directly to the scene, the scope of practice of ALS-level providers is usually greater and they are allowed to work more independently. Combat medics in the military frequently operate at the ALS level. EMS physicians, flight nurses, and critical care EMTs provide a level of care above and beyond ALS.

Models

Worldwide, a high degree of variability exists as to how prehospital care is organized and staffed. It would be beyond the scope of this chapter to describe all the nuances of the different EMS systems worldwide; rather, we will outline the differences between the two main models, which primarily differ by their level of direct physician involvement in prehospital emergency care: EMT-based models versus physician-based models. These two models are also known as the U.S. model and the "Franco-German" model.[14] Although controversy exists which model provides superior patient care and outcomes, the design of the EMS system is dictated by tradition and fiscal constraints.

Single-Tiered Versus Multi-Tiered EMS Systems

If an EMS system is composed only of units providing the same level of care—BLS or ALS—it is referred to as a *single-tiered* system. The advantage of a single-tiered EMS system is that it eliminates overtriage or undertriage by emergency medical dispatch. In rural areas with a low frequency of emergency calls, a single-tiered EMS system—often composed of volunteer EMTs at the BLS level—is the only possible model; and in dense urban areas with a high frequency of emergency calls, an all-ALS EMS system might be advantageous. The disadvantage of single-tiered all-ALS EMS systems is that the highly trained paramedics will not be exposed to the same number of high priority situations, making it difficult to maintain their skills and experience.

Multi-tiered EMS systems use priority dispatch to determine the adequate level of response; it would dispatch an ALS unit to a patient with myocardial infarction but a BLS unit to a patient with a broken wrist.

EMT- and Paramedic-Based EMS Systems

In North America, EMTs provide organized prehospital care.[15] Only rarely will physicians be directly involved in out-of-hospital patient care on the scene.[16] By U.S. law, physicians are required in most states to oversee the medical operations of EMS systems, either *online* through direct communication or *offline* as EMS medical directors responsible for developing and implementing standardized treatment protocols. Besides developing standard operating procedures and approving new medical devices, EMS medical directors are responsible for quality control and improvement and are an integral part of EMT education.[17] In the United States, EMS medical directors are often emergency physicians working in the emergency department of the local hospital.

In general, three levels of EMTs can be distinguished by their educational background and experience in the United States: EMT-basic (EMT-B), EMT-intermediate (EMT-I), and EMT-paramedic (EMT-P). EMT-basic providers usually spend between 80 and 120 hours of training and are only allowed to perform basic life support (BLS) skills. The basic level is the minimum level required to work in an organized ambulance service. Often, EMT-basic providers staff nonemergent ambulance transport but are also used to respond to non–life-threatening situations. EMT-I providers are regulated differently among the individual states, and their skills range between BLS and ALS. Often, EMT-I providers can be found in rural areas where it would be too expensive to employ paramedics only but where more advanced skills than those of an EMT-B level are needed. Most states do not allow EMT-I providers to perform endotracheal intubation or administer drugs, except very few deemed safe, such as albuterol for asthma, but allow the placement of an intravenous (IV) line. Paramedics (EMT-P), on the other hand, are the most advanced EMTs. They undergo intensive 1- to 2-year training in all different aspects of advanced prehospital emergency care. Their scope of practice is ALS, and they are allowed to perform advanced techniques such as endotracheal intubation, administration of selected drugs, and manual defibrillation. Most developed countries have training requirements for their EMT work force similar to the U.S. model.

Physician-Based EMS Systems

Germany and France represent the two most well-known examples of countries where doctors are an integral part of prehospital emergency care.[14] These integrated EMS systems combine BLS-level ambulances with physician-staffed ALS ambulances and helicopters in a noncompetitive but complementary fashion. Physician-based EMS systems are always part of a multi-tiered system and often use what is referred to as a "rendezvous system" to dispatch two units simultaneously to the scene, one unit staffed with EMTs (BLS or ALS level) and one ambulance carrying the doctor. Often, the physician-staffed vehicle will be a nontransport vehicle aimed to provide quick response to emergencies without having to move a large and slow truck through traffic. EMS physicians are licensed physicians from various medical specialties who undergo a specialized training in prehospital emergency care. The level of mandatory education varies from country to country. In many countries with direct physician involvement in prehospital care, anesthesiologists compose the largest fraction of physicians and often assume the role of chief emergency physician/medical director.[18,19]

Helicopter EMS

In many countries worldwide, helicopter EMS (HEMS) continues to expand as an integral component of EMS. Although being mostly privately organized and funded in the United States, several European countries have implemented a nationwide HEMS network that is strategically distributed to be able to respond to emergency calls from every location in the country. HEMS have historically been mostly associated with rapid

Figure 73-1 Train accident in Wampersdorf, Austria. Mass-casualty incident with 6 fatalities and 17 injured patients. In addition to more than 50 EMS personnel and EMS physicians on the ground, 5 EMS-physician–staffed helicopters provide invaluable EMS-physician level backup and transport capacity.

response to and fast transport from the scene of an accident, particularly from remote rural accident scenes. However, HEMS is now considered more and more as a vital ALS-level backup for all emergency situations in rural areas lacking local ALS-level response.[20] EMS helicopters are usually staffed with experienced personnel, either paramedic and flight nurse or EMS physician.[9,21] In mass-casualty incidents, all helicopters from a large area can be concentrated at the scene of the accident within a short period of time and provide several highly trained ALS teams to support local rescue operations and transport the victims quickly to trauma centers (Fig. 73-1). Another area where HEMS have become the most important means of evacuation is in mountain rescue operations. Pioneered in the Alps, helicopter evacuation by ALS teams specially trained in mountain rescue techniques is now considered the standard of care in countries such as Switzerland, Austria, Germany, and France (Fig. 73-2).

Communication

Starting with the emergency call, communications is a vital aspect of prehospital emergency care. The implementation of a universal emergency telephone number (911 in the United States and Canada, 112 in several European countries, 000 in Australia, and 999 in the United Kingdom)[17] was a milestone in prehospital care, and nowadays the location of the caller can be automatically identified by the system except if calling from a cellular phone. Emergency medical dispatchers will determine the type and priority of the response based on standardized questionnaires and will provide invaluable prearrival instructions to the caller to start potentially lifesaving interventions before the ambulance arrives. For example, dispatcher-assisted CPR has been shown to improve survival after cardiac arrest.[22] Two-way radio communication has long been an indispensable part of EMS communications, allowing not only fast communication between ambulance and dispatcher but also to the hospital and other emergency response teams such as fire department, police, and helicopters.

Basic Techniques and Skills

Patient Examination and Initial Assessment on the Scene

Emergency patients show a wide range of symptoms, challenging the prehospital care team to obtain a tentative diagnosis quickly and start a specific treatment. In contrast to the emergency department, fewer diagnostic tools are available in the prehospital setting. The classic approach of "look, listen, and feel" is still the most important aspect of the patient examination.

On approaching the patient, a rapid appraisal of the scene should assess potential hazards that could endanger patient and prehospital personnel. The initial assessment should take into account the surrounding circumstances such as environmental factors and should focus on the vital signs of the patient using a systematic approach.[23] Visual impressions from the scene help to understand the circumstances of an accident or medical emergency, such as intoxication. The medical history of the patient can guide the presumptive diagnosis. In case the patient is unresponsive, relatives or bystanders must be queried. The most common chief complaints encountered in the prehospital setting are dyspnea/respiratory distress, cardiac/circulatory dysfunction, altered level of consciousness, and trauma.

Basic Evaluation

Vital Signs

The first quick survey employs the A-B-C-D scheme well known by ALS.[24] The first step is to use acoustic and tactile stimuli to rule out unconsciousness in the emergency patient. The next step

Figure 73-2 In mountain rescue, helicopter EMS systems have become the standard of care for evacuating patients from alpine accidents and emergencies. Here, a rescue helicopter supports a complex mock rescue operation from a ski lift in alpine Austria.

is to identify airway (A) obstruction and, if necessary, to secure the airway. In trauma patients, manual in-line stabilization of the cervical spine should be performed at this point. While maintaining an open airway, breathing (B) is assessed by look, listen, and feel.[23] Respiratory rate, efficacy, work and pattern of breathing are also assessed. If indicated, supplemental oxygen or assisted ventilation will be administered to support oxygenation and ventilation. Circulation (C) is initially checked by feeling the pulse centrally at the carotid artery and can be extended to feel pulses proximally and distally on the extremities. The pulse should be assessed for rate, quality, and regularity. To complete C, the capillary refill time should be measured. The level of responsiveness and consciousness (D, disability) should be determined according to the Glasgow Coma Scale (GCS) and a quick pupil check performed to determine size and reaction to light. The GCS is a reliable prognostic tool for head trauma[25,26] and other forms of nontraumatic altered level of consciousness.[27] For children younger than the age of 3 years, the verbal component of the GCS score must be adjusted. In case of trauma, exposure and environment (E) are assessed to complete the primary survey. At this point, the patient should be checked from head to toe, and his or her back should be evaluated after a log-roll maneuver.[28]

Auscultation—Palpation—Percussion

Auscultation is a versatile and useful tool in most prehospital settings, limited primarily by ambient noise in the environment. Palpation, also an important tool, may be more useful in such settings. In trauma, the entire body can be examined by palpation only. During the primary and secondary survey in the field, the rescuer has to rely solely on palpation. Percussion is specifically helpful to detect abnormal air or gas collections, such as tension pneumothorax and large amounts of free intra-abdominal air.

Capillary Refill Time

Capillary refill time is a quick and reliable parameter to detect hypovolemia; 5% dehydration can be detected by capillary refill time with 87% sensitivity and 82% specificity.[29] After compression of the skin for at least 5 seconds, the time is measured until normalization of skin color occurs. Normal findings are less than 2 seconds. Capillary refill time may be especially useful to detect significant dehydration in children.[30]

Monitoring and Equipment

In a similar development compared with standard monitoring in operating room and intensive care, monitoring in the prehospital setting is now considerably standardized with noninvasive blood pressure monitoring, electrocardiography (ECG), and pulse oximetry regarded as the classic "trifecta." Capnography and temperature monitoring have begun to supplement the diagnostic and monitoring armamentarium in the field.

Pulse Oximetry

After the first prehospital uses in the 1980s,[31] pulse oximeters have become the universal, easy to attach and use monitor for the prehospital patient. The improvement of the devices led not only to smaller machines but also to pulse oximeters with better quality even in motion and the cold.[32,33] Additionally, new features such as detection of methemoglobin and carboxyhemoglobin[34,35] can help diagnose conditions such as carbon monoxide poisoning.

Arterial Blood Pressure

Noninvasive blood pressure measurement is the most common form of blood pressure monitoring in the prehospital setting. Automatic or manual cuffs are mostly used and use an oscillometric technique that has known limitations.[36] The precision and accuracy of noninvasive oscillometric blood pressure monitoring is reduced by movement during transport. During interhospital transfer of a critically ill patient, intensive care unit (ICU) monitoring with invasive blood pressure monitoring is frequently used.

Electrocardiography

ECG monitoring has two major goals in the prehospital setting. A quick 3- or 4-lead ECG or an ECG rhythm obtained from defibrillator paddles is sufficient for a rapid ECG rhythm diagnosis. This is of importance for treatment decisions during ALS in cardiac arrest to decide if a shockable rhythm is present. On the other hand, to identify myocardial ischemia or infarction, a 12-lead ECG is needed. It is more cumbersome to apply and requires more experience for interpretation. Prehospital ECG allows for a focused prehospital therapy in acute coronary syndrome[37] and has been shown to shorten the door-to-reperfusion time.[38-40] This benefit can be further improved by transmission of the ECG to medical oversight.[41]

Temperature Monitoring

Oral, esophageal, and some tympanic thermometers[42-45] are reliable tools in the field given the more extreme weather conditions in which they must operate. The most important aspect of measuring temperature on the scene is to identify hypothermia. Special temperature probes are required to assess severe hypothermia (<28°C) because most commercially available instruments become unreliable at these low temperatures. Trauma patients, patients at the extremes of age, disabled patients (stroke, coma), and intoxicated patients are especially vulnerable to hypothermia, particularly during winter months. Even relatively mild outside temperatures can result in hypothermia with long exposure times.[46,47]

Capnography

Colorimetric, main- or side-stream capnographs are primarily used in the prehospital setting for identification of the correct positioning of the endotracheal tube.[48-50] With a single measurement the correct tube position can be identified. Capnography became the standard for identifying the correct tube position in addition to auscultation and identifying chest movements. Continuous monitoring of end-tidal CO_2 allows the monitoring of hemodynamics and the success of resuscitation.[51] In cardiac arrest, low CO_2 levels are a predictor for fatal outcome.[52] Hyperventilation may also contribute to poor outcome[53] and may be preventable by controlling ventilation with the aid of end-tidal CO_2 monitoring.[54,55] Significant cardiorespiratory failure may limit the usefulness of capnography owing to significantly reduced pulmonary perfusion.

Prehospital Blood Tests

Despite proposals for prehospital point-of-care testing,[56] only blood glucose testing is routinely used. Troponin and blood gas analysis are examples of tests that may have potential utility.[53,57]

Ultrasonography

Small and portable ultrasound machines have been developed that are applicable in the prehospital setting. Diagnostic ultrasound requires a physician on the scene (or online through medical oversight if adequate transmission of the image can be achieved) but offers very interesting possibilities. Focused abdominal sonography for trauma (FAST) is a rapid and reliable technique even in inexperienced hands in the emergency department and could be used in the field.[58] It has the potential to improve the triage and management of trauma patients.[59] During resuscitation from cardiac arrest, cardiac activity is a predictor for return of spontaneous circulation (ROSC).[60] Nevertheless, diagnostic prehospital ultrasonography is still considered experimental and may interfere with management priorities.

Prehospital Airway Management and Ventilation

Early and adequate airway management and ventilation in the out-of-hospital setting are lifesaving interventions that define prehospital emergency and trauma care (see Chapter 50). For anesthesiologists who perform advanced airway management on a daily basis it is often difficult to comprehend why airway management is such a contentious issue in prehospital emergency medicine, particularly in the United States.[61-67] The reasons are many. The major difference from the operating room environment, as an EMS saying goes, is that *there is no easy airway in the field*. Challenges include nonstandard environments; difficult access to the patient's head; bad weather and lighting conditions; and blood, vomitus, secretions, and foreign bodies obstructing the airway. In a patient who is critically ill with limited oxygen reserves and a higher baseline oxygen consumption all of these factors contribute to a significantly more difficult prehospital airway management compared with the operating room, even for an experienced anesthesiologist.[68-72]

Airway Management at the BLS Level

Supplemental oxygen is the most important component in prehospital airway management, hence the saying "The patient does not die because of a lack of an endotracheal tube but because of lack of oxygen." EMTs are trained and qualified to administer supplemental oxygen, often via a non-rebreather facemask allowing for a significantly higher F_{IO_2}. Furthermore, EMTs are allowed to use nasopharyngeal or oropharyngeal airways to maintain a patent airway and to ventilate a patient by bag-mask-valve ventilation. The use of the Combitube (or Easytube), a double-lumen tube with a proximal and a distal balloon that was initially developed for ventilation during CPR, is considered a BLS skill.[73,74] The use of other alternate supraglottic airways, such as the King-LT (laryngeal tube) or laryngeal masks, is increasingly recommended at the BLS level if adequate training and experience are provided.[75] These alternate airways have been shown to be safe and easy to apply and have excellent success rates when used by EMTs and paramedics.[76-79] The limitations of these alternate airways are a disability to ventilate if misplaced in the larynx and lack of airway protection compared with a cuffed endotracheal tube. It is of note that many anesthesiologists who do not work in EMS medicine are currently not familiar with many new alternate airway devices used in prehospital care, such as the King-LT, which is rapidly becoming the standard alternate airway in the field.[75]

Ventilation in the prehospital setting is most commonly achieved by bag-mask-valve ventilation. Although fairly common in Europe, only a few EMS services in the United States currently use portable field ventilators to ventilate intubated patients. The major disadvantage of relying on bag-mask-valve ventilation is that minute ventilation and tidal volumes are uncontrolled, often leading to significant hyperventilation that has been shown to be detrimental in patients in cardiac arrest[53,80,81] and with head trauma.[82-88]

Airway Management at the ALS Level

Endotracheal intubation is considered the standard of care in prehospital airway management and a standard intervention for paramedics and EMS physicians because it provides a definitive airway and protection from aspiration of gastric contents. Compared with standard endotracheal intubation in the operating room, several differences exist. First, most prehospital intubations (50%-70%) are performed in patients with cardiac arrest, obviating the need for any anesthetic induction or muscle relaxation.[89] Most other intubations in spontaneously breathing patients require sedation or induction of general anesthesia, most commonly performed as RSI. Particular emphasis should be placed on adequate preoxygenation because these critically ill patients have little to no oxygen reserves,[90] as well as on maintaining cervical in-line stabilization in trauma patients. Oral, direct laryngoscopic, and tracheal intubation while maintaining cricoid pressure (Sellick's maneuver) is the recommended approach. Endotracheal intubation in the field requires confirmation by auscultation and end-tidal CO_2 monitoring.

Adverse intubating conditions in the field lead to more frequent incidences of difficult endotracheal intubations,[70] including higher incidences of multiple attempts[91] and of unrecognized esophageal or endobronchial intubation. This occurs even by experienced EMS physicians and anesthesiologists and is associated with a high mortality rate.[71] However, experienced physician "airway managers" and, in particular, anesthesiologists have more frequent success rates and lower complication rates after prehospital endotracheal intubation.[92-94]

A significant portion of failed field intubations results from inadequate operator training or experience. Less than one half of field intubation failures were remedied in the emergency department by the use of neuromuscular blocking agents.[95] Because of the higher complication rate, every prehospital provider performing advanced airway management must be trained also in alternate airway management, such as Combitube, King-LT, or laryngeal masks. A special training for managing the unanticipated difficult airway according to adapted international guidelines should be required.[96,97] Surgical airway access such as cricothyroidotomy is considered the last resort but can be lifesaving in patients when every other airway technique fails.[98]

Sedation, Anesthesia, and Pain Control in the Prehospital Setting

In this section, the focus will be on generally accepted strategies for providing prehospital sedation, induction, and maintenance of anesthesia and pain control (see Chapters 26 and 27). Drugs

commonly used in the field will be discussed with an emphasis on the differences from use in the hospital. There is hardly any area of greater controversy than RSI in the field.

Drugs Commonly Used for Prehospital Sedation, Anesthesia, and Pain Control

In general, not all drugs routinely used in the operating room for general anesthesia are safe in the prehospital setting.[99] Nonanesthesia personnel such as paramedics and nurses are much less experienced than anesthesiologists in the use of these drugs, and critical patients often require a more cautious approach and dosage titration. Therefore, drugs used for analgesia, sedation, and anesthesia in the field should have the following desirable properties[100]:

- Wide safety margin—even for inexperienced providers
- Hemodynamic stability
- Minimal respiratory depression
- Ease of administration via different routes (IV, IM, IO, rectal)
- Rapid onset
- Minimal side effects

Benzodiazepines, such as midazolam (0.05-0.2 mg/kg IV) and diazepam (3-10 mg IV), are well suited for sedation in adult and pediatric patients and can be administered via several different routes; however, the complete lack of analgesic properties usually requires the concurrent administration of a potent analgesic in patients with severe pain. *Ketamine,* on the other hand, is closer to an ideal agent for sedation and analgesia (0.5-2 mg/kg IV) and in higher doses for induction of anesthesia (2-5 mg/kg IV) in the field.[101] It provides potent analgesia and sedation, maintains hemodynamic stability in patients with hypovolemic shock, is a potent bronchodilator, and causes minimal respiratory depression. The use of ketamine in severe head trauma is controversial: some make a case for its use if ventilation is controlled.[102] Owing to its hallucinogenic properties, a benzodiazepine should be coadministered. The new isoform, S(+) ketamine, is twice as potent but has otherwise a similar profile as a racemic drug. Ketamine can be administered intramuscularly (IM) and is ideally suited to provide analgesia and sedation for entrapped trauma patients during extrication (4-12 mg/kg IM). *Etomidate* is rarely used for sedation but is often used as an anesthetic induction agent for RSI in the field (0.2-0.3 mg/kg IV). It maintains hemodynamic stability but frequently produces myoclonus, rendering intubating conditions less favorable. Furthermore, etomidate may cause adrenocortical suppression, but this is controversial and has not been sufficiently studied in the EMS setting.[103,104] *Propofol* has become the anesthetic induction agent of choice in the operating room but has several disadvantages for use in the field. It causes significant hemodynamic compromise and respiratory depression, both highly undesirable properties, especially for inexperienced nonanesthesiologists. *Barbiturates,* such as thiopental, share similar pharmacologic properties and side effects with propofol and should be used only by experienced providers and only in selected patients, for example, in those with status epilepticus. The prehospital muscle relaxant of choice is still *succinylcholine* (1-1.5 mg/kg IV) during RSI,[105] although rocuronium has been successfully used by anesthesiologists in EMS.[106] For pain control in the prehospital setting, *opioids* are useful owing to the rapid onset and the ability to control severe pain.[107] *Morphine* is considered the standard of care in acute coronary syndrome (0.1-0.2 mg/kg IV), but in trauma other opioids, such as *fentanyl* (1-3 µg/kg IV), *piritramide* (0.1-0.2 mg/kg IV, currently not available in the United States but widely used in Europe), and sometimes *tramadol* (50-100 mg bolus IV) are more frequently used. Nonopioid analgesics are infrequently used in the prehospital setting, although they offer a potential additive analgesic effect with opioids.

Box 73-1 Prehospital Rapid-Sequence Induction

1. Preparation of necessary equipment (suction, oxygen, laryngoscopes, endotracheal tube, Ambu bag plus masks, stylet)
2. Preoxygenation with 100% oxygen (at least 3 minutes)
3. Pretreatment (optional) with small defasciculation dose of a nondepolarizing neuromuscular blocking agent, such as vecuronium (0.01-0.015 mg/kg IV)
4. Pretreatment (optional) with sedative (midazolam) and/or opioid analgesic (fentanyl)
5. Induction agent (etomidate, 0.3 mg/kg IV, or ketamine, 2-3 mg/kg IV) plus succinylcholine (1.0-1.5 mg/kg IV)
6. Cricoid pressure (Sellick's maneuver), plus manual in-line stabilization for trauma patients
7. Direct laryngoscopy with oral intubation (use of stylet is recommended)
8. Confirmation of correct endotracheal tube placement: bilateral auscultation plus end-tidal CO_2 confirmation

Induction of Anesthesia

The management of prehospital induction of anesthesia will nearly always be performed as RSI, also known as drug-assisted intubation (DAI) in EMS literature (see Chapter 50). The goal is twofold: (1) the provision of a definitive airway and ventilation control and (2) the provision of potent analgesia and sedation. The actual principles of RSI do not differ from RSI in the emergency department, operating room, or ICU, only in the environment in which it is applied, as discussed earlier.[63] A standard RSI sequence consists of the steps presented in Box 73-1. Extremely important in the prehospital setting is to have a backup plan, if intubation fails. Bag-mask-valve ventilation, placement of an alternative airway such as a laryngeal mask airway or intubating laryngeal mask airway, or Combitube are acceptable options. EMS providers must understand that prehospital RSI is not trivial and is associated with significant morbidity and mortality if performed improperly.[108] Life-threatening hypoxemia will ensue if intubation is prolonged and ventilation is difficult (Fig. 73-3).

Prehospital Trauma Care

The management of a severely injured patient is one of the biggest challenges in prehospital care. Trauma represents a leading cause of death and disability among all ages but disproportionally affects the younger age groups. The potential for saving lives is probably nowhere more prevalent in EMS than in major trauma, which was also historically the driving force behind the creation of modern EMS systems. The challenges for EMS providers

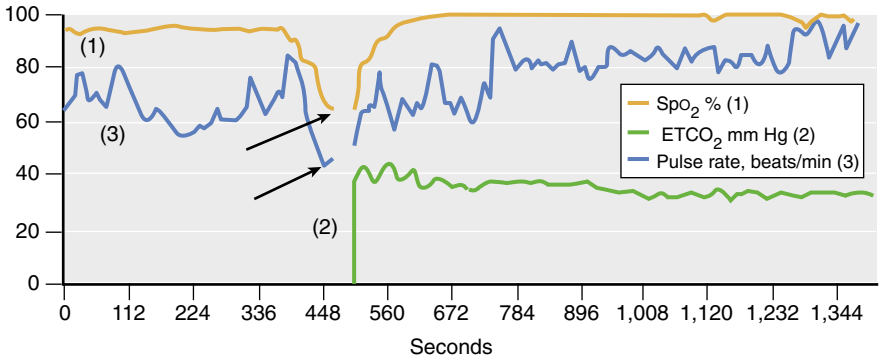

Figure 73-3 Potentially life-threatening desaturation and bradycardia after out-of-hospital rapid-sequence induction and endotracheal intubation. (*From Dunford JV, et al: Incidence of transient hypoxia and pulse rate reactivity during paramedic rapid-sequence intubation. Ann Emerg Med 42:721-728, 2003.*)

responding to major trauma begin with assessment of safety at the scene, scene assessment (number of injured patients, mechanism of injury, injury severity, difficult weather and lighting conditions), and coordination with other first-responder services (police, fire department). Significant pressure exists to minimize on-scene and transport times, based on the "golden hour" and "platinum 10 minutes" concept.[109] The most commonly used guideline for prehospital trauma care is Prehospital Trauma Life Support (PHTLS) developed by the National Association of Emergency Medical Technicians (NAEMT) in cooperation with the Committee on Trauma, American College of Surgeons.[28] PHTLS is based on the Advanced Trauma Life Support (ATLS) concept that is used as standard for in-hospital trauma care.[110]

Patient Evaluation on the Scene and Initial Management

Before turning the attention to the trauma patient, the EMS crew must ensure that the accident scene is safe. Crew protection is paramount, in particular in hazardous accidents involving fire, chemical agents, or electricity or on busy highways. Motor vehicle accidents often involve more than one patient; therefore, the EMS team must perform a quick but thorough scan of the entire accident scene and triage all victims. The overriding goal of the initial patient assessment on the scene is to identify life-threatening injuries. This usually follows the well-known A(irway), B(reathing), C(irculation), D(isability), and E(xposure/Environment) algorithm. Treatment is immediately initiated if a life-threatening injury is identified ("Treat what kills first"). This often involves emergent airway management to protect the airway or hemorrhage control for major bleeding. Supplemental oxygen via a nonrebreathing facemask should be started on the scene, as well as standard monitoring (ECG, pulse oximetry, blood pressure, capnography) applied. The goal is to maintain Spo_2 above 90%. If the patient's respiratory status deteriorates or if he or she is unable to protect the airway (due to unconsciousness, intoxication, hypoperfusion, or direct trauma), establishing a definitive airway is indicated. Endotracheal intubation in the field with or without RSI by paramedics has been intensely scrutinized over the past decade,[62,68] especially in traumatic brain injury,[111] and it is currently unclear if field airway management with RSI by paramedics decreases or contributes to trauma mortality.[67] It appears that experience of the provider in endotracheal intubation and RSI is a strong predictor for successful prehospital airway management,[112] and therefore it should not come as a surprise that success rates are higher and complication rates lower if anesthesiologists perform airway management in the prehospital setting.[93]

Hemorrhage control is probably the most critical aspect of prehospital trauma care, particularly in combat casualty care. A large fraction of traumatic deaths within the first hour can be attributed to exsanguination.[113] The recommended first step in controlling the bleeding is direct pressure to the wound, including application of an appropriate pressure dressing. Compressing the major artery proximal to the wound at pressure points is the next step, and tourniquets should only be used as a last resort in civilian trauma.[114] In military trauma, the use of tourniquets has recently surged again in Iraq and Afghanistan and has been accredited with having saved many lives.[115,116] Several different hemostatic wound dressings have been advocated and used in combat casualties suffering from severe hemorrhage[117]; their use in civilian EMS is currently not well defined.[118] In patients with hemorrhagic shock, it is currently recommended to start two large-bore IV lines and give a fluid bolus of 2 L of a warm crystalloid solution.[28] This practice, however, has been repeatedly questioned, particularly for penetrating trauma in an urban setting.[119,120] Newer concepts, such as small-volume resuscitation with either hypertonic saline or hypertonic-hyperoncotic hydroxyethyl starch solution,[121,122] permissive hypotension/hypotensive resuscitation,[123] or hemoglobin-based oxygen carriers,[124] are promising but currently still under investigation. The controversy regarding optimal fluid therapy goes hand in hand with the ongoing discussion of if a "scoop-and-run" (evacuate) or "stay-and-play" (resuscitate on site) or BLS versus ALS approach is superior in major trauma (see Controversies in Prehospital Emergency and Trauma Care).[125] There is evidence supporting a minimalistic on-the-scene management (BLS only) for penetrating trauma to the torso in an urban setting because transport times are very short, usually a younger age group is affected that will tolerate a period of hypotension well, and the injury can only be treated by emergent surgery. On the other hand, evidence is scant to support a scoop-and-run approach for blunt trauma, especially in the rural setting where transport times are much longer than in an urban setting. Irrespective of the current controversy regarding fluid resuscitation in major trauma, the goal is to minimize on-scene time to less than 10 to 15 minutes (or less than 5 minutes in a hypotensive penetrating trauma victim) as well as transport times. Helicopter transport has been advocated for major trauma patients because it was shown to reduce mortality as well as facilitate treatment in a trauma center.[126] Current criteria that patients should be transported to a trauma center can be found in Table 73-2. In major head trauma (see Chapter 63), a modified approach is required in the field: adequate oxygenation

Table 73-2 On-Scene Triage Criteria for Major Trauma Necessitating Transport to Trauma Center

Mechanism of Injury
Extrication time >20 minutes
High-speed crash with:
Intrusion into passenger compartment >20 cm
Speed >40 mph
Ejection
Death of another passenger in same car
Rollover
Pedestrian or bicyclist hit by motor vehicle
Motorcycle crash >20 mph or with separation of rider from motorcycle
Falls >3 m (9.8 ft)
Physiologic Criteria
Systolic blood pressure <90 mm Hg
Respiratory rate <10 or >29 breaths/min
Glasgow Coma Scale score <14
Pregnancy
Anatomic Criteria
Flail chest
Two or more proximal long bone fractures
Pelvic fracture
Penetrating injury to head, neck, torso, or extremities proximal to elbow or knee
Open or depressed skull fracture
Amputation proximal to wrist or ankle
Paralysis
Discretion of EMT
Per discretion of EMT, patients can be declared a major trauma patient. In addition, preexisting conditions of the patient can lead to an upgraded status, such as coronary artery disease, congestive heart failure, severe COPD, morbid obesity, or bleeding disorders.

COPD, chronic obstructive pulmonary disease.
From O'Connor RE: Trauma triage: Concepts in prehospital trauma care. Prehospital Emerg Care 10:307-310, 2006.

and avoiding hypoxemia (SpO_2 >90%), maintaining an adequate cerebral perfusion pressure >70 mm Hg with a systolic blood pressure of at least 90 mm Hg with isotonic or hypertonic fluids, endotracheal intubation for patients with a GCS less than 9, maintaining normoventilation (end-tidal CO_2 of 35-40 mm Hg) and avoiding hyperventilation or hypoventilation are considered the mainstays of prehospital therapy in traumatic brain injury.[127] However, if cerebral herniation is suspected, moderate hyperventilation (end-tidal CO_2 of 30-35 mm Hg) and hyperosmolar therapy with mannitol or hypertonic saline should be instituted.

Adult Medical Emergencies

Most textbooks on prehospital emergency medicine discuss adult medical emergencies under the patient's final diagnosis, such as congestive heart failure (CHF) or chronic obstructive pulmonary disease (COPD). This, however, is not how patients present to the EMS team on the scene; instead, patients usually present with a chief complaint (or lead symptom), such as dyspnea or chest pain. Most often, adult medical emergencies fall into only three separate chief complaints: dyspnea/respiratory distress, cardiac/circulatory emergencies, and altered level of consciousness. Therefore, we will discuss adult medical emergencies in this chapter by their respective chief complaint.

Dyspnea/Respiratory Distress

Dyspnea is one of the most common presenting symptoms in prehospital care, carrying a significant mortality rate of 12% to 18% in adults.[128] Each year in the United States alone, 2 million patients with respiratory distress are transported by EMS. As shown in a large Canadian outcome study (OPALS), prehospital ALS decreases mortality in these patients.[128] In adults, acute shortness of breath is most commonly caused by either bronchospasm or pulmonary edema secondary to CHF, but other differential diagnoses such as pulmonary embolism, pneumonia, and foreign body obstruction must be considered (Table 73-3).[129] Identifying the correct diagnosis on the scene is not always as straightforward as it may seem[130-132] because the etiology of dyspnea can be multifactorial, for example, in a patient with severe COPD and CHF who develops pneumonia.

Patient Evaluation

The most important aspect of the initial evaluation in a patient with acute dyspnea is to identify if the condition is life threatening with imminent respiratory failure and requires immediate treatment. Physical signs and symptoms indicating a life-threatening condition are cyanosis, tachypnea (respiratory rate <6 breaths/min or >30 breaths/min), stridor, tachycardia, inability to speak in full sentences (<5 to 6 words), and the use of accessory respiratory muscles.[133] The use of pulse oximetry has quickly become the standard of care in diagnosing hypoxemia and adds an objective measurement of the severity of respiratory distress.

Irrespective of the underlying cause, all patients with respiratory distress should receive high-flow oxygen, ideally through a non-rebreathing facemask. Owing to space constraints, we will focus on the two most common causes of respiratory distress in adults: bronchospasm due to asthma and COPD and pulmonary edema due to CHF.

Prehospital Management

Bronchospasm: COPD and Asthma

Bronchospasm as a cause for dyspnea is often suggested by the patient's medical history and current medications. Asthmatics and COPD patients often use inhaled β-agonists and corticosteroids and, in severe cases, also systemic agents. These patients tend to have frequent encounters with EMS and emergency departments. In addition to the clinical signs of dyspnea, wheezing and coughing are classic symptoms of bronchospasm. In extreme forms of bronchospasm, no breath sounds can be auscultated,

Table 73-3 Common Nontraumatic Causes of Acute Shortness of Breath in Adults

Exacerbated chronic obstructive pulmonary disease
Asthma
Cardiogenic pulmonary edema (congestive heart failure)
Noncardiogenic pulmonary edema (inhalational, sepsis-related)
Pneumonia
Pulmonary embolism
Foreign body obstruction
Aspiration

resulting in a "silent chest." It has been a long-standing myth in EMS that patients with severe COPD should not receive high-flow oxygen to prevent respiratory arrest.[129] However, these patients often die as a result of hypoxemia and thus should be given the same oxygen therapy as any other patient in respiratory distress.

On-the-scene management for patients with asthma attacks or acute COPD exacerbations is very similar and follows the recommended guidelines.[134] Besides providing oxygen to prevent hypoxemia, the first line of treatment is inhaled β-agonists plus an anticholinergic agent such as albuterol or salbutamol plus ipratropium, either via nebulized aerosol or metered-dose inhaler. Often these patients will already have made extensive use of their inhalers before calling EMS, so in moderate to severe exacerbations the use of systemic corticosteroids, for example, an IV bolus of methylprednisolone, 60 to 125 mg, is clearly indicated. In life-threatening asthma and COPD exacerbations, IV β-agonists (epinephrine, 100-200 µg IV bolus—equals one tenth of the recommended resuscitation dose) are particularly helpful. In case of impending or actual respiratory arrest, endotracheal intubation is warranted, often after RSI with ketamine as the preferred induction agent owing to its favorable bronchodilating properties. The EMS crew must be vigilant for additional conditions that add to the severity of hypoxemia, such as pneumonia, pneumothorax, anaphylaxis, and pulmonary embolism.

Pulmonary Edema: Congestive Heart Failure

In addition to standard monitoring, a 12-lead ECG should be obtained to guide prehospital therapy for patients with acute pulmonary edema and rule out acute myocardial infarction. As a biomarker, brain natriuretic peptide (BNP) has become the mainstay in the clinical diagnosis of cardiogenic pulmonary edema, and some EMS systems now use point-of-care BNP testing on the scene to determine the cause of dyspnea.[132] Noninvasive positive-pressure ventilation (NIPPV) such as continuous positive airway pressure (CPAP) has become a standard therapy over the past several years in the treatment of acute pulmonary edema.[135] Recently published recommendations suggest NIPPV for every patient with acute pulmonary edema.[136,137] The subsequent therapy should be guided by the patient's systolic blood pressure (SBP):

- SBP greater than 140 mm Hg: NIPPV plus nitrates (nitroglycerin spray or continuous IV infusion; recommended starting dose: 5-20 µg/min)
- SBP 140 to 100 mm Hg: NIPPV plus nitrates plus diuretics (furosemide) if signs of systemic fluid retention
- SBP less than 100 mm Hg: hypoperfusion is predominant and signs of cardiogenic shock are present. These patients require inotropic agents such as dopamine and dobutamine and a carefully titrated volume challenge.
- Pulmonary edema with signs of acute coronary syndrome (ACS): these patients require ACS specific management in addition to NIPPV plus nitrates.[136]

The treatment goals are to stabilize the patient, improve oxygenation and perfusion, and reduce dyspnea.

Cardiac and Circulatory Emergencies

Chest pain and circulatory problems (e.g., syncope, hypertension) are encountered frequently in the prehospital setting (see Chapter 60). Much emphasis has been put on the role of EMS in the management of ST-segment myocardial infarction (STEMI), but other conditions such as pulmonary embolism, hypertensive emergencies, or dysrhythmias require a similar high quality of prehospital diagnostic and therapeutic skills. In this overview, we will focus on the most common emergencies resulting in chest pain—acute coronary syndrome (ACS) and pulmonary embolism—and also on hypertensive emergencies.

Patient Evaluation

The most important goal in evaluating a patient with acute chest pain or circulatory problems is to rule out a life-threatening condition such as ACS or pulmonary embolism. Because chest pain is a common complaint, identifying high-risk patients among all the patients with back spasm, esophageal acid reflux, or other gastrointestinal disorders is difficult. History and physical examination as well as a 12-lead ECG often guide the diagnosis. Prehospital 12-lead ECG can be quickly performed by the EMS crew and transmitted to physician oversight if required and prolongs on-scene time only 3 to 4 minutes while offering very high sensitivity and specificity for detecting myocardial ischemia and in particular for detecting patients with STEMI. Assessing the type and quality of chest pain (stabbing versus burning, radiation, severity, and provocation) is critical in determining the differential diagnosis (Table 73-4). However, some patients with ACS have atypical pain symptoms (epigastric discomfort, jaw pain) or no pain at all in case of silent myocardial ischemia in diabetic patients.

Prehospital Management

Acute Coronary Syndrome

Patients with acute coronary syndrome should immediately be put on continuous ECG monitoring in addition to blood pressure and oxygen saturation monitoring. Rapid access to a defibrillator is mandatory, especially for patients with STEMI. The most recent guidelines recommend starting supportive therapy on the scene consisting of morphine (pain control), high-flow oxygen, nitrates (if patient is not hypotensive), and oral aspirin, easily memorized as the well-known "MONA" acronym.[138,139] β-Blockers can be considered if the patient is tachycardic and/or hypertensive. The goal is to reduce myocardial oxygen demand while improving oxygen supply. The 12-lead ECG is a vital component of prehospital care for ACS because it is the only tool that can reliably identify patients who may benefit from prehospital reperfusion therapy (Fig. 73-4). The overarching goal is to limit myocardial ischemia time to less than 120 minutes (ideally <60 minutes). Early out-of-

ECG, electrocardiogram; EMS, emergency medical service; PCI, percutaneous coronary intervention; STEMI, ST-segment myocardial infarction. *(Modified from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the Management of patients with acute myocardial infarction]. J Am Coll Cardiol 44:e1-e211, 2004; and Armstrong PW, Collen D, Antman E: Fibrinolysis for acute myocardial infarction: The future is here and now. Circulation 107:2533-2537, 2003.)*

hospital fibrinolysis reduces mortality in patients with STEMI or new-onset left bundle branch block[140] and is the recommended standard for fibrinolysis-capable EMS systems.[138] Several fibrinolytic agents are available, and the choice is often based on the institution. Streptokinase was the first fibrinolytic agent but is now rarely used in prehospital care. Most EMS systems now use recombinant tissue plasminogen activator (rt-PA or t-PA) or modified forms of t-PA, such as reteplase or tenecteplase (TNKase). The latter offer convenient single- or double-bolus dosing, making them preferable fibrinolytic agents in the prehospital setting.[141] It is important to note, however, that fibrinolytic therapy has several contraindications (Table 73-5) and also carries the risk of intracranial hemorrhage, resulting in major disability or death in 1% to 2% of the patients. If fibrinolysis cannot be performed on the scene, rapid transport to a facility with percutaneous coronary intervention is warranted with the goal of EMS arrival-to-balloon time of less than 90 minutes.

Pulmonary Embolism

A definitive diagnosis of pulmonary embolism is difficult to establish on the scene because signs and symptoms are nonspecific and no rapid objective measure, such as the 12-lead ECG in STEMI, is available for on-site diagnosis. Often, the patient's medical history is telling; for example, an immobilized leg and signs of a preexisting deep venous thrombosis can be found, such as unilateral, tender swelling in one extremity. The severity of pulmonary embolism directly relates to the size of the clots and ranges from mild symptoms of dyspnea and coughing to acutely life-threatening states of cardiogenic shock due to acute right-sided heart failure. Classic symptoms of pulmonary embolism include distended neck veins, hypoxemia, tachycardia, tachypnea, and chest pain. More objective, but nevertheless unspecific find-

Table 73-5 Contraindications of Fibrinolytic Therapy in ST-Segment Elevation Myocardial Infarction

Absolute Contraindications
Any prior intracranial hemorrhage
Known structural cerebrovascular lesion (e.g., AVM)
Known malignant intracranial neoplasm (primary or metastatic)
Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed-head trauma or facial trauma within 3 months
Relative Contraindications
History of chronic, severe, poorly controlled hypertension
Severe uncontrolled hypertension on presentation (SBP > 180 mm Hg or DBP > 110 mm Hg)*
History of prior ischemic stroke < 3 months, dementia, or known intracranial pathologic process not covered in contraindications
Traumatic or prolonged (>10 minutes) CPR or major surgery (<3 weeks)
Recent (within 2 to 4 weeks) internal bleeding
Noncompressible vascular punctures
For streptokinase/anistreplase: prior exposure (<5 days ago) or prior allergic reaction to these agents
Pregnancy
Active peptic ulcer
Current use of anticoagulants: the higher the INR, the higher the risk of bleeding

AVM, arteriovenous malformation; SBP, systolic blood pressure; DBP, diastolic blood pressure; INR, international normalized ratio.
*Could be an absolute contraindication in low-risk patients with myocardial infarction.
Adapted from American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Part 8. Stabilization of the Patient with Acute Coronary Syndromes. Circulation 112(24 Suppl):IV-89-110, 2005.

ings are new right bundle branch block, symmetric T-wave inversion in the anterior leads (V_1-V_4), and S_IQ_{III} pattern in the 12-lead ECG.[142] Often the 12-lead ECG is more useful to rule out other conditions as myocardial infarction than ruling in pulmonary embolism.

In absence of an objective means to reliably diagnose pulmonary embolism in the prehospital setting, the management is largely supportive. Applying standard monitoring, administration of high-flow oxygen, establishing an IV line, and pain control with opioid analgesics are considered standard therapy. In severe pulmonary embolism that is usually accompanied with systemic hypotension (SBP < 90 mm Hg), in other words with signs of shock, circulatory support with inotropic agents is often required. The prehospital use of heparin in pulmonary embolism is not universally recommended and must be determined on a case-by-case basis, taking into account the likelihood of pulmonary embolism and the severity of symptoms. Prehospital fibrinolysis in a patient with pulmonary embolism is not recommended, although it has been successfully used in extremis.[143]

Hypertensive Emergencies

EMS often responds to patients with acute hypertensive episodes, but these are rarely true hypertensive emergencies. The classification of hypertensive episodes is very helpful in determining the urgency of a prehospital intervention (Table 73-6). Acute end-organ damage in conjunction with a hypertensive episode, such as hypertensive encephalopathy, stroke, pulmonary edema, myocardial infarction, aortic dissection, acute renal failure, and preeclampsia must be immediately treated and progression must be stopped. The goal is to lower the blood pressure by 20% to 25% within 30 to 60 minutes.[144] However, in the setting of cerebral infarction, great care must be exercised in reducing blood pressure as needed because the ischemic territory may be critically dependent on collateral perfusion pressure; this is an area of controversy in need of further study. Evidence for benefits of antihypertensive treatment is scant; some argue that only excessively high SBP or diastolic blood pressure (DBP) should be treated.[145] On the other hand, patients with an aortic dissection require swift and aggressive treatment with a target blood pressure of SBP less than 120 mm Hg and DBP less than 80 mm Hg.[146] The choice of antihypertensive should take into account the underlying pathophysiology. For example, patients with acute hypertension plus acute coronary syndrome and tachycardia might benefit from a β-blocker and nitroglycerin, whereas in intracranial hemorrhage labetalol is the preferred agent. The antihypertensive agent of choice in many European EMS systems, urapidil, an α-adrenoceptor antagonist, is currently not available in the United States.

Table 73-6 Classification of Acute Hypertensive Episodes

Hypertensive emergency	Also termed *hypertensive crisis;* hypertension with acute end-organ dysfunction
Hypertensive urgency	Hypertensive episode with high risk of imminent end-organ damage that has not yet occurred
Acute hypertensive episode	SBP > 180 mm Hg or DBP > 110 mm Hg without signs of evolving or imminent end-organ dysfunction
Transient hypertension	Related to anxiety or primary complaint

SBP, systolic blood pressure; DBP, diastolic blood pressure.

Altered Level of Consciousness

Altered level of consciousness is often encountered in prehospital care. The differential diagnoses are vast; therefore, most patients will receive only supportive care in the field. The overarching goal is to stabilize the patient's vital signs, quickly identify and treat potentially life-threatening conditions, and determine a likely cause.[147] For example, rapid detection of severe hypoglycemia in an unconscious patient can be assessed by point-of-care testing and reversed by administration of an IV glucose bolus. In this section, we focus on general principles but briefly mention a few specific conditions, such as stroke or seizure.

Patients with an altered level of consciousness should immediately receive high-flow oxygen and IV access, be undressed, and undergo standard monitoring. The addition of continuous capnography, when available, is helpful to assess adequate ventilation. Level of unconsciousness and determination of the GCS score should be performed (see Chapter 46). In the prehospital setting, it is often sufficient to distinguish if the patient is alert (responsive to verbal commands), only responsive to painful stimuli, or is completely unresponsive (unconscious).[148]

Because patients with impaired consciousness are at risk for aspiration, the need for airway protection needs to be assessed. Recommended diagnostic steps on the scene include determining the pupil size and reaction to light, measuring core body temperature, and obtaining point-of-care blood glucose levels. During the initial neurologic examination, EMS providers must determine if the main neurologic symptoms are global or if there is a focal neurologic deficit. Nasal or oral airways equipment may be inserted to keep the airway open and to test for a gag reflex. Once these basic steps have been accomplished, the EMS team should try to obtain as much information about the patient and the circumstances as possible to narrow the possible causes for the patient's unconsciousness (Table 73-7). Often, this can only be accomplished by involving bystanders and family members. Important aspects are onset and progression of unconsciousness (quick or over a few hours), fever, the patient's status before the onset of symptoms, headache, medical history and medications (e.g., hypertension, diabetes, depression), signs of intoxication (open drug containers, needles, drug paraphernalia), and signs of trauma.

For patients with *hypoglycemia,* the recommended treatment plan is to immediately administer dextrose ($D_{50}W$, 50 mL = 1 ampule). If an IV cannot be established, IM glucagon (1-2 mg) is a viable alternative. On average, blood glucose levels rise after this treatment between 100-150 mg/dL and patients are fully awake within a few minutes. In cases where *opioid overdose* is suspected (miosis, respiratory rate <10 breaths/min), the opioid antagonist naloxone should be administered. The recommended starting dose is 0.4 mg IV, but it should be titrated to clinical effect, which in this case is restoration of spontaneous ventilation and not complete awakening. A wide range of required dosages may be required, sometimes requiring as little as 0.2 mg and sometimes up to 10 mg.[148] If too much naloxone is administered,

severe opioid withdrawal symptoms can result. Similarly, if patients with benzodiazepine overdose ("sleeping pills") are treated aggressively with the antagonist flumazenil, generalized seizures can result that may be unresponsive to further benzodiazepine treatment. Patients with hypoglycemia or opioid intoxication comprise probably the only category of patients with an altered level of consciousness that can be successfully identified and treated in the field.

Only over the past decade, *stroke* patients have received similar attention in prehospital care as patients with acute myocardial infarction. It is now clear that a similar "window of opportunity" exists in stroke patients as in patients with acute myocardial infarction.[149] The goal is to quickly identify stroke in the field and rapidly transport the patient to a facility that can perform computed tomography (CT) to aid in diagnosis and rule out the presence of intracranial hemorrhage. Ischemic stroke without hemorrhage may be treated with thrombolysis. Classic symptoms of stroke are hemiparesis, aphasia, and altered level of consciousness. Formal prehospital screening tools such as the Cincinnati Prehospital Stroke Scale are useful and should be used.[150] Stroke is a leading cause of death in the United States and is the number one cause for disability in adults. Rapid identification and treatment of stroke limits brain damage and improves survival after stroke.[145,151] Because of the inability to clinically distinguish between ischemic stroke (85% of cases) and hemorrhagic stroke (15%), prehospital thrombolysis cannot be performed as in patients with STEMI. Thus, supportive care to stabilize the patient's vital signs and to avoid risk factors that negatively influence outcome, such as hypoxia, hypotension, and hyperglycemia are main treatment goals in stroke in the prehospital setting.[152] Therefore, stroke patients require supplemental oxygen, IV access, continuous ECG monitoring, as well blood pressure monitoring. Hyperglycemia should be corrected to normal levels. Blood pressure management in stroke patients is controversial; it is clear that any aggressive lowering of SBP worsens outcome and that a certain degree of hypertension in acute stroke might be beneficial. If other end organ dysfunction is apparent, such as myocardial ischemia, or SBP greater than 220 mm Hg, cautious antihypertensive treatment can be started on the scene. One of the most important aspects of prehospital care for stroke patients is the expeditious transport to a facility that specializes in stroke treatment, ideally a stroke center.[153]

Seizure is a common disorder seen in EMS practice. Often, the seizure is over when EMS arrives and the patient will be found in a post-seizure state that seldom requires intervention. If the seizure is ongoing, however, the seizure may be usually treated by the IV administration of benzodiazepine and prevention of secondary complications such as hypoxia. IV access is difficult to establish during a generalized seizure. High-flow oxygen should be administered via a non-rebreathing facemask. Status epilepticus is a state of ongoing, refractory general seizure activity and is a true life-threatening emergency; sometimes treatment requires induction of general anesthesia.[154]

Pediatric Emergencies

Pediatric emergencies are one of the biggest challenges for a prehospital provider (see Chapter 82). Between 5% and 8% of emergency calls to an EMS are pediatric emergencies.[155,156] In the first years of age, common pediatric emergencies are respiratory problems and febrile seizures. Trauma increases in incidence in higher age groups.[155] Some of the skills, such as securing the airway and vascular access, are more difficult to perform for EMS providers in children than in adults.

In this section, the main differences in etiology, diagnostic procedures, and treatment are stressed and the chief symptoms and their relevance in the pediatric population are discussed.

Dyspnea/Respiratory Distress

Respiratory failure is the leading cause for cardiac arrest in children. The anatomy of the airway and the smaller respiratory reserve due to a smaller residual capacity as well as a higher basal metabolism make children more vulnerable to hypoxic events. Infections or an obstructed airways by foreign bodies dominates the respiratory problems in younger children; in older children the airway problems are usually due to direct trauma or altered level of consciousness after head trauma or shock.

Patient Evaluation

Assessing the child may be more difficult if the child is frightened. An agitated child interferes with many diagnostic procedures, and the resultant stress level increases oxygen consumption, potentially leading to a decompensation of the situation.

After assessing the airway, the work of breathing is estimated. Physical signs and symptoms indicating respiratory distress are tachypnea and intercostal, sternal, and subcostal retractions. Children use accessory muscles to support breathing, which may manifest as head bobbing and nasal flaring. An early sign of distress is use of chest wall muscles. Paradoxical breathing movements of chest and abdomen (see-saw respiration) indicate decompensated respiration. Abnormal sounds from the airway pinpoint the level of airway obstruction. Inspiratory stridor indicates an extrathoracic airway problem. In contrast, expiratory noises are signs of lower tracheal problems, whereas wheezing leads to a problem at the bronchial level. Hypoxia can cause vasoconstriction, and cyanosis can be masked by skin pallor. Pulse oximetry should be mandatory in respiratory distress.

Prehospital Management

Pediatric respiratory support may include facemask with supplemental oxygen, assisted bag-mask-valve ventilation, or controlled ventilation with a secured airway. Because of the different anatomy dependent on the age of the child and the limited skills in most nonanesthesiologist prehospital providers, difficulties in airway management occur more often than in adults.

Infection: Asthma

Laryngotracheobronchitis (croup) is a typical emergency of the 6-month- to 3-year-old child. Because of the dramatic onset, usually during the night with sudden loud inspiratory stridor and sometimes respiratory distress, it frightens both child and parents. Except for a minor infection of the upper respiratory tract, the medical history is usually noncontributory.

On-the-scene management of mild croup (without retractions) consists of psychological support by the EMS team, humidified oxygen via facemask in a nonthreatening manner, and transport to a pediatric emergency department. More severe cases with retractions and/or neurologic signs such as apathy or agitation require oral dexamethasone (0.15-0.6 mg/kg) and, as a next step, nebulized epinephrine (0.5 mL of 2.25% racemic epinephrine or 5.0 mL of epinephrine 1 : 1000, irrespective of the weight of the child).[157] The need for prehospital intubation is rare.

Another pediatric infection of the upper airway is much more dangerous but fortunately very rare: epiglottitis. Epiglottitis usually occurs in patients age 2 to 7 years and is characterized by inspiratory stridor, hypersalivation, high fever, and inability to swallow. The voice sounds muffled. Any anxiety-provoking maneuvers such as examination or IV access should be avoided. The child should be attended at all times by someone capable of establishing an airway and brought to a facility where endoscopy can be done. Cricothyroidotomy may be necessary in very severe cases.[158]

Bronchospasm is a frequent symptom in pediatric respiratory infections. Therapy ranges from supportive therapy only in mild cases to inhalational β-adrenergic agonists and corticosteroids and intravenous drug therapy sometimes requiring anesthesia and intubation in status asthmaticus. Ketamine is the anesthetic drug of choice in exacerbated bronchospasm.

Foreign Body Airway Obstruction

Foreign body airway obstruction is characterized by the sudden onset of respiratory distress associated with coughing, gagging, or stridor in a child with no other signs of illness.

If the child is coughing effectively, then no immediate action to remove the foreign body by the EMS is necessary. The child is monitored and brought to the hospital and advised to try to expel the foreign body by coughing. If the coughing becomes ineffective, intervention is required. With a series of back blows (5) in turn with thrusts (abdominal in children >1 year and chest thrusts in infants <1 year of age) attempts are made to remove the foreign body. If the child becomes unconscious, standard BLS must be started[159] and the airway must be rapidly checked with direct laryngoscopy. If the foreign body cannot be removed, an effort can be made to advance the foreign body into the bronchus and ventilate the remaining lung.

Cardiac Emergencies and Shock

Life-threatening cardiac rhythm disturbances in children are more frequently the result, rather than the cause, of acute emergencies. Nevertheless some arrhythmias are seen, especially in children with congenital problems.

Patient Evaluation

After assessing consciousness, airway, and breathing, the circulatory status is determined. Heart rate, pulse quality, and capillary refill time are quick tools for evaluation. Blood pressure and preload assessment complete the picture. To determine if the child is already decompensated, additional information of the neurologic status (apathetic or agitated) is taken into account.

Prehospital Management

Arrhythmia

Bradyarrhythmia is usually the result of hypoxia or poisoning. If the heart rate is below 60 beats/min and the child shows signs of inadequate perfusion (unconsciousness, apnea), resuscitation is started and the underlying cause can then be identified and reversed.

Most tachyarrhythmias are supraventricular and need only be treated if decompensated. After exclusion of causes for a reflex tachyarrhythmia, specific therapy starts with vagal maneuvers, adenosine, and, if the child is severely decompensated, cardioversion.

During resuscitation, epinephrine (10 µg/kg), atropine (0.02 mg/kg), and amiodarone (5 mg/kg) are given according to international guidelines (see Chapter 97).[160]

Recurrent ventricular tachycardia/ventricular fibrillation in an otherwise healthy child or a torsades de pointes pattern on an ECG suggests a long-QT syndrome, which follows a different path in the universal algorithm of resuscitation. In a long-QT syndrome, amiodarone is contraindicated and magnesium is given as a bolus (3-12 mg/kg).[161]

Shock

Hypovolemic shock due to acute blood loss or acute diarrheal disease is the most common type, followed by septic, cardiogenic, and distributive shock.[162,163]

Obtaining quick vascular access in a decompensated situation is essential, but difficult. Venous access is the first choice; but if it cannot be rapidly established, intraosseous access is the next alternative. Intraosseous access provides a quick and reliable venous access, adequate for all IV medications. An initial fluid bolus of 20 mL/kg of fluid should be given. Crystalloids are preferred.[164] After reassessing the child, a second bolus can be given. If shock persists after the second reassessment, packed red blood cells should be administered, especially in trauma victims, which usually can only be done in the emergency department.[159] This requires rapid transport to the nearest hospital and minimizing on-scene times.

Altered Level of Consciousness

Altered level of consciousness is one of the first signs for a decompensation of a respiratory or circulatory failure. Besides that, disorders of the brain (infection, ischemia, trauma, intoxication, metabolic disorders like diabetic coma, hepatic or nephrologic problems and tumors) will alter the level of alertness.

Patient Evaluation

After evaluation of the respiratory and circulatory status, a quick neurologic assessment should be made. The GCS examination is adapted to the age-related abilities of the child.[165] Especially, the

motor quality of the GCS has a good predictive value for the outcome after traumatic brain injury.[166] In unconscious children, the repeated assessments of the pupils can give information about intracranial injury and/or elevated intracranial pressure. Blood glucose measurement is mandatory.

Prehospital Management

Infection

If signs of meningeal irritation are seen, bacterial meningitis accounts for roughly 30%, whereas viral or aseptic meningitis is the cause in approximately 13% of cases. Other diagnoses are pneumonia (8%), other serious bacterial infections (2%), upper respiratory tract infections or other self-limiting diseases (46%).[167] Independent predictors of the presence of bacterial meningitis obtained from a patient's history and physical examination are the duration of the main complaint, a history of vomiting, and meningeal irritation, cyanosis, petechial bleeding, and altered consciousness at physical examination.[168] Identifying this potentially life-threatening disease is an important challenge for the prehospital provider. Airway management and fluid resuscitation may be necessary before transferring the child to a pediatric emergency department. If the diagnosis of bacterial meningitis is confirmed, antibiotic prophylaxis of all persons having had direct contact with the patient is necessary.

Seizures

Febrile seizures are the most common seizure disorder in childhood, occurring in 2% to 5% of children, typically between the age of 6 months to 5 years.[169] Usually the seizure has already terminated when the EMS team arrives and the patient is postictal. An antipyretic therapy may prevent a recurrence of the seizure.

To rule out other underlying conditions for a seizure, such as hypoxia, intoxication, infectious reasons, metabolic disorders, trauma, or sunstroke, the child should be hospitalized after stabilization of the vital signs. If seizures recur or are still ongoing (status epilepticus) the initial assessment should follow the ABC principle. High-flow oxygen should be given and blood glucose should be tested. For those children in whom intravenous access can immediately be established, lorazepam, 0.1 mg/kg, should be given intravenously. If a rapid IV access is not possible, diazepam (0.5 mg/kg) is given rectally. If after 10 minutes the initial seizure has not stopped or another seizure has begun, a second dose of lorazepam (0.1 mg/kg) should be given.[170] The child has to be repeatedly reassessed to verify that an unrecognized underlying cause has not been missed. During transport, epileptogenic maneuvers should be avoided, such as overzealous papillary examination with a strong light.

Trauma

Trauma is a leading cause of death from the ages 1 to 18. Boys are more at risk than girls are.

Patient Evaluation

Although the pattern of injury differs from that of the adult patient (more pelvis, chest, abdominal, and head trauma) the evaluation and the treatment principles are in accordance with the adult management guidelines.

Prehospital Management

Carrying out a quick primary survey, treating the life-threatening conditions according to the ABCDE approach, and organizing the communication and quick transport to an adequate facility are the main issues of trauma treatment of children.

The Abused Child

Child abuse is common and a major challenge for prehospital providers (see Chapter 82).[171] Typical injuries include evidence of injuries of different ages, atypical burns, abrasions and hematomas reflecting the form of the beating hand or instrument, shaken baby syndrome, and injuries at unusual locations and on the top of the head. A delayed or inconclusive patient history should arouse suspicion. A management goal is to guarantee the well-being of the child. In suspected cases of child abuse, the appropriate authorities are informed, depending on the local system, and the patient is transferred to a hospital or another safe facility.

Prehospital Mass Casualty Incident Management and Disaster Medicine

Prehospital providers are often faced with situations such as multiple vehicle accidents where the number of simultaneous patients initially exceeds the capabilities of the rescue squad or local rescue forces. This creates an inadequate ratio of rescuers to victims. In these mass casualty situations (Table 73-8; see Chapter 74), the concept of *triage* must be employed: trying to save as many patients as possible without being able to provide individual one-on-one care. During the mass casualty event, the boundaries between an emergency, a major incident (mass casualty situation), and a disaster are constantly in a state of flux. The first and most important duty of the first prehospital team at the scene is to communicate the dimension of the accident/disaster and the ongoing hazards to the dispatcher. A mass casualty situation creates many problems for EMS providers. Frequent errors included having multiple communicators on site (38%), misidentifying the number of victims (56%), and having unclear information for the resource physician (43%).[172] It has been estimated that prehospital triage information was deemed appropriate in only one third of mass casualty events. After alerting local backup resources, patients must be triaged.

In man-made and natural disasters, prehospital providers and their EMS systems have to shift their triage methodology from a daily operational framework of treating the most severely injured patient first and providing the highest level of care for each patient to the concept of providing the greatest good for the greatest number of casualties. This shift is necessary to identify those critically injured patients who can benefit from immediate, lifesaving interventions and to conserve resources.[173] In disasters such as hurricane Katrina, coordination of the rescue and relief effort on a national level is required. National disaster resources such as DMAT (disaster medical assistance teams) from unaffected states will be deployed as will be military forces (National Guard).

Table 73-8 Definitions in Disaster Medicine

Term	Definition	Level of Prehospital Medical Care Possible	Examples
Emergency	Incident that demands urgent action; impact: minutes to hours	Individual medicine	Patient with bicycle accident, stroke, angina
Mass casualty	Large number of casualties in a short period that initially exceed local logistic support capabilities; impact: hours to days	Triage; increasing level of medical treatment dependent on resources	Airplane crash, train collision, mass poisoning
Disaster	Large number of casualties and destroyed infrastructure; exceeds local response capabilities. Supraregional (national) forces are needed to solve the problem; damage and interruption last long-term (weeks to years)	Triage; first aid; significant delay until professional medical help available usually only after temporary infrastructure was set up	Hurricane, earthquake, tsunami, nuclear disaster (e.g., Chernobyl)

Different triage strategies (Simple Triage and Rapid Treatment-START, CareFlight Triage, modified START) show comparable results in identifying the severely injured (Table 73-9). Triage implies constant reevaluation of victims because conditions of the victims and of available resources change continuously.[174] Patients whose injuries are so grave (i.e., traumatic cardiac arrests) that their prognosis is dismal should not be classified as critical in the setting of a large mass casuality incident (MCI). They are likely to consume large quantities of resources in a futile resuscitative effort.[175] The motor score of the GCS and systolic blood pressure show good association with severe injury.[175] The emergency physician on the scene has to guarantee that the treatment priorities are followed by the EMTs rather than treating patients by himself or herself.

In the first phase, only BLS, such as opening the airway, recovery position, tourniquets, and positioning, should be done. Advanced procedures such as IV access, oxygen therapy, anesthesia, intubation, and ventilation can be performed as soon as resources are available. With incoming transport capacity, patients are stabilized and transported according to urgency priorities. For example, patients with intra-abdominal bleeding requiring emergent surgery have the highest transport priority. For disposition of the patients to adequate hospitals, a quick registration and documentation stage is necessary.

Table 73-9 Triage Groups in Mass Casualty Incidents

With the aid of triage tags or colored flags the patients are sorted into four groups:		
Green/minor	Minor injuries with no immediate need of treatment; psychological support needed; patients can walk	Wounds, minor fractures
Yellow/delayed	Urgent treatment, no vital threat	Fractures, joint injuries, amputation, major blood loss, burns
Red/immediate	Immediate vital threat	Respiratory insufficiency, shock, brain trauma, burns with immediate vital threat, abdominal trauma
Black/expectant	Dead or moribund	Respiratory arrest, cardiac arrest, head injuries with dismal prognosis

Controversies in Prehospital Emergency and Trauma Care

The EMS literature is full of conflicting opinions and recommendations about what the ideal EMS system and the ideal level of prehospital care are. The plethora of differing opinions is likely due to the vast differences in how EMS systems are organized around the world and probably also to a lack of reliable evidence from high-quality research. In the United States, one of the most important documents ever written on the current problems in EMS, *The Future of Emergency Care: Emergency Medical Services at the Crossroads,* was published in 2007 by the Institute of Medicine of the National Academy of Sciences.[12] It is the third part of a comprehensive study on the state of emergency medicine in the United States that also includes in-hospital emergency medicine[176] and pediatric emergency care.[177] It is likely that this report will have a similar effect on EMS as did *The White Paper* published in 1966.[11] Here, we focus on those areas in prehospital care engendering the fiercest debate and where anesthesiologists could, in our opinion, make the biggest impact.

The Optimal Level of Prehospital Care: BLS Versus ALS or "Scoop-and-Run" Versus "Stay-and-Play"

Numerous articles have been published over the past decades favoring either a minimalistic approach to prehospital care, basically BLS level only, or the opposite, an aggressive strategy trying to bring the level of care in an emergency department to the scene. In our opinion this discussion is misguided. It is unlikely that a country that currently employs a paramedic-level EMS system will abandon this system in favor of a BLS-only system or vice versa (see Chapter 97). More importantly, this discussion leads away from the most important determinant of the overall efficacy and efficiency of any EMS system: the outcome of the

patient. Whereas it makes perfect sense to argue in favor of a minimalistic prehospital approach in young patients in severe hemorrhagic shock after penetrating torso trauma in an urban area with transport times of only a few minutes,[119,125] the same approach might be detrimental in rural areas with long transport times, an older patient population with significant comorbidities, and a predominantly blunt trauma mechanism.[178-180] Therefore, in our view, it is overly simplistic to strongly argue for one or the other system. The condition of the patient, the environment, and the setting should determine the adequate EMS response and level of treatment. However, a well-trained physician or paramedic can easily "downgrade" his or her level of response on the scene and rush the patient to the hospital, whereas a basic level EMT cannot "upgrade" his or her response if required by the nature of the emergency.

A similar discussion is going on between advocates of paramedic-based EMS models and physician-based models.[14,94] Again, this is more a theoretical discussion about advantages and disadvantages of the two different systems rather than a realistic option for change. The discussion shows, however, the impact well-trained physicians and, in particular, anesthesiologists, can have on patient outcomes when directly involved in prehospital care.[8,19,181] Airway management immediately comes to mind.

Prehospital Endotracheal Intubation and Rapid-Sequence Induction

This area might be the one where the clearest difference between an anesthesiologist-run and a paramedic EMS system materializes. Success rates for out-of-hospital endotracheal intubation performed by paramedics are unacceptably low compared with standards in the operating room and are associated with a high complication rate.[182,183] More than 15 studies have shown that prehospital endotracheal intubation and RSI by paramedics are associated with an increased mortality rate or poorer neurologic outcomes compared with patients who were not intubated.[66,67] Most of the studies focused on prehospital airway management in patients with severe traumatic brain injury,[111,184,185] but also studies investigating prehospital pediatric intubation delivered sobering results.[186-188] These results should serve as a wake-up call among anesthesiologists, especially in the United States, but so far they have failed to do so. The central question is: why are endotracheal intubation and RSI, procedures that many consider the standard of care and lifesaving, associated with worse outcomes when performed in the out-of-hospital setting? The reasons are manifold, but over the past several years research has shown that not only is airway management in the field much more challenging and difficult than in the hospital[70] but also that paramedics and many nonanesthesiologist physicians are inexperienced in airway management and fail to maintain their airway skills learned during training because the actual numbers of intubations performed per year are very small.[61,65,67,189,190] Less experience equals more intubation attempts, a more frequent complication rate, including severe hypoxemia and bradycardia during field RSI and airway management, and a higher rate of failed intubations.[67,68,84,111,191] Unbeknown to many anesthesiologists, paramedics require only five successful endotracheal intubations in a clinical setting to graduate and not a single pediatric intubation, numbers that are significantly lower than any medical specialty training such as anesthesiology or emergency medicine.[66,67] Even in the landmark paper on out-of-hospital pediatric intubation by Gausche and colleagues,[188] paramedics who were previously not trained in advanced pediatric airway management received only 6 hours of classroom training including manikin intubations but not a single live intubation in a pediatric patient! Taken together, it appears that there is currently a great unmet need for our specialty to reach out to nonanesthesiologist airway providers and help define the ideal strategy for prehospital airway management focusing on the infrequent, occasional "airway manager." It may be the case that endotracheal intubation and RSI as a standard of care need to be reassessed with a clearer vision of to whom this standard applies. Perhaps, alternate airways are safer and more efficient for EMS personnel who lack the necessary training or who cannot maintain their skills.

74 Chemical and Biological Warfare Agents: The Role of the Anesthesiologist

Key Points

1. The management of injury from chemical and biological warfare (CBW) is a continuing process from the site of release of noxious agents to the hospital. The anesthesiologist may be involved at all stages in the provision of essential early life support through intensive care unit care.
2. CBW management requires advanced life support and other specialized skills that are part of the anesthesiologist's sphere of operation.
3. CBW injury should not be approached in isolation from the many clinical lessons that already exist from accidental hazardous materials (HAZMAT) releases and natural epidemic infections. CBW release poses a risk to the medical responder, and he or she should be trained and equipped to operate safely in a contaminated or infected zone.
4. Chemical and biological hazards form part of a continuous hazard spectrum. Agents from different parts of the spectrum may have common effects on susceptible somatic systems. Because detection of a released agent may not be immediate, response should be based on presenting signs and symptoms and may require the provision of life support.
5. Each hazard in the spectrum has four key properties: toxicity, latency, persistency, and transmissibility. The first two determine the management of the patient, and the second two determine the management of the incident.
6. A wide range of potential hazards (often loosely described as threats) have been suggested in a climate of apprehension because of the possibility of terrorist attack. On the basis of preexisting military and intelligence information, these potential hazards can be refined down to provide a framework of genuine hazards and management protocols that can be applied across the hazard spectrum.
7. CBW agents should not be regarded medically as weapons of mass destruction (WMD); rather, they are agents that may cause mass injury. Early life support and specific therapy can break the link between mass injury and mass loss of life.
8. Most of the toxic hazards likely in civil life are part of the United Nations HAZMAT classification. Planning for accidental industrial releases is relevant to the management of deliberated CBW release.
9. Toxic agents have been used in military and civil releases over the past 30 years and currently should be regarded as a potential terrorist threat.
10. Management of exposed patients depends on the protection of medical responders, early provision of life support, and specific antidote and antimicrobial therapy. Decontamination of patients may cause delays in starting treatment and is not always necessary. Essential life support (TOXALS) should be given during decontamination if required. Mass ventilation capability in the hospital is important in the management of accidental and deliberate respiratory failure from chemical and biological causes.
11. Military chemical warfare agents, such as nerve agents, vesicants, pulmonary edemagens, cyanides, and certain toxins, pose the greatest hazard in civil releases. Many industrial chemicals are equally hazardous.
12. Classic biological warfare agents, such as anthrax and plague, are used in deliberately induced epidemics with far longer latencies than chemical warfare attacks. Anesthetic involvement is usually at the intensive care stage.
13. Lessons learned from the current fears of deliberate toxic release will have value for the management of the increasing number of accidental individual and mass toxic exposures that form the greater risk for human life in the 21st century.

*The views expressed in this chapter are those of the author and do not necessarily represent those of SAMU de Paris or the United Kingdom Health Protection Agency.

Until more recently, the effects of exposure to chemical and biological warfare (CBW) agents were a remote area of clinical practice, which concerned military specialists, microbiologists, and toxicologists. Since the World Trade Center attack in New York City in September 2001, there has been increased concern about the possible impact of CBW agents released by terrorists on a civilian population. The attacks in London in July 2005 involved the use of high explosive devices in a confined space. There were toxic effects, and the use of a chemical device by the terrorists was considered by the emergency responders. Anesthesiologists from the helicopter emergency service were among the first to treat the injured on site.[1] With the continuing real threat of the use of CBW agents by terrorists, anesthesiologists have become more involved in the prehospital and hospital management of CBW injuries. As a result, CBW casualty management, previously dominated by considerations only of toxicity and pathogenicity, now includes considerations of modification of outcome by provision of early and continuing life support.

This chapter discusses the anesthetic aspects of management of casualties involving injury or infection after a deliberate exposure to CBW agents. There are important lessons for management of CBW incidents from plans for accidental toxic releases. In some countries, anesthesiologists are part of the initial emergency medical response and are trained in the essentials of personal protection and decontamination.[2] They also may be involved in the initial reception of contaminated casualties at the hospital itself, particularly when autoreferral occurs.[3] Casualties with toxic injuries also may have conventional injuries requiring surgery, and this brings a whole new dimension to the management of operative anesthesia, modified by the effects of a toxic agent. Finally, many of the victims of a CBW attack require immediate and long-term ventilation and other intensive care, which is an area where anesthesiologists and intensivists are actively involved.

In this chapter, the nature and management of chemical and biological hazards are approached first by considering their definition and classification, and second by discussion of the properties of key representative agents in terms of pathophysiologic effects. There is a wide range of potential CBW hazards that have been the subject of exhaustive literature, and it is not the intention here to repeat specialized information. Instead, key features of representatives of various classes of hazard are discussed from the standpoint of anesthetic and intensive care practice. Finally, the practical aspects of the involvement of the anesthesiologist and intensivist in management of CBW agent release are considered. This discussion covers the management of the patients and safe operation during the incident, including detection of release, protection of responding personnel, and decontamination.

Nature of Chemical and Biological Warfare Hazards

Approaches to the Literature

Many different scientific and clinical specialties have been involved in the study of CBW for more than a century. The literature is very extensive and covers a wide clinical range. Of the specialties involved, toxicology, microbiology, and occupational health have been the most dominant and have left their particular influences. Much of the literature relevant to CBW agents predates the Medline era and is not readily accessible from this source. Many reviews and books exist, however, particularly in the exhaustively studied area of cholinergic transmission, which make the careful and relevant work of early researchers still accessible to modern anesthesiologists.[4-10] The reader is advised to consult these resources to gain a working background on the nature of CBW agents.

Evidence-Based Studies

The study of CBW agents in humans has been less extensive than human studies in other areas of clinical medicine. This is understandable because prospective studies that involve exposure of human subjects either willingly or otherwise have been strictly controlled or proscribed by international convention. There is a large amount of information in the literature, however, from early clinical volunteer studies and from accidental exposures to chemical warfare agents, and many unpublished or inaccessible reports are now openly available.[8] In the biological warfare field, there also are more recent reviews[11-13] and valuable continuing clinical study in the parallel field of accidental (rather than deliberate) infection together with literature on the development of antimicrobial and antiviral agents, which is of immediate relevance to biological warfare release.

Secrecy

Although considerable information about the pathophysiology and management of CBW cases exists in the open literature, it is highly likely that far more information is still classified by governments involved in the subject and is not easily accessible.[8] Nevertheless, much historical information is available from time-declassified government sources[14] and from searching the sources provided by the Freedom of Information Act in the United States. Other nongovernmental organizations, such as Stockholm International Peace Research Institute (SIPRI), also have published extensive information, although this information may have a certain political bias.[15] The most research on CBW agents was carried out by the Soviet Union (USSR) during the Cold War, and large amounts of this remain unpublished. Soviet scientists involved in programs such as Mikrobioprom[16] and the application of genetic engineering to CBW did publish many articles on techniques openly, however, and these can be readily accessed through the databases because the major part of the Soviet program started after the signing of the 1972 biological warfare treaty,[17] which led to the discontinuation of biological warfare research by the West.

Definitions

Classic Definitions of Chemical and Biological Agents

The accepted classic definition of a chemical warfare agent is a chemical substance that is intended for use in military operations to kill, seriously injure, or otherwise incapacitate humans through pathophysiologic effects.[18] Traditionally, riot control agents and herbicides were excluded from this definition, although they frequently have been used in a way that would be compatible with the definition of a chemical warfare agent. Biological agents were defined by the 1972 biological warfare treaty as living organisms,

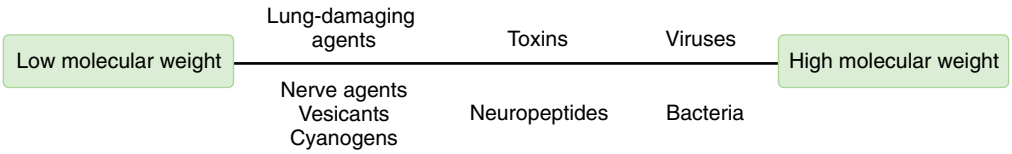

Figure 74-1 The chemical-biological hazard spectrum. Agents originally classified as chemical or biological are arranged in order of ascending molecular weight. Toxins, originally classed as biological agents, occupy the middle of the spectrum, together with neuropeptides, which normally act as transmitters in the central nervous system. These agents, sometimes called agents of biological origin, can be synthesized using genetic engineering techniques. (Adapted from Baker DJ: Anesthesia in extreme environmental conditions,. Part 2: Chemical and biological warfare. *In* Grande CG [ed]: Textbook of Trauma Anesthesia and Critical Care. St Louis, Mosby-Year Book, 1993, p 1331.)

whatever their nature, or infective material derived from them, which are intended to cause disease or death in humans, animals, or plants.[17] Toxins, which are an essential part of the pathophysiologic process in bacterial infection, were excluded from the biological warfare treaty and are regarded essentially as chemical agents.

Chemical-Biological Hazard Spectrum

Although chemical and biological agents traditionally have been separated, it is appropriate medically to regard them as part of a continuous spectrum of hazards[19]; this is shown diagrammatically in Figure 74-1. Agents in Figure 74-1 are arranged in ascending order of molecular weight from chemical toxic agents on the left to self-replicating agents such as bacteria and viruses on the right. The spectral approach to hazards is useful in emphasizing that agents from different parts of the line act in a similar way on the body. The failure of the neuromuscular junction caused by nerve agent anticholinesterases and botulinum toxin is a good example. Bacteria exert their toxic effects through toxins that may affect various somatic systems. The spectral approach serves as a reminder that medical management of CBW injury should respond primarily to system dysfunction, rather than to specific etiologic factors.

Essential Properties of Chemical and Biological Warfare Agents

There are four essential properties of hazards within the CBW spectrum: toxicity, latency, persistency, and transmissibility.[10] These four characteristics are common to chemical and biological agents, and determine the degree of risk and the appropriate response. Toxic effects of CBW agents seem to have a specific latent period. Generally, chemical agents and toxins have short periods of latency before the appearance of specific signs and symptoms. In contrast, classic biological warfare agents have extended latency periods (usually familiar as incubation periods) before the effects of the induced disease begin to appear.

Persistency relates to the ability of a toxic agent to remain in the environment into which it has been released and is a function of the physicochemical properties of the agent. For chemical agents, the persistency may vary, but for most biological warfare agents, with the exception of spore-forming agents such as anthrax, persistency is usually very short. Finally, transmission of a hazard may occur as a result of the physical contamination of the victim owing to a persistent chemical agent or as a result of infection in the case of an airborne agent. Chemical transmission can be contained by decontamination, but biological warfare agent transmissibility is more difficult to control because of continuing activity. Toxicity and latency determine the management of the casualty, whereas persistency and transmissibility determine the management of an incident involving the release of a CBW agent.

Toxicity and Its Modifications

Toxicity is usually expressed in terms of median lethal dose (LD_{50}) or LCt_{50}, where C is the concentration of agent inhaled for the time (t) required to produce lethality in 50% of the exposed population. LD_{50} usually relates to toxicity via injected routes. In the case of most chemical agents, the inhaled route is usual, so expressions of concentration and time are used.

Haber defined a *lethality coefficient* as follows:

$$W = C \cdot t$$

where C is the inhaled concentration of toxic agent, and t is the time of exposure. In practice, the absorbed amount of agent depends on the respiratory minute volume of the exposed individual. This is just one factor modifying the expression of toxicity. Others include life support responses in the case of respiratory failure and the effects of antidotes. The reader is referred to specialized texts for a more detailed discussion.[8]

NBC Classification

Since the end of World War II, nuclear, biological, and chemical weapons have by convention been classified together as "NBC" agents, which gave rise to a new subsection of warfare that was developed by both sides during the Cold War. Although all three components are "toxic," necessitating the development of detection, protection, and decontamination, the classification ignored the very intense level of physical damage caused by nuclear explosions. In more recent years, the term *weapons of mass destruction* (WMD) has been applied to NBC agents, although the term was originally used by the United Kingdom at the end of World War II.[14] The term *NBC* has been altered more recently to reflect the threat perception from the use of explosive devices that can spread radioisotopes (rather than create them as in a fission process) into chemical, biological, radiologic, and nuclear hazards. CBW agents are defined by their effects after mass release on large populations. The term *chemical and biological warfare* is not usually applied to the use of such agents for individual or small group poisonings, although agents have been used in assassinations in this way.

Myth and Reality of Chemical and Biological Warfare Agents as Weapons of Mass Destruction

At the end of World War II, the Tizard report[14] appeared, which looked at the future potential of nuclear and biological weapons, both of which had been used during the war. The term *weapons of mass destruction* apparently was used for the first time in this report because it seemed that both agents would cause mass loss of life. Chemical weapons were added to this group during the 1950s when the equilibrium of international power depended on analysis of the possession of the three WMD agents. In retrospect, the WMD classification is (at least medically) inappropriate. Consideration of the events of World War II showed that nuclear weapons should be classified with conventional weapons systems that cause mass loss of life and destruction to material and the environment, such as the conventional high explosive and fire bombing of Germany in the latter part of the war.

Civil Toxic Hazards (Hazardous Materials)

Parallel to the definitions of CBW agents, there is a classification of hazardous materials (HAZMAT) used in everyday industrial life. HAZMAT are usually released by accident. Many are as toxic as chemical warfare agents. Such toxic substances classified as HAZMAT are covered by the United Nations convention controlling the use and transportation of such materials.[20,21] HAZMAT are defined as materials that cause mass injury and death if released from a confined state. The civil equivalent of biological warfare agent release is natural infection expressed as an epidemic. Another term for HAZMAT is *toxic industrial chemicals*. These are substances that could be used as improvised chemical agents in a terrorist attack.

Background and Development of Agents of Chemical and Biological Warfare

World War I

Chemical agents were used from 1915 to 1918 in World War I. Their use was catalyzed by the battlefield stalemate of trench warfare; chemical warfare agents have usually been used in such conditions because they do not fit well with the tactics of a mobile war. Large-scale releases of chlorine and phosgene in 1915 had considerable effects against unprotected troops and caused large numbers of casualties, including deaths. These early attacks probably gave rise to the notion of CBW agents being weapons of mass destruction. (In fact, chemical agents had the lowest ratio of dead to wounded of all the arms used during the war at <4%,[14] whereas explosive shells had the highest at >15%. Artillery caused 59% of the overall mortality on all sides.)

Many different chemical agents were tried during World War I, delivered usually by shell fills, but there was difficulty in building high enough concentrations of agent to be lethal, and the continuing countermeasures meant that better-trained troops with masks were less affected. Although phosgene could be regarded as the most lethal of the agents used, causing untreatable toxic pulmonary edema, mustard agent, a vesicant disabling agent, probably caused the most injury and removed many soldiers from the field of battle (usually temporarily). One feature of the casualties from World War I that is overlooked is the possibility of mixed toxic and physical trauma. The exact figures are unavailable, but of 546 American soldiers who died after exposure to chemical warfare agents during the period March to November 1918, 6% also had ballistic injuries.[22] The figures for dead and wounded do not reveal the true extent of the disability caused by exposure to toxic agents, and it is likely that the long-term pathology was high, particularly given the limited postwar medical facilities at that time.

Development and Use of Chemical and Biological Warfare Agents during World War II

Organophosphate (OP) pesticide research by Schrader in 1936 led to the development of anticholinesterase "nerve agents" by Germany under conditions of the strictest secrecy during World War II. Although never used in action during that time, these agents became the major toxic hazard during the Cold War and beyond.[14] A major nerve agent plant was captured by the Russians and rebuilt in the USSR in 1945, giving the USSR a "mass-destructive" capability long before it possessed nuclear weapons. A lesson for military and civil anesthesiologists is that mixed casualties can be expected after the use of toxic agents, given it has been known for some time that Soviet commanders saw the use of chemical weapons as part of a normal armamentarium, rather than being exceptional weapons.[23]

There is some evidence of the use of biological warfare agents in China by the Japanese, who had a secret unit devoted to the subject since the early 1930s.[14] Plague and clostridia were used in tests on prisoners and against civilian populations. The considerable knowledge gathered was passed on to the United States by the head of the section after his capture and formed the basis of an offensive biological warfare development program, which was terminated in 1972 with the signing of the biological warfare treaty.

Cold War Development

It is now known that a major Soviet biological warfare program began in the early 1970s that used genetic engineering and other techniques to develop a whole new range of possible agents, including toxins and "agents of biological origin,"[15] which are probably deployed at the present time. There also was continued development of nerve and other agents during the Cold War and extensive research into an antidote-based approach to the management of the wounded. With the end of the Cold War, much of the expertise in USSR laboratories may have moved to other countries, increasing the risk that developed CBW agents and delivery technology may be more easily available to terrorist groups.

Iran-Iraq War

The Iran-Iraq War during the 1980s saw not only the sustained use of chemical agents, but also the first application of modern medical techniques to chemical warfare injuries. Extensive investigations by the United Nations established that sulfur mustard and lewisite, vesicant agents, had been used together with the nerve agent tabun and a toxin agent, mycotoxin.[24,25] Casualties were almost exclusively on the Iranian side and numbered about 27,000, with a mortality rate less than 1%. This continued the trend noted during World War I of the low mortality rate for chemical warfare compared with other weapons, and almost certainly reflects the impact of organized medical care for the casualties and techniques of protection. In comparison, the Iraqi attack against an unprotected Kurdish village at Hallabjah in 1989 produced 5000 dead.

Terrorist Chemical and Biological Warfare Releases during the Last Part of the 20th Century

In 1995, the first recorded terrorist use of a chemical warfare agent against a civilian population occurred with the use of the nerve agent sarin in attacks in Matsumoto and Tokyo, Japan, and for the first time hospital medical teams were brought into direct contact with a chemical warfare incident during the initial and continuing management of the casualties.[2,26] Because of lack of experience, there were numerous casualties among the attending emergency staff, but the number of fatalities was low. The incident brought home many lessons for medical responders, including anesthesiologists. The first was that the use of a hitherto military chemical warfare agent was possible by a terrorist group. Second, the incident management underlined all the lessons taught by the HAZMAT system, in that secondary casualties occurred among the attending staff because of lack of control, protection, and decontamination. Third, fatalities that occurred at the release site were essentially due to lack of on-site resuscitation. Fourth, the well-documented clinical management of the many thousands of victims who were admitted to the hospital provided for the first time a significant clinical database for a population exposed to a nerve agent.[27]

Hazards and Threats

There is often confusion regarding the concept of a hazard versus a threat. CBW agents are, by definition, hazardous and are strictly controlled by the provisions of the HAZMAT system. The term *threat* is usually used in the military context if a hazard has been weaponized, and the assailant has the capability and the intention to use the weapon. The relationship may be expressed by the following simple equation:

$$\text{Threat} = \text{hazard} + \text{capability} + \text{intention}$$

For a balanced medical response to a CBW attack, the reality is that many of the CBW hazards causing public concern are difficult to weaponize and deliver. Such understanding is important for the medical responder because it reduces the likelihood of encountering casualties from a CBW attack to a restricted number of agents, the properties and pathophysiology of which can be considered before casualties present.

Modes of Release of Chemical and Biological Warfare Agents

Chemical Agent Release

Military Release. In warfare, the release of CBW agents is a deliberate action achieved through the use of shells or missiles or through spraying. Agents that are active through the respiratory route are dispersed as an aerosol, but more persistent agents, designed to contaminate terrain, are usually spread by spray. These agents are active through the skin.

By the end of World War I, delivery of chemical warfare agents was almost exclusively through explosive shells, and by the end of the war, 40% of the fills were chemical, indicating the effectiveness of chemical warfare agents on the battlefield.[14] The advent of aerial bombardment before World War II brought great fears that cities would be wiped out by gas attacks, but these fears were never substantiated, and it is now understood that dissemination of chemical warfare agents over a wide area (rather than a limited tactical area) by explosion is not easy. During the Cold War, the Soviets developed considerable expertise in the use of BM21/24 multiple rocket launchers (Stalin Organs), which could deliver rapidly a high concentration of nonpersistent agents, such as hydrogen cyanide (HCN). Missiles such as the Scud also were developed for chemical warfare release at this time, and it was feared that they had been developed for chemical warfare use by Iraq before the Gulf War of 1991.

In the military context, release of toxic agents may be revealed or concealed. Attack, by whatever means, is usually predicted and detectable with the considerable resources that the military can bring to bear in this area for chemical and biological agents. Tuned detection systems are employed wherever there is perceived to be a threat, and the threat itself is usually supported by intelligence information about the hazards concerned, which means that the systems can be tuned. Broad detection systems such as mass spectrography also are employed by CBW reconnaissance units in the field.

Release on a Civilian Population. In civil life, toxic agent release is usually accidental and is usually revealed by the circumstances. Road and other transportation accidents, particularly when vehicles carrying HAZMAT plates are involved, give an immediate warning about the nature of the problem.[20] Accidental releases, particularly in nations with poor emergency response resources, still can be catastrophic, as in the case of the mass release of methyl isocyanate in the Indian city of Bhopal in 1984, which caused more than 5000 deaths and 50,000 casualties.[28] Civil populations, in contrast with military populations, are usually untrained and unprotected against release of toxic agents. In addition, the panic induced by the fear of the actions of CBW agents compounds the flexibility of the emergency medical response.

Biological Warfare Agent Release

The deliberate release of classic biological warfare agents such as bacteria or viruses may not be as easy as the media have led the public to believe. Effective mass release implies aerosol release, and very few biological warfare agents are capable of withstanding the environmental stresses involved. Some, such as anthrax spores, have long been recognized as being sufficiently robust and have attracted the most research attention. The only other bacterial diseases that have probably been used as biological warfare agents are tularemia, spread through infected fodder, and plague, which was said to have been used by the Japanese during the World War II campaign against China, and where the vector used was the traditional one of the rat-borne flea.[14]

Considerable research work was carried out by the USSR during the Cold War to try to find new ways of delivering biological agents and for their modification using genetic engineering.[16] This work also developed agents of biological origin that lie in the middle of the CBW spectrum, and that produce subtle pathophysiologic effects and are difficult to detect postmortem in the body. In military terms, biological warfare has always been seen as a debilitating weapon, self-propagating and of long latency, which could be used to degrade the capability of static enemy formations or key formations operating behind front lines, such as air fields. In the civil context, biological warfare agents have yet to be used in a terrorist attack, but there is evidence of continued interest.[29]

Role of the Anesthesiologist in the Clinical Management of Hazards and Threats from Chemical and Biological Warfare Agents

Extensive reviews[6-11,13,17] are available giving details of agents that are regarded as being CBW hazards. This section concentrates on selected hazards that can be regarded as being potential threats and that are likely to be encountered by the responding anesthesiologist.

In the management of CBW casualties, the anesthesiologist acts as part of a clinical team. To provide a safe and effective response, the following information is required for each toxic hazard:

1. Physical, pharmacologic, and immunologic methods of individual protection
2. Immediate measures for life support
3. Specific antidote therapy
4. Latent effects

In this section, specific agents have been selected that are representative of classes of hazards and have in some cases been used as weapons of warfare. They are hazards that either can be synthesized easily or are potentially available from stockpiles or from reference laboratories.

Nerve Agents

Nerve agents are OPs, a very large group of chemical compounds known since the 19th century, but first examined in detail in the 1930s.[7,8] More than 50,000 OP compounds have been synthesized, and several are in regular use as insecticides around the world, including parathion, malathion, and fenthion.[30] Although OPs were originally developed as insecticides, certain highly toxic members of the class, known as nerve agents, were developed before World War II specifically for military use. As a result of development by Germany and later by Russia, the United States, and Great Britain, at least five nerve agents have been produced. The formulas of the more common nerve agents are shown in Figure 74-2. Tabun (GA) was the first nerve agent to be produced, followed during World War II by sarin (GB) and soman (GD). VX, VR, and cyclosarin (GF) were developed during the Cold War. Cyclosarin (in which the isopropyl group in sarin is replaced by a cyclopropyl group) was found stockpiled in Iraq during the First Gulf War in 1992. Currently, the most important nerve agent hazard likely to face an anesthesiologist is sarin (isopropyl methyl phosphonofluoridate), which has been widely produced and stockpiled, and synthesized and used by terrorists.[3,27]

In terms of physical properties, GA, VX, and VR are persistent, whereas GB, GD, and GF are not. GD may be made in a thickened form, however, which is persistent. The relevance of the physicochemical data to the clinical situation is that the nonpersistent agents generally pose a respiratory risk, whereas the persistent agents are a danger because of absorption through the skin. Different agents pose specific risks to victims and to medical attendants.

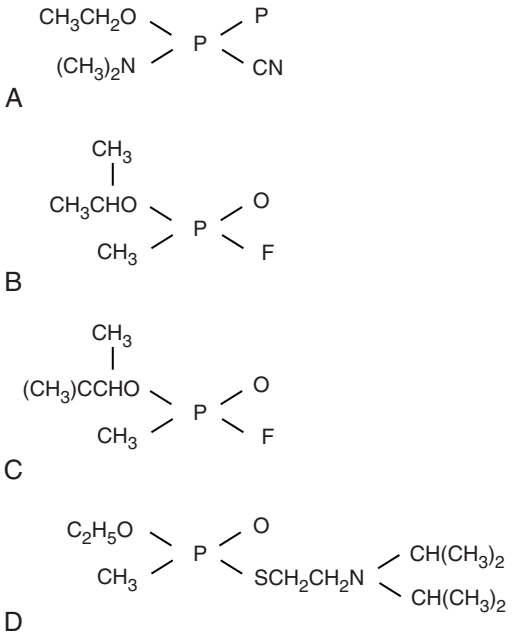

Figure 74-2 A-D, Chemical formulas of organophosphate nerve agents: tabun (GA) (**A**), sarin (GB) (**B**), soman (GD) (**C**), and VX (**D**). (From Baker DJ: Anesthesia in extreme environmental conditions, Part 2: Chemical and biologic warfare. *In* Grande CG [ed]: Textbook of Trauma Anesthesia and Critical Care. St Louis, Mosby-Year Book, 1993, p 1331.)

Nerve agents were originally termed *nerve gases,* but are liquids with volatilities varying between that of petrol and heavy lubricating oil. None of the agents freeze until −40°C. They are pale yellow to colorless in appearance, are odorless, and are soluble in water where they undergo slow hydrolysis. In the presence of strong alkalis and hypochlorite solution, the hydrolysis is rapid, and this is the basis of the field decontamination of the G agents. Decontamination of V agents with hypochlorite can itself produce toxic products and is not recommended. Nerve agents can penetrate clothing, skin, and leather. Rubber and synthetic materials, such as polyethylene and butyl rubber, are more resistant. The physical properties of the nerve agents are shown in Table 74-1.

Actions of Nerve Agents

The main effect of nerve agents is inhibition of acetylcholinesterase (AChE) and butaryl cholinesterase in the cholinergic nervous system. Both of these enzyme systems are familiar to anesthesiologists, who inhibit them on a daily basis using the carbamate anticholinesterase neostigmine to reverse the action of nondepolarizing neuromuscular blocking agents. OPs also inhibit other enzymes, notably neurotoxic esterase. This inhibition causes long-term neurologic effects unrelated to cholinergic changes. The interaction of OPs with AChE is complex and is analogous to the interaction of the enzyme with the natural substrate acetylcholine (Fig. 74-3).[4] Inhibition of AChE causes a buildup of acetylcholine at muscarinic and nicotinic synapses of the cholinergic nervous system. Central and peripheral signs and symptoms can be directly explained from the classic pharmacologic knowledge of how the cholinergic system operates.

Although the classic effects of OPs are cholinergic in nature, there are important effects on other receptor systems, notably γ-aminobutyric acid and *N*-methyl-D-aspartate, which gives rise to central excitation causing the initial convulsions seen in acute OP

Table 74-1 Physicochemical Properties of Nerve Agents

Properties*		**Tabun (GA)**		**Sarin (GB)**		**Soman (GD)**		**VX**

poisoning. The interaction of OPs with AChE is nonreversible after a certain time depending on the nerve agent. The formation of an irreversible complex is known as aging. Each nerve agent has an aging half-life. For GB, this is about 5 hours, whereas for GD, it is only 2 minutes. GA and VX have aging half-lives of 40 hours. After 5 half-lives, more than 95% of the enzyme AChE has aged and cannot be reactivated. This has important consequences on the window of clinical opportunity[31] for treatment to try to reverse the AChE inhibition (see section on oximes later).

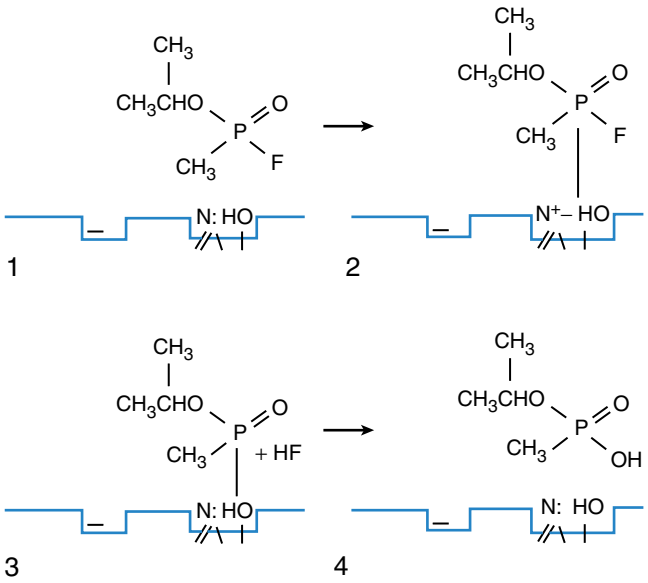

Figure 74-3 Reaction of acetylcholine and sarin with acetylcholinesterase. (From Baker DJ: Anesthesia in extreme environmental conditions, part 2: Chemical and biologic warfare. *In* Grande CG [ed]: Textbook of Trauma Anesthesia and Critical Care. St Louis, MO Mosby-Year Book, 1993, p 1341.)

Signs and Symptoms of Nerve Agent Poisoning

The classic signs and symptoms of nerve agent poisoning are shown in Table 74-2. Poisoning is caused by the accumulation of acetylcholine and not by the OP itself. As a result of stimulation of muscarinic synapses, there is miosis; ciliary body spasm causing pain[32]; glandular hypersecretion, including salivary, bronchial, and lacrimal; sweating; cardiac effects, including bradycardia, atrioventricular block, and Q–T prolongation; bronchoconstriction; vomiting; severe diarrhea; and fecal incontinence. The nicotinic effects are manifested by fasciculation and paralysis at the neuromuscular junction. Sometimes anomalous tachycardia may occur after nicotinic ganglionic stimulation in the sympathetic system. Central effects lead to apprehension, dizziness, amnesia, seizures, coma, and respiratory depression.[33] Lower long-term doses of OPs lead to irritability, fatigue, loss of concentration, and memory loss.

Clinical Experience with Intoxications from Organophosphates. Much of the information about actions of OPs in humans has been gathered from animal studies and from management of pesticide poisoning. Animal studies do not represent human reactions, and pesticide studies may not accurately represent the cholinergic syndrome after nerve agent exposure. Although there is some evidence from accidental exposure to sarin and from some human volunteer studies conducted early in

Table 74-2 Symptoms and Signs of Nerve Agent Poisoning by Type of Cholinergic Receptor and Target Organ

Receptor	Target Organ	Symptoms and Signs
Muscarinic	Iris muscle; ciliary muscle accommodation	Miosis; spasm leading to failure of pain in the eyes; nausea and vomiting; headache
	Conjunctival vessels	Vasodilation and hyperemia
	Nasal glands	Rhinorrhea and hyperemia
	Bronchial glands	Increased secretion
	Bronchial muscle	Bronchoconstriction; tightness in the chest; expiratory wheezing; dyspnea
	Gastrointestinal tract	Anorexia; nausea; vomiting; abdominal cramps; diarrhea; tenesmus; involuntary defecation
	Sweat glands	Increased activity
	Salivary glands	Increased activity
	Lacrimal glands	Lacrimation (not usually marked)
	Heart	Bradycardia; occasionally tachycardia
	Bladder	Frequency; involuntary micturition
Nicotinic	Skeletal muscle	Weakness; fatigue; fasciculations; cramps; flaccid paralysis (early effects on respiratory muscles may produce dyspnea)
	Autonomic ganglia	Pallor; occasional elevation of blood pressure
Muscarinic and nicotinic	Central nervous system	Anxiety; giddiness; restlessness; headache; withdrawal and depression; memory failure; impaired concentration; slurred speech; depression of respiratory and cardiovascular centers; Cheyne-Stokes respiration

From Baker DJ: Anesthesia in extreme environmental conditions, Part 2: Chemical and biologic warfare. *In* Grande CG (ed): Textbook of Trauma Anesthesia and Critical Care. St Louis, Mosby-Year Book, 1993, pp 1320-1354.

the Cold War, the clinical evidence base is smaller than that for pesticide poisoning. During the early stages of the Cold War, many experimental studies were done on human volunteers exposed to nerve agents; these studies have been reviewed by Marrs and colleagues.[8] The attacks in Japan in 1994 and 1995 also have provided important information concerning the signs and symptoms after sarin release.[3,27]

Clinical Evidence from More Recent Military Experience. The Iran-Iraq War produced first-hand clinical information about the effects and management of nerve agent poisoning.[24] Iranian casualties from nerve agents apparently fell into four broad categories. Individuals who had the greatest exposure died in the field; mask protection by Iranian troops was severely compromised by their having to wear beards for religious reasons. Despite the fact that Iraqi attacks were made against troops having compromised or poor protection, the number of deaths seems to have been low. The most severely injured individuals who reached medical care were unconscious and unresponsive and often in respiratory arrest. The next group who were seriously poisoned had symptoms of dizziness, disorientation, anxiety, salivation, and respiratory difficulty. Disorientation was a problem, and often cases with only mild symptoms were difficult to manage because of this (this parallels experience gained with the management of OP pesticides). Finally, the greatest number of casualties required only decontamination.

Individuals with nerve agent poisoning were treated with large doses of atropine, usually 50 to 200 mg intravenously. These patients were usually comatose, and the degree of advanced life support given was limited. Most patients received only 2 mg of atropine every 8 hours. Comatose patients with significant cardiovascular deterioration did not usually survive.

Clinical Evidence from Pesticide Poisoning. There is considerable clinical evidence about the effects of OP pesticides from the many thousands of cases that occur in agricultural areas of the world each year.[34] Although these cases give an overall picture that corresponds to the signs and symptoms described previously, there are considerable differences with nerve agents. It also is likely that different nerve agents have different effects on the central and peripheral nervous systems.

Cardiovascular Effects of Nerve Agents. Critical care management of OP pesticide poisoning has indicated short-term and medium-term cardiac changes.[35,36] After an initial tachycardia (mediated through the anomalous sympathetic nervous system) and a vagally induced bradycardia, there may be ventricular dysrhythmias, including torsades de pointes and prolongation of the Q–T interval. Dysrhythmias have been reported as a poor prognostic sign.

Treatment of Nerve Agent Poisoning: Antidotes and Life Support

Atropine. Atropine has long been a mainstay in the management of OP poisoning.[30,34] Its antagonistic action against acetylcholine at the muscarinic synapses allows control of the muscarinic effects, the most severe of which is bradycardia. Atropine has been used for many years in the management of OP pesticide poisoning. The relevance of the experience with pesticides to poisoning with nerve agents is uncertain, however.[8] The traditional military response to a confirmed or suspected attack with nerve agents is to use a self-administered autoinjector containing 2 mg of atropine, a benzodiazepine, and an oxime (Fig. 74-4). During the Cold War, NATO troops were provided with three such devices to be used sequentially.

Useful treatment indications have been gained from the Iran-Iraq War[37] and from the Japanese terrorist experience.[27] Atropine, 2 mg, is given intravenously (pediatric dose 0.02 to 0.05 mg/kg) with repeat doses every 5 to 10 minutes until pupillary dilation occurs, and the heart rate increases to greater than 80/min.[8,38] Atropine infusions may be used for persistent bradycardia in pesticide poisoning.[39]

Figure 74-4 Military automatic intramuscular injection device containing nerve agent antidotes (Combopen).

Oximes. Oximes are compounds capable of reactivating in some cases the complex formed by the OP and AChE. Clinically, this means that oximes can reverse the actions of OP at the nicotinic receptor and reduce the degree of paralysis.[40,41] Oximes are widely used in the clinical management of OP pesticide and nerve agent poisoning. Chemically, they are monopyridinium or bispyridinium compounds that can bind to the complex and cause the nerve agent molecule to separate from the enzyme. Oximes are a mainstay of the standard military response to nerve agent attacks and are widely used in the management of pesticide poisoning. Their effectiveness depends, however, (1) on the exact nature of the nerve agent involved and (2) on the length of time after the attack before they are given.

Chemical changes known as aging occur in the nerve agent–enzyme complex. Aging occurs very rapidly in humans after GD exposure, but less so after exposure to the other nerve agents. A major problem related to oxime research is the selection of a suitable animal model. Originally, monkeys and guinea pigs were thought to be good models for human OP intoxication, and human treatment protocols were developed from such studies. There are known to be major differences, however, between aging rates for primates and rates for rodents.[42] The rate of formation of aged enzyme in different species increases in the following order: mouse << rat < guinea pig < rabbit < dog < cow < monkey = human. From erythrocyte studies in humans, the rate of aging is known to be very rapid (half-life = 1.3 minutes), indicating that the guinea pig would not be a good model for humans.

Several oximes are available, and recent years have seen the development of new compounds.[40,41] The most commonly used is pralidoxime (as either the chloride or methane sulfonate [mesylate]). Obidoxime is used in some countries for OP pesticide poisoning and may be effective against GA. More recent research has concentrated on the rational use of a range of oximes in terms of the type of oxime used and dose and timing.[40,41,43] HI-6, a Hagedorn oxime, was thought to be able to reactivate the GD-enzyme complex, the most difficult clinical situation to treat. HI-6 may be useful because of other pharmacologic properties, and may be advantageous in the treatment of GF poisoning and other cases in which obidoxime was previously used.

For most anesthesiologists treating patients with symptoms of nerve agent poisoning, a civilian setting is the most likely. Exposure to sarin is the most probable situation, and treatment schedules logically should be based on this premise. Military anesthesiologists may face other hazards, but would be provided with specialized detection equipment and treatment modalities based on a threat assessment. In the civil context, all nerve agent casualties should receive pralidoxime mesylate initially in addition to atropine and ventilatory life support.

Practical Treatment Regimen. Oxime therapy should be given simultaneously with atropine.[38,40] Slow intravenous injection of pralidoxime is recommended to prevent laryngospasm, muscle rigidity, and hypertension. Pralidoxime, 15 to 30 mg/kg intravenously or intramuscularly is given over 20 minutes for adults and children. This dose may be repeated after 4 hours (or 1 hour if paralysis is worsening). The target therapeutic blood concentration should be 4 μg/mL. Studies by Worek and colleagues[41] have shown, however, that the full therapeutic effects of pralidoxime may be achieved at higher concentrations. The same group has shown that there is a possibility of reinhibition of AChE after pralidoxime treatment in human erythrocytes, but the relevance to the whole body is unclear. Sarin is broken down rapidly in the blood by hydrolysis. Oxime treatment in the hospital should continue for as long as atropine is required.

Benzodiazepines. The central actions of OPs lead to spike discharges and convulsions. Benzodiazepines have long been used to counter this action. Given the known action of OPs at the γ-aminobutyric acid receptor and the antagonistic action of benzodiazepines at this site, the action may be noncholinergic in nature.[44,45] Convulsions may be an early sign of severe nerve agent poisoning and must be controlled quickly to avoid long-term cerebral damage.

Pyridostigmine Pretreatment. The problem of aging of the OP AChE complex, particularly with GD and the ineffectiveness of oxime therapy, gave rise to a novel military approach to prophylaxis against nerve agent poisoning.[9] Pyridostigmine is a dimethyl carbamate compound with a quaternary nitrogen atom. As a result, it does not penetrate the blood-brain barrier to any extent. In common with other carbamates such as neostigmine and physostigmine, pyridostigmine is an anticholinesterase and has essentially the same action as OPs. In the case of carbamates, the complex formed with the enzyme is readily reversible. The normal treatment dose of pyridostigmine is 30 mg every 8 hours. There is no plasma protein binding and no drug interactions involving competition for binding sites. Of the absorbed dose, 79% to 90% is excreted unchanged in the urine. The reversibility of the complex formed with AChE is such that the enzyme returns to 90% of normal within 12 hours after the last dose. In addition, at the steady state, only 40% of the available AChE is complexed. Given the considerable safety margin that exists in the level of enzyme at cholinergic synapses, treatment with pyridostigmine does not produce any more than mild parasympathetic signs.[46]

The protective action of pyridostigmine against OPs is based on the fact that the carbamylate-complexed AChE is resistant to attack after subsequent exposure to OPs. If a person taking pyridostigmine is exposed to a subsequent potentially lethal dose of OP, there is a reserve of enzyme that is effectively autotransfused into the patient during the subsequent period. This process does not require the presence of an oxime. OP is rapidly hydrolyzed in the bloodstream after exposure and has no further action on the released AChE. The amount of enzyme released from the carbamylate complex is sufficient to restore neuromuscular transmission because of the safety margin that exists at the synapse. In severe cases of OP poisoning, life support measures are necessary, however, to bridge the gap between OP attack on the synapse and restoration of the AChE level through the autotransfusion.

Anesthetic Implications of Pyridostigmine Pretreatment. The anticholinergic actions of pyridostigmine have considerable relevance to normal anesthetic practice. Butaryl cholinesterase, a determinant of the metabolism of succinylcholine, also is inhibited, and prolonged action of this drug may be expected in patients taking pyridostigmine.[47] The carbamate neostigmine is usually given at the end of an operation to reverse the action of nondepolarizing neuromuscular blocking drugs. Pretreatment with a carbamate in a patient who is not subsequently exposed to OP may be expected to produce some resistance to the action of the neuromuscular blocker. Experimental studies[48] indicate that pyridostigmine does not alter the overall characteristics of neuromuscular block in an isolated human forearm, and the neuromuscular effects may be minimal, particularly because more central muscles of respiration such as diaphragm have a higher safety margin of neuromuscular transmission and are less affected by treatment with pyridostigmine. Estimations of the degree of neuromuscular block using fade relationships such as the train-of-four[49] theoretically may be affected by pyridostigmine pretreatment because the determinant of fade is feedback to the prejunctional cholinergic receptor.[50] The hysteresis loops for the onset and offset of fade and paralysis relationships in the isolated forearm are not affected, however, by pyridostigmine pretreatment.[48] The civilian anesthesiologist is referred to more specialized military texts[8,13] for a more complete discussion of pyridostigmine and its clinical actions.

Vesicant Agents

Vesicant agents were first used as chemical weapons during World War I.[14] The most well-known agent is sulfur mustard (1917, commonly known as "mustard gas"). It was used as a disabling agent and has a long latency of 2 to 4 hours. Its successor lewisite (1919), an arsenic-based compound (2-chlorovinyl dichloroarsine), is more volatile and has a short latency and causes immediate eye pain in addition to its vesicant properties.[18] Mustard gas is the most commonly encountered vesicant. Although an early chemical warfare agent, it is still widely distributed around the world, and its easy synthesis makes it a possible agent for use by terrorists. It has numerous pathologic properties that make it of concern to anesthesiologists. The overall management of mustard gas injury is the domain equally of the surgeon and specialized pulmonary physician.[8,51,52] Intensive care unit (ICU) management presents longer term problems, which are mainly respiratory. Eye and skin injuries fall within the aegis of other specialities.

Properties

Sulfur mustard (bis-2-chloroethyl sulfide) is a colorless or pale yellow, oily liquid that smells faintly of mustard. Its odor threshold is 1.3 mg/m^3, which is below the concentrations usually reached in a battlefield, and several minutes of detection are possible before incapacitating doses are reached. The LCt_{50} is about 1500 mg/min/m^3. Although the latency of action in cooler climates is about 4 hours, information from the Iran-Iraq War, the scene of its most recent use, [53,54] indicates that at higher ambient temperatures the agent has a far shorter latency and causes significant respiratory damage apart from its classic action as a skin vesicant.

Signs and Symptoms

After exposure to mustard gas, there is a latent period of 4 to 12 hours, following which ocular symptoms comprise eye pain, blurred vision, and lacrimation, accompanied by a diffuse erythema of exposed skin with edema and first-degree burns. The groin and genital areas are particularly susceptible. Exposure to high doses produces severe cutaneous injury with necrosis. The burns bear some resemblance to thermal burns, but are very slow to heal and are prone to secondary infection. The bullae that are characteristic of exposure to mustard agent are filled with a fluid that is not itself corrosive (Fig. 74-5). A feature of exposure is that fluid-filled bullae appear for several days afterward in an apparently random way (i.e., not cropped). The eyes are particularly vulnerable to mustard gas, causing usually a temporary blindness (Fig. 74-6). The fluid in the bullae has no vesicant effect.

Figure 74-5 Cutaneous vesication caused by mustard gas exposure. (Courtesy of Her Majesty's Stationery Office, London, United Kingdom.)

Respiratory Effects

The respiratory effects of mustard gas exposure are potentially serious, particularly when the ambient temperature is high.[54,56] After exposure, there is an early tracheobronchitis with dry cough and hoarseness. Heavy exposure produces severe damage to the tracheal and main bronchial architecture with necrosis, sloughing, and blockage (Fig. 74-7). A chemical bronchiolitis occurs at lower doses in high ambient temperatures and causes severe bronchospasm, requiring ventilation and intensive care.[54] Lung damage after mustard exposure can be severe and permanent with chronic obstructive pulmonary disease, bronchiectasis, and reactive airways dysfunction syndrome.

Cellular Action of Mustard Agent

Sulfur mustard agent acts at a cellular level forming highly reactive sulfonium ions, which attack DNA by alkylation of sulfhydryl

Figure 74-6 Eye injury caused by mustard gas exposure. (Courtesy of Her Majesty's Stationery Office, London, United Kingdom.)

and amino groups.[8] This causes the epithelial manifestations of exposure and long-term carcinogenesis, particularly of the skin, pharynx, and respiratory tract.

Treatment

There is no specific treatment for mustard gas exposure, but experimental studies in animals have shown that a combination of sodium thiosulfate, vitamin E, and dexamethasone can improve survival and reduce organ damage.[8] The key points of treatment are (1) the need for decontamination, (2) the latent period of action, and (3) respiratory support for exposure affecting the respiratory tract. Willems[52] reviewed information concerning the clinical management of mustard gas casualties, reporting that 87% of patients requiring ventilation died. The onset of severe respiratory symptoms is a serious development and underscores the need for a proactive approach to airway management and ventilation. Endotracheal intubation should be done early to allow adequate ventilation and access for débridement of the large airways. Another point of concern for longer term management is the leukopenia that follows exposure to mustard gas. This becomes evident 3 to 5 days after exposure and usually reaches its lowest point 7 to 9 days after exposure. Cellular replacement, either peripherally or as marrow, could be considered here because mustard gas is bound very quickly in the body after exposure and does not cause destruction of new cells.

More Recent Clinical Evidence

Sulfur mustard was used extensively in the Iran-Iraq War during the 1980s, producing a significant amount of clinical information about casualties[53] with cutaneous and respiratory injuries. The treatment given reflects the experience gained in the treatment of burn injuries since its first use. Decontamination was achieved early to limit the contact time with the agent. Because of the long latency of mustard gas, vesicle formation often was not present at this time. Shaving of the affected areas was done, and the agent was diluted by irrigation. The management of the vesicles followed the pattern of aspiration, removal of necrotic tissue, and the use of silver sulfadiazine cream.

From the anesthetic standpoint, the respiratory effects found in casualties were important and unprecedented from the use of mustard gas in the lower temperature conditions of World War I. Chemical bronchiolitis giving rise to increased airway resistance was reported together with soiling of the larger airways secondary to sloughing. Intermittent positive-pressure ventilation with positive end-expiratory pressure was required with ICU support for cases of more serious injury. Many of these cases were managed in hospitals around Europe, introducing chemical warfare injury to many anesthesiologists and intensivists for the first time. For the casualties who reached definitive hospital care, the recovery period was often long, and patients had cachexia with significant negative nitrogen balance.

Lung-Damaging Agents

Lung-damaging agents were formerly known as choking agents, a term that does not adequately describe the many levels of the lung at which they act. Lung-damaging agents act at the upper and the lower respiratory levels, but their main lethal action is to cause toxic pulmonary edema. Lung-damaging agents were the first to be used as chemical weapons during World War I with the use initially of chlorine, followed by phosgene. These agents are a universal hazard in military and civilian populations because they also are used widely as industrial feedstocks in many chemical engineering processes. The isocyanates are widely used in this respect, and the accidental release of methyl isocyanate in Bhopal, India, in 1984 caused the largest number of casualties ever recorded after toxic release in either war or peace, with more than

5000 deaths from toxic pulmonary edema.[57,58] Chemical warfare and HAZMAT sources list many lung-damaging agents.[8,19]

Phosgene

Phosgene[59] has been used as a chemical warfare agent, is an established worldwide industrial hazard, and may be regarded as a potential terrorist threat. It is a model for consideration of other hazards in its class. Phosgene is carbonyl chloride, familiar to earlier anesthesiologists as the product of the reaction of trichloroethylene with soda lime. First synthesized in the 19th century, phosgene has been in industrial use for more than a century, but achieved notoriety during World War I when it was used extensively by both sides from 1915 onward. It caused greater than 85% of all deaths from chemical warfare agents.[14] Phosgene is a gas at normal temperatures and is nonpersistent (Table 74-3). It is less water soluble than chlorine, its immediate chemical warfare predecessor in 1915, a feature that results in the gas being taken further down the respiratory tree and into the alveoli. Phosgene has been known since World War I to have a dual latency of action, which underlies its essentially dangerous character. The stages after exposure are as follows:

1. Immediately after exposure, there is an intense upper respiratory irritation with coughing, retching, choking, and chest tightness. These symptoms are accompanied by eye irritation and lacrimation. In some cases, death has followed exposure to high concentrations of phosgene without the development of toxic pulmonary edema. The reason for this is obscure, but may be related to hypoxia as a result of intense laryngeal or bronchospasm.
2. The immediate choking symptoms are followed by a latent period of 2 to 24 hours before the onset of more serious symptoms and signs, including dyspnea, painful cough, and cyanosis, with increasing signs of pulmonary edema leading to circulatory collapse and cardiac arrest.

Pathophysiology of Toxic Pulmonary Edema

Phosgene reacts through covalent attack on many substrate groups, including NH_2 and SH.[60] Potential cell targets are type I and II pneumocytes and alveolar macrophages. Covalent binding can be seen as the primary attack leading to free radical release. This stage is followed by a secondary attack involving released inflammatory mediators, including prostaglandins (causing vasoconstriction, vasodilation, and platelet disaggregation), bradykinin (causing increased capillary permeability), 5-hydroxytryptamine (causing constriction of postcapillary vessels), and thromboxane A_2 (causing vasoconstriction), and the release of complement activating enzymes (leading to attraction of leukocytes and leukotriene release).

Table 74-3 Properties and Toxic Exposure Levels of Phosgene

Properties
Chemical name: carbonyl chloride ($COCl_2$), chloroformyl chloride
Boiling point: 8.2°C
Vapor pressure: 1215 mm Hg at 20°C
Vapor density: 3.5 × air
Breakdown: slow aqueous hydrolysis to HCl and CO_2
Toxic Exposure Levels
1 ppm chronically—chronic lung disease
>25 ppm/min—acute lung effects
50-100 ppm/min—initial inflammatory response that may be followed by pulmonary edema
>150 ppm/min—clinically significant and life-threatening pulmonary edema
Lethal exposure in humans—800 ppm for 2 min

Management of Phosgene Exposure

Patients who have been exposed to phosgene should be removed from the site of exposure as quickly as possible by protected emergency responders. There is usually no requirement for decontamination, unless liquid contamination has occurred. There is no specific antidote to phosgene, and treatment is based on use of supportive measures and pharmacologic modification of the effects of the inflammatory mediator cascade.[59] One of the firm rules for the management of phosgene exposure dating from World War I was complete bed rest and observation for 24 hours, and this still applies. No patient who has had a risk of significant exposure should be discharged from the hospital in less than 24 hours, unless accompanied by a responsible observer.

Provision of specialized respiratory care is at the prehospital and hospital level. Some cases may require early intubation and ventilation, and more require oxygen and supported ventilation in the early stages. The method of provision of emergency ventilation is a matter of interest. More recent work in physical trauma has indicated that the "open lung" strategy[61,62] is of value in the prevention of inflammatory cascades by opening the alveoli and keeping them open by use of the correct level of positive end-expiratory pressure. This technique follows the hypothesis that repeated opening and closing of alveoli causes kinin release through the action of shear forces in the alveolar walls. There may be an important lesson for the early management of lungs damaged by phosgene exposure, and the manner of emergency ventilation may be critical. Bag-valve ventilation, which can lead to very high inflation pressures and high flow rates, may be harmful. Emergency ventilation strategies that provide controlled flow rates with the early use of positive end-expiratory pressure are more appropriate. These can be provided by the use of small automatic gas-powered ventilators (Fig. 74-8).

Modern experience of the management of mass casualties with toxic pulmonary edema is limited, but it must be assumed that a considerable proportion who survive the acute toxic pulmonary edema would develop acute respiratory distress syndrome unless the appropriate measures are taken. A study by Parkhouse and colleagues[63] showed improved oxygenation, decreased shunt fraction, and decreased mortality in phosgene-exposed pigs that received a protective compared with a conventional ventilation strategy.

Use of Steroids. The use of inhaled and systemic steroids in the treatment of toxic phosgene exposure has been controversial for many years, and Diller,[64] a leading authority on phosgene poisoning, believed in 1985 that the case was unproven. More recently, there has been renewed experimental interest in the subject using chlorine injury, which has produced some encouraging results in pig and rat studies. Gunnarsson and colleagues[65] found in a study of 18 pigs subjected to 140 ppm chlorine for 10 minutes that inhaled beclomethasone dipropionate produced higher Pao_2 and ventilation-perfusion ratios, with less histologic damage, than in the control group. In another study, Wang and colleagues[66] exposed 24 pigs to a higher concentration of 400 ppm for 10 minutes. They found that the inhaled steroid budesonide,

Figure 74-8 The compPAC portable gas-powered emergency and transport ventilator for use in contaminated environments. (Courtesy of Pneupac Ltd, Luton, United Kingdom.)

0.1 mg/kg given within 30 minutes of exposure, was associated with more favorable cardiorespiratory symptoms and lower wet lung weights at autopsy. Demnati and coworkers[67] studied the effects of dexamethasone in rats exposed to high concentration of chlorine (1500 ppm for 5 minutes). They found that the dexamethasone group had significantly reduced pulmonary airway resistance and methacholine-induced bronchoconstriction than the controls.

There have always been noted species differences in challenges to chemical warfare agents, and these results should be applied with caution to humans. In a clinical area where few therapeutic options are available, however, the results provide encouragement for further research and for clinical intervention if the need arises. Borak and Diller[68] reviewed the available evidence for treatment regimens in human phosgene exposure.

Role of Cyclic Adenosine Monophosphate Diesterase Inhibitors. Kennedy and associates[69] suggested that aminophylline may protect against phosgene exposure as a result of its ability to increase cyclic adenosine monophosphate levels. Other compounds, including β-adrenergic agonists, also have this effect and may indicate a new therapeutic direction.

Phosgene and Glutathione Modification. Another promising therapeutic approach is provided by compounds that can increase intracellular reduced glutathione levels as a means of preventing lipid peroxidation–induced phosgene exposure. The rationale behind this approach is that phosgene reacts with cellular SH groups, reduces reduced glutathione redox state, and increases arachidonic acid mediator production and lipid peroxidation. Sciuto and coworkers[70] studied the effect of *N*-acetyl cysteine on anesthetized rabbits exposed to 1500 ppm phosgene. The *N*-acetyl cysteine–treated group had smaller increases in pulmonary wet weight, lower leukotriene levels, and higher glutathione levels. This work suggests that *N*-acetyl cysteine may protect against phosgene exposure by maintaining reduced glutathione levels and inhibiting production of inflammatory leukotrienes.

Hydrogen Cyanide

HCN is one of several agents known originally as *blood agents,* although the term is a misnomer because the agent acts at the cellular mitochondrial level.[71] HCN is a highly volatile liquid used widely in industry and potentially available to terrorists. It has been used since World War I as a chemical warfare agent. Its very short persistence means that decontamination is usually not required after release. It is not absorbed by the activated charcoal of level C respirators (see later), but is removed by impregnating the charcoal with silver salts with which HCN reacts. HCN in high concentrations is rapidly fatal. The LCt_{50} has been estimated at 200 mg/m^{-3} for 10 minutes. HCN acts by binding to the iron atom in cytochrome oxidase enzymes, inhibiting the catalytic function that allows oxygen to act as an electron receptor and produce adenosine triphosphate. Because of this mitochondrial uncoupling, the resulting lactic acidosis theoretically cannot be reversed by restoring oxygenation of the blood by resuscitation measures to improve tissue oxygenation.

Signs and Symptoms

After exposure in humans, the first sign is hyperventilation, which has the effect of increasing the absorbed dose. This is followed by dizziness, rapid loss of consciousness, and convulsions, followed by respiratory arrest. At levels that are not fatal, patients report a smell of almonds and a feeling of apprehension. There is a metallic taste in the mouth, and there may be dyspnea. Because of the rapid action of HCN, patients with acute intoxication are unlikely to be encountered in hospital. This is because antidote therapy plays a key role and, if successful, is curative. Long-term management of the consequences of HCN poisoning is unlikely, although survivors of near-fatal doses can have long-term effects, such as intellectual deterioration, mental confusion, and parkinsonism.

Treatment

In the body, HCN is broken down by rhodanase, which detoxifies cyanide to thiocyanate. This process can be accelerated by provision of sodium thiosulfate, which provides a store of sulfane sulfur for the enzyme.[72-74] The usual dose of sodium thiosulfate is 25 mL of 50% solution (pediatric dose 1.65 mL/kg of 25% solution). It is usually administered in conjunction with sodium nitrite (300 mg given intravenously over 10 minutes [pediatric dose 0.15 to 0.33 mL/kg of a 3% solution]), which causes the formation of methemoglobin. The methemoglobin acts as a scavenger for HCN and reduces its plasma levels. Sympathomimetic support may be required for hypotension produced by sodium nitrite. HCN also reacts with heavy metals, and this is the basis of the use of dicobalt edetate and hydroxycobalamin as cobalt providers for this reaction. Cobalt ions themselves are toxic, but

the toxicity can be countered by giving glucose, which is part of standard therapy. Dicobalt edetate is thought to be more effective in the binding of cyanide ions than methemoglobin despite its secondary effects of hypertension and nausea.

It has long been believed that oxygen therapy and ventilation has no role in the treatment of cyanide intoxication because the blood is fully oxygenated in this condition. This view has been challenged more recently because some studies have shown that oxygen enhances the antidotal effects of the classic cyanide antidotes.[75] Table 74-4 details current antidote treatment approaches.

Toxins

Toxins are high-molecular-weight compounds that are in the middle of the CBW spectrum.[19] They do not reproduce and have characteristics of chemical warfare agents, although they have been considered with biological agents by international convention. They are produced naturally by bacteria and by organisms ranging from protozoans to reptiles such as snakes and scorpions.[76] Toxins are hazardous to humans from natural and deliberate exposure, and this has fueled much research into their actions and treatment.[77] Scientifically, they are of considerable interest and are used as research tools to probe natural processes such as nerve conduction and neuromuscular transmission. In the context of toxic warfare, toxins often have been cited as *doomsday weapons,* and there is considerable public fear about their actions. More than 500 toxins have been described, but only a few are suitable for battlefield and terrorist attacks because of difficulties in production and lack of stability in a released aerosol. Table 74-5 presents the characteristics of common toxins.

In the chemical warfare context, the anesthesiologist may encounter toxins with short latency (neurotoxins, such as botulinum toxin) requiring immediate life support and treatment or with long latency (DNA toxins, such as ricin), which cause major organ dysfunction and present intensive care problems.

Botulinum Toxin

Botulinum toxin is produced by the anaerobe *Clostridium botulinum* and has the reputation of being the most toxic substance by weight known; it is at least 5000 times more toxic than sarin.[78] Botulism, the natural occurrence of the toxin in food poisoning, is a disease of humans and animals. Seven different functionally related neurotoxins (A through G) are produced by the parent organism. Botulism is essentially an intoxication, brought on by ingestion of the toxin produced by clostridial infection of food, usually incorrectly canned meats. Primary botulism, a direct infection, is rare and affects only infants among humans. The interest of botulinum toxin as a toxic agent is that it can be easily produced by fermentation processes (which have been developed to produce antitoxins), and that it is stable as an aerosol, making mass delivery a theoretical possibility. Calculations that 1 kg of the toxin would be sufficient to destroy every human on the planet have rested on this fact.

Botulinum intoxication can be treated, and this modifies the toxicity considerably. It is estimated that less than 10% of natural cases receiving ventilatory and antitoxin support are fatal. A consensus document has been published that examines the risks to civilian populations exposed to botulinum toxin.[80]

Botulinum toxin acts at the nerve terminal of cholinergic synapses. It blocks the release of acetylcholine by being taken up into the vesicles and translocated to the cytoplasm, where it catalyzes the proteolysis of components involved in the calcium-mediated exocytosis of acetylcholine. The inhibition is permanent, and recovery occurs only after the creation of new terminal boutons. The toxin blocks neurotransmission, parasympathetic synapses, and peripheral ganglia. The signs and symptoms of botulism can be explained on this basis.

Conventionally, after ingestion of the toxin (the usual route), there is a latent period of several hours, following which the parasympathetic action produces a dry mouth, followed by signs of a progressive bulbar palsy (dysarthria, dysphasia, and dysphagia) and ocular signs (diplopia and ptosis). These signs are followed by a progressive symmetric descending muscular weakness leading to respiratory failure requiring prolonged ventilatory support. Neuromuscular testing shows a classic presynaptic decremental pattern to repeated stimuli with post-tetanic facilitation. Single-fiber electromyography detects the neuromuscular changes before conventional nerve stimulation; there is increased jitter and blocking, which is reduced by increasing the nerve firing rate.[79] The pattern of signs and symptoms after a deliberate mass inhalation release is unknown, but botulinum toxin must be considered along with the nerve agents in any cases manifesting with sudden disturbances of cholinergic transmission.

Conventional level C protection (see section on personal protection) and decontamination procedures are effective against botulinum toxin, and several antisera exist. A heptavalent antitoxin exists for all the serotypes, but the human efficacy is not known with certainty.[80] Established cases require supportive treatment with antitoxin and positive-pressure ventilation. The latter may be required for a long time.

Saxitoxin

Saxitoxin has been suggested as a possible terrorist toxic agent, but there is no record of its production or use in a military context. In nature, saxitoxin is produced by dinoflagellate sea organisms (causing the "red tide"), including *Alexandrium tamarense, Gymnodinium catenatum,* and *Pyridonium hamense.* The toxin is concentrated in shellfish and is the cause of paralytic shellfish poisoning.[76] The toxin is about 20 times more toxic than sarin, having an LD_{50} in mice of 8 μg/kg. Saxitoxin is active by the inhaled route, causing bulbar palsy, respiratory failure, and cardiovascular failure. The toxin acts by blocking voltage-gated sodium channels.[82] Treatment is based on ventilatory and organ support. An antitoxin has been developed in guinea pigs.[82]

Ricin

Ricin is considered a serious terrorist threat because it can be extracted easily from the seeds of the castor bean plant, *Ricinus communis*. Waste from the production of castor oil contains about 5% ricin, making it a potential source for terrorists. Ricin has been used in assassination,[14] and high inhaled concentrations are thought to be fatal. There is a substantial latent period before generalized signs and symptoms of the inhibition of protein synthesis occur, including fever, abdominal pain, diarrhea, drowsiness, confusion, convulsions, coma, weakness, cardiovascular collapse, and respiratory failure, all progressing to multiple organ failure and death within 36 to 72 hours. Ricin poses a considerable

Table 74-4 Antidotes Used in the Treatment of Cyanide Poisoning

Antidote	Action	Route	Dose	Concurrent Drugs	Duration of Administration	Possible Side Effects
Oxygen	Increases arterial O_2 content, potentiates activity of other antidotes	Inhalation via mask or ETT	High flow via mask or 100% via ETT	Oxygen used as primary antidote in all cases	≤24 hr	Unlikely—possible in patients with COPD
Amyl nitrite	Methemoglobin formation	Inhalation	Adult: 0.2 mL Pediatric: 0.2 mL; may need repeating	Oxygen (not simultaneously)	30 sec/min	Difficult to achieve effective antidotal levels without cardiovascular collapse
Sodium nitrite	Methemoglobin formation	Intravenous injection	Adult: 300 mg (10 mL of 30 mg/mL 3%) Pediatric: 0.13-0.33 mL/kg of 30 mg/mL (3%) solution (i.e., 4-10 mg/kg body weight)	Adult: sodium thiosulfate 25 mL of 500 mg/mL, (50%) solution and oxygen Pediatric: sodium thiosulfate 1.65 mL/kg body weight of 250 mg/mL (25%) solution (approximately 400 mg/kg body weight) and oxygen	≥5 min, ≤20 min	Methemoglobinemia, vasodilation and cardiovascular collapse
Dicobalt edetate	Binding of cyanide ions by dicobalt edetate and by free cyanide ions	Intravenous injection	Adult: 300 mg (20 mL of 15 mg/mL (15%) Pediatric: 4-7.5 mg/kg (0.3-0.5 mL/kg of 15 mg/mL (15%)	50 mL dextrose (500 g/L) intravenously immediately after each dose and oxygen	1 min	Urticaria, edema of face and neck, chest pains, dyspnea, hypotension, convulsions
4-DMAP	Methemoglobin formation	Intravenous injection	Adult: 3.25 mg/kg Pediatric: 3.25 mg/kg	Oxygen and sodium thiosulfate	1 min	Methemoglobinemia, vasodilation and cardiovascular collapse, hemolysis, elevated bilirubin and iron (this is unlikely to be relevant to single-dose exposure)
Hydroxocobalamin	Binds cyanide ions	Intravenous injection	Adult: 5-10 g Pediatric: 70 mg/kg	5 g reconstituted in 100 mL 0.9% saline; oxygen	20 min	Reddish discoloration to skin and mucous membranes
Sodium thiosulfate	Sulfur donor for endogenous enzymatic conversion of cyanide to thiocyanate	Intravenous injection	Adult: sodium thiosulfate 25 mL of 500 mg/mL (50%) solution and oxygen Pediatric: sodium thiosulfate 1.65 mL/kg body weight of 250 mg/mL (25%) solution (approximately 400 mg/kg body weight) and oxygen	Oxygen and sodium nitrite *or* oxygen and DMAP	10 min	Excess administration may cause hypernatremia

COPD, chronic obstructive pulmonary disease; ETT, endotracheal tube.

Table 74-5 Characteristics of Common Toxins

Source	Toxin	Action
Bacteria		
Bacillus anthracis	Anthrax toxin	DNA toxin
Staphylococcus aureus	Staphylococcal enterotoxin B	Enterotoxin
Vibrio cholerae	Cholera toxin	Enterotoxin
Clostridium botulinum	Botulinum toxins	Prejunctional decrease in acetylcholine release
Clostridium perfringens	Perfringens toxin	Necrosis through phospholipase C
Clostridium tetani	Tetanus toxin	Neurotoxin increase in excitability of motor neurons
Protozoa		
Gonyaulax catenella	Saxitoxin	Depolarization block
Fungi		
Fusarium spp.	Tricothecenes	DNA toxin; hemorrhagic syndrome
Plants		
Ricinus communis (castor bean)	Ricin	DNA toxin; hepatorenal failure
Amphibia		
Colombian frog	Batrachotoxin	Irreversible; Na^+ channel blockade; depolarization block
Reptilia		
Asian cobra (*Naja naja oxiana*)	Cobra toxin	Postsynaptic neurotoxin via phospholipase A_2
Taiwan banded krait (*Bungarus multicinctus*)	α-Bungarotoxin	Acetylcholine receptor blocker
Fish		
Deadly pufferfish	Tetrodotoxin	Depolarization block

ICU problem. Treatment is supportive, but an antitoxin has been developed for use in animals.[83]

Pharmacologic Agents and Agents of Biological Origin

The events in the Moscow theater siege in 2002[84] have highlighted the possible use of substances that were originally developed as anesthetic agents or adjuncts as "knock-down" weapons. In the siege, a substance was released into the air conditioning system by special forces entering the theater, which led to the deaths from respiratory failure of 127 of 800 of the hostages. The event emphasized the need for immediate life support after toxic attack with short-latency agents. The Russian government, after challenge, declared that the agent used was "fentanyl." Many fentanyl agents have been synthesized apart from the agents familiar in clinical practice, and some are too toxic for general use. Another possibility is the use of a short-chain neuropeptide. Considerable research effect went into investigating such compounds during the last days of the USSR.[16] Agents such as BZ (also initially considered as a possible cause of the theater casualties) have been known for many years and are centrally acting anticholinergic agents. Phencyclidine compounds (related to ketamine) and other hallucinogens were tested during the early days of chemical warfare research during the Cold War and should be considered as part of the differential diagnosis of patients presenting with central nervous system symptoms after a possible toxic attack.

Classic Biological Warfare Agents

General Considerations

Although many organisms have been suggested as being capable of use as biological warfare agents, only a few have been studied to the point of being a threat rather than a hazard.[14] Management of deliberate epidemics is the role of specialist physicians, and anesthesiologists are likely to encounter only agents that have serious pulmonary effects and are likely to require ICU care. There are many analogies from normal epidemic outbreaks that are relevant to deliberate biological warfare attacks, particularly by terrorists. The SARS epidemic in 2004 was a valuable lesson about the spread of a new infectious pathogen in a world linked by fast air connections. Although previous slower forms of travel allowed the incubation of symptoms before arrival at the destina-

tion, air travel does not, and patients may be asymptomatic at the time of their arrival. All hospital practitioners must now be aware of the possibility of transmission of infection from distant locations. Recent travel history should be an essential part of the initial patient interrogation process.

Anthrax

Bacillus anthracis, an aerobic gram-positive, spore-forming, rod-shaped organism, is one of the few listed "standard" biological warfare agents that has been proven to be a hazard and a weaponized threat The natural reservoir of the disease is spores in the soil, and these highly resilient spores form the basis for its use as a biological warfare agent. During tests in World War II, a whole Scottish island was experimentally contaminated and remained in this condition for more than 40 years.[14] There has been evidence for weaponization of the bacillus by several other countries. An accidental release from a military installation in the USSR in 1979 claimed more than 100 lives.[15] The Iraq War in 2003 was fought under the shadow of a possible anthrax attack, although no such weapons were found. Although the standard biological warfare release is seen to be aerosolization spores, the agent was distributed in the United States by mail as a powder in 2001 and claimed several lives, showing its terrorist use.

Anthrax exists in cutaneous, gastrointestinal, and pulmonary forms. The pulmonary form is the major concern of the anesthesiologist and intensivist. In the natural state, pulmonary anthrax is rare, but deliberate release of spores in an aerosol would make the presentation more common.

Physical Findings. The physical findings in pulmonary anthrax are nonspecific, but chest radiography may show signs of effusion or phosgene exposure and mediastinal widening There is an immunoassay available that can detect circulating toxin. The infective dose of anthrax when inhaled is 8000 to 15,000 spores. Spores 2 to 5 µm reach the alveoli; spores greater than this size are trapped in the upper airways. After trapping, the spores are removed to the mediastinal and hilar lymph nodes by pulmonary macrophagocytes. After a germination period of 1 to 3 days, large amounts of anthrax toxin are released into the circulation, causing the clinical manifestations of the pulmonary form of the disease. An initial phase is insidious, lasting 1 to 4 days and consisting of general malaise, fatigue, myalgia, nonproductive cough, and fever. During the next phase of the pulmonary disease, a necrotizing hemorrhagic mediastinitis occurs causing chest discomfort, dyspnea, and stridor. In untreated cases, multiple organ failure follows, which is very refractory to treatment and causes death within 24 to 36 hours. In 50% of cases, hemorrhagic meningitis with coma occurs.

Pathogenesis. Considerable work has been done on the mechanism of the pathogenesis of anthrax infection and the effects of the toxin. The pathogenesis consists of three proteins with a central protective component binding the other two, known as the edema and lethal factors. After transfer to the cytoplasm, edema factor, a calmodulin-dependent adenyl cyclase, converts adenosine triphosphate to cyclic adenosine monophosphate,[85] which causes tissue edema and suppression of the oxidative burst associated with polymorphonuclear phagocytosis.[86] Lethal factor is thought to be associated with macrophage expression of tumor necrosis factor and interleukin-1, cytokines that are a fundamental part of the systemic inflammatory response.

Treatment. Treatment of anthrax infection classically has been founded on the use of benzyl penicillin, but there is evidence of resistance. The current antibiotic recommendation is to use ciprofloxacin, 400 mg every 8 hours, and this was widely used as prophylaxis during the 2001 U.S. terrorist scare. Other approaches may be more appropriate, including doxycycline (200 mg intravenously followed by 100 mg intravenously every 8 hours), gentamicin, erythromycin, and chloramphenicol (Table 74-6).

The recommended antibiotic prophylaxis is ciprofloxacin, 500 mg every 12 hours, or doxycycline, 100 mg every 12 hours. This should be started as soon as possible after exposure.[87] Vaccines have been studied, and the standard Michigan vaccine should be given at 0, 2, and 4 weeks and then at 6, 12, and 18 months, followed by annual boosters. If vaccines are unavailable, antibiotic prophylaxis should be continued for 60 days. For anesthesiologists, intensivists, and other staff involved in the longer term care of anthrax patients, prophylaxis is important, together with careful filter protection of ventilation and disinfection. Wherever possible, disposable circuits should be used.

Plague

Plague was the scourge of the medieval world, and natural outbreaks continued well into the 20th century. Plague has long been considered as a potential biological warfare agent and was researched extensively by the USSR.[16] The pulmonary form is very serious and requires ICU support. The causative organism, *Yersinia pestis,* is an anaerobic, gram-negative coccobacillus that is transmitted to humans via fleas carried by rodents or by animal-human or human-human droplet infection.[88,89] Bubonic, pneumonic, and septicemic forms of plague exist; the last two are fatal without treatment. Only about 100 to 5000 organisms constitute an infective dose. There is an incubation period of 2 to 3 days, following which a pneumonia develops with malaise, high fever, myalgia, hemoptysis, and finally septicemia. There is dyspnea, stridor, and cyanosis. With the worsening condition, intermittent positive-pressure ventilation is required with aggressive antibiotic treatment.

Confirmation of the diagnosis comes from the causative organism in blood, lymph nodes, or sputum cultures. An enzyme-linked immunosorbent assay also is available. Pneumonic plague has long been recognized as being fatal, but antibiotic treatment reduces the mortality to at least 60%. The first line of treatment is streptomycin, 30 mg/kg every 12 hours for 10 days. Alternatives are gentamicin or chloramphenicol. There is an inactivated vaccine (Greer vaccine), but its effectiveness is not thought to be high.

Cholera

Cholera is a widespread natural infection originating from the Far East, which caused several epidemics in Europe throughout the 19th century. Although cholera is the domain of a specialized physician, the profound fluid imbalances caused by the disease make admission of patients to the ICU likely in severe cases. Cholera has been suspected of being weaponized, but it can be spread effectively only by causing mass poisoning through the water supply. Outbreaks occurring in China during World War II were thought to be caused in this way.[14]

Pathogenesis. The infection is localized to the small bowel and causes a major outpouring of fluid and electrolytes. Paradoxi-

Table 74-6 Treatment for Patients Exposed to Biological Warfare Agents

Agent	Infective Dose	Incubation Period	Effects (after Inhalation)	Staff Protection	Specific Treatment	Chemoprophylaxis	Vaccine	Mortality if Untreated
Bacillus anthracis	8000-15,000 spores	1-5 days	Mediastinitis, meningitis, MOF	Isolation, vaccination, universal precautions	Ciprofloxacin 400 mg IV tid; doxycycline 200 mg IV once, then 100 mg IV tid; penicillin 2 MU IV 2 hourly + streptomycin 30 mg/kg IM qd	Ciprofloxacin 500 mg PO bid × 4 wk + vaccinate; doxycycline 100 mg PO bid × 4 wk + vaccinate	Michigan at 0, 2, 4 wk, 6, 12, 18 mo, then annually	Pneumonic, 100%
Yersinia pestis	100-500 organisms	2-3 days	Pneumonia, septicemia, MOF	Isolation, universal precautions	Streptomycin 30 mg/kg IM qd × 10 days; doxycycline 200 mg IV, then 100 mg IV tid × 14 days (chloramphenicol)	Doxycycline 100 mg PO bid × 7 days; tetracycline 500 mg PO qd × 7 days	Greer at 1-3 mo + 3-6 mo	Pneumonic, 100%
Viral hemorrhagic fevers	1-10 organisms	4-21 days	Coagulopathy, edema, MOF	Isolation, HEPA masks, universal precautions	Ribavirin 30 mg/kg IV once, then 15 mg/kg IV qd × 4 days, then 7.5 mg/kg IV tid × 6 days (immunoglobulin)	NA	None	90% (Ebola-Zaire)
Viral encephalitides	10-100 organisms	2-6 days (VEE) 7-14 days (EEE/WEE)	Encephalitis, convulsions, coma, CNS damage	Universal precautions	Supportive, anticonvulsants	NA	Available for VEE, EEE, and WEE	75% (EEE)
Francisella tularensis	10-50 organisms	2-10 days	Pneumonia, pleural effusions	Universal precautions	Streptomycin 30 mg/kg IV qd × 10-14 days; gentamicin 3-5 mg/kg IV od	Doxycycline 100 mg PO bid × 14 days	Live attenuated	35%
Variola organisms	10-100	7-10 days	Rash, secondary pneumonia	Isolation, universal precautions	Cidofovir 5 mg/kg IV once every 2 wk	Vaccinia immunoglobulin	Wyeth	Unvaccinated 30%, vaccinated 3%
Burkholderia mallei	1-10 organisms	10-14 days	Septicemia, pneumonia, lymphadenopathy	Universal precautions	Co-amoxiclav 20 mg/kg IV tid	Tetracycline 500 mg PO qd × 14 days	None	Uncertain: >30% if septicemic
Coxiella burnetii	1-10 organisms	10-14 days	Myalgia, malaise, fever	Barrier nursing	Doxycycline 100 mg PO bid × 5-7 days after exposure × 5 days	Doxycycline 100 mg PO bid for 8-12 days	Q vax	<1%
Brucella spp.	10-100 organisms	5-60 days	Malaise + cough, sacroiliitis, pancytopenia	Barrier nursing	Doxycycline 100 mg PO bid + rifampicin 900 mg tid PO for 6 wk	Doxycycline and rifampicin for 3 wk	None	<5%
Escherichia	10-100 organisms	1-5 days	Vomiting + diarrhea, renal failure	Barrier nursing	Antibiotics not required	NA	None	<5% *E. coli* O157:H2

CNS, central nervous system; EEE, eastern equine encephalitis; HEPA, high-efficiency particulate air filter; MOF, multiple organ failure; NA, not applicable; VEE, Venezuelan equine encephalitis; WEE, western equine encephalitis.
Adapted from White SM: Chemical and biological weapons: Implications for anaesthetic and intensive care. Br J Anaesth 89:306, 2002.

cally, fluid can still be absorbed, and this is the basis of the use of oral rehydration solutions in mass outbreaks in developing countries.

Treatment. The management of cholera essentially comprises fluid and electrolyte replacement. Traditionally, the intravenous route was used, but modern practice is to use oral rehydration solutions containing electrolytes and glucose.[90] Early rehydration in this way avoids the need for admission to the ICU. In the case of a deliberate cholera epidemic, early oral rehydration would be a high priority for mass casualties. Tetracyclines traditionally have been the antibiotic treatment of choice, but resistance has been reported.[91]

Glanders

Glanders is an equine disease caused by the gram-negative bacillus *Burkholderia mallei*. It has long been considered to be a potential biological warfare agent in a modified form because the organism is known to be highly infectious in the aerosolized form. There are acute and chronic forms in humans.[91] The septicemic form appears 10 to 14 days after exposure, making the agent one of long latency. There is a sudden onset of high fever, rigors, and myalgia with cervical lymphadenopathy, splenomegaly, leukopenia, or leukocytosis. In this form, septic shock and multiple organ failure occur, and the fatality rate without treatment is high.

After inhalation of the organism, the acute pulmonary form is seen with septicemia, bilateral pneumonia, and pulmonary nodular necrosis. The chest radiograph shows miliary shadowing. The severe acute forms of the disease are most likely to concern intensivists, but there is an oropharyngeal form with ulceration of the septum and turbinate and a blood-stained mucopurulent discharge and a macropapular or pustular rash similar to smallpox. In the chronic form, glanders can produce chronic lymphadenopathy, multiple musculocutaneous abscess formation, and oropharyngeal nodules. The first-line treatment of glanders is an antibiotic combination (co-amoxiclav and sulfadiazine, 30 mg/kg every 8 hours for 3 weeks). Doxycycline, rifampicin, and ciprofloxacin are second-line drugs. No vaccine against glanders exists.

Viral Diseases Regarded as Potential Biological Warfare Hazards

Numerous viral illnesses are considered to be potential biological warfare agents. They are the province of the specialized infectious disease physician, and the anesthesiologist is referred to specialized texts for a broader discussion.

Of the potential listed agents, smallpox is placed high on the potential terrorist hazard list because of the continuing presence of laboratory stocks of virus, which is normally promulgated only through human hosts. The success of the worldwide vaccination campaign led the World Health Organization to declare smallpox an extinct disease, and mass vaccination programs were stopped. Laboratory studies continued, however, and there is a fear at present that strains could be stolen and used to create a deliberate widespread epidemic in a largely unprotected population. Intensive care may be required for cases contracting overwhelming secondary infection. Although treatment is based on isolation and supportive therapy, there is current interest in the use of the antivirals cidofovir and ribavirin.[92]

Involvement of the Anesthesiologist in the Management of Casualties from Chemical and Biological Warfare Agents

Approaches to Management of Chemical and Biological Warfare Incidents

Anesthesiologists may be confronted with the management of victims from the deliberate or accidental release of CBW hazards inside and outside the hospital. It is important to have a system of management of such cases that allows for the safety of the medical responders and provides the correct treatment for the patient. Given the risks associated with CBW release, management should be considered in terms of (1) management of the incident and (2) management of the patient's condition. In terms of the four properties of agents in the CBW spectrum (see the section on agents of chemical and biological warfare—background and development), management of the incident is determined by persistency and transmissibility, and management of the patient's condition is determined by toxicity and latency.

Many chemical hazards have limited persistency, and decontamination is not required. "Limited persistency" means reduced risk of contact transmission to other individuals. Certain chemical agents have long persistency, however, and high transmissibility. Many such agents do not pose a significant threat by inhalation, but may be absorbed through the epithelia (e.g., nerve agent VX). For such agents, careful decontamination is essential.

Most classic biological warfare agents have low persistency, and are rapidly degraded by the environment and depend on host transmission via an incubation period. In such cases, transmissibility is high. Anthrax is a notable exception; its spores have very long persistency, but no infective transmissibility. At the other extreme, the viral hemorrhagic fevers have very short persistency, but high infective transmissibility.

Management of the Incident

Disaster planning, which is a process familiar to many anesthesiologists, provides a good model of how to approach toxic releases. A toxic release is a special case of disaster and may be either accidental or deliberate. Plans put in place for a terrorist release of a CBW agent would be equally valuable for the more likely case of accidental release. Moles[93] summarized the essential points of disaster planning as follows:

1. The importance of risk assessment—not all listed hazards are identifiable risks.
2. Preplanning—this essential stage should bring together all the different emergency agencies, such as fire, civil defense, and police, that would be involved in CBW incident management.
3. The importance of a phased response, based on exercises and assessment.

Personal Protection

Protection is a key feature of incident management, and anesthesiologists should be familiar with personal protection levels (Table 74-7) and protective suits and masks, and with techniques of decontamination. As Table 74-7 shows, several levels of protection are used in the management of toxic releases, but the appropriate level for medical intervention is level C, which allows reasonable tactile dexterity and contact with the patient to provide essential life support and antidote therapy on site.[21] Level C protection (Fig. 74-9) is equivalent to that used by the military to provide protection against the most toxic chemical warfare agents and virulent biological warfare organisms.

Table 74-7 Levels of Personal Protection in HAZMAT Incidents

Level A
Positive-pressure SCBA
Fully encapsulating chemical-resistant suit
Double layer of chemical-resistant gloves
Chemical-resistant boots
Airtight seal between suit and gloves and boots
Level B
Positive-pressure SCBA
Chemical-resistant, long-sleeved suit
Double layer of chemical-resistant gloves
Chemical-resistant boots
Level C
Full-face air-purification device (respirator)
Chemical-resistant suit
Chemical-resistant outer gloves
Chemical-resistant boots
Level D
Equipment does not provide specific respiratory or skin protection and usually consists of regular work clothes

SCBA, self-contained breathing apparatus.

Detection and Identification of the Hazard

In contrast with military CBW releases, civil incidents may not provide early information about the nature of the hazard. Patterns of signs and symptoms manifesting in victims may be the first indication of the nature of the causative agent. Detection and monitoring devices for established military chemical warfare hazards exist, but are not widely available in the civil context. Intelligence information may be available for terrorist attacks. In the case of accidental toxic agent release, information would be available from the HAZMAT system and the appropriate identification codes.

Early Patient Management after Chemical and Biological Warfare Release

If the released hazard is persistent and transmissible, decontamination is essential in the decontamination zone. In some countries, level C–protected medical staff or paramedics can now operate in this area and work alongside fire personnel in providing (1) triage, in terms of whether or not the patient requires decontamination and the patient's medical status; (2) immediate life support measures (TOXALS); and (3) immediate antidote and other pharmacologic support.

Figure 74-10 shows a medically operated chemical warfare casualty reception facility at a Parisian hospital. The importance of early life support measures in the decontamination zone has been recognized by many emergency services.[94] The concept of *TOXALS*, introduced in 1996,[95] expands the familiar *ABCs* of life support to relate to toxic releases as follows:

*A*irway of the casualty must be maintained at all times. In an unconscious patient, this may involve simple basic airway maneuvers plus suction of the copious secretions associated with chemical poisoning. Occasionally, there may be a requirement for advanced airway management, such as tracheal intubation, to protect the airway from the excessive secretions and to prevent aspiration of regurgitated stomach contents.

*B*reathing must be carefully observed until full decontamination and recovery have occurred. Supplemental oxygen speeds the recovery from volatile chemical poisoning. If breathing becomes compromised, it must be supported by

Figure 74-9 Civil (**A**) and military (**B**) level C protective respirators and suits. *(Courtesy of Service d'Aide Médicale Urgente [SAMU] de Paris, France.)*

Figure 74-10 Special triage, decontamination, and resuscitation center set up at a Parisian teaching hospital. *(Courtesy of Service d'Aide Médicale Urgente [SAMU] de Paris, France.)*

artificial ventilation with supplemental oxygen using a self-inflating resuscitation bag-valve-mask or automatic ventilator. Entrained air must be filtered when ventilating casualties in a contaminated environment.

*C*irculation must be carefully observed and monitored. Noninvasive blood pressure, pulse oximetry, and electrocardiogram monitoring all are useful indicators of circulatory function. The early establishment of intravenous access aids the administration of fluids and drugs.

*D*isability (conscious level) should be assessed using the simple *AVPU* scale (*A*lert, responds to *V*oice, responds to *P*ain, *U*nresponsive). This assessment should be repeated at frequent intervals to assess the progress of the casualty.

*D*rugs, especially the specific antidotes, should be administered when a specific agent has been identified.

*E*xposure of the casualty is essential not only to assess physical damage, but also to remove all clothes that have been contaminated by the chemical. Approximately 80% of surface contamination is removed by undressing.

*E*nvironment. The primary management as described may be severely limited by the need of the rescuer to wear protective clothing. Only individuals skilled in these techniques and trained in protective clothing should enter and treat casualties in a contaminated area. All others should await the casualties' arrival in cold/clean zone, following decontamination.

The identification of the chemical and its specific antidote might take some time. This situation must not delay the basic medical management of the casualty, however.

Somatic Systems Affected by Toxic Hazards

Early patient management is based on (1) identification information and (2) the presenting signs and symptoms. Usually, information is available to help with identification of the agent used. On the basis of presenting signs and symptoms, it is useful to consider attacks on the various systems as guide to the agent used (Table 74-8). A wide range of chemical agents affect the respiratory system and are summarized in Table 74-9.

Problems in Chemical and Biological Warfare Incident Management

The numerous recognizable problems in the medical management of CBW incidents include the following:

1. Failure to recognize CBW release
2. Failure to implement appropriate HAZMAT procedures to limit the number of secondary casualties
3. Release of the agent overwhelming the available emergency and medical resources
4. Insufficient planning and training
5. Lack of appropriate protective equipment
6. Lack of resuscitation skills for early life support
7. Lack of specific knowledge for the management of toxic or infectious hazards
8. Panic and hysterical reactions from a frightened general public fueled by irresponsible reporting

These problems may be minimized by careful planning, equipping, and training, with the objective of making a CBW release manageable in the same sense as for other mass disasters.

Effects of Chemical and Biological Warfare Agents on Anesthetic Practice

Management of Mixed Toxic and Physical Injury

Chemical warfare and HAZMAT release may be accompanied by explosion and fire causing associated injuries requiring surgical intervention. The effects of the release agent on the subsequent

Table 74-8 Effects of Chemical and Biological Warfare Agents on Somatic Systems

System Affected	Agents
Epithelial	Vesicants (e.g., sulfur mustard), smallpox, ricin
Respiratory	
Upper, lower airway	Vesicants, phosgene
Respiratory control system	Nerve agents, ABO
Gaseous exchange	Pulmonary edemagens
Mechanics of breathing	Nerve agents, neurotoxins
Central nervous system	Nerve agents, cyanide, neuropeptides, agents of anesthetic origin (phencyclidines, BZ)
Peripheral nervous system	Nerve agents, neurotoxins (e.g., botulinum, saxitoxin)
Immune system	Vesicants, ABO (provocation of immune responses, inflammatory responses, organ failure)
Cardiovascular	Nerve agents, ABO
Alimentary, renal	Nerve agents, toxins, infectious agents

ABO, agents of biological origin.

Table 74-9 Effects of Toxic Agents on Respiration

Respiratory Component	Effect	Toxic Agent
Central nervous system	Depression of respiratory drive and convulsions leading to apnea	Nerve agents, cyanide, neuropeptides
Peripheral nervous system	Neuromuscular paralysis of respiratory muscles	Nerve agents, neurotoxins
Nasopharynx	May become blocked by excess secretions Prodromal rhinitis and rhinorrhea Sneezing	Lung-damaging agents, nerve agents Vesicants Early symptom of mustard
Larynx	Irritation, laryngeal spasm	Upper respiratory irritant, lung-damaging agents Riot-control agents, particularly CS and CR (tear gas)
Large airways	Blocked by secretions Blocked by inhaled vomitus Sloughing of walls of trachea and main bronchi, produces "pseudodiphtheritic" membrane, serious cause of large airway obstruction, leading to bronchopneumonia and death	Nerve agents (theoretical) Various agents Nerve agents
Small airways	Blocked by secretions Cholinergic innervation affected; bronchospasm (relieved by atropine) Chemical bronchiolitis, followed by serious bronchospasm	 Nerve agents Mustard agents
Alveoli	Toxic pulmonary edema	Various agents, especially lung-damaging agents (latency 6-24 hr) Vesicant agents, particularly if inhaled at high ambient temperature*

*Data from Willems JL: Clinical management of mustard gas casualties. Ann Med Mil Belg 3(Suppl):1-61:47, 51, 1989.
From Baker DJ, Rustick JM: Anesthesia for casualties of chemical warfare agents. *In* Zaitchuk R, Grande C (eds): U.S. Army Textbook of Military Medicine, part IV, vol I. U.S. Department of the Army, Office of the Surgeon General Borden Institute, Washington, DC, 1995, pp 833-856.

conduct of general anesthesia are important. Many of the agents described earlier affect the condition of the patient and the action of anesthetic agents.

Effects on the Condition of the Patient

Shock and toxic airway injury can produce ventilation-perfusion inequality, which affects preoxygenation for emergency induction. The respiratory uptake of anesthetic vapors and alveolar ventilation itself are affected by degrees of shunt and pulmonary edema. Above all, the action of toxic agents may be expected to alter the balance and flow of general anesthesia and may cause delays in recovery, which would be manpower-intensive in management. In terms of postoperative intensive care, patients who have been exposed to pulmonary edemagens and to OPs may pose the greatest problem.

Intensive Care Implications

Exposure to chemical warfare agents may give rise to numerous syndromes that have already been mentioned that require medium-term or long-term ICU treatment. These include pulmonary edema and acute respiratory distress syndrome. In the case of OP exposure, there may be a possibility of developing the intermediate syndrome,[96,97] with a reparalysis of the patient requiring several days of ventilation. Experience with OP anticholinesterases in this area is lacking, although there is considerable evidence from pesticide poisoning.

Many of the infectious agents that are considered as biological warfare agents could give rise to infections that cause an overwhelming inflammatory response and organ dysfunction. Although the management of the infections caused by biological warfare agents is the domain of the specialized physician, intensive care is required for cases of systemic inflammatory response syndrome and multiple organ dysfunction syndrome. The continued possibility of an avian flu pandemic has highlighted the need to provide simple mass ventilation systems in high-dependency units. In such units, patients can be ventilated using simpler machines than the ones found in the ICU and that can be operated by non-ICU personnel. Mass procurement of devices and training is necessary. The ability of hospitals to provide intermittent positive-pressure ventilation for large numbers of casualties is a necessary step in managing not only respiratory epidemics, but also the consequences of the numerous CBW agents considered in this chapter in which respiratory failure is the end stage of the pathology.

75 Anesthesia for Eye, Ear, Nose, and Throat Surgery

Key Points

Ear, Nose, and Throat

1. Patients can present with an acute onset of stridor from various conditions, including epiglottitis, laryngotracheobronchitis, inhaled foreign bodies, angioneurotic edema, tracheitis, burns, and bilateral vocal cord palsies after surgery.
2. Facial injuries can produce severe bleeding with the aspiration of blood, bone, loose teeth, and soft tissue fragments, so the priority is to clear and secure the airway.
3. For ear surgery, several anesthesia and airway management devices are available, all of which offer different advantages and disadvantages.
4. Bleeding from a tonsil after surgery usually occurs within the first 6 hours.
5. The optimal anesthetic technique for endoscopy procedures depends on the patient's general condition; the size, mobility, and location of the laryngeal lesion; the use of a laser; and surgical requirements.

Eye

1. Understanding ocular anatomy and physiology and the systemic effects of ophthalmic medications is essential to prepare an appropriate anesthesia plan.
2. Pressure on the globe or any orbital contents can result in a trigeminovagal or oculocardiac reflex with bradycardia, atrioventricular block, or asystole.
3. The blood supply to the retina is driven by the ocular perfusion pressure, which is determined by the arterial blood pressure and the intraocular pressure (IOP).
4. Deep inhaled anesthesia reduces IOP, whereas ketamine and succinylcholine can increase IOP.
5. Sudden increases in IOP in the setting of open globe injury can lead to vitreous loss and blindness.
6. Complications of retrobulbar block include retrobulbar hemorrhage, increased IOP, intra-arterial injection with convulsions, and subarachnoid injection via the optic nerve sheath with respiratory arrest.
7. Nitrous oxide should be avoided for 15 minutes before the use of intraocular gas. Nitrous oxide must be avoided for 7 to 45 days after use, or until the gas bubble is resorbed.
8. True ophthalmic emergencies, such as chemical burns and central retinal artery occlusions, must be treated within minutes to avoid permanent vision loss. Open globe injuries and other urgent procedures can be scheduled after appropriate NPO status.
9. Eye compression from a facemask or positioning can lead to central retinal artery occlusion.

General Principles of Ear, Nose, and Throat Surgery

Anesthesia for ear, nose, and throat (ENT) surgery encompasses a range of operations varying in duration, severity, and complexity from high-volume cases, such as myringotomy, tonsillectomy, and simple nasal procedures, to complex procedures in head and neck cancer patients. Probably in no other branch of surgery is the requirement for understanding between the surgeon and the anesthesiologist greater than in "shared airway" procedures, and careful planning, preoperative evaluation, and close cooperation are essential.

Airway Safety and Maintenance

The provision of a clear, free, and unobstructed airway is the principal concern for all ENT procedures. Numerous factors have an impact on the ability to maintain a safe and patent airway, and careful attention is mandatory during the whole procedure, including cessation of surgery if necessary. Chapter 50 contains a

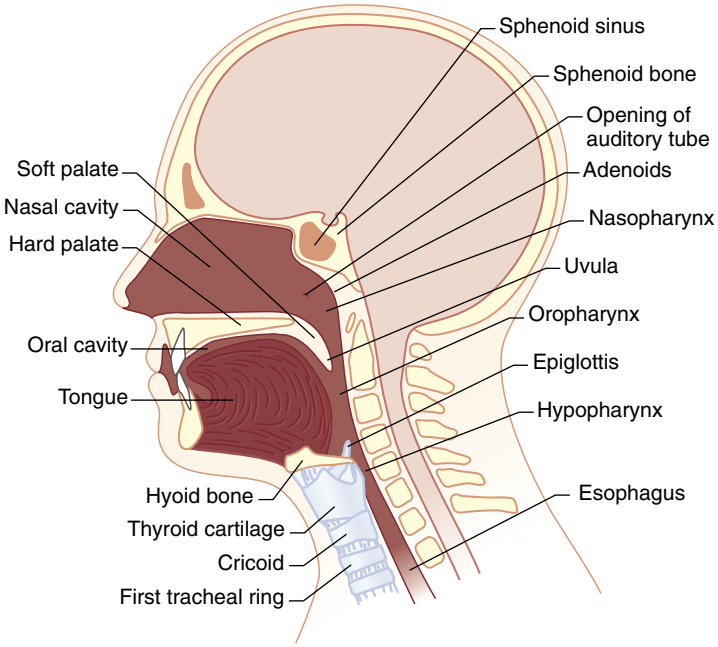

Figure 75-1 Anatomy of nasal cavity, oral cavity, nasopharynx, oropharynx, and hypopharynx.

thorough discussion of airway anatomy and management (Figs. 75-1 to 75-3).

Factors affecting airway safety and maintenance may be classified into the following four groups:

1. *Patient factors*: Patients may present with distorted upper airway anatomy or airway obstruction.
2. *Remote surgery*: After surgery has begun, the anesthesiologist is remote from the airway, making adjustments more difficult and disruptive.
3. *Surgical factors*: Significant lateral rotation of the head may be required for ear procedures, and head extension may be required for neck procedures. During intraoral procedures, instruments to keep the mouth open may obstruct the airway. For nasal and intraoral surgery, the airway requires protection from blood and secretions.
4. *Shared airway*: Shared airway procedures involving surgery of the glottis, subglottis, and trachea require an understanding of specialist equipment, techniques, and laser safety.

Physiology

Vocal Cord Palsy

Nerve damage can result from surgical trauma during operations on the thyroid gland, operations on the parathyroid glands, anterior approaches to the cervical spine, neck procedures, and left-sided thoracic procedures. Short-duration tracheal intubation for peripheral elective surgery is associated with unilateral vocal cord palsy, which has an incidence of approximately 1 per 1000 procedures.[1]

The superior laryngeal nerve provides innervation to the cricothyroid muscle, which tenses the vocal cord. Superior laryngeal nerve injury results in a loss of tension, with the vocal cord appearing wavy, or at a lower level during inspiration and a higher level during expiration. Bowing of the true vocal fold, prolapse of the false vocal fold, and altered waveform on videostroboscopy are seen with this injury. Patients are at a higher risk of aspiration because of their sensory deficit and have a lower pitched, weak, monotonous, and easily tired voice.[2]

The recurrent laryngeal nerve provides innervation to all the other intrinsic muscles of the larynx, including the only abductor of the vocal cords, the posterior cricoarytenoid. The recurrent laryngeal nerve supplies abductor fibers (posterior cricoarytenoid) and adductor fibers to the other intrinsic laryngeal muscles. The abductor fibers within the recurrent laryngeal nerve are more sensitive and vulnerable to trauma than the adductor fibers. A partial injury to the recurrent laryngeal nerve can produce a pure abductor paralysis, whereas complete transection of the recurrent laryngeal nerve produces an abductor and adductor fiber injury.[3] This variable sensitivity of the recurrent laryngeal nerve to either abductor injury or abductor and adductor injury accounts for the different clinical presentations of patients with nerve damage.

With a partial injury of the nerve in which only the abductor fibers have been damaged, the vocal cord on the affected side remains in the midline on phonation and inspiration, while the nonaffected vocal cord moves (adducts). With a complete unilateral palsy of the recurrent laryngeal nerve, abductor and adductor fibers are affected. In this case, the vocal cord assumes a paramedian position with the vocal cord neither abducted nor adducted. In this situation, on phonation the unaffected vocal cord crosses the midline to meet the affected vocal cord, and on inspiration the unaffected vocal cord moves to full abduction.

A bilateral complete recurrent laryngeal nerve palsy (affecting abduction and adduction) results in both vocal cords adopting a paramedian position. A partial bilateral recurrent laryngeal nerve palsy involving only the abductor fibers can result in bilateral adducted vocal cords, an inability to open the vocal cords on inspiration, serious compromise to airflow, and a critically obstructed airway, which may require immediate intervention. Bilateral incomplete palsy is more dangerous than complete palsy.[3]

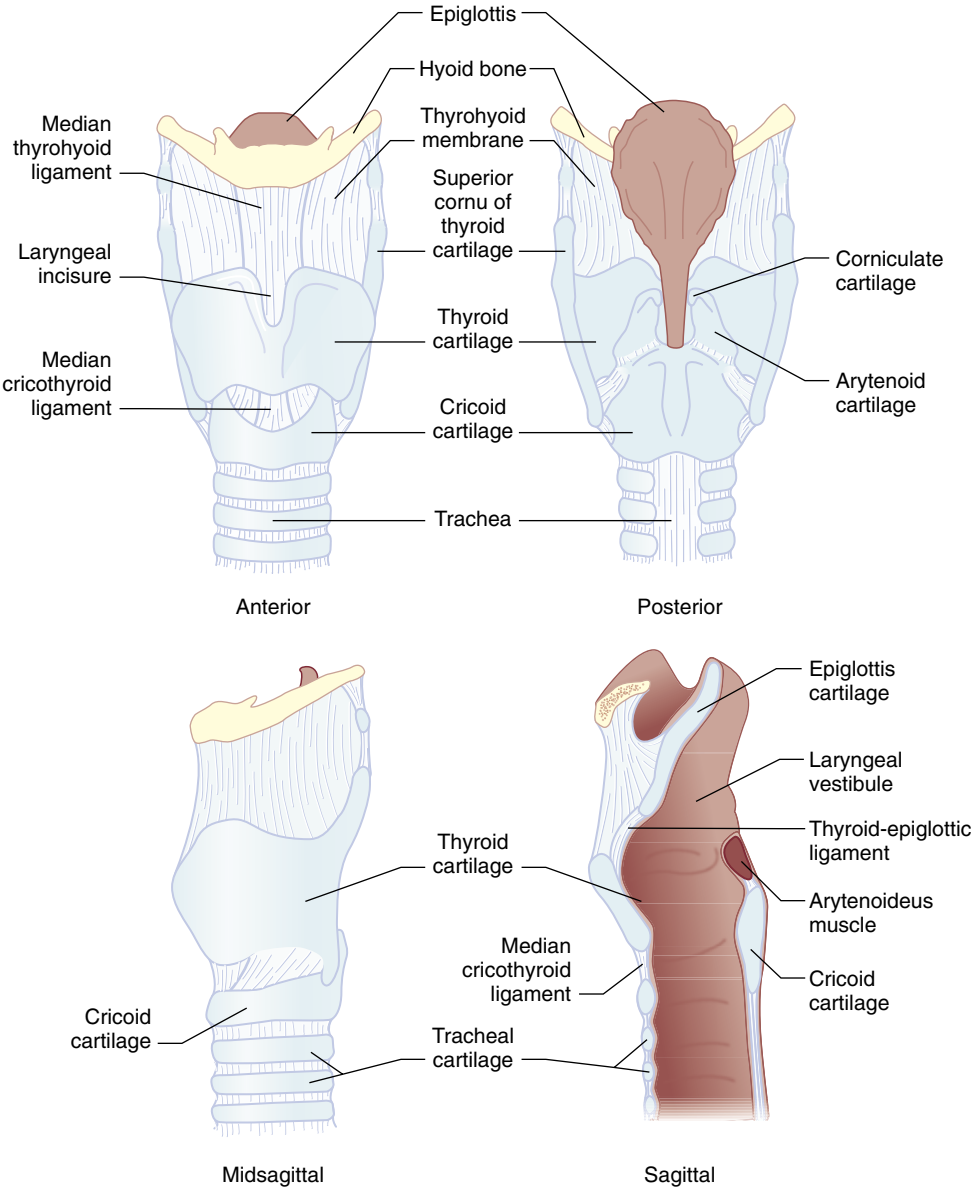

Figure 75-2 Schematic representation of the anatomy of the larynx: anterior, posterior, midsagittal, and sagittal views.

Laryngospasm

Laryngospasm is an exaggeration of the normal glottic closure reflex that persists long after the removal of the stimulus.[4] Reflex glottic closure is a dominant and stable reflex produced by the stimulation of the superior laryngeal nerve. Laryngospasm is an exaggeration of this response stimulated by the presence of blood, secretions, or surgical debris, particularly in the presence of a light plane of anesthesia. During light planes of anesthesia, buccal, pharyngeal, laryngeal, and upper abdominal stimulation or manipulation; smell; and nasal irritation all have been implicated in the production of laryngospasm. Laryngospasm is more common after upper airway procedures, particularly ENT procedures in which blood, secretions, and surgical debris are present. Typically, laryngospasm manifests with stridor that can proceed to complete airway obstruction and requires an immediate response. Strategies to reduce the incidence of postextubation laryngospasm, particularly in children undergoing ENT procedures, include intravenous lidocaine,[5] topical lidocaine,[6] intravenous magnesium,[7] and "deep" extubation.[8]

The management of laryngospasm involves immediate suctioning to remove obvious blood and secretions from the airway and the application of a tightly held facemask with 100% oxygen acting as a pneumatic splint to keep the airway open. Larson's maneuver, a forcible jaw thrust with bilateral digital pressure on the body of the mandible just anterior to the mastoid process, known as Larson's point, may resolve laryngospasm by clearing the airway and stimulation.[9]

The general principle for the management of laryngospasm is to apply 100% oxygen with either positive end-expiratory pressure or continuous positive airway pressure acting as a pneumatic splint. Any obvious secretions are suctioned out, and these maneuvers are used as a holding point to allow the patient's depth of anesthesia to lighten and the laryngospasm to resolve. If these holding maneuvers fail to provide enough airflow, and oxygen

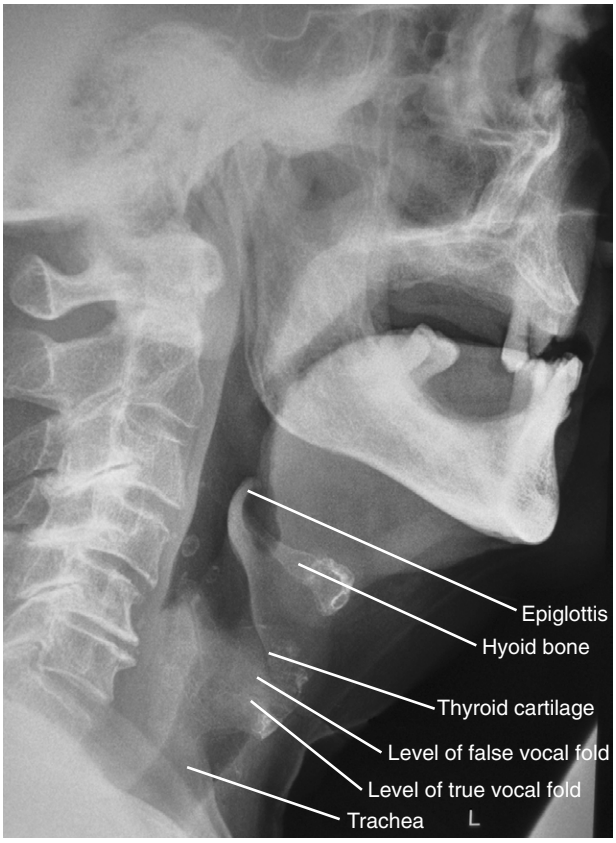

Figure 75-3 X-ray of larynx anatomy.

desaturation starts to occur, an increase in the depth of anesthesia is required with intravenous propofol or other intravenous drugs to diminish the exaggerated glottic closure reflex causing the laryngospasm. If, despite the application of 100% oxygen, positive end-expiratory pressure or continuous positive airway pressure, and intravenous agents, the laryngospasm continues, and oxygen saturation levels continue to decrease, a small dose of succinylcholine (0.1 to 0.5 mg/kg) should be considered. If laryngospasm does not resolve, other causes of postextubation stridor need to be assessed for, including laryngomalacia, tracheomalacia, vocal cord paralysis, airway edema, hematoma, soft tissue obstruction, and the presence of foreign material such as throat packs.

The incidence of laryngospasm is greater in children than in adults, and hypoxia develops more rapidly. This is a particular problem for children undergoing ENT procedures, requiring vigilance and immediate treatment.

Stridor

Stridor is a noisy, high-pitched, predominantly inspiratory sound from turbulent airflow secondary to upper airway obstruction and can be a medical emergency requiring immediate intervention. The initial management is the same regardless of the cause; 100% oxygen should be administered by a facemask with the patient sitting upright and nebulized, with racemic epinephrine, 1 mg of a 1 : 1000 solution (1 mL) in 5 mL of 0.9% saline, repeated every 30 minutes with monitoring. Epinephrine works by droplet deposition on inflamed swollen mucosa and its intense vasoconstrictor actions. Dexamethasone, 0.1 mg/kg intravenously every 6 hours, helps reduce airway edema, but takes 4 to 6 hours to work. Heliox (70% helium, 30% oxygen) greatly increases flow for any given pressure gradient, or allows the same flow for a smaller pressure gradient. In contrast with laminar flow, in which resistance depends on gas viscosity during turbulent flow, resistance depends on gas density. Heliox leads to a dramatic decrease in airway resistance and improvement in ventilation. The higher the concentration of helium in the mixture, however, the lower the F_{IO_2}.

Patients can present with an acute onset of stridor from various conditions, including epiglottitis, laryngotracheobronchitis, inhaled foreign bodies, angioneurotic edema, tracheitis, burns, and bilateral vocal cord palsies after surgery. Typically with acute-onset stridor, as the airway diameter decreases, a noisy inspiratory stridor is audible, and in a typical adult this is most pronounced as the airway diameter reaches about 4 mm. In chronic stridor, the patient slowly compensates for the reduction in airway diameter; it is possible to have a patient with an airway diameter of 3 to 5 mm, who at rest appears to have no stridor, although stridor becomes obvious on simple exertion. Although the presence of stridor in an acute setting is always an alarming sign, its absence does not imply the airway is not compromised. Chronic causes of stridor include subglottic stenosis, laryngomalacia, malignancy, mediastinal masses, webs, cysts, and vascular malformations.

Trauma (see also Chapter 72)

Airway Trauma

Trauma to the airway can result from blunt or penetrating injuries, burns, inhalational injury, and iatrogenic trauma. The initial response is influenced by the degree of airway compromise (Figs. 75-4, 75-5, and 75-6), and patients with obvious respiratory distress need immediate intervention to secure a patent airway. Immediate airway control may involve orotracheal intubation, intubation through a large open wound in the airway, or an emergency surgical airway, under local anesthesia. Fiberoptic intubation can be extremely difficult, or may not be possible when severe airway distortion is present with swelling, edema, and bleeding. Orotracheal intubation should be performed by an experienced practitioner, with the help of a skilled assistant.

In blunt laryngeal trauma, cricoid pressure may result in cricotracheal separation and should be avoided. A high index of suspicion should be maintained when assessing and observing patients with laryngeal trauma because late diagnosis and intervention can result in poor airway and voice outcome.[10] Symptoms that suggest laryngeal trauma include dyspnea, dysphonia, odynophagia, pain, dysphagia, and hoarseness.[11,12] Careful, gentle assessment should be undertaken to avoid accidental dislodgment of unstable cartilage fragments, which may cause further airway compromise. Examination may reveal abrasions over the anterior neck, subcutaneous emphysema, stridor, hemoptysis, bruits, loss of palpable landmarks, and signs of a pneumothorax. Flexible fiberoptic laryngoscopy may reveal edema, hematoma, and abnormal vocal cord position.

Patients with neck trauma who are hemodynamically unstable or who have an obvious injury to the aerodigestive tract require urgent surgery.[13] Iatrogenic trauma,[14] resulting in cricoarytenoid joint dysfunction,[15] vocal cord palsy,[1] granuloma formation, hematoma, or subglottic stenosis, is a significant cause of morbidity after routine tracheal intubation.[16]

Facial Trauma

Facial injuries to the mandible, injuries to the midface, and Le Fort I, II, and III fractures can produce severe bleeding with the risk of aspiration of blood, bone, loose teeth, and soft tissue fragments. Clearing and securing the airway is the priority, but this may be complicated by cervical spine, vascular, and head injuries. Unilateral mandibular fractures are usually stable, whereas bilateral mandibular fractures are unstable.

Ear Surgery

Types of Ear Surgery

Operations on the ear range from high-volume, short-duration procedures such as myringotomy and ventilation tube placement to long, complex procedures such as mastoidectomy or skull-based procedures requiring ENT and neuroanesthetic attention. Ear procedures can be divided into external, middle ear, mastoid, and inner ear procedures.

External Ear

External ear procedures can be done under general or local anesthesia, and involve removal of simple lesions, foreign bodies in the external auditory canal, preauricular abnormalities, and exostoses and complex reconstruction of the external auditory canal.

Middle Ear and Mastoid

In children, otitis media can result in middle ear effusions with hearing loss and may require repeated procedures for fluid drainage and tube placement to allow ventilation of the middle ear. This is the second most common procedure undertaken in children,[17] and is often done with adenoidectomy or tonsillectomy, the most common procedure in children, or both.

Chronic infections can lead to a perforation of the tympanic membrane and damage to the middle ear ossicles, and with cholesteatoma can erode bone, spreading into the mastoid cavity, inner ear, lateral sinus, meninges, and brain. Facial nerve paralysis and intracranial extension is rare, but in the past this was a common cause of morbidity after chronic ear infections.

Myringoplasty involves the closure of a persistent perforation in the tympanic membrane using a graft of tissue from the temporalis muscle and fascia. A tympanoplasty involves a more extensive repair to the tympanic membrane and reconstruction of the damaged underlying ossicular chain. Stapedectomy involves the removal of a damaged stapes resulting in a conductive hearing loss and replacement by a prosthetic implant. Damage to the stapes results from otosclerosis, an inherited condition in which new bone formation occurs at the base of the stapes. A stapedectomy can be done under general anesthesia or with sedation in suitable patients and usually involves the use of a laser. A mastoidectomy is done to remove cholesteatoma and chronic infections and as part of a more complex procedure to allow surgical access to deeper structures.

Inner Ear

Inner ear procedures require complex specialist surgical intervention and include operations on the cochlea, endolymphatic sac, and labyrinth. Cochlear implants are used for patients with sensorineural hearing loss and are now being placed in increasingly younger children. Patients with disorders of the labyrinth and endolymphatic sac, such as Meniere's disease, can have severe vertigo and hearing loss. With all ear procedures, patients are more prone to nausea and vomiting perioperatively, but with inner ear disorders, this can be particularly difficult to treat.

Anesthesia for Ear Surgery

Local Anesthesia

Local anesthesia with or without sedation can be undertaken safely in suitable patients. Preoperative assessment and intraoperative monitoring should be the same as for general anesthesia. The choice of local anesthetic with or without sedation or general anesthesia depends on numerous factors, including patient cooperation, duration of procedure, patient preference, patient understanding, and surgical preference. Simple external ear and some middle ear procedures involving the tympanic membrane and stapes are suitable for local anesthesia with or without sedation. Patient understanding and cooperation are vital to prevent sudden movements at critical stages of the surgery, and usually most young children and uncooperative adults require a general anesthetic.

Light sedation during these procedures can be achieved by careful bolus doses of midazolam, titration or infusion of propofol, and, more recently, careful titration with an infusion of remifentanil. Local anesthetic can be administered by infiltration with lidocaine and epinephrine, topical instillation of lidocaine onto the tympanic membrane, and, more recently, topical application of EMLA cream onto the tympanic membrane.

Nerve Block

The sensory nerve supply of the ear comes from the auriculotemporal nerve, greater auricular nerve, auricular branch of the vagus nerve, and tympanic nerve. Local anesthesia involves infiltration of the anterior and posterior external meatal wall blocking the auriculotemporal and greater auricular nerve. Infiltration through an aural speculum blocks the auricular branch of the vagus, and topical infiltration of local anesthetic on the tympanic membrane blocks the tympanic nerve.

General Anesthesia

Nearly all surgery on the external, middle, and internal ear requires the use of an operating microscope, where movements, coughing, and straining are greatly magnified. Access to the airway during the procedure is limited, and a safe, unobstructed airway is essential. A thorough preoperative assessment, as for any general anesthetic, should be undertaken with specific attention paid to hypertension or other cardiovascular disease, which contraindicates or limits attempts to control blood pressure intraoperatively.

For most ear procedures, usually no specific preoperative medication is required. Anxiolytics, such as temazepam, are useful for anxious patients. Preoperative β-blocking drugs and clonidine have been used in the past as premedicants, but are not used commonly now. If β-blockade or clonidine is required, it can be given intravenously with intraoperative monitoring. Specific issues relating to general anesthesia for ear surgery are the choice of airway, use of nitrous oxide, head and body position, facial

nerve monitoring, adequate surgical field, nausea and vomiting, duration, deep vein thrombosis prophylaxis, and temperature control, and these are considered later.

Airway—Facemask, Tracheal Tube, or Laryngeal Mask Airway (see also Chapter 50)

The choice of facemask, tracheal tube, or laryngeal mask airway (LMA) depends on the duration of surgery, experience of the anesthesiologist, and patient factors (Fig. 75-7).

Facemask

Historically, a facemask was used for simple, short ear procedures, such as myringotomy and tube insertion. The patient retained spontaneous ventilation, but this required the anesthesiologist to hold the facemask and the surgeon to "work around" the anesthesiologist's hands and the facemask. Most of these short-duration procedures are now undertaken with an LMA. The quality of airway management with an LMA is superior to a facemask with better oxygenation,[18,19] improved seal with less oropharyngeal air leaks,[20,21] better monitoring of tidal gases particularly at low flow,[22] and less pollution.[23-25] Patients with features that make facemask ventilation difficult, such as beards, edentulism, and facial burns,[26-28] also are better managed with an LMA.

Tracheal Tube

For most long-duration procedures, a reinforced or armored tracheal tube is used to prevent kinking or partial compression with head rotation. Alternatively, south-facing preformed tracheal tubes are used. The advantages of using a tracheal tube are familiarity with its use and the ability to secure the airway and provide airway protection from above (debris and blood) and below (regurgitated gastric contents) during spontaneous and positive-pressure ventilation.

Laryngeal Mask Airway

Laryngeal mask airways also are used in ear surgery. The Flexible LMA (Laryngeal Mask Airway Company, San Diego, CA) is designed for ENT procedures. For minor ear surgery, the LMA has specific advantages over facemask ventilation, as has been discussed. The Flexible LMA has a flexible shaft and is better suited and tolerant to head rotation and flexion and extension during surgery. For longer duration procedures, a Proseal LMA (Proseal LMA North America, San Diego, CA) with a gastric drain tube and superior airway seal characteristics has allowed major ear surgery for 5 hours.[29]

Nitrous Oxide

Nitrous oxide diffuses from blood to airspaces within the body; the amount depends on the concentration of nitrous oxide and

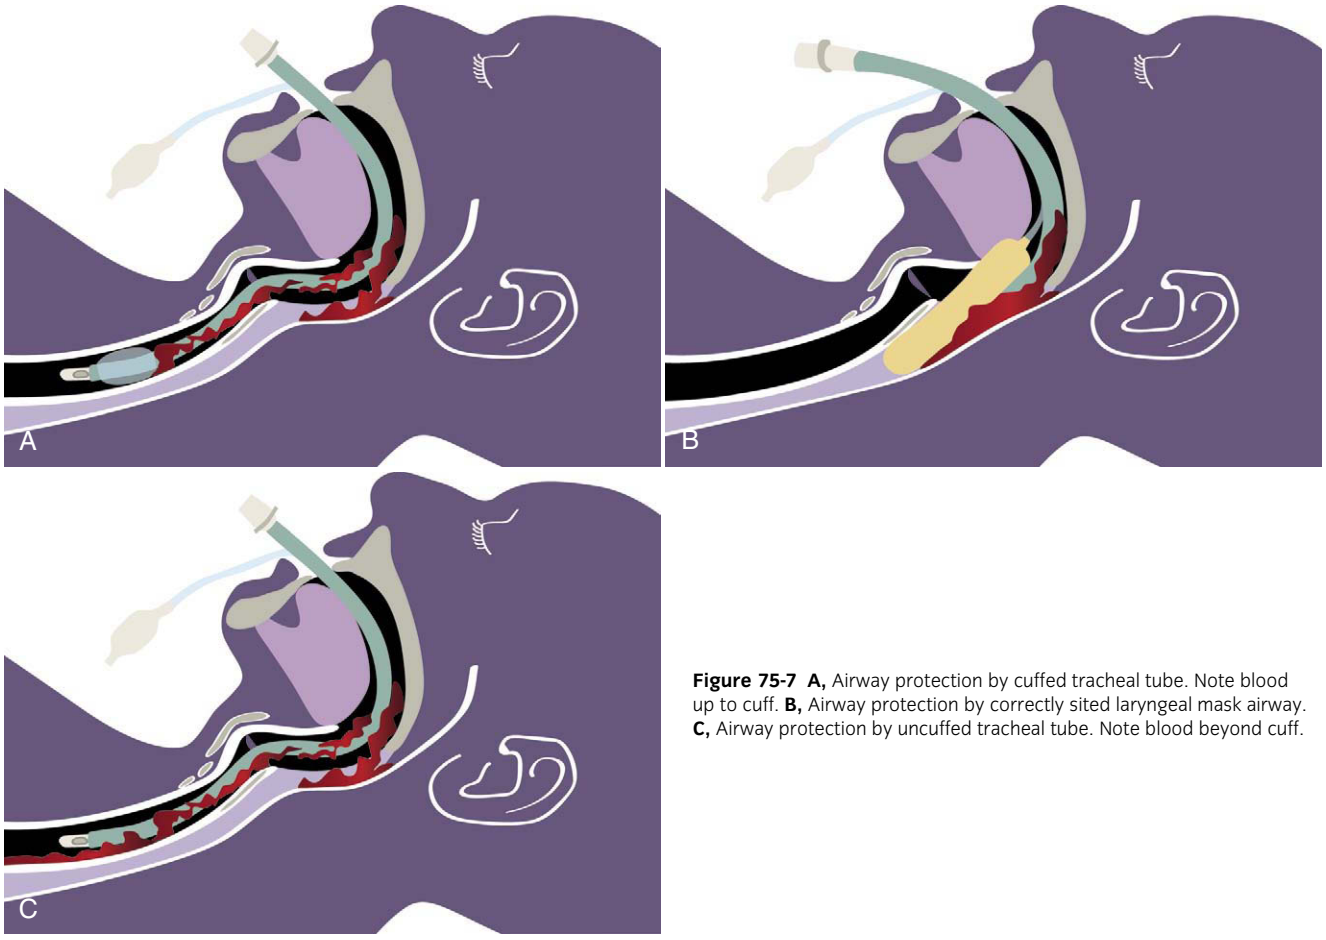

Figure 75-7 **A,** Airway protection by cuffed tracheal tube. Note blood up to cuff. **B,** Airway protection by correctly sited laryngeal mask airway. **C,** Airway protection by uncuffed tracheal tube. Note blood beyond cuff.

the duration of anesthesia. As nitrous oxide diffuses into the middle ear cavity, the pressure increases and is relieved only by reabsorption after discontinuation of nitrous oxide at the end of the procedure, or by eustachian tube opening allowing gas to escape into the nasal cavity. At the end of surgery after discontinuation, rapid reabsorption of nitrous oxide can produce negative middle ear pressures, particularly when there is eustachian tube dysfunction resulting in graft displacement. Nitrous oxide can displace grafts by causing the middle ear pressure to be too high or too low.

Early types of surgery to repair the tympanic membrane involved "overlay" grafts, in which a high middle ear pressure would displace and lift up the graft. Most ENT surgeons now use "underlay" grafts, in which increased middle ear pressures can help hold the graft in position. Many anesthesiologists do not use nitrous oxide during ear surgery for these reasons, and instead use a mixture of air and oxygen or limit nitrous oxide concentration to 50%.

Position

Rotation of the head and extension of the neck is necessary for most ear procedures, and measures to prevent significant compression of internal and external jugular veins and the carotid artery in vulnerable patients should be considered. A lateral tilt of the operating table may improve surgical access without the need for extreme head and neck rotation, which may reduce venous compression and improve arterial blood supply. Arms should be placed in a neutral position and well padded. A head-up tilt typically around 15 degrees is useful in reducing venous pressure and improving the operative field.

Facial Nerve Monitoring

Facial nerve monitoring is used during middle ear, mastoid, and inner ear procedures to identify the facial nerve and reduce the incidence of iatrogenic facial nerve injury. Various monitors are used; the general principle involves an audible and visible signal on the monitor to identify when surgical movement or stimulation is close to, or at, the facial nerve. When the nerve is stimulated, electrodes attached to the face detect nerve activity, and the monitor signals. Partial or complete neuromuscular blockade with muscle relaxants reduces or abolishes this nerve activity, and accidental transection of the facial nerve does not generate a signal. It is essential that neuromuscular blockade be stopped or reversed and peripheral nerve function be assessed to ensure adequate neuromuscular function before surgery proceeds in the vicinity of the facial nerve. With the introduction of remifentanil, an adequate depth of anesthesia can be maintained more easily with a tracheal tube in place and no neuromuscular blockade.

Surgical Field

During ear surgery, significant bleeding obscures the surgical field and makes surgery difficult under an operating microscope. Simple measures to limit bleeding and improve the surgical field should be used first. A head-up position to reduce venous pressure and bleeding is often successful. A smooth, balanced anesthetic with adequate analgesia (remifentanil infusion) avoids tachycardia and hypertension, and optimal ventilation avoids hypercapnia. For most patients, these maneuvers are sufficient to improve the operative field; however, additional measures may be needed. Induced hypotension requires a careful assessment of the risks and benefits, and should not be performed on patients with preexisting cardiovascular compromise.

For American Society of Anesthesiologists class I patients, a mean arterial pressure greater than 50 to 60 mm Hg, an intraoperative systolic pressure greater than the preoperative diastolic pressure, and a heart rate around 60 beats/min should provide an adequate surgical field. Drugs used include β-blockers (metoprolol, labetalol), α_2-agonists (clonidine), and opioids (remifentanil).

Antiemetics

Middle ear and inner ear procedures have a greater incidence of postoperative nausea and vomiting than general surgical procedures. Postoperative nausea and vomiting is particularly common after inner ear surgery involving the labyrinth and vestibular nerve. In addition to being unpleasant for the patient, retching and vomiting increase venous pressure, intracranial pressure, and bleeding, and dislodge or disrupt delicate surgical grafts and prosthesis. If possible, opioids should be avoided, the patient should be kept hydrated with intravenous fluids, and prophylactic antiemetics should be administered. Drugs are used alone or in combination; various regimens include serotonin antagonists[30,31] such as ondansetron and granisetron, butyrophenones such as droperidol, anticholinergics such as scopolamine,[32] dexamethasone, and gastrokinetic agents such metoclopramide.

Duration, Deep Vein Thrombosis Prophylaxis, and Temperature Control

The duration of surgery varies from 10 to 20 minutes for simple ear procedures such as myringotomy and tube insertion to 4 hours or more for complex middle ear and inner ear surgery. Standard deep vein thrombosis prophylaxis should be established for all procedures that are not very short duration. Temperature monitoring with avoidance of hypothermia and hyperthermia should be undertaken. For longer surgical procedures, urinary catheterization should be considered.

Recovery

Smooth emergence and recovery from anesthesia are important. Some anesthesiologists advocate changing tracheal tubes to a LMA for a superior recovery profile; this is known as the Bailey maneuver.[33]

Nasal Surgery

Types of Nasal Surgery

Surgery of the nose can be divided into (1) procedures on the external aspect of the nose, (2) procedures within the nasal cavity,

(3) procedures within the nasal sinuses, and (4) procedures involving the bony structures. Fractures of the nasal bones are usually corrected within 10 days when the initial swelling has resolved. If these fractures are corrected later, they can be more difficult to align and cause significant rebleeding. Septal surgery is undertaken to improve airflow through the nasal passages and ventilation of the sinuses. Patients can present with near-total nasal airway obstruction as a result of gross septal deviation blocking one nasal passage, and contralateral inferior turbinate hypertrophy blocking the other passage.[34] Nasal polyps can be single or multiple and cause significant obstruction of airflow within the nasal cavity or sinuses and even total nasal blockage.

Most sinus surgery nowadays is undertaken using endoscopes and is termed functional endoscopic sinus surgery. Intranasal antrostomy and Caldwell-Luc procedures, which allowed access to the maxillary sinuses, generally have been replaced by functional endoscopic sinus surgery.

Local or General Anesthesia

Some nasal procedures can be performed under local anesthesia with or without sedation,[35-37] and others usually require general anesthesia. The choice of general or local anesthetic depends on patient factors and duration, site, and complexity of the procedure. Generally, local anesthesia is suitable for procedures on the anterior septum, septoplasty, turbinectomy, cauterization, simple polypectomy, and reduction of simple nasal fractures. For more complex or longer procedures, including sinus surgery, rhinoplasty, septorhinoplasty, nasolacrimal surgery, frontal sinus surgery, anterior skull base procedures, and craniofacial resections, general anesthesia is preferred. During these procedures, movements under local anesthesia at critical stages of the operation can have serious consequences, causing blindness, carotid artery damage, and intracranial extension.[38]

Small children have a propensity to place foreign material into the nasal cavity. Some material, such as small batteries, can be corrosive to the nasal mucosa and septum and require urgent removal. In uncooperative children, attempts at foreign body removal carry the risk of inhalation of the foreign body, and general anesthesia may be necessary. Ideally, spontaneous ventilation should be maintained to reduce the risk of foreign material entering the lower airway.

Preoperative Evaluation (see also Chapter 34)

Preoperative evaluation and anesthetic assessment should be the same for local and general anesthesia. Specific assessment for obstructive sleep apnea (OSA), use of nasal continuous positive airway pressure, cardiovascular status, and suitability for topical nasal vasoconstrictors should be sought and a history of nonsteroidal anti-inflammatory (NSAID) drug use. Samter's triad, the association of NSAID sensitivity in patients with asthma and nasal polyps, who can have severe life-threatening bronchospasm, should be kept in mind.

Nasal Vasoconstrictors

Nasal vasoconstrictors are commonly used to reduce bleeding from vascular nasal mucosa, and many agents applied alone or in combination are used to vasoconstrict and provide local anesthesia. Some agents, such as cocaine, have local anesthetic and vasoconstrictor properties, and others, such as lidocaine, have local anesthetic properties. Commonly used vasoconstictors include cocaine, epinephrine, and phenylephrine. Cocaine has been used alone and in combination with epinephrine. Phenylephrine has been used in combination with lidocaine, and lidocaine has been used in combination with epinephrine.

Cocaine has a rapid onset of action and excellent vasoconstrictor properties. Small doses are vagotonic, producing a reduction in heart rate, whereas increasing blood concentrations cause tachycardia, hypertension, ventricular tachycardia, and direct cardiac muscle depression, any of which may cause sudden death,[39] myocardial infarction,[40] and ventricular fibrillation.[41] The cardiovascular effects of cocaine are attributed to its ability to block the reuptake of norepinephrine at sympathetic nerve terminals and potentiate sympathetic activity.[39] Cocaine use should be avoided in patients with a history of myocardial infarction, coronary artery disease, congestive heart failure, irregular heart rhythm, and hypertension, and in patients taking monoamine oxidase inhibitors.

Cocaine has been used as a nasal vasoconstrictor in a topical solution, paste or gel, and spray. The safe recommended maximum dose of cocaine is 1.5[34] to 3 mg/kg,[39,42-44] with a maximum dose of 200 mg. It is difficult to establish dosing with paste and gel, and these are not recommended.

Cocaine solution is available in various concentrations from 0.5% to 20%, but solutions of more than 4% are not required.[39] The addition of epinephrine, 1 mg (1 mL 1:1000), to cocaine solution is intended to provide additional vasoconstriction and to reduce the absorption of cocaine. In one study of 30 adults comparing serial plasma concentrations of cocaine between two groups, one with epinephrine and the other without, there were significantly lower plasma cocaine levels in the epinephrine group.[45] It also was noted, however, that in two patients in the cocaine and epinephrine group there were unusually high plasma concentrations, although these were below levels associated with toxicity. The cause of this idiosyncratic rapid absorption is unknown, although it has been suggested that decay in the adrenaline-induced vasoconstriction occurs in a few patients and may account for this.[34]

Phenylephrine is a potent α-adrenergic agonist and is used as a topical vasoconstrictor alone or in combination with lidocaine. Guidelines on the topical use of phenylephrine in the operating room recommend the following:[46]

1. Initial phenylephrine dose should not exceed 0.5 mg, and in children weighing 25 kg or less, it should not exceed 20 μg/kg.
2. Blood pressure and pulse should be closely monitored.
3. The dose should be administered in a calibrated syringe and should be verified by a physician.
4. The anesthesiologist should be aware of all medications given.
5. Severe hypertension should be treated immediately with direct vasodilators or α-receptor antagonists.
6. β-Receptor blockers and calcium channel blockers should be avoided. They can worsen cardiac output and result in pulmonary edema.
7. If a β-receptor blocker is used to treat hypertension, glucagon administration should be considered to counteract the loss of cardiac contractility.

Airway (see also Chapter 50)

Nearly all nasal surgery has the potential to contaminate the lower airway with blood or secretions, and it is essential that the anesthesiologist recognize this and take measures to prevent it. Significant nasal blockage can make facemask ventilation difficult, and an oral airway may be needed. Airway maintenance can be a particular problem in obese patients with OSA and nasal blockage.

Tracheal Tube or Flexible Laryngeal Mask Airway

The choice of a tracheal tube or Flexible LMA for nasal procedures depends on the experience of the anesthesiologist, duration of surgery, and patient factors. Using a Flexible LMA during nasal surgery is an advanced use of the device, and if there is incorrect sizing, insertion, malposition, dislodgment, or suboptimal recovery, there is the potential for airway obstruction and blood contamination of the lower airway.

A south-facing or reinforced tracheal tube is often used with a throat pack to reduce blood contamination of the lower airway. The advantages of using a tracheal tube are its familiarity and ability to secure the airway and provide airway protection during positive-pressure ventilation and spontaneous pressure ventilation.

It seems intuitive that that a tracheal tube would protect the airway more effectively than a Flexible LMA because of the seal offered by contact of the tracheal tube cuff on the tracheal wall; however, this may not be true. The tracheal cuff is below the glottic and subglottic airway, and blood can pass down from the nasopharynx, past a throat pack, along the outer surface of the tracheal tube to the level of the vocal cords and subglottis. In contrast, a correctly sited Flexible LMA covers and protects the supraglottic and glottic airway, and blood is diverted laterally to the piriform sinus and postcricoid region.

Direct comparisons of lower airway contamination by fiberoptic examination at the end of surgery show that patients managed with a Flexible LMA by experienced anesthesiologists are significantly less likely to have blood staining the airway (glottis and trachea) than patients managed with a tracheal tube.[47] The Flexible LMA effectively and satisfactorily protects the glottic and tracheobronchial airway from blood exposure during nasal and sinus surgery, and can offer better protection of the tracheobronchial airway than a tracheal tube in many instances.[47,48]

Extubation

Extubation of a tracheal tube is usually undertaken with the patient "awake" or "deep," and extubation of a Flexible LMA is undertaken when the patient can open the mouth to command. For nasal surgery, awake extubation involves removal of the tracheal tube when the patient responds to commands and makes purposeful attempts to remove the tracheal tube. The advantage of awake extubation for nasal surgery is the intrinsic airway control in an awake patient with return of laryngeal reflexes and protection from further airway contamination by blood and secretions. The disadvantage is the higher incidence of laryngospasm, coughing, bucking, oxyhemoglobin desaturation, and increased risk of bleeding.

Deep extubation is used in an attempt to improve the recovery profile; however, for nasal surgery, this leaves an unprotected airway. After surgery, the nasal airway is often blocked with surgical packs, and the patient is dependent on oropharyngeal airflow. In practice, this may make it extremely difficult to maintain an airway in an OSA patient extubated deep lying on his or her side.

Recovery with an LMA provides protection of the lower airway from blood from the pharynx[47,49] and a superior recovery profile compared with awake or deep extubation.[47-50] Compared with recovery with a Flexible LMA, awake tracheal extubation was accompanied by excessive coughing with increased risk of bleeding, increased incidence of oxyhemoglobin desaturation early after extubation, delay in patient fitness for discharge from the operating room, and increased incidence of oxyhemoglobin desaturation on admission to the postanesthesia care unit.[48] Compared with removal of the Flexible LMA, tracheal extubation in patients deeply anesthetized was accompanied by an increased incidence of coughing, laryngospasm, and oxyhemoglobin desaturation early after extubation.[48] Emergence quality and overall airway protection after nasal surgery seem to be better for a Flexible LMA than a tracheal tube.[47-50]

Coroner's Clot

A throat pack is often used around a tracheal tube in an attempt to absorb blood, limit blood from the nasopharynx entering the oropharynx, and prevent surgical debris pooling in the laryngopharynx. At the end of surgery, the pack should be carefully removed and noted. Laryngoscopy and pharyngoscopy should be undertaken in every patient, and a careful inspection of the oral cavity and postnasal space should be made. This inspection involves standard laryngoscopy, followed by neck flexion to encourage any clot to fall past the soft palate, and direct visualization of the passage of a suction catheter behind the soft palate. Any clot left behind can be inhaled after removal of a tracheal tube and lead to total airway obstruction and death—hence the term "coroner's clot."

Postoperative Considerations

Postoperatively, all patients with nasal packs have a partially or completely obstructed nasal airway, but this is particularly significant in OSA patients. OSA patients need high-dependency care for airway observation and can have nasopharyngeal airways incorporated into the nasal pack.

Severe pain postoperatively is not a feature of most nasal surgery, and analgesia usually can be provided with oral acetaminophen and an NSAID. An intravenous cannula should be retained until after removal of the nasal pack in case of unexpected bleeding.

Throat and Head and Neck Surgery

Throat and head and neck procedures can be divided as follows:

1. Intraoral procedures—tonsillectomy, adenoidectomy, and palatal surgery
2. Laryngeal procedures—benign, malignant, and stenotic laryngeal lesions; airway endoscopy; and laser surgery
3. Head and neck—parotid surgery, thyroid surgery, nasopharyngeal wall tumors, neck dissection, laryngectomy, and pharyngolaryngectomy

Intraoral Surgery

Tonsillectomy

The tonsils and adenoids are part of Waldeyer's ring of lymphoid tissue around the pharynx and are often the sites of acute and chronic inflammation. Tonsillectomy and adenoidectomy are not minor procedures; they involve a shared airway, often in a small child, with difficult access, obstructive airway symptoms, and the potential for blood contamination of the lower airway. Mortality associated with tonsillectomy ranges from 1:40,000[51] to 1:12,000.[52]

Tonsillectomy is one of the most frequently performed surgical procedures, and its main indication is severe recurrent tonsillitis. Other indications include chronic tonsillitis, peritonsillar abscess (quinsy), OSA, and tonsillar biopsy or resection for tumor. Adenoidectomy is usually performed in children when there is evidence of enlarged adenoids causing symptoms such as blocked nose, mouth breathing, or OSA. As a child grows, the postnasal space enlarges in proportion to the other pharyngeal structures, and adenoidectomy is seldom required.[34]

A large prospective tonsillectomy audit[51] with data from 277 hospitals and more than 40,000 tonsillectomy or adenotonsillectomy procedures described the indications for and complications of these operations. Children younger than 5 years of age accounted for 23% of procedures, children 5 to 16 years of age accounted for 49%, and individuals 16 years old and older accounted for 28%. A tonsillectomy was performed alone in 71%, and an adenotonsillectomy was performed in 27% of patients. For children younger than 5 years of age, 61% of tonsillectomies were performed for recurrent acute tonsillitis, and 33% were performed for pharyngeal obstructive symptoms. As age increased, indications for surgery changed with an increase in acute recurrent tonsillitis, chronic tonsillitis, and quinsy, but a reduction in pharyngeal obstructive symptoms. Generally, in children, the tonsils can be dissected and removed more easily than in adults, in whom the tissue is often scarred and fibrotic from repeated infections, and this may account for the greater postoperative hemorrhage rates seen in the older age group.

Obstructive Sleep Apnea

In children, enlarged tonsils and adenoids cause varying degrees of pharyngeal obstruction ranging from simple snoring to upper airway resistance syndrome, in which partial upper airway obstruction occurs. With very large tonsils and adenoids, OSA can be present with loud persistent snoring interrupted by gasping or choking episodes and silent periods of apnea. Children and adults with OSA are at increased risk for postoperative respiratory complications.[53] In severe OSA, hypoxemia, hypercarbia, pulmonary hypertension, and cor pulmonale can be present. These children should be looked after in specialist pediatric centers with appropriate postoperative monitoring and high-dependency care.

Preoperative Assessment

Preoperative evaluation aims to identify patients with OSA, loose teeth, vulnerable dental implants, bleeding disorders, anemia, active infection, and sickle cell disease status. Active respiratory tract infections increase the risk of bleeding, and surgery should be postponed. Some uncooperative children may require sedative medication, but this should not be given to patients with OSA, unless appropriate observation and care is available.

General Anesthesia

The principles of anesthesia for tonsillectomy are to maintain a sufficient depth of anesthesia to allow the introduction of a mouth gag, and prevent reflex-induced hypertensive responses, tachycardia, and hypertension. During the procedure, intermittent positive-pressure ventilation or spontaneous ventilation can be used; at the end, a careful inspection for blood should be performed. The timing and manner of extubation is crucial to reduce the incidence of laryngospasm, and high-quality recovery care is essential to identify problems in the immediate postoperative period.

Induction of anesthesia can be by inhaled or intravenous route. Intravenous induction with propofol and fentanyl with or without a short-acting muscle relaxant provides a smooth, quick induction with reduced airway irritability. Inhaled induction is used principally in uncooperative children with poor venous access and needle-phobic adults.

An inhaled induction in the presence of significant airway obstruction can be a difficult, lengthy procedure to undertake. Patients with OSA may have reduced hypoxic and hypercapnic ventilatory responses and may tolerate hypoxia and hypercapnia with little attempt to increase respiratory rate or tidal volume. Early loss of upper airway muscle tone exacerbates the hazards of inhaled induction further. During spontaneous ventilation, constant observation of the reservoir bag is required, particularly during mouth gag insertion to identify obstruction.

A tonsillectomy is usually more painful in adults and requires significant analgesia intraoperatively and postoperatively. Intraoperative opioids, including morphine, are usually necessary.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are routinely used analgesics after tonsillectomy. Despite this fact, their use is controversial because of concerns about increased bleeding in the postoperative period owing to inhibition of platelet aggregation. Moiniche and colleagues,[54] in a meta-analysis with data from 25 studies, looked at four bleeding end points (intraoperative blood loss, postoperative bleeding, hospital admission, and reoperation because of bleeding), and concluded that the risk of bleeding after tonsillectomy was equivocal, but

there was some evidence for an increased likelihood of reoperation because of bleeding. Others also have found no significant increase in the risk of bleeding with NSAIDs,[55,56] although aspirin has been shown to increase the risk[56] and should not be used for tonsillectomy. NSAIDs seem to have no significant increase in postoperative bleeding,[54-56] to have less associated nausea and vomiting compared with other analgesics,[55] and to be generally well tolerated.

Steroids

The role of steroids with single intravenous doses of dexamethasone, 0.05 to 0.15 mg/kg, to improve recovery after tonsillectomy has been investigated.[57-59] Steroids decreased postoperative emesis,[57,58] increased tolerance to regular diet,[57,58] and reduced pain.[59]

Postoperative Nausea and Vomiting

Various prophylactic antiemetic interventions have been reported after tonsillectomy. Bolton and associates[60] found good evidence for the prophylactic antiemetic effect of dexamethasone and the serotoninergic antagonists ondansetron, granisetron, tropisetron, and dolasetron. Metoclopramide was found to be efficacious,[60] although ondansetron, 0.15 mg/kg, was superior to metoclopramide, 0.25 mg/kg.[61,62] Patients should be well hydrated, receive regular nonopioid analgesia, and have intravenous fluids continued until normal oral intake is resumed.

Antibiotics

The routine administration of antibiotics, although common, is controversial. No reduction in pain or analgesia requirements was seen; however, a reduction of halitosis, reduction in fever, and return to normal oral intake 1 day earlier was identified.[63,64]

Postextubation Laryngospasm and Stridor

For tonsillectomy, the incidence of laryngospasm and stridor after removal of a tracheal tube is greater than that after recovery with a Flexible LMA.[65-69] The incidence of laryngospasm after routine tracheal tube extubation following tonsillectomy in control groups is reported as 12% to 25%.[5-7,70-72] Attempts to reduce the incidence of laryngospasm involve either topical anesthesia to the upper airway,[6,71] limiting the exaggerated glottic closure reflex and subsequent laryngospasm, or intravenous agents administered close to extubation, increasing the depth of anesthesia and limiting glottic closure reflex–mediated laryngospasm.[5,7,70,72] Topical lidocaine (4 mg/kg) can be used in concentrations of 2% to 4% and is as effective as intravenous lidocaine (1 mg/kg)[6] without the sedative effects. Intravenous magnesium,[7] subhypnotic doses of propofol,[72] and lidocaine[5,6,70,71] all have been suggested as agents to reduce the incidence of postextubation laryngospasm.

Airway—Tracheal Tube or Flexible Laryngeal Mask Airway

The choice of tracheal tube or Flexible LMA depends on the experience of the anesthesiologist, the surgeon, and the recovery staff. The use of a Flexible LMA for tonsillectomy is an advanced technique; the Flexible LMA should be used only by an experienced anesthesiologist who is familiar with the insertion and maintenance of the device and by a surgeon who is competent at working around a Flexible LMA. In small children, an inexperienced anesthesiologist should not use a Flexible LMA.

Tracheal Tube. A south-facing tracheal tube is the most commonly used means of airway maintenance during tonsillectomy.[73] For an inexperienced anesthesiologist, a tracheal tube is easier to place than a Flexible LMA, is more resistant to compression from the mouth gag, is less likely to obstruct during the operation, and occupies less space in the oropharynx than a Flexible LMA.

At the end of the operation, extubation of a tracheal tube is undertaken after careful inspection and laryngoscopy to ensure no blood clots are present. The child is placed in a left lateral or semiprone ("tonsil position"), slight head-down position, and often a pillow is placed under the chest to allow blood or secretions to drain down and out. Extubation can be done "awake" or "deep." Deep extubation is associated with fewer airway complications,[8] but leaves an unprotected lower airway.

Flexible Laryngeal Mask Airway. The use of a Flexible LMA for tonsillectomy requires close cooperation and meticulous attention to detail by the anesthesiologist and the surgeon.[74] Particular care is required by the surgeon on placement and opening of the mouth gag and intraoperative manipulation of the gag. Mechanical obstruction during the use of a tonsillar gag occurs in 2% to 20% of cases,[65,67] and for most of these cases the obstruction is correctable. Access to the inferior pole of the tonsil also has been documented as being more difficult.[75] Advantages of using a Flexible LMA for tonsillectomy include (1) the avoidance of muscle relaxants; (2) the superior recovery profile with fewer episodes of bronchospasm, laryngospasm, bleeding, and desaturation; (3) less aspiration of blood compared with an uncuffed tracheal tube; and (4) better protection of the lower airway from blood and secretions until the patient is awake.[65-69]

The Flexible LMA is removed when patients open their eyes to command. The cuff should remain inflated allowing blood and secretions on the backplate to be suctioned out as the Flexible LMA is removed from the mouth.

Bleeding Tonsil

The incidence of postoperative hemorrhage increases with age.[51] In a national audit with more than 33,000 tonsillectomies, hemorrhage rates were 1.9% in children younger than 5 years old, 3% in children 5 to 15 years old, and 4.9% in individuals older than 16. The return to the operating room rate was 0.8% in children younger than 5 years old, 0.8% in children 5 to 15 years old, and 1.2% in individuals older than 16. Hemorrhage rates are higher in adults, patients with quinsy, and male patients.[51]

Primary bleeds usually occur within 6 hours of surgery[53] and may not be obvious in the immediate recovery period because the blood is swallowed. The bleeding is usually a venous or capillary bleed, rather than arterial, and problems arise because of hypovolemia, aspiration risk, and difficult laryngoscopy. Signs suggesting hemorrhage are an unexplained tachycardia, excessive swallowing, increased capillary refill time, pallor, restlessness, sweating, and airway obstruction. Hypotension is a late feature.

Anesthesia for these patients is challenging, and help from a senior anesthesiologist should be requested. Patients should be given oxygen; should be adequately resuscitated; should have hemoglobin, hematocrit, and coagulation checked; and should have blood typed and crossmatched. Large-bore reliable intravenous access should be established. Laryngoscopy can be difficult because of the presence of blood clots, continuous oozing of blood, and reduced venous and lymphatic drainage causing

intraoral swelling and edema. The case of a patient with an uneventful initial laryngoscopy can become difficult very quickly.

After resuscitation, options for anesthesia include a rapid-sequence induction, which is usually the preferred technique, or an inhaled induction. For a rapid-sequence induction, patients should be in a slightly head-down position, protecting the airway from aspiration of blood. Some patients may not tolerate lying supine, and preoxygenation, induction, and cricoid pressure may have to be applied with the patient semi-upright. The advantage of a rapid-sequence induction is the rapid induction and control of the airway with less chance of regurgitation during induction. The disadvantages are the potential to inhale blood and cardiovascular depression from induction. A difficult laryngoscopy should be anticipated and prepared for, and a selection of smaller tracheal tubes may be needed if airway and tracheal edema is significant. After tracheal intubation, a large-bore gastric tube should be placed to decompress the stomach and evacuate swallowed blood at the beginning and at the end of the procedure.

An inhaled induction may be an option for anesthesiologists experienced with the technique, but can be challenging in the lateral or head-down position. This technique can be slow, and blood can be inhaled and precipitate laryngospasm. For an inexperienced anesthesiologist, tracheal intubation in a lateral position is more difficult.

At the end of the procedure, extubation should be done with the patient fully awake. Careful postoperative monitoring with close observation and high-quality recovery care should be available, and hemoglobin levels should be rechecked.

Laryngeal Procedures

Operations on the airway are unique in that the anesthesiologist and the surgeon are working in the same anatomic field. Patients range from young, otherwise fit and healthy individuals presenting with minor vocal cord lesions to elderly patients with glottic carcinoma and stridor. During these procedures, the anesthesiologist has to maintain oxygenation, remove carbon dioxide, protect the airway, and keep the patient anesthetized, while the surgeon is operating in the same area. Close cooperation and communication between the anesthesiologist and the surgeon are essential for success.

Vocal Cord Pathology

Vocal cord pathology can be classified as follows:

1. Nodules are benign lesions of the vocal fold that can be bilateral and that are usually caused by vocal abuse.
2. Polyps are benign lesions of the vocal fold and are common in adults. They are usually unilateral.
3. Cysts are benign lesions commonly seen in professional voice users. They are caused by obstruction of a glandular duct resulting in a mucus retention cyst.
4. Granulomas are benign lesions induced by healing granulomatous tissue, which develops after microtrauma. They are usually found on the posterior third of the vocal process after trauma during intubation or extubation.
5. Papillomas are benign lesions caused by human papillomavirus infection and can undergo malignant transformation. In adults, hoarseness is usually the main symptom, whereas in children airway obstruction can occur. After laser resection, papillomas can recur, and some patients require repeated laser surgery at 3- to 12-monthly intervals.
6. Malignant tumors are usually unilateral and can occur mainly in the middle third of the vocal fold. Of tumors, 80% are found in men 45 to 65 years old. More than 97% of patients are smokers with a high alcohol intake. Treatment depends on tumor staging and involves local resection, radiotherapy, transoral laser resection, hemilaryngectomy, or laryngectomy.
7. Other lesions are caused by hemangiomas, submucous hemorrhage, Reinke edema, chronic laryngitis, amyloidosis, sarcoidosis, tuberculosis, and rheumatoid arthritis.

Preoperative Assessment

At the end of the preoperative assessment, the anesthesiologist should have some idea of the size, mobility, and location of the lesion (Table 75-1). Standard airway assessments to predict the ease of ventilation, visualization of the laryngeal inlet, and tracheal intubation should be performed. Airway pathology and its impact on airway management should be assessed. The severity and size of lesions at the glottic level are assessed by direct or indirect laryngoscopy, undertaken by surgeons in an outpatient setting, and a photograph of the findings is often included in the notes. Information about subglottic and tracheal lesions is provided by chest radiography, computed tomography (CT), and magnetic resonance imaging (MRI).

Size of the lesion gives an indication of potential airflow obstruction. Stridor indicates a significantly narrowed airway. In an adult, stridor implies an airway diameter of less than 4 to 5 mm, but the absence of stridor does not exclude a significantly narrowed airway.

Very mobile lesions (e.g., multiple large vocal cord polyps or papillomas) may cause partial airway obstruction after induction of anesthesia, but total airway obstruction is rare. Obstruction is worse with a spontaneously breathing patient because of the loss of supporting tone in the oropharynx and hypopharynx.

Supraglottic lesions, if mobile, can obstruct the airway or make visualization of the laryngeal inlet difficult. Subglottic lesions may allow a good view of the laryngeal inlet, but cause difficulty during the passage of a tracheal tube.

Anesthetic Techniques for Endoscopy

There is no ideal anesthetic technique for all endoscopy procedures. The technique depends on the patient's general condition; the size, mobility, and location of the lesion; the use of a laser; and the surgical requirements. An ideal technique would (1) be simple to use; (2) provide complete control of the airway with no risk of aspiration; (3) control ventilation with adequate oxygenation and carbon dioxide removal; (4) provide smooth induction and maintenance of anesthesia; (5) provide a clear motionless surgical field, free of secretions; (6) not impose time restrictions on the surgeon; (7) not be associated with the risk of airway fire or cardiovascular

Table 75-1 Preoperative Assessment

Assessment	Implication
History of endoscopic procedures	Any previous difficulty is significant, and anesthetic records should be reviewed to assess severity and site of obstruction, vascularity of lesion, and previous anesthetic techniques used
Hoarse voice	Nonspecific symptom; patients can be hoarse with only minor lesions on the vocal cord or have significant vocal cord pathology and airway compromise
Voice changes	Nonspecific symptom; minor lesions can result in significant voice changes
Dysphagia	Significant and suggests supraglottic obstruction; if associated with carcinoma implies upper esophageal extension
Altered breathing position	Significant; patients with partially obstructing lesions compensate by changing their body positioning to limit airway obstruction
Unable to lie flat	Significant; suggests severe airway obstruction, and patients may need to sleep upright
Breathing during sleep	Significant; difficulty in breathing at night or waking up at night in a panic suggests severe obstruction
Stridor	Significant; indicates critical airway obstruction with >50% reduction in airway diameter and in adults an airway diameter of 4-5 mm
Stridor on exertion	Significant; suggests airway obstruction is becoming critical; patients may have no stridor at rest
Stridor at rest	Significant; critical airway obstruction is present
Inspiratory stridor	Significant; suggests extrathoracic airway obstruction
Expiratory stridor	Significant; suggests intrathoracic airway obstruction
Absence of stridor	Generally reassuring, *but* in exhausted adults and children there are limited chest movements and insufficient airflow to generate enough turbulent flow for stridor; these circumstances suggest life-threatening compromise
Fiberoptic awake flexible laryngoscopy	All adult patients should have this to visualize the vocal cords; in patients with symptoms and signs of severe airway obstruction, great care must be taken to avoid local anesthetic and fiberscope contact with the vocal cords, precipitating total airway obstruction
Chest x-ray/CT/MRI scans	Can identify severity and depth of glottic, subglottic, tracheal, and intrathoracic lesions

instability; (8) allow safe emergence with no coughing, bucking, breath holding, or laryngospasm; (9) produce a pain-free, comfortable, alert patient at the end of the operation.

Some of these ideals conflict. The presence of a cuffed tracheal tube provides control of the airway and prevents aspiration, but may obscure a glottic lesion and is not laser safe. A cuffed laser tube provides some protection against laser-induced airway fires, but has a greater external-to-internal diameter ratio and may obscure laryngeal lesions. Jet ventilation techniques require specialist equipment and knowledge and an understanding of their limitations. Anesthetic techniques can be broadly classified into two groups: first, "closed" systems, in which a cuffed tracheal tube is employed with protection of the lower airway, and second, "open" systems, in which a cuffed tracheal tube is absent using either spontaneous ventilation and insufflation techniques or muscle paralysis and jet ventilation.

Closed System

The advantages of a closed system are (1) routine technique for all anesthesiologists, (2) protection of the lower airway, (3) control of the airway, (4) control of ventilation, and (5) minimal pollution by volatile agents. The disadvantages of a closed system are (1) surgical access and visibility of the lesion may be limited, (2) high inflation pressure may be required through small tubes, (3) tube-related damage to the vocal cords during intubation, and (4) risk of a laser airway fire.

Open System

The advantages of an open system are (1) laser safety, (2) reduced risk of tube-related trauma, and (3) complete laryngeal visualization. The disadvantages are (1) an unprotected lower airway and (2) specialist knowledge, equipment, and experience are required. The decision to use a closed or open technique depends on the experience of the anesthesiologist; the experience of the surgeon; the equipment available; the requirements for surgical access; and the size, mobility, vascularity, and location of the lesion.

The technique chosen for any given procedure is not absolute and may have to change as surgical and anesthetic requirements change. An open system using jet ventilation on a lesion thought to be avascular may have to change to a closed system employing a cuffed tracheal tube if the lesion is bleeding significantly, and there is a considerable risk of soiling of the tracheobronchial tree. Conversely, a system employing a cuffed tracheal tube may have to change during surgery to an open system if the tracheal tube obscures the lesion, making surgery very difficult or impossible.

For most benign vocal cord lesions and early malignant lesions (T1 and most T2 lesions), airway obstruction is not a feature, and most techniques described are appropriate. An intravenous induction technique is suitable for lesions in which airway obstruction is not anticipated. After preoxygenation and intravenous induction of anesthesia, laryngoscopy is undertaken to visualize the lesion, establish laryngoscopy grade, and administer

topical local anesthetic (lidocaine). Confirmation of pathology is important because the disease may have progressed since the last outpatient visit, and the anesthetic plan may have to be changed. Topical local anesthetic reduces airway reflexes, and improves the recovery profile.

Closed System—Intubation Techniques

Microlaryngoscopy Tubes

Microlaryngoscopy tubes are long, have a small internal and external diameter, and are designed specifically for endoscopy procedures. Typically, 4- to 5-mm internal diameter tubes with high-volume, low-pressure cuffs are used in nasal or oral versions. These tubes are not suitable for laser surgery.

Laser Tubes (see also Chapter 77)

Laser microsurgery of the airway allows precise surgical cutting, coagulation, and sealing with little postoperative edema. Lasers are used for the resection of papillomas, vascular lesions of the vocal cord, granulomas, and laryngeal carcinoma. Carbon dioxide lasers are the most commonly used in airway surgery and are targeted toward the glottis by aiming mirrors integral to the operating surgical microscope. Two main hazards exist from the use of a laser: first, the risk to the patient from a laser-induced airway fire, and, second, the risk to the operating room staff and patient from diverted laser radiation. Operating room staff should be aware of these risks, and specific precautions should be taken to avoid them. Before use, alignment of the carbon dioxide laser with the visible tracer beam should be confirmed. Unprotected areas of the patient's face and neck should have wet gauze swabs placed over them.

An airway fire occurs only if the three components of the fire triangle are present—fuel, oxidant, and ignition source. The transient flaring of fat deposits occasionally seen in the airway during laser surgery is self-terminating and would not produce a blow torch laser airway fire regardless of the ambient oxygen concentration. For a blowtorch airway fire to occur, a nonmetal foreign material, such as a tracheal tube, has to be present.

To minimize these risks, the inspired oxygen concentration should be the lowest that maintains adequate oxygen saturations, and air should be used in preference to nitrous oxide. The potential fuel source should have laser-resistant properties (laser tubes) or be removed (supraglottic jet ventilation technique). The only nonflammable, *laser-proof* tube is the all-metal Norton tube, which has no cuff. Most laser tubes have *laser-resistant* properties around the shaft, but can ignite with sustained laser energy strikes, particularly around the cuff, which is not protected. Commercially available laser tubes have product information leaflets that describe their laser-resistant properties at different power settings and with different types of laser. Anesthesiologists involved in procedures using lasers for airway surgery should be familiar with the causes of a laser airway fire, the limitations of laser-resistant tubes, and an airway fire drill.

Open Systems—Nonintubation Techniques

Spontaneous Ventilation and Insufflation Technique

Spontaneous ventilation and insufflation techniques are useful in the removal of foreign bodies, evaluation of airway dynamics (tracheomalacia), and removal of noncompromised glottic and subglottic lesions. The technique requires a spontaneously breathing patient and provides a clear view of an unobstructed glottis.

Inhaled induction is begun with sevoflurane in 100% oxygen. At a suitable depth of anesthesia as assessed by clinical observations on the rate and depth of respiration, pupil size, eye reflexes, blood pressure, and heart rate changes, laryngoscopy is undertaken, and topical lidocaine is administered above, below, and at the level of the vocal cords. One hundred percent oxygen is administered by facemask with spontaneous ventilation, and anesthesia is continued with inhalation (insufflation) or an intravenous route (propofol infusion). At a suitable depth of anesthesia, again assessed by clinical observations, the surgeon undertakes rigid laryngoscopy or bronchoscopy. Insufflation of anesthetic gases and agents can be via numerous routes: (1) a small catheter introduced into the nasopharynx and placed immediately above the laryngeal opening, (2) a tracheal tube cut short and placed through the nasopharynx emerging just beyond the soft palate, (3) a nasopharyngeal airway, and (4) the side-arm or channel of a laryngoscope or bronchoscope.

Movements of the vocal cords are usually minimal with a spontaneously breathing technique, provided that an adequate level of anesthesia is maintained. If the depth of anesthesia is too light, the vocal cords may move, the patient may cough, or laryngospasm may occur. If the depth of anesthesia is too great, the patient may become apneic with cardiovascular instability. Careful observation throughout the procedure, noting movements, respiratory rate and depth, cardiovascular stability, and unobstructed breathing, is vital, with the concentration of the volatile anesthetic adjusted accordingly.

The limitations of spontaneous ventilation or insufflation techniques include the lack of control over ventilation and the potential for airway soiling. Operating room pollution secondary to insufflation of volatile agents also is an issue and requires the presence of high-intensity suction catheters near the mouth. Insufflation techniques may be unsuitable for large, soft, floppy lesions, particularly in the supraglottis or glottis, which may obstruct the airway after the onset of general anesthesia with spontaneous ventilation.

Jet Ventilation Techniques

In 1967, Sanders first described a jet ventilation technique using a 16-gauge jet placed down the side-arm of a rigid bronchoscope, relying on air entrainment to continue ventilation with an open bronchoscope.[75a] Sanders used intermittent jets of oxygen (rate 8/min, 3.5-bar driving pressure) to entrain air and showed that the technique maintained supranormal oxygen pressure with no increase in the carbon dioxide partial pressure. Since 1967, modifications to Sanders' original jet ventilation technique have been made for endoscopic airway surgery. These modifications include the site at which the jet of gas emerges and the frequency of jet ventilation.

Supraglottic jet ventilation is a technique in which the jet of gas emerges in the supraglottis by attachment of a jetting needle to the rigid suspension laryngoscope. Subglottic jet ventilation involves placing a small (2 to 3 mm in diameter) catheter or specifically designed tube (Benjet, Baldwin Medical, Melbourne, Australia) through the glottis and into the trachea. Transtracheal jet ventilation involves the placement of specifically designed percutaneous transtracheal catheters through the cricothyroid membrane or trachea.

In addition to modifications to the site at which the jet of gas emerges, changes to the frequency of jet ventilation have been described. High-frequency (>1 Hz, 60 breaths/min) is used with ventilator rates typically around 100 to 150/min. This allows (1) continuous expiratory flow of air, enhancing the removal of fragments of blood and debris from the airway; (2) reduced peak and mean airway pressures with improved cardiovascular stability; and (3) enhanced diffusion and interregional mixing within the lungs, resulting in more efficient ventilation. These advantages are of particular importance in patients with significant lung disease and obesity. High frequencies are achieved by automated high-frequency jet ventilators, which have alarms and automatic interruption of jet flow when preset pause pressure limits have been reached (i.e., blockage of entrainment or exhalation has occurred).

Jet ventilation techniques are suitable for most benign glottic pathology and early malignancy where airway obstruction is not anticipated. A typical jet ventilation technique includes preoxygenation followed by intravenous induction and the administration of muscle relaxants. Laryngoscopy is undertaken, and topical local anesthetic (lidocaine) is administered. An LMA is inserted, and ventilation is continued with 100% oxygen until the surgeon is ready to site the rigid (suspension) laryngoscope onto which a jetting needle has been attached in preparation for supraglottic jet ventilation.[76] Alternatively, facemask ventilation is continued until the surgeon is ready to site the laryngoscope. Anesthesia is maintained with a target-controlled infusion of propofol, supplemented by bolus administration or infusion of alfentanil or remifentanil is undertaken. At the end of surgery, the LMA is reinserted before antagonism of residual muscle relaxation and cessation of intravenous anesthesia, to facilitate smooth emergence.[76]

During the procedure, the adequacy of jet ventilation should be assessed continuously by observation of chest movements, by oxygen saturation readings, and by listening for changes to the sound during air entrainment and exhalation. The patency of the airway and any surgical obstruction also can be assessed by watching the endoscopic image on a television screen.

Supraglottic Jet Ventilation. Supraglottic jet ventilation describes a technique in which the jet of gas emerges in the supraglottis by attachment of a jetting needle to the rigid surgical suspension laryngoscope. High-frequency or low-frequency ventilation can be used. Supraglottic jet ventilation techniques allow a clear, unobstructed view for the surgeon with no risk of a laser airway fire. If the surgeon places surgical swabs into the operating field, however, and these swabs are dry, there is a risk of an airway fire with the swab acting as a "fuel" source. The limitations of supraglottic techniques relate to (1) misalignment of the suspension laryngoscope to the glottic inlet, which results in poor ventilation and the risk of gastric distention with entrained air; (2) blood, smoke, and debris are blown into the distal trachea; (3) considerable vibration and movement of the vocal cords occurs, which may require ventilation to be stopped while operating; (4) inability to monitor end-tidal carbon dioxide concentration; and (5) risk of barotrauma with pneumomediastinum, pneumothorax, and subcutaneous emphysema.

Subglottic Jet Ventilation. Subglottic jet ventilation allows delivery of a jet of gas directly into the trachea by the placement of a small catheter through the glottis and into the trachea. The technique is more efficient than supraglottic jet ventilation and results in reduced driving pressures, minimal vocal cord movements, a good surgical field, and no time constraints for the surgeon in the placement of the rigid laryngoscope. The main disadvantages are the potential for a laser-induced airway fire because of the presence of a potential fuel source within the airway, and a greater risk of barotrauma than in supraglottic jet techniques.

Transtracheal Jet Techniques. Elective transtracheal catheter placement under local anesthesia in individuals with significant airway pathology or under general anesthesia for elective laryngeal surgery has been described. Transtracheal jet techniques carry the greatest risks of barotrauma. Other potential problems include blockage, kinking, infection, bleeding, and failure to site the catheter. The use of transtracheal jet ventilation techniques for endoscopic surgery of the larynx requires careful evaluation of the potential risks and benefits.

Recovery from Anesthesia

Smooth emergence and recovery from anesthesia is particularly important for patients who have undergone airway procedures where recovery profiles and reintubation rates are significantly greater than in the general surgical population. The recovery profile with an LMA provides smooth emergence from anesthesia, and many groups advocate the exchange of microlaryngoscopy tubes, tracheal tubes, and laser tubes for an LMA for recovery.[33]

Inhaled Foreign Bodies

Foreign body aspiration is the most common indication for bronchoscopy in children 1 to 4 years old. Inhaled foreign bodies can lodge in the larynx, trachea, main bronchi, or smaller airways, and their effects depend on the duration, degree, and site. Peanuts are commonly inhaled foreign bodies, and as they absorb water, they swell, become friable, cause a chemical irritation of the airway, and require urgent removal. Patients with foreign bodies within the larynx and trachea present with acute dyspnea, stridor, coughing, and cyanosis. The Heimlich maneuver may be needed to dislodge the obstruction. If the obstruction is in the bronchus, the child is more likely to be wheezy, coughing, and dyspneic with evidence of decreased air entry on the side of the obstruction. Chest radiographs may not reveal the lesion because most foreign bodies are radiolucent, so a positive history and clinical symptoms of aspiration may be the only guide to the diagnosis. A child may present much later if the obstruction does not pose a functional problem with mucosal irritation, edema, and pneumonitis distal to the obstruction.

Dislodging an inhaled foreign body can convert a partial obstruction to a more severe or even complete obstruction. The general principle of removal of inhaled foreign bodies during laryngoscopy and tracheobronchoscopy is to maintain spontaneous ventilation and reduce the chances of the foreign body being pushed distally into the airway. In practice, however, maintenance of spontaneous ventilation in a critically obstructed airway can be extremely difficult to sustain, and intermittent positive-pressure ventilation may be needed. Some centers routinely use controlled ventilation with muscle paralysis.[77]

Sedative premedication should be avoided because it may precipitate total airway occlusion. Induction is usually by an inhaled technique with sevoflurane or halothane in oxygen. At a deep plane of anesthesia, laryngoscopy is performed, and topical local anesthetic (lidocaine) is administered. Intravenous anticholinergic agents (atropine, 20 µg/kg, or glycopyrrolate, 10 µg/kg) can help reduce secretions and reflex bradycardia associated with airway instrumentation. Close observation and monitoring throughout the procedure is required to ensure a correct depth of anesthesia to prevent movement, coughing, and laryngospasm. Because of its shorter duration of effect, sevoflurane is often changed to isoflurane when a deep plane of anesthesia is achieved. Maintenance may be in the form of a propofol infusion.

Some bronchoscopes allow the attachment of a T-piece to a side arm on the bronchoscope through which oxygen and volatile agent can pass directly into the distal trachea. Here the bronchoscope acts in a similar manner to an uncuffed tracheal tube. Some bronchoscopes do not allow T-piece attachment, however, and insufflation techniques are required. Postoperative care requires observation for airway edema and intravenous steroids (dexamethasone, 0.1 mg/kg), antibiotics, and humidified oxygen; high-dependency postoperative care may be needed.

Epiglottitis

Acute epiglottitis is an acute inflammatory disease of the epiglottis, arytenoids, and aryepiglottic folds. The onset and progression of the symptoms can be rapid and lead to complete airway obstruction, hypoxemia, and death. In adults, the incidence has been around 1 per 100,000 adults per year,[78] although the incidence seems to be increasing because of the frequent use of antibiotics in childhood with an associated failure to develop immunity against *Haemophilus influenzae*. Adults and children present with a sore throat, fever, dysphagia, drooling, open mouth, muffled voice, stridor, and respiratory distress. Patients often assume the tripod position, sitting up with their hands outstretched. In children, the main differential diagnosis is laryngotracheobronchitis (croup). The diagnosis is made on the history and physical examination, and an experienced anesthesiologist and ENT surgeon should be available. In children, indirect laryngoscopy, placement of intravenous lines, oropharyngeal examination, intramuscular injections, and lateral neck radiographs should not be performed because further distress may precipitate complete airway obstruction. In cooperative adults, very careful flexible fiberoptic laryngoscopy, intravenous lines, and careful oropharyngeal examination by experienced personnel may be beneficial.

For adults and children, preparation for a difficult intubation and emergency tracheostomy should be made. Inhaled induction with sevoflurane or halothane in oxygen is begun with the child usually sitting or in the preferred position. Nitrous oxide is not used. After inhaled induction, further monitoring and intravenous access are established as anesthesia deepens. Intravenous fluids and atropine may be administered to reduce the likelihood of bradycardia associated with intubation. On laryngoscopy, the epiglottis and aryepiglottic folds are swollen, and the classic "cherry-red" epiglottis may be seen. Often, the glottic opening is not seen, and the only clue may be a small mucous bubble during spontaneous ventilation or by gentle pressure on the child's chest. An uncuffed tracheal tube usually 1 to 3 mm smaller than normal is placed. Initially, this is an oral tube, and when the child is stable, this is replaced with a nasal tube, which is less likely to become dislodged during the subsequent 24 to 72 hours of ventilation in a pediatric intensive care unit. Throat and blood cultures are taken, antibiotic therapy is started, and the child is transferred to a pediatric intensive care unit.

In adults, management follows similar principles[78,79]; however, inhaled anesthesia in an adult with a compromised airway is often unfamiliar, difficult, and slow, and the depth of anesthesia can be difficult to assess. The patient can become more hypoxic and hypercarbic with long periods of instability and arrhythmias. The traditional view is that the technique is safe because if the patient obstructs, the volatile agent is no longer taken up, and the patient lightens and wakes up. This may not always be reliable, and some centers use an intravenous induction technique in adults with epiglottitis.

Head and Neck Surgery

A large part of head and neck surgery involves treatment for patients with diseases of the upper airway, larynx, and pharynx. When airway compromise is not an issue, most procedures are routine and largely uneventful. When airway compromise is a feature, the anesthetic plan needs to change according to the severity and site of obstruction. All patients with airway compromise should be considered as a possible difficult intubation, whereas not all patients with a difficult intubation have airway compromise.

Major head and neck procedures include laryngectomy, pharyngolaryngectomy, radical neck dissection, and resection of large thyroid lesions. A laryngectomy involves the resection of the larynx and the creation of an end tracheal stoma. A pharyngolaryngectomy also resects structures within the pharynx, including part or all of the tongue and esophagus. A radical neck dissection resects sternomastoid, internal and external jugular veins, and cervical lymph nodes. The treatment of upper airway tumors depends on the staging (TNM [tumor, node, metastasis]) and site. Chemotherapy, radiotherapy, laser endoscopic resection, transoral laser surgery, major soft tissue and organ excision, radical neck dissection, and flap reconstruction alone or in combination are the principal treatment options.

The recognition of a compromised or anatomically distorted upper airway is paramount in the preoperative assessment of patients. For elective procedures, a detailed history, physical examination, and investigations should be undertaken, but for more urgent procedures with severe airway compromise, investigations may not be possible.

General Considerations

More than 80% of laryngeal and oropharyngeal cancers are found in men 40 to 75 years old, and greater than 97% of patients are smokers with a high alcohol intake. Patients may have had previous radiotherapy and surgery resulting in altered anatomy, tissue edema, induration, and "stiff" tissues. Preoperative evaluation includes assessment of alcohol intake, use of tobacco, nutritional status, and electrolyte disturbance. Patients with a significant alcohol intake require an alcohol withdrawal regimen and optimization of nutritional, electrolyte, and hematologic indices.

Cardiovascular and respiratory disease, including chronic obstructive pulmonary disease, hypertension, and coronary artery disease, should be assessed.

Major head and neck operations are long procedures lasting many hours with the potential for significant blood loss. Monitoring including intra-arterial blood pressure and central venous pressure should be strongly considered. After a radical neck dissection and removal of the jugular veins, head and neck venous drainage depends on jugular veins from the nonoperative side, and central venous pressure lines are usually placed in the femoral vein or antecubital fossa, avoiding the neck.

Surgical manipulation of the carotid sinus can produce vagal reflexes causing severe bradycardia, hypotension, and even asystole. When this occurs, the surgeon should stop manipulation of the carotid sinus immediately, which usually resolves the bradycardia, and intravenous atropine should be administered. Occasionally, with manipulation of the carotid sinus, persistent vagal reflexes occur, and local anesthetic infiltration with lidocaine is required. Air embolism is possible, although rare, in head and neck surgery during dissection with open neck veins.

Blood loss during head and neck surgery can be significant, and some degree of hypotension is usually required. This can be achieved with inhaled agents and a 10- to 15-degree head-up tilt aiming for systolic blood pressures of around 85 to 90 mm Hg. A remifentanil infusion also is very effective[80,81] in controlling the stress response during surgery, providing moderate hypotension. At the end of surgery, when the remifentanil infusion is discontinued, additional analgesia, usually morphine, is necessary to prevent hypertensive responses.

After a laryngectomy, a J-shaped laryngectomy (Montandon) tube is inserted into the distal trachea allowing the breathing circuit to be connected at some distance from the stoma, which helps the surgeon suture the end tracheal stoma to the anterior neck wall. The cuff in a laryngectomy tube is sited at the end of the tube, and there is no distal bevel to prevent accidental endobronchial intubation. At the end of the procedure, careful suctioning of the area above the cuff of the laryngectomy tube should be performed to prevent blood and secretions entering the trachea after cuff deflation and replacement by a new cuffed tracheostomy tube.

The presence of a new tracheostomy tube often produces coughing and irritation, which can be reduced by topical local anesthetic (lidocaine) around the stoma. Patients who have had previous laryngectomy procedures can present with stoma stenosis or recurrence of disease. The airway can be managed by local anesthetic (lidocaine) spray to the stoma and trachea, and the placement of a tracheostomy tube awake. Ventilation can be achieved through the stoma by applying a partially inflated LMA cuff over the stoma. Postoperative considerations for laryngectomy patients include humidification, regular suctioning for blood and secretions, and a head-up position to reduce edema.

Head and Neck Difficult Airway

The head and neck difficult airway is caused by numerous disease states at different levels within the airway, and no single anesthetic management technique can be used safely in all patients. Many investigators have provided guidelines for the management of patients with compromised airways, which also is reviewed in Chapter 50.[82-86]

Level of Obstruction

Generally, difficult airways can be divided according to the level at which a problem exists and include (1) oral cavity, (2) oropharynx, (3) tongue base and supraglottis, (4) glottis, (5) subglottic and upper tracheal, (6) midtracheal, and (7) lower tracheal and bronchial. Disease states are not confined to these anatomic areas and can pass through many levels.

Management Options

Anesthetic management depends on the urgency of the intervention, site of the lesion, size of the lesion, level of obstruction, extension of the lesion, and degree of airway compromise. Symptoms and signs of airway compromise include respiratory distress, tachypnea, accessory muscle use, sternal retraction, tracheal tug, stridor, hypoxia, tachycardia, and exhaustion.

Management options include (1) awake regional laryngeal blocks, (2) intravenous induction of general anesthesia, (3) inhaled induction with maintenance of spontaneous ventilation, (4) inhaled induction with "takeover" of ventilation, (5) awake fiberoptic intubation, (6) asleep fiberoptic intubation, (7) awake transtracheal catheter placement and jet ventilation, (8) awake tracheostomy under local anesthesia, and (9) asleep tracheostomy under general anesthesia. Whatever technique is chosen as the primary anesthetic technique, a backup plan should be thought through, discussed with the surgeon, and instituted when difficulties arise.

Oral Cavity and Oropharyngeal Lesions

Small oral cavity lesions, such as early tonsillar carcinoma, often have no features suggestive of airway compromise, and the upper airway is essentially normal. Many of the standard airway management techniques can be used successfully for these early noncompromised patients. For larger lesions in the oral cavity, partial or near-complete airway obstruction can be a feature. An intravenous induction in these patients may result in oral cavity airway obstruction secondary to the loss of supporting tone on the structures within the oral cavity, and an inability to ventilate or oxygenate. The normal techniques to prevent this obstruction, such as facemask ventilation with oral or nasal airways, may not be effective. Passage of an oral or nasal airway past large, obstructing, vascular, necrotic oral tumors causes trauma and bleeding. The glottis and lower airway are often normal in these patients, and the principal problem around intubation is one of bypassing a large obstructing mass without traumatizing it, while maintaining a patent airway. An awake fiberoptic intubation technique is often used in this group of patients.

Large obstructing lesions within the oral cavity are usually seen by anesthesiologists working with ENT and maxillofacial surgeons, and this may account for the experience within this group of awake fiberoptic techniques. Other anesthetic techniques include awake transtracheal catheter placement with jet ventilation and awake tracheostomy.

Abscess and Ludwig's Angina

Any abscess causes pain and swelling, but abscesses around the peritonsillar area also may lead to airway compromise with

obstruction, trismus, dysphagia, and severe pain. Aspiration under local anesthetic may be possible, but extensive surgery may need to be done under general anesthesia. For patients without symptoms and signs suggesting airway compromise, an intravenous induction with careful laryngoscopy and tracheal intubation, avoiding rupture of the abscess, can be done. If airway compromise or anatomic distortion is present, an awake fiberoptic intubation technique or tracheostomy under local anesthetic may be indicated.

Ludwig's angina is a bilateral, rapidly spreading submandibular cellulitis, originating usually from the second or third molars. It was originally described by Ludwig in 1836, and angina implies the suffocating sensation. The tongue is elevated and displaced with hard, firm induration of the floor of the mouth and perioral edema.

Spread of the infection can cause trismus and mediastinitis. Airway management involves the placement of a nasotracheal tube usually by an awake fiberoptic technique. Occasionally, in severe disease, an awake local anesthetic tracheostomy is indicated.

Tongue Base and Supraglottic Lesions

Even small lesions at the tongue base and supraglottis can have significant effects on the airway because of their location at the entrance to the glottis, and their effect on the epiglottitis. As a tongue base lesion expands, it fills the space in the valleculae and directs the epiglottis downward, increasing airway obstruction at the glottic inlet. A large epiglottic or vallecular cyst results in airway obstruction and compromise in a manner similar to epiglottitis. The danger of an intravenous induction in these patients is airway obstruction after the loss of supportive tone from the soft tissues. An oral or nasal airway may be ineffective in relieving the obstruction, and a strong jaw thrust maneuver displacing the mandible and tongue base forward, creating an airspace at the supraglottic inlet, may be required.

Standard curved blade laryngoscopy can traumatize any lesion at the tongue base and valleculae, causing bleeding and swelling with the potential for complete airway obstruction. Although straight blade laryngoscopy aims to pass below the epiglottic tip and lift the epiglottis upward, this can be difficult with a distorted epiglottis. Great care and attention need to be taken during attempted laryngoscopy with these lesions.

Any patient in whom there is concern about a lesion at the tongue base or supraglottis, or in whom there is evidence of significant airway obstruction, an awake fiberoptic intubation, awake transtracheal catheter, awake laryngeal block with direct laryngoscopy, or an awake local anesthetic tracheostomy should be considered.

Glottic Lesions

Laryngeal pathology with no symptoms or signs of airway compromise, such as early T1 and some T2 tumors, can be managed by numerous anesthetic techniques, including intravenous induction of general anesthesia and placement of a cuffed tracheal or laser tube. Alternatively, a supraglottic or subglottic jet ventilation technique can be employed for biopsy and laser resection. When airway symptoms or signs suggest airway compromise with significant airway obstruction or stridor, the options for anesthesia are limited.

Awake fiberoptic techniques are suitable for oral cavity, oropharyngeal, and tongue base lesions because they *pass around* the mass, but may be unsuitable for advanced obstructing laryngeal disease, in which the fiberscope has to *pass through* the mass, resulting in complete airway occlusion.[87] Good topical anesthesia is difficult to achieve, and technically fiberoptic intubation through an anatomically distorted large vascular friable necrotic tumor is difficult. Awake fiberoptic intubation techniques have an associated morbidity and mortality.[88]

Some investigators have used inhaled induction techniques for the obstructed airway in which spontaneous ventilation is maintained throughout.[87] Inhaled induction for advanced laryngeal tumors with airway obstruction is difficult and challenging. Physiologic problems include a reduction in airflow with spontaneous ventilation, an increased collapsibility of the airway, increased work of breathing, critical instability at points of narrowing leading to further airway collapse, and a reduction in functional residual capacity.[89] Induction is slow with apneic periods, and episodes of obstruction are common.

Controversy exists regarding the suitability of "taking over" the patient's own spontaneous ventilation with bag-mask ventilation. Retaining spontaneous ventilation throughout is the theoretical inherent advantage of this technique. Taking over ventilation allows a suitable depth of anesthesia for laryngoscopy to be achieved quicker, however, which avoids the long periods of spontaneous ventilation waiting for an adequate depth of anesthesia in which the patient may become unstable.

The administration of a muscle relaxant provides optimal ventilation and intubating conditions. Calder and Yentis[90] commented on the perceived "safe practice" of not giving muscle relaxants until facemask ventilation has been documented, and argued that the theoretical advantage is not fulfilled in practice. They commented on two studies[91,92] looking at the incidence and prediction of difficult and impossible mask ventilation in which no patient was woken up, and suggested that when a patient has an obstructed airway, it is not feasible to await awakening, and something has to be done to ventilate the lungs before catastrophic desaturation occurs.[90]

At a suitable depth of anesthesia, laryngoscopy is undertaken, and the best chance of success is usually at the first attempt when bleeding, trauma, and swelling are minimal. A gum elastic bougie or stylet may be useful. Failure to intubate requires an urgent tracheostomy, and the surgeon should be gowned and immediately ready.

Transtracheal catheter placement[93,94] under local anesthesia at a level below the distal margin of the tumor is a recognized technique for the difficult airway. The catheter is placed usually at the level of the second or third tracheal rings, avoiding the tumor and the risk of bleeding and tumor seeding. When catheter placement has been confirmed in an awake patient by an end-tidal capnography trace, intravenous induction is started. After induction, jet ventilation through the transtracheal catheter is begun, ideally with a high-frequency ventilator with automated cutoff at a preset pause pressure limit to reduce the incidence of barotrauma. An experienced anesthesiologist should remain at the head end of the patient ensuring a patent and adequate upper airway by chin lift, jaw thrust, or oral or nasal airway.

Subglottic and Upper Tracheal Lesions

Lesions in the subglottis are usually an extension of glottic lesions, and the anesthetic problems and principles are similar. Acquired laryngotracheal stenosis in the glottis, subglottis, and upper trachea has an incidence of around 1 in 200,000 adults.[95] After intubation, nonspecific changes in the glottis and subglottis occur that result in edema and superficial ulceration forming granulation tissue, which progresses to firm scar tissue. Surgical management of these patients involves (1) laser resection, (2) serial dilation, (3) stent insertion, (4) topical chemotherapy (mitomycin), (5) resection of stenotic areas with an end-to-end anastomosis, and (6) tracheal homografts. Patients with advanced laryngotracheal stenosis may have airway diameters of 2 to 4 mm, and airway management usually involves a supraglottic jet ventilation technique.

Mid and Lower Tracheal Lesions

Tracheal obstruction can be caused by lesions arising within the trachea itself or by compression from surrounding structures or tumors. The upper airway is usually normal at laryngoscopy, and the problems are secondary to an inability to pass a tracheal tube and difficulties placing a surgical airway below the obstruction. Awake fiberoptic intubation should be considered, but may be impossible. A rigid bronchoscope may be required to secure the airway. Lower tracheal lesions and large mediastinal masses should be managed in specialist thoracic centers.

Tracheostomy

With severe life-threatening airway compromise, a tracheostomy may be indicated. Ideally, tracheostomy should be performed under a general anesthetic allowing the surgeon optimal operating conditions; however, a general anesthetic may be unsafe and risk total airway occlusion, requiring an emergency surgical airway under suboptimal conditions. The decision to perform a tracheostomy under local anesthesia is made in conjunction with the surgeon and depends on many factors, including the experience of the anesthesiologist, the severity of airway disease, and surgical requirements after resection. Technically, tracheostomy with an awake local anesthetic in a patient with severe airway compromise is difficult. Ideal patient positioning with an extended head and supine is often not tolerated by the patient, and the procedure has to be undertaken in a semiupright sitting position. Surgical infiltration, manipulation, and dissection are often poorly tolerated with increasing airway compromise. Sedation should be avoided during this period because of the risk of total airway obstruction.

A tracheostomy tube change in a patient with a long-term tracheostomy in which the tract has been stable for many months is usually uncomplicated and can be performed at the bedside. Changing a fresh tracheostomy tube within the first week can be dangerous because the tract is unstable, and the soft tissues can easily close after the tracheostomy tube has been removed. Attempts to force a tracheostomy tube past the tract can result in false passages, subcutaneous emphysema, an inability to oxygenate, and a critical situation. Early tube changes should be avoided, but may be necessary to optimize size and reduce air leaks. These early tube changes with airway exchange catheters should be done after preoxygenation by an experienced clinician who can rescue the airway.

Anesthesia for Eye Surgery

Ocular Anatomy

The eye is a sphere about 24 mm in diameter. It sits in the pyramidal bony orbit. The wall of the globe has three layers—the sclera, the uveal tract, and the retina.

The sclera is the outermost layer. It is the tough, fibrous "white of the eye." The transparent cornea is the most anterior part of the sclera. Most of the focus power of the eye is from the curvature of the cornea.

The middle layer, the uveal tract, has three structures—the choroid, the iris, and the ciliary body. The choroid is a layer of blood vessels located posteriorly. Bleeding in this layer is one cause of intraoperative expulsive hemorrhage. The pigmented iris controls light entry with muscle fibers that change the size of the pupil. Sympathetic stimulation dilates the pupil by causing iris dilator muscles to contract, whereas parasympathetic stimulation causes miosis, or pupillary constriction, by causing the iris sphincter muscles to contract. The ciliary body lies just behind the iris; it produces aqueous humor. Ciliary muscle fibers adjust the focus by releasing tension on the suspensory fibers, or zonules, of the lens. Opacification of the lens causes a cataract. Uveitis is an inflammatory condition of these structures (iris, choroid, and ciliary body).

The innermost eye layer is the retina. Light stimulates retinal photoreceptors to produce neural signals that the optic nerve carries to the brain. There are no capillaries in the retina; the choroid layer provides the retina with oxygen. Retinal detachment from the choroid layer compromises the retinal blood supply and is a major cause of vision loss. The retinal layer ends about 4 mm behind the iris. The area between the limbus of the cornea and the retina is called the pars plana. Because there is no retinal layer there, it is a safe entrance site for vitrectomy procedures.

The center of the eye is filled with vitreous gel. This thick fluid has attachments to blood vessels and the optic nerve. Traction of the vitreous on the retina is a cause of retinal detachment. Scarring, bleeding, or opacification of the vitreous is treated by vitrectomy.

The extraocular muscles move the globe within the orbit. They arise from a fibrous ring near the apex of the orbit and insert on the sclera. The six extraocular muscles lie within a cone behind the eye surrounding the optic nerve, ophthalmic artery and vein, and ciliary ganglion.

The eyelids have an outer layer of skin, a muscle layer, a tarsal plate of cartilage, and a layer of conjunctiva. The conjunctiva is a mucous membrane that lines the inner eyelids and covers the globe up to the corneal-scleral junction.

The lacrimal gland sits in the superior temporal orbit. It releases tears across the surface of the globe. Tears drain via the puncta near the medial canthus of the eyelids. Tears flow through the canaliculi to the lacrimal sac and duct, to drain into the nasopharynx.

The ophthalmic artery provides most of the blood supply to the orbital structures. It is a branch of the internal

carotid artery, very close to the circle of Willis. The superior and inferior ophthalmic veins drain directly into the cavernous sinus.

Cranial nerves innervate the ocular structures. The optic nerve (CN II) carries the neural signals from the retina. The oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) control the extraocular muscles. Touch and pain sensation is carried via the trigeminal nerve (CN V). Sensation to the lower lid is via the maxillary nerve. Sensation to the upper lid is via the frontal branch of the ophthalmic nerve. The nasociliary branch of the ophthalmic nerve sends sensory fibers to medial canthus, lacrimal sac, and ciliary ganglion.

The ciliary ganglion provides sensory innervation to the cornea, iris, and ciliary body. Parasympathetic fibers originate from the oculomotor nerve (CN III) and synapse in the ciliary ganglion before supplying the iris sphincter muscle. Sympathetic fibers originate from the carotid plexus and travel through the ciliary ganglion to innervate the dilator muscle of the iris. Local anesthetic blockade of the ciliary ganglion produces a fixed, mid-dilated pupil.

The facial nerve (CN VII) exits the base of the skull from the stylomastoid foramen. It supplies motor innervation to the orbicularis muscle via the zygomatic branch. Local anesthetic block of the facial nerve can prevent lid squeezing.

Oculocardiac Reflex

The oculocardiac reflex was first described by Aschner and Dagnini in 1908.[95a,95b] Traction on the extraocular muscles or pressure on the globe causes bradycardia, atrioventricular block, ventricular ectopy, or asystole. It is especially seen with traction on the medial rectus muscle, but can occur with stimulation of any of the orbital contents, including the periosteum.

The reflex is trigeminovagal. The afferent limb is from orbital contents to ciliary ganglion to ophthalmic division of the trigeminal nerve to the sensory nucleus of the trigeminal near the fourth ventricle. The efferent limb is via the vagus nerve to the heart.[96]

The reflex may be seen more often with procedures under topical anesthesia. Retrobulbar block is not uniformly effective, however, at preventing the reflex. Orbital injections can trigger the response. The response is exacerbated by hypercapnia or hypoxemia.

In the event of arrhythmia, the anesthesiologist first should ask the surgeon to stop manipulations. The ventilatory status is assessed. If significant bradycardia persists or recurs, intravenous atropine is administered in 7 μg/kg increments. Rarely, severe bradycardia or asystole occurs. Although chest compressions might be required to allow the atropine to circulate, usually the heart rhythm returns to normal with cessation of manipulation alone. The response fatigues with repeated stimulation.

Pretreatment with intravenous atropine or glycopyrrolate can be effective. Pretreatment may be indicated in patients with a history of conduction block, vasovagal responses, or β-blocker therapy.

Intraocular Pressure

The blood supply to the retina and optic nerve depends on the intraocular perfusion pressure.[97] This perfusion pressure is defined as the difference between the mean arterial pressure and the intraocular pressure (IOP). High IOP impairs the blood supply, leading to a loss of optic nerve function. After an incision in the globe is made, factors that would increase IOP can cause prolapse and loss of intraocular contents; this can cause permanent vision loss.

The globe is a relatively noncompliant compartment. The volume of the internal structures is fixed except for aqueous fluid and choroidal blood volume. The quantity of these two factors regulates IOP.

Two thirds of the aqueous fluid is actively secreted by the ciliary body by a sodium-pump mechanism. One third comes from passive filtration through vessels on the iris. Aqueous fluid is produced at a rate of 2 μL/min. Aqueous flows over the lens and through the pupil to bathe the inner corneal endothelium. It then enters the angle of the anterior chamber to flow through the trabecular meshwork to the canal of Schlemm. The canal of Schlemm is continuous with channels to the episcleral veins. IOP is primarily regulated by the resistance at the trabecular meshwork. Normal pressure is 10 to 20 mm Hg.

Impairment of aqueous drainage at any point can elevate the IOP. Sclerosis of the trabecular meshwork is believed to cause the chronic pressure elevation in open-angle glaucoma. Closed-angle glaucoma occurs when there is an obstruction to aqueous drainage from closure of the anterior chamber angle. This happens from peripheral iris swelling or anterior displacement. Patients with a preexisting narrow angle may be predisposed to this condition. The acute increase in pressure causes severe pain. This is an ophthalmologic emergency.

Changes in choroidal blood volume can increase IOP rapidly. Hypercapnia causes choroidal congestion.[98] Coughing, straining, or vomiting can increase IOP to 30 to 40 mm Hg. Endotracheal intubation can cause similar increases. These increases are transient and are relatively innocuous in a closed eye. In an open eye, such as after traumatic injury or during cataract surgery, these increases can lead to loss of intraocular contents, hemorrhage, and permanent vision loss.[99]

Extrinsic compression of the eye also increases the IOP. A normal blink increases the IOP by 10 mm Hg. A forceful lid squeeze can increase IOP to more than 50 mm Hg.[100] A poorly placed anesthesia mask can put enough pressure on the eye to reduce blood flow to zero.

Deep inhaled or thiopental anesthesia causes a dose-related reduction in IOP by 30% to 40%.[101] Opioids have little effect. Atropine in the usual doses does not cause a significant increase in IOP, even in patients with open-angle glaucoma. Ketamine may cause a modest increase in IOP.

Intravenous succinylcholine causes IOP to increase by 6 to 12 mm Hg.[102] This lasts for 5 to 10 minutes. The use of succinylcholine for induction in cases of open-globe injury with full stomach has been controversial. Loss of vitreous in patients from succinylcholine has not been reported.

Ophthalmologic Drugs

Ophthalmologic drugs are systemic medications. Eyedrops can have systemic effects and important drug interactions with anesthetics. Acetazolamide is a carbonic anhydrase inhibitor. It is used in the treatment of glaucoma to decrease chronically elevated IOP. It induces an alkaline diuresis that may result in potassium depletion. Patients taking acetazolamide should have electrolytes

checked preoperatively. Atropine eye drops can cause tachycardia, dry skin, fever, and agitation.[103] Overdosage can be treated with incremental doses of physostigmine.

Echothiophate is a topical anticholinesterase drug used to maintain miosis in the treatment of glaucoma. Systemic absorption leads to total body inhibition of plasma cholinesterase. Subsequent administration of succinylcholine can cause prolonged muscle paralysis.[104] Inhibition of the metabolism of ester-type local anesthetics may predispose a patient to local anesthetic toxicity. Echothiophate is very long-acting. Return toward normal enzyme activity may take 4 to 6 weeks after discontinuation of the drug.

Mannitol is an osmotic diuretic. It causes a decrease in IOP lasting 5 to 6 hours. Patients who receive the drug during surgery may need a urinary catheter to avoid overdistention of the bladder. Mannitol causes an increase in the circulating blood volume, which may lead to congestive heart failure in patients with poor ventricular function.

Phenylephrine is an α-adrenergic agonist applied topically to dilate the pupil. Systemic absorption of the 10% solution is associated with severe hypertensive reactions.[105] The 2.5% concentration is safer, but may exacerbate hypertension in some patients.

Pilocarpine and acetylcholine are cholinergic drugs used to constrict the pupil. Bradycardia and acute bronchospasm have been reported.

Timolol maleate is a topical β-blocker. It is used in the treatment of glaucoma. Systemic absorption causes β-blockade, with possible bradycardia, bronchospasm, or exacerbation of congestive heart failure.[106] Care should be taken especially in a patient with severe chronic obstructive pulmonary disease.

Tamsulosin hydrochloride (Flomax) has selective α-adrenoreceptor antagonistic properties and binds for a long period to nerves to the iris dilator muscle, affecting iris dilation and leading to complications in cataract surgery. The iris remains floppy even after 7- to 28-day interruption of the tamsulosin regimen.[107]

Preoperative Evaluation (also see Chapters 34 and 71)

Eye surgery is the most common surgery in the elderly. In 2005, the Medicare program paid for nearly 3 million claims for cataract surgery. These are quick outpatient procedures that do not involve blood loss or much postoperative pain. They are not minor procedures, however; ophthalmic surgery can be a major life event. Establishing a professional relationship reduces anxiety and helps the patient prepare for surgery. Giving information to the patient is just as important as getting information from the patient. An informed patient is more calm, comfortable, and cooperative. The patient needs to know what to expect.

Eye surgery patients are a high-risk group. Adults tend to be old. Most have other risk factors, such as diabetes, hypertension, and atherosclerosis.[108] Cataracts were shown to be a marker for increased mortality in the Nurses' Health Study.[108a] Ophthalmic surgery is low risk, however. Mortality after eye procedures is much lower than for the general surgical population. Backer et and colleagues[109] found that eye surgery did not pose the risk of myocardial reinfarction seen with general surgical procedures. Patients' chronic diseases have less effect on outcome with these procedures. In a study of unanticipated hospital admissions after outpatient ophthalmic surgery, age and American Society of Anesthesiologists physical status were not significant factors.[110]

There is controversy regarding the best preoperative management. Some clinicians say that because cataract extraction is a low-stress procedure with no blood loss, no preoperative evaluation is needed. Publication of a large, multicenter trial showed no effect of preoperative blood tests and electrocardiogram on postoperative outcome.[111] Another opinion is that every patient must receive a full evaluation to include every possible test, to detect every possible finding, to institute every possible therapy, and to delay as long as possible, so that the patient can be in the best possible condition and have the lowest possible risk. Appropriate preoperative medical consultation is important. A study of malpractice litigation in cataract surgery found that medical consultation accounted for 16% of the liability; this compared with 17% attributed to either local or general anesthesia.[112]

We do not want to ignore risk. Neither should we reduce every risk to the lowest conceivable minimum. The anesthesiologist's goal is to prepare the patient to present an acceptable risk at surgery. Acceptable risk is determined by the medical care team with the informed consent of the patient. If a patient's condition would indicate inpatient admission for medical treatment, or if a reversible condition would likely lead to a perioperative complication, the risk is unacceptable.

The goal is to develop guidelines that would encourage consistency of care and minimize disruption to patients and the operating room. The following guidelines are presented after review of literature and published guidelines.

Patient History

Previous hospitalizations and surgical procedures are reviewed. Allergies and drug sensitivities are noted. Latex allergy should be addressed specifically. A current list of medications is obtained. Patient factors that could influence anesthetic management include dementia, deafness, language difficulty, restless legs syndrome, obstructive sleep apnea, tremors, dizziness, and claustrophobia. A preoperative patient questionnaire can be very helpful. A thorough review of the patient history helps perioperative planning and establishing a physician-patient relationship.

Physical Examination

Check for signs of major cardiac or pulmonary decompensation. Particular attention should be paid to positioning issues, such as severe scoliosis or orthopnea.

Laboratory Studies

No routine screening tests have been shown to improve outcome. Laboratory studies should be determined on the basis of the results of the history and physical examination. Generally, the tests that a patient needs before ophthalmic procedures are the same tests a patient would require at a routine examination if surgery were not planned. Tests are chosen when the results are likely to change management. Urgent medical management is obtained for results reaching critical limits. Indications for laboratory studies and critical results are as follows:

Electrocardiogram: New chest pain, decreased exercise tolerance, palpitations, near-syncope, fatigue, or dyspnea. Tachycardia, bradycardia, or irregular pulse on examination. *Critical results*: Signs of acute ischemia or injury, malignant

arrhythmia, complete heart block, atrial fibrillation that is new, or heart rate greater than 100 beats/min.

Serum electrolytes: History of severe vomiting or diarrhea, poor oral intake, changes in diuretic management, or arrhythmia. *Critical results*: Sodium less than 120 mEq/L or greater than 158 mEq/L. Potassium less than 2.8 mEq/L or greater than 6.2 mEq/L.

Urea nitrogen: Signs or symptoms of renal decompensation. *Critical result*: Greater than 104 mg/dL.

Serum glucose: Polydipsia, polyuria, or weight loss. *Critical results*: Less than 46 mg/dL or greater than 484 mg/dL.

Hematocrit/hemoglobin: History of bleeding, poor oral intake, fatigue, decreased exercise tolerance, or tachycardia. *Critical results*: Hematocrit less than 18% or greater than 61%. Hemoglobin less than 6.6 mg/dL or greater than 19.9 mg/dL.

Ophthalmic Evaluation

Visual acuity of both eyes should be noted. Patients with poor vision in the nonoperative eye face much greater potential functional loss. These patients have a higher anxiety level. If the patient is to be patched overnight, the physician should anticipate the increased need for postoperative assistance for a temporarily blind patient.

The axial length of the globe should be assessed. When ultrasound measurements are available, the axial length should be noted. If no ultrasound is available, a myopic patient should be assumed to have an increased axial length. If a posterior staphyloma is present, the risks of injection anesthesia may be dramatically increased. Preoperative glaucoma history, increased IOP, and increased axial length are important risk factors for suprachoroidal hemorrhage. The risk may be reduced with tighter control of intraoperative heart rate and blood pressure. Preoperative softening with a compression device also may decrease risk.

Cardiovascular Evaluation

The American Heart Association and American College of Cardiology published guidelines for perioperative cardiovascular evaluation for noncardiac surgery.[113] Ophthalmic procedures such as cataract extraction are specifically identified as low-risk procedures. For these procedures, evaluation is focused on patients with major clinical predictors of risk. These major predictors and the evaluation of the patient are reviewed in Chapters 34 and 35.

Hypertension

Hypertension is a common problem in ophthalmic patients. Severe hypertension may lead to perioperative complications. Degrees of hypertension have been defined. Stage 3 of severe hypertension is defined as a systolic blood pressure of 180 mm Hg or more or a diastolic blood pressure of 110 mm Hg or more. It would be prudent to reschedule elective procedures in patients with sustained stage 3 hypertension until after 2 weeks of antihypertensive therapy.

Pulmonary Considerations

Ophthalmic procedures generally require that the patient lie flat comfortably and quietly. If the patient cannot lie flat, or if there is intractable cough, a perioperative complication is more likely. Preoperative risk reduction strategies include cessation of cigarette smoking, treatment of airflow obstruction with bronchodilators or steroids, and administration of antibiotics for respiratory infections.

Patients should be assessed for sleep apnea. Intravenous sedation is often contraindicated in these patients. For some patients, treatment with a mild stimulant such as caffeine can be helpful in keeping them awake and cooperative during a procedure.

Endocrine Considerations

Diabetes mellitus is very common in patients undergoing ophthalmic surgery.[112] It is best if these patients can be done early in the morning with as little disturbance as possible to their usual daily routine. Severe hyperglycemia and hypoglycemia should be avoided. A fasting blood glucose should be checked preoperatively. Insulin therapy should be used, if needed, to maintain blood glucose at 150 to 250 mg/dL. The potential for autonomic neuropathy needs to be considered, especially when elevating the patient from the supine position.

Patients on long-term steroid therapy generally do not require "stress-dose" steroid treatment for ophthalmic surgery. The patient should be given his or her normal steroid dose on the day of surgery. The physician should be alert to the occasional patient who may require additional glucocorticoid perioperatively. Unexpected hypotension, fatigue, and nausea may be signs of a patient who needs additional steroid.

Anticoagulation

Many patients undergoing ophthalmic surgery take anticoagulants. Perioperative management of anticoagulants involves weighing the relative risks of thrombotic against possible hemorrhagic complications. Either of these results can be devastating to the patient. In a study of more than 19,000 cataract procedures, the incidence of hemorrhagic and thrombotic complications was very low.[114]

The risk of thrombotic complications depends on the following:

1. The indication for anticoagulation. Serious complications from arterial thromboembolic disease, such as atrial fibrillation or valvular heart disease, are much more common than complications from venous disease, such as deep vein thrombosis.
2. The risk factors for thromboembolism, especially if and when the patient had a previous episode of thromboembolism.

The risk of hemorrhagic complications depends on the following:

1. The degree of anticoagulation.
2. The hemorrhagic potential of the surgical procedure. Serious hemorrhagic complications are most probable in orbital and oculoplastic surgery; of intermediate probability in vitreoretinal, glaucoma, and corneal transplant surgery; and least likely in cataract surgery.

A consensus is developing that cataract surgery may be safely performed while maintaining patients on warfarin. For intermediate-risk procedures, such as some glaucoma surgeries, stopping warfarin for 4 days preoperatively is indicated. For high-

risk cases for hemorrhage or thrombosis, conversion from warfarin to heparin may be required.

Anesthetic Techniques

Regional Techniques

Eye surgery usually requires immobility (or akinesia) of the eye and profound anesthesia of the surgical site. Any discomfort during the procedure can be magnified by the patient's anxiety and fear of possible vision loss.[115] Various regional anesthetic techniques have been developed that satisfy the requirements of ophthalmologic surgery and are generally reliable and safe. Discomfort and anxiety are associated with many of these blocks, and rare but severe complications. Supplementation with intravenous sedation and continuous patient monitoring are frequently preferred.[116,117] Intravenous sedation also may be associated with increased incidence of medical events.[118]

Regional anesthesia has several advantages over general anesthesia. The local block gives significant postoperative analgesia. Nausea and vomiting are infrequent. The patient can return to ambulation faster. Most patients meet recovery discharge criteria at the end of surgery, and can bypass a stay in the postanesthesia care unit.

An intravenous infusion is started. Blood pressure, electrocardiogram, and oxygen saturation monitors are placed. Supplemental oxygen is given by nasal prongs. A foam wedge is placed to keep the knees flexed to prevent lower back pain. An air blower is often placed with the outlet on the chest to eliminate carbon dioxide and oxygen buildup under the drapes and to prevent claustrophobia.

A combination of midazolam (0.5 to 1 mg), fentanyl (12.5 to 50 μg), and propofol (30 to 50 mg) provides excellent amnesia and sedation for the placement of the blocks. We omit midazolam and fentanyl in patients with limited cognitive reserve as a result of stroke or mild dementia. For local anesthesia, we use a 1 : 1 ratio of bupivacaine 0.75% and lidocaine 2% without epinephrine.[119] Hyaluronidase is added to speed tissue penetration.

Facial Nerve Blocks

A facial nerve block is done when complete akinesis of the eyelids is desired.[120] Three methods for the eyelid block are as follows:

1. *Modified van Lint block*: The needle is placed 1 cm lateral to the orbital rim, and 2 to 4 mL of anesthetic is injected deep on the periosteum just lateral to the superolateral and inferolateral orbital rim. The disadvantages of this block include discomfort, proximity to the eye, and common postoperative ecchymoses.
2. *O'Brien block*: The mandibular condyle is palpated inferior to the posterior zygomatic process and anterior to the tragus of the ear as the patient opens and closes the jaw. The needle is inserted perpendicular to the skin about 1 cm to the periosteum. As the needle is withdrawn, 3 mL of anesthetic is injected.
3. *Nadbath-Rehman block*: A 12-mm, 25-gauge needle is inserted perpendicular to the skin between the mastoid process and the posterior border of the mandible. The needle is advanced its full length, and after careful aspiration, 3 mL of anesthetic is injected as the needle is withdrawn. This blocks the entire trunk of the facial nerve. The patient should be told to expect a lower facial droop for several hours postoperatively. The major disadvantage to this block is the proximity of the injection to important structures such as the carotid artery and the glossopharyngeal nerve.

Retrobulbar Block

The retrobulbar block provides excellent akinesia and anesthesia of the eye.[121] A 3-cm, 23- to 25-gauge blunt Atkinson needle is recommended to protect against ocular perforation. The needle is placed at the junction of the inferior and lateral walls of the orbit just above the inferior orbital rim.[122] The needle is advanced about 15 mm along the wall of the orbit until it is past the equator of the eye. The needle is turned superiorly to aim toward the superior orbit. The needle is advanced until it enters between the extraocular muscles; 2 to 3 mL of anesthetic solution is injected. Some intorsion on downgaze is expected because the superior oblique muscle is outside the muscle cone and may not be blocked.

Retrobulbar hemorrhage is the most common complication of this block; proptosis and subconjunctival ecchymosis also are seen. Monitoring of the IOP is mandatory. If the pressure becomes elevated, a lateral canthotomy is performed to decompress the orbit. Bleeding outside the muscle cone is seen as subconjunctival ecchymosis without proptosis. After some monitoring, if no increased IOP develops, the surgical procedure may be done safely.

Intravascular injection can occur despite a negative aspiration test. The total dose of local anesthetic used is small, and even if the total dose is given intravenously, no systemic effects would be likely. Accidental intra-arterial injection can give high brain levels via retrograde flow in the internal carotid artery. Central nervous system excitation and seizures can be seen, but are usually very transient, as the local anesthetic redistributes out of the brain. Obtundation and respiratory arrest have been reported. These prolonged effects are thought to be due to injection into the optic nerve sheath, which is continuous with the subarachnoid space.

Optic nerve damage and ocular perforation with retinal detachment and vitreous hemorrhage also have been reported. Special care must be taken when injecting patients with high myopia. If the axial length of the globe is greater than 25 mm, the eye is larger, and the sclera is thinner, increasing the risk of ocular penetration. A different anesthesia technique may be advisable in such cases.

Posterior Peribulbar Block

To prevent retrobulbar hemorrhage, posterior peribulbar anesthesia has become more popular.[123] A blunt 23-gauge ⅞-inch Atkinson needle is placed at the junction of the middle and lateral thirds of the lower lid just above the inferior orbital rim; 1 mL of local anesthetic is put just below the orbital septum, 3 mL at the equator, and 2 mL posterior outside the muscle cone. If no bulging is noted at the superior nasal lid area, a second injection of 2 to 3 mL is administered inferonasally. Disadvantages of the technique include a longer onset time (9 to 12 minutes) and lower incidence of complete akinesia. Globe perforation from peribulbar injection has been reported.[124]

Sub-Tenon's Block

To avoid the complications of sharp needles, a technique was developed using a blunt cannula under Tenon's fascia.[125] Various

lengths of cannulas have been used. Under topical anesthesia with sedation, a speculum is placed to retract the lids. A 2- to 3-mm spot of cautery is made 5 mm from the limbus in the inferonasal or inferolateral quadrant. A 2-mm snip is made in the conjunctiva with blunt dissection through Tenon's fascia. A blunt cannula is directed under Tenon's fascia posteriorly, but not beyond the equator of the globe, with injection of 1 to 3 mL of local anesthetic. Some degree of conjunctival edema is often seen. Analgesia is usually excellent.

Topical Anesthesia

Cataract surgery can be done under topical anesthesia alone.[126] This technique arose with the increase in popularity of small incision surgery and phacoemulsification. Topical anesthesia avoids the potential complications associated with retrobulbar and peribulbar injections. In addition, patients have the most rapid visual rehabilitation, with improved vision almost immediately after the procedure. Disadvantages of the technique include the potential for eye movement during surgery, increased patient anxiety, and discomfort from the microscope light.[127] Tetracaine 0.5% and lidocaine 4% have been used successfully. Two drops of tetracaine are given initially. About three more doses of tetracaine or lidocaine are applied every 5 minutes just before surgery.

Appropriate patient selection is crucial. A confident, calm, and cooperative patient usually does well. A nervous, hypersensitive patient may be a better candidate for another technique. Other problems may be presented by photophobic patients, patients with small pupils, or patients who require a large incision.

General Anesthesia

The choice of general versus regional anesthesia is made on the basis of the duration of the surgery, the relative risks and benefits of each technique for the patient, and patient preference. Neither technique has been shown to be safer.

In the past, regional anesthesia had an advantage of greatly reduced postoperative nausea and vomiting. With the advent of shorter-acting general anesthetics and nonopioid analgesia, the incidence of nausea and vomiting has decreased dramatically. Droperidol has been used frequently as an antiemetic, although it has been associated with late postoperative anxiety in some individuals. Ondansetron may be as effective with fewer side effects. A comparison of memory function in patients after general anesthesia or local anesthesia with sedation showed no advantage to either technique.[128]

The goals of general anesthesia include a smooth intubation, stable IOP, avoidance of severe oculocardiac reflexes, a motionless field, and smooth emergence. These goals can be accomplished with inhaled anesthesia, balanced opioid anesthesia, or intravenous agents, with or without muscle relaxants. The LMA can be used for ophthalmologic surgery and may be associated with less coughing on emergence. Because of the inaccessibility of the airway during the surgery, and the risk of laryngospasm or aspiration, LMA should be used only by anesthesiologists very skilled in the technique. It may be more appropriate for extraocular surgery.

Nitrous oxide presents a special problem in some vitreoretinal procedures.[129] In the technique called fluid-gas exchange, the surgeon injects an intravitreal air bubble to tamponade the retina against the wall of the globe. Sulfur hexafluoride is a poorly soluble gas used to prolong the resorption of intravitreal air bubbles. Nitrous oxide diffuses and causes bubble expansion, with the potential for dangerous increases in IOP. Nitrous oxide should be shut off for 15 minutes before placing the sulfur hexafluoride bubble and should be avoided for 7 to 10 days thereafter.

This problem is potentially worse with a newer agent, perfluoropropane (C3F8), because this agent can persist for weeks. Here, nitrous oxide should be avoided for at least a month, or until the bubble is resorbed. If a patient presenting for nonophthalmic surgery has a history of a recent retinal procedure, it is critical to establish whether the patient has an intravitreal gas bubble before using nitrous oxide. Otherwise, blindness can result.

Anesthesia for Pediatric Ophthalmologic Procedures

(see also Chapter 82)

Anesthesia for pediatric eye surgery can be considered a subspecialty of its own.[130] Small children may need examination under anesthesia. Intramuscular ketamine sometimes can be a good choice; it can be used when intravenous access may be problematic. Some ophthalmologists prefer ketamine because it does not reduce IOP as barbiturates and deep inhaled anesthetics do.

The most common eye surgery in children is for strabismus, or misalignment of the eyes. There is generally no severe postoperative pain, but nausea and vomiting are significant 50% to 80% of the time without treatment. Droperidol 5 to 75 µg/kg seems to decrease nausea and vomiting significantly without undue delay of discharge. Ondansetron has similar effects without sedation. If forced duction testing is used to assess the muscle tightness, the surgeon should be notified if succinylcholine is used. Succinylcholine causes a tonic increase in eye muscle tone, which resolves in about 20 minutes.

Strabismus is a very common condition, and most children are otherwise healthy. There is a higher incidence of strabismus in trisomy 21 or Down syndrome, cerebral palsy, and hydrocephalus. Malignant hyperthermia and myotonic dystrophy also have been associated with strabismus. Myotonic dystrophy also is seen in patients with ptosis and cataracts.

Cataracts can be seen in children with Pierre-Robin syndrome and phenylketonuria. Patients with Marfan syndrome have a high incidence of subluxation or dislocation of the lens. Aniridia, the congenital absence of the iris, is associated with Wilms' tumor and hypertension. Congenital glaucoma also can be seen with Sturge-Weber syndrome and with seizures and angiomas of the mouth and larynx. Pediatric ophthalmic conditions associated with congenital syndromes are summarized in Table 75-2.

Ophthalmologic Procedures

General Procedures

Most general ophthalmologic procedures are done with topical or local anesthetic injection techniques. Enucleation can be done under block, but usually is done under general anesthesia.

Incision and Drainage of Chalazion

A chalazion is an eyelid mass that results from chronic inflammation of the meibomian gland. Surgical treatment is indicated when there is inadequate response to conservative methods.

Tarsorrhaphy

The partial or total suturing together of the eyelids is performed to protect the eye and to allow healing of ulcers or exposure problems.

Table 75-2 Ocular Manifestations and Pediatric Syndromes

Strabismus	Trisomy 21 Cerebral palsy Meningomyelocele Prematurity Retinoblastoma Craniopharyngioma Malignant hyperthermia Myotonic dystrophy Ehlers-Danlos syndrome
Ptosis	Malignant hyperthermia Myotonic dystrophy
Cataract	Trisomy 21 Myotonic dystrophy Pierre-Robin syndrome Phenylketonuria Homocystinuria Lowe's syndrome Rubella Sarcoidosis Galactosemia Hypoparathyroidism Diabetes mellitus Glucose-6-phosphate dehydrogenase deficiency
Lens subluxation	Marfan's syndrome Homocystinuria Ehlers-Danlos syndrome
Glaucoma	Homocystinuria Lowe's syndrome Rubella Aniridia Sturge-Weber syndrome Neurofibromatosis Ehlers-Danlos syndrome
Retinal hemorrhage	AIDS Multiple myeloma
Vitreal hemorrhage	Sickle cell syndromes
Orbital tumor	Multiple myeloma
Glioma of the optic nerve	Neurofibromatosis
Retinopathy	Diabetes mellitus Hypertension
Ophthalmopathy	Juvenile diabetes Graves' disease
Ocular muscle weakness	Myasthenia gravis
Ocular erosions	Stevens-Johnson syndrome (erythema multiforme)
Conjunctivitis or iritis	Reiter's syndrome Infectious mononucleosis Rheumatoid arthritis
Keratoconjunctivitis sicca	Sjögren's syndrome Sarcoidosis Systemic lupus erythematosus
Uveitis	Ankylosing spondylitis Juvenile arthritis Sarcoidosis
Optic neuritis	Multiple sclerosis

AIDS, acquired immunodeficiency syndrome.

Temporal Artery Biopsy

A biopsy of the temporal artery is performed to diagnose temporal arteritis.

Anterior Chamber Paracentesis

A tap of the anterior chamber fluid is done for diagnostic testing or to reduce IOP quickly.

Enucleation

Enucleation refers to the removal of the entire eyeball after the muscles and optic nerve have been cut. Indications for surgery are a blind painful eye and intraocular tumors.

Cataract Extraction

Cataracts are opacities of the crystalline lens of the eye. Cataract extraction is performed under topical or regional block. General anesthesia is rarely used.

Intracapsular Cataract Extraction. Intracapsular cataract extraction is the total removal of the opaque lens with the lens capsule. It may be done with a cryoprobe. Intracapsular cataract extraction is done in selected cases of lens subluxation, dislocation, or a lens containing a foreign body.

Extracapsular Cataract Extraction. Extracapsular cataract extraction refers to the removal of the lens, while leaving the posterior lens capsule and zonules intact. A rim of the anterior capsule also is preserved. This provides an excellent location for an intraocular lens implant.

Phacoemulsification

Phacoemulsification refers to the use of ultrasonic vibration of fragments of the lens with simultaneous irrigation and aspiration. This technique allows for very small incisions.

Glaucoma Procedures

Glaucoma is a general term for diseases of the eye characterized by an increase in IOP.

Filtration Procedures. Trabeculectomy is a surgical excision of the trabeculum to increase the drainage of aqueous humor. Baerveldt and Ahmed devices are glaucoma drainage implants that shunt aqueous fluid out of the eye to drain under the conjunctiva of the orbit.

Procedures for the Cornea

Penetrating Keratoplasty. A corneal transplant is done to replace an optically poor, infected, or traumatized cornea. Control of IOP and avoidance of patient movement are especially important in these open-globe procedures.

Radial Keratotomy. A series of incisions is made in the cornea in a spikelike manner to change the shape of the cornea to correct myopia.

Pterygium Excision. A pterygium is an abnormal fold of membrane in the interpalpebral fissure. An excision is generally performed when the abnormal tissue impinges on the cornea, affecting vision, or for cosmetic improvement.

Vitreoretinal Surgery

Retinal Cryotherapy. A cryoprobe is used for prophylaxis of certain retinal breaks and tears. It also is used in some patients with retinal tumors and vascular malformations.

Repair of Retinal Detachment. Retinal reattachment involves localizing all tears and holes, creating chorioretinal adhesions, and scleral buckling with silicone belts around the globe to pull the sclera in to support the retina.

Vitrectomy. Vitrectomy is the surgical extraction of the contents of the vitreous chamber and their replacement with a physiologic solution. A posterior vitrectomy is indicated for the removal of foreign bodies, to repair retinal detachments, to remove membranes and media opacities, and to alleviate vitreous traction on the retina. These may be prolonged procedures. Many patients have diabetes or severe chronic hypertension and offer difficult challenges to the anesthesiologist.

Oculoplastic Surgery

Most oculoplastic surgery is performed with local infiltration anesthesia. Some longer, more invasive procedures require general anesthesia.

Ectropion Repair. Ectropion usually results from the effects of aging on the eyelid. Other causes include mechanical or congenital lid pathology. The eyelid is turned outward.

Entropion Repair. Involutional entropion usually results from aging. The eyelid is inverted or turned inward.

Ptosis Repair. Ptosis, or drooping of the upper eyelid, can be congenital (dystrophy of the levator muscle) or acquired from aging or trauma.

Blepharoplasty. Blepharoplasty is plastic surgery of the eyelids to remove redundant tissue that is obstructing vision, or for improved appearance.

Dacryocystorhinostomy

Dacryocystorhinostomy refers to the formation of a communication channel between the lacrimal sac and the nasal cavity. This is performed for congenital or acquired nasolacrimal duct obstruction. It usually requires general anesthesia.

Orbital Surgery

Most orbital surgery is performed using general anesthesia. If the surgery is anterior, local anesthesia can be used. Examples of orbital surgery include the following:

Repair of blow-out fracture
Drainage of orbital abscess
Decompression of the optic nerve
Exenteration of the orbit for malignancy.

Ophthalmologic Emergencies

Most urgent ophthalmologic procedures do not need to be done on an emergency basis. This is important because the anesthetic plan must consider the NPO status and general medical condition of the patient. This does not apply to true eye emergencies. In these rare conditions, therapy should be started within minutes. Other urgent ophthalmologic conditions can start within 1 to several hours without change in outcome.

True Emergencies. Therapy should be started within minutes for chemical burns of the cornea and central retinal artery occlusion.

Urgent Situations. Therapy should be started in 1 to several hours. Urgent situations include open-globe injuries, endophthalmitis, acute narrow-angle glaucoma, acute retinal detachment, corneal foreign body, and lid laceration.

Semi-urgent Situations. Therapy should be started within days, but sometimes can be rescheduled for several weeks. Semi-urgent situations include ocular tumors, blow-out fractures of the orbit, congenital cataract, and chronic retinal detachment.

Open Globe and Full Stomach. A patient with eye trauma presents a challenge to the anesthesiologist. The dilemma is to protect the patient from aspirating stomach contents and to protect the eye from acute changes in IOP, which could cause vitreous loss, retinal detachment, and blindness. A rapid-sequence induction provides rapid airway control, but succinylcholine is associated with a modest increase in IOP. Other suggested strategies include precurarization, large-dose vecuronium or pancuronium, and succinylcholine using the priming principle. Regional anesthetic techniques also have been shown to be applicable.[131] Factors to consider include the following:

Size of the perforation: Small punctures have higher resistance to vitreous loss with changes in IOP.
Pulmonary status: Patients with decreased functional residual capacity become hypoxic faster, making a more rapid technique preferable.
NPO status: What is the magnitude of the aspiration risk?
Length of procedure: If the surgery is short, and a large dose of nondepolarizer is used, will the patient require postoperative mechanical ventilation?

Anesthesia-Related Eye Injuries

Anesthesiologists must be aware of possible ocular damage during anesthesia and surgery. If a patient emerges from a general anesthetic complaining of vision impairment, it must be considered an emergency because of the possibility of central retinal artery occlusion. When using a facemask, care must be taken to avoid applying undue pressure to the eye. Systemic hypotension and anemia also can be contributing factors in vision loss.

A second potential complication is corneal abrasion. General anesthesia has been shown to decrease basal tear production. Proper eye care with taping of lids with or without an ocular lubricant provides protection. If a patient emerges from general anesthesia with eye pain or a foreign body sensation, the patient must be followed up to ensure improvement. If left untreated, corneal abrasions can progress to form corneal ulcers.

76 Anesthesia for Robotic Surgery

Key Points

1. Robotic surgery is accomplished by an autonomous, reprogrammable manipulator designed to move and articulate specialized instruments through programmed motions that achieve a specific task. A robot can be given three-dimensional coordinates from any imaging device (e.g., computed tomography) that allows it to recognize surfaces on which it will do a specific, programmed task.
2. Robotically assisted surgery involves mechanical devices that move by a motorized system under partially programmed control, and that can be instantly controlled or modified by a surgeon's intervention.
3. Computer-assisted surgery involves systems that are manually controlled by the surgeon, and that include a tracking system, sensors, and end-effector instruments. This system provides direct and continuous control of movements.
4. Telesurgery refers to the ability to perform surgery using computer-assisted instruments from a remote location.
5. Telemanipulation refers to the ability to produce electronically precise instrument movements at a distance from a remote location.
6. Telepresence refers to virtual projection of images from remote sites. This virtual projection allows the surgeon to visualize intended robotic movements at distant locations. It also enables telementoring, which is supervision and instruction from a distant location.
7. Initially, robotically assisted surgical thoracic procedures increased the duration of required general anesthesia. Concomitantly, the duration of one-lung ventilation has been taken to new time extremes, which has given us insight into the respiratory physiology of prolonged one-lung ventilation. As surgeons gain expertise with robotically assisted surgery, operative times are expected to shorten dramatically to approach those for traditional open surgery.
8. Because of the proximity of the side cart to the patient, the patient must be guarded against inadvertent contact from the motions of the robotic arms. Even more important, after the instruments are engaged to the arms of the robot and are inside the patient, the patient's body position cannot be modified unless the instruments are disengaged entirely and removed from the body cavity.

Robotic surgery is the resulting transformation of the minimally invasive surgical evolution. Robotic devices are being introduced to surgery because they allow unprecedented control and precision of surgical instruments in minimally invasive procedures. The anticipated benefits of robotic or robot-assisted surgery to the patient include less pain and trauma, shorter hospital stays, quicker recovery, and a better cosmetic result. With these technologic innovations, new anesthetic implications for patient care are being discovered. As surgery evolves into the robotic era, anesthesiologists must keep abreast of these changes and their impact on patient care and safety.

First-generation surgical robots are being installed in numerous operating rooms around the world. These are not true autonomous robots that perform surgical tasks; rather, they are mechanical "helping hands" that offer assistance in various fields of surgery. These machines still require human intervention to operate or to provide input instructions. Robotic devices are here to help surgeons, not to replace them.

History

The word *robot* was first used by Capek in his play *Rossum's Universal Robots* in 1921. It is derived from the Czech word *robota,* meaning "forced labor."[1] Robots were first developed by the National Aeronautics and Space Administration (NASA) for use in space exploration.[2] These devices, or telemanipulators, were capable of doing manual tasks aboard a spacecraft or out in space. The slave devices were controlled electronically from a remote master control on Earth or aboard a spacecraft. Telemanipulators were used extensively aboard NASA's space shuttle missions between 1983 and 1997. Research in trajectory and missile guidance systems eventually led to highly precise targeting mechanisms. Precision pointing at targets, such as the Earth and stars, was crucial for Spacelab telescope experiments. Telemanipulators such as the Instrument Pointing System were specifically designed for extreme accuracy (±1.2 arcsec). Scientists at NASA Ames

Research Center were responsible for developing virtual reality. The idea took root with contributions of VPL, a visual programming language, and Dataglove. Their integration made it possible to interact with three-dimensional virtual scenes. It took the integration of robotic engineering and virtual reality, however, to develop a dexterous telemanipulator for the anastomoses of nerves and vessels in hand surgery.

From these applications, it became apparent to the U.S. Department of Defense that virtual reality and telepresence might serve a useful function in treating wartime casualties on the battlefield. Through virtual reality, the surgeon could be brought to the patient's side, an idea described by the term *telepresence*. Data from wounded casualties of the Vietnam War estimated that, of all wounded soldiers, one third died of head and massive injuries, and another third died of exsanguinating hemorrhage, but had the potential to survive if they were treated in time.[2] The Department of Defense sought to improve medical presence on the battlefield given that one third of casualties could be saved. Telepresence allowed a surgeon located aboard an aircraft carrier to perform surgery (with the aid of telemanipulation) on wounded soldiers located in a remote location on the battlefield. With this idea in mind, the Department of Defense funded much of the research in telemanipulation for remote mobile surgical units that would allow for telepresence.

Another impetus for development of robotic surgery came from limitations of laparoscopic surgery. Mouret[3] performed the first videolaparoscopic cholecystectomy in Lyons, France, in 1987[3]; in 1988, Perissat and coworkers[4] presented the innovation to the Society of American Gastrointestinal Endoscopic Surgeons, and an exponential spread of laparoscopic surgical procedures began. Although laparoscopic surgery provided a great benefit for the patient, it brought tremendous surgical limitations, such as loss of three-dimensional vision, impaired touch sensation, and poor dexterity provided by the long instruments and the fulcrum effect. The fulcrum effect is a nonintuitive motion of the instrument tips in opposite direction around a fixed point, usually at the skin entrance site. New skills had to be learned. Initial attempts to surmount the burdens of endoscopic surgery provided the impetus for robotic support systems that can enhance surgical skills and control of instruments.

The first robotic devices appeared in the 1980s for use in stereotactic brain surgery. In 1992, ROBODOC (Integrated Surgical Systems, Sacramento, CA) was introduced for grinding bone to make space for prostheses in hip replacement surgery. By the mid-1990s, positioning robots were introduced. Automated Endoscopic System for Optimal Positioning (AESOP) (Computer Motion Inc, Goleta, CA) was introduced for voice-controlled optimal camera positioning, and Laparoscopic Assisted Robotic Systems (LARS) (John Hopkins University, Baltimore, MD), an automated robot, was introduced for organ retraction.[5] The master-slave telemanipulator concept was developed for medical use in the early 1990s. The first master-slave manipulator for medical use was developed at Stanford Research Institute in 1991. The goal was to have computer algorithms that translate a surgeon's master manual movements to end-effector slave instruments at a remote site. Early designs had only 4 degrees of freedom, but by 1992, a German prototype was developed with 6 degrees of freedom (Fig. 76-1).[6] In 1994, Intuitive Surgical obtained technologic rights from Stanford Research Institute, and a prototype DaVinci system was released in 1997.

Engineers realized that the distance between patient and surgeon had an upper limit, beyond which accuracy and dexterity of instrument control would become degraded. Latency is the time it takes to send an electric signal from a hand motion to actual visualization of the hand motion on a remote screen. The lag time to send an electric signal to a geosynchronous satellite at 22,300 miles above the Earth and return is 1.2 seconds. This transmission delay would prohibit practical surgery. Humans can compensate for delays of less than 200 msec. Longer delays compromise surgical accuracy. Tissue moves when force is applied to it, and with a visual delay greater than 200 msec, the movement would not be noticed fast enough to avoid cutting in an unintended place.

The most optimistic attempt to provide telesurgical presence over long distances was undertaken using high-bandwidth fiberoptic ground cable. The latency time of 155 msec allowed Marescaux and colleagues[7,8] to perform a robot-assisted laparoscopic cholecystectomy between New York City and Strausbourg, France, in 2001. In 2003, a telerobotic surgical service was established between a teaching hospital in Canada, and a community hospital 250 miles away. This service was designed to provide telerobotic assistance by an "expert" surgeon to a community-based surgeon. Some of the procedures performed include laparoscopic Nissen fundoplication, laparoscopic right hemicolectomy, laparoscopic sigmoid/anterior resection, and laparoscopic hernia repair.[9]

Recent years have witnessed a surge in robotic surgery. In 2000, 1500 robotic procedures were performed. In 2004, more than 20,000 robotic procedures were done. Urology accounted for the bulk of these procedures, with 8000 prostatectomies being done.

Robotic Systems

The word *robot* is a ubiquitous term that describes an autonomous device capable of various tasks (see the previous section on history). Industrial robots used in assembly lines perform highly precise, repetitive tasks. The robots are preprogrammed off-line, and tasks are invoked on command. Robots used in orthopedic surgery and neurosurgery are examples.[10] Precise tasks, such as drilling and probe insertion, are based on registration. Registration is a mathematical process that allows location and anatomic orientation in three dimensions based on data derived from preoperative computed tomography (CT) or magnetic resonance imaging (MRI).

A second type of robot is defined as an assist device, such as AESOP. These robots are used to control instrument location and guidance. Assist-device robots are not autonomous; they need input cues from the operator.

A third type of robot is a telemanipulator. These robots are under constant control of the operator. These devices mimic the operator's hand motions in an exact or scaled motion. Several telemanipulator robotic devices are available throughout the world. The da Vinci Robotic Surgical System (Fig. 76-2) has been approved by the U.S. Food and Drug Administration (FDA) for laparoscopy, thoracoscopy, and intracardiac mitral valve repair surgery, and the ZEUS Surgical System (Fig. 76-3) has been developed in parallel and approved by the FDA for general and

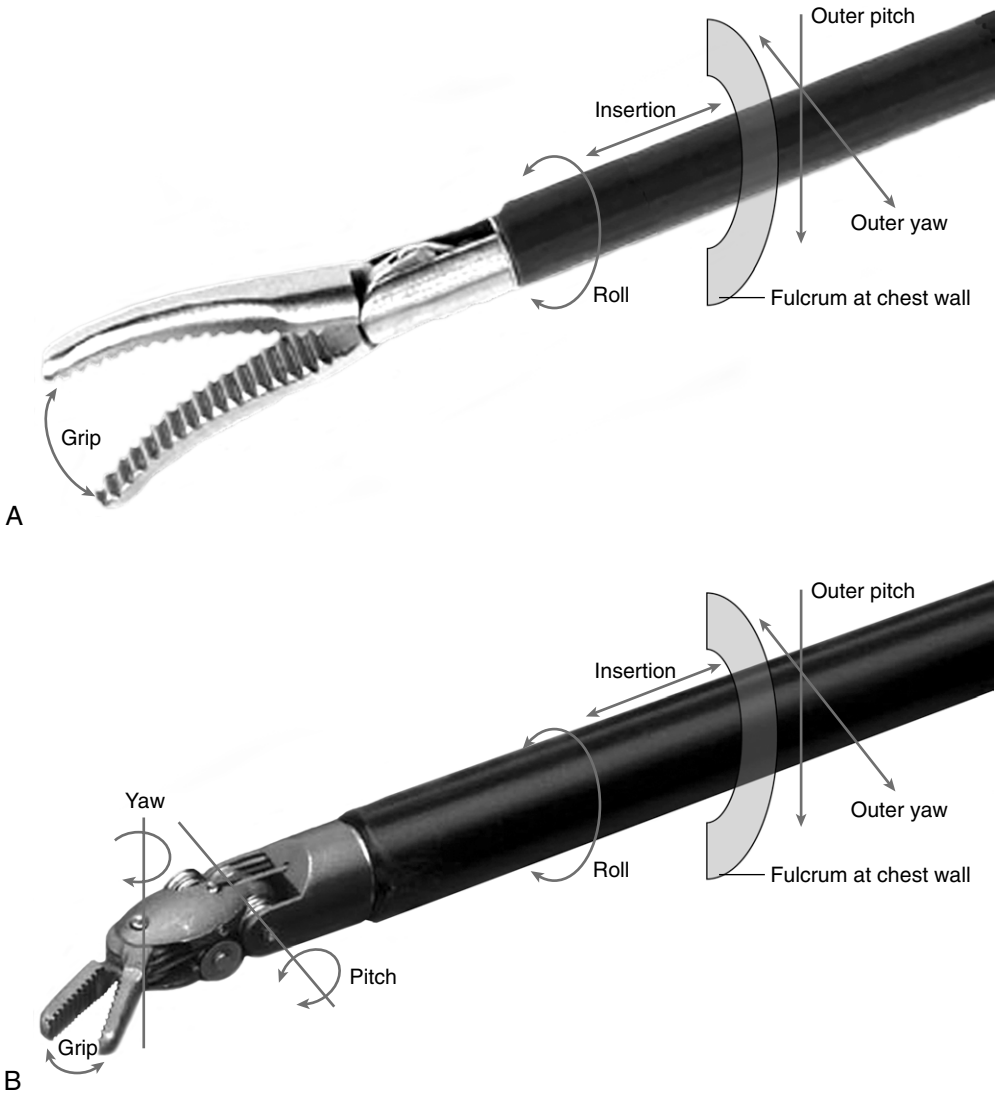

Figure 76-1 Degrees of freedom (DOF) in motion. **A,** Conventional laparoscopic instruments have only 4 DOF and grip. Insertion (i.e., movement in the *z* axis), roll, and movement along the *x* and *y* axis outside the body relative to a fulcrum point constitute the 4 DOF. **B,** Depiction of the EndoWrist instrument with two added intracorporeal joints, producing 7 DOF. *(**A** and **B,** Copyright © 1999 Intuitive Surgical, Inc, Sunnyvale, CA.)*

laparoscopic surgery. The two systems are very similar, with some minor differences. The ZEUS system was subsequently shelved after the company making it was acquired by its competitor, Intuitive Surgical, the makers of Da Vinci systems. The da Vinci Robotic Surgical System is described in this chapter as a representation of most modern surgical robots.

The da Vinci system has three components: a console, an optical three-dimensional vision tower, and a surgical cart (see Fig. 76-2). The surgical cart has four arms that can be manipulated by the surgeon through real-time computer-assisted control. The first two arms represent the surgeon's right and left arms, to hold the instruments, and the third arm positions the endoscope. The optional fourth arm enables the surgeon to hold another instrument or perform additional tasks, such as holding countertraction and following running sutures, eliminating the need for a patient-side surgeon. The system allows the surgeon to be physically remote from the patient (Fig. 76-4).

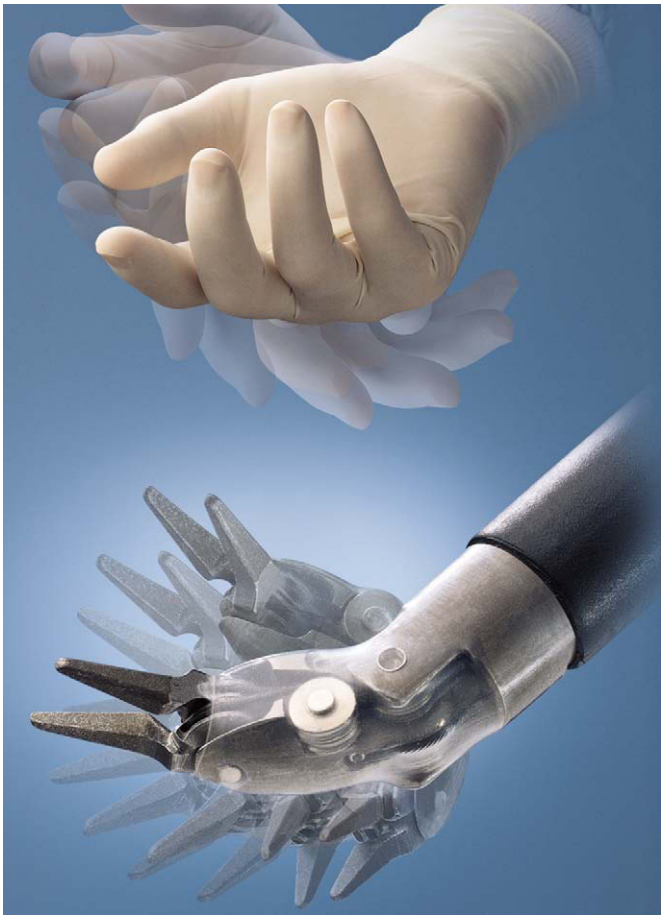

Figure 76-5 The da Vinci Robotic Surgical System: Master controls that translate the surgeon's hand, wrist, and finger movement into real-time movements of surgical instruments inside the patient. *(Courtesy of Intuitive Surgical, Inc, Sunnyvale, CA.)*

The system's instruments are designed to have 7 degrees of freedom, which enables it to approach the identical articulation of the human wrist (Fig. 76-5). Seven degrees of freedom include three arm movements (in out, up down, side to side), and three wrist movements—yaw (side to side, left and right), pitch (up and down), and roll or rotational. The seventh degree of freedom is grasping or cutting. The system design incorporates a frequency filter that eliminates hand tremor greater than 6 Hz. Motion scaling also can be invoked up to a ratio of 5:1 (i.e., the surgeon moves 5 cm, and the robot moves 1 cm). Scaling allows for work on a miniature scale. The console also provides a three-dimensional image of the surgical field. The endoscope consists of dual, independent optical channels capable of transmitting digital images to the console's visual monitor. At the console, the surgeon is actually looking at two separate monitors; each eye sees through an independent camera channel to create a virtual three-dimensional stereoscopic image. The images are controlled through two independent light sources found on the optical three-dimensional vision tower.

The surgeon sits at the console and controls the telescope arm and three robotic manipulator arms. The viewing space provided is similar to a double-eyepiece microscope (Fig. 76-6). Each eyepiece displays a mirror reflection of a computer monitor screen. Each monitor displays one channel of the stereo endoscope to an eye, creating a virtual three-dimensional stereoscopic image of the surgical field.

Figure 76-6 The da Vinci Robotic Surgical System: Stereo viewer that creates a virtual three-dimensional stereoscopic image. *(Courtesy of Intuitive Surgical, Inc, Sunnyvale, CA.)*

The surgeon controls the manipulators with two masters (Fig. 76-7). The masters are made of levers that attach to index fingers and thumbs of each hand. Wrist movements replicate the movements of the instruments at the end of the robotic arms. The console has a foot pedal that disengages the robotic motions (i.e., clutching), another that allows adjustment of the endoscopic camera, and a third pedal for controlling the energy of electric cauterization.

The side cart of the robotic device has four arms that respond to the manipulative controls of the surgeon while sitting at the console. The cart is bulky and very heavy. It has to be wheeled to the vicinity of the patient's surgical area and is locked into place. Because of the proximity of the side cart to the patient,

Figure 76-7 The EndoWrist instrument of the da Vinci Robotic Surgical System mimics the natural kinematics of the surgeon's hand and wrist. This design allows 7 degrees of freedom. *(Copyright © 1999 Intuitive Surgical, Inc, Sunnyvale, CA.)*

the patient must be guarded against inadvertent contact from the motions of the robotic arms. Even more important, after the instruments are engaged to the arms of the robot and inside the patient, the patient's body position cannot be modified unless the instruments are disengaged entirely and removed from the body cavity. Any patient movement from lack of muscle relaxant may be disastrous. The clutching buttons allow for the robotic arms to be grossly positioned without moving the instruments within the trocars or access ports. A clutching function allows surgical assistants to exchange various instruments.

The optical tower contains the computer equipment needed to integrate the left and right optical channels to provide stereoscopic vision and to run the software needed to control the kinematics of the robotic arms. The computer interfaces the translated motion of the surgeon's hands to a digital code that moves mechanical levers, motors, and cables that allow the robot to articulate the exact motions of the surgeon's hand.

The instruments in the body cavity must remain sterile, but interface with nonsterile robotic arms. Detachable disposable instruments facilitate this interface. Each type of instrument requires different forces and motion scaling intrinsic to the task at hand and requires specific computer software processing. Additional operating room staff is required for detaching and exchanging task-specific instruments throughout the case. Monitors are positioned on top of the tower so that all individuals in the operating room have a view of the surgical field.

An obstacle that still needs research is tactile sensing. The feedback that the robot offers for the surgeon's applied force is inferior. The robot offers some sensation, but the applied force does not correlate well with the force applied to the tissues. This correlation varies with the type of instrument and depends on the torque applied; the operator must rely on visual cues from tissue distortion to gauge how much pressure is being generated.

The ZEUS Surgical System is another example of a master-slave telemanipulator. It employs the assistance of the AESOP Robotic System for visualization. It is basically one mechanical arm used by the physician to position the endoscope, which is a surgical camera inserted into the patient. Foot pedals or voice-activated software allow the physician to position the camera, leaving his or her hands free to continue operating on the patient. The manipulators of the ZEUS system are freely mounted on the operating table, similar to the AESOP. It provides tremor filtering and motion scaling from 2:1 to 10:1.

General Surgery

Robotic technology has defined itself in the field of gastrointestinal laparoscopic surgery.[11] The first surgical operation using robotic telemanipulation was a laparoscopic cholecystectomy performed in 1997 in Brussels, Belgium.[12] Robot-assisted surgical techniques permit the surgeon to provide the smallest possible incision and lowest surgical stress. This technology allows surgeons to work on a very small scale in cramped spaces. Virtually all gastrointestinal procedures have been performed safely by surgeons using this technology. Procedures most commonly performed include cholecystectomy, fundoplication, Heller myotomy, bariatric surgery, and colectomy.[13]

Robotic surgery overcomes some of the disadvantages of conventional laparoscopic procedures with three-dimensional imaging, elimination of motion reversal, motion scaling, and filtering of resting tremors, while offering an ergonomically comfortable position. Other reported apparent advantages of robotic laparoscopic surgery are a short learning curve,[14] better quality of repair,[15] and ease of operation in morbidly obese patients because stiff instruments help counteract abdominal wall torque.[16] Robotic laparoscopic surgery also is associated with high patient satisfaction.[17] Because outcome data on laparoscopic robotic surgery are lacking, its higher costs may prove to be a deterrent to some surgical programs.

Anesthetic Considerations

In the operating room, the patient is monitored with an electrocardiogram, pulse oximetry, axillary temperature probe, and noninvasive blood pressure cuff. Bilateral peripheral intravenous access is valuable because the left upper extremity is not immediately available during the surgery. Anesthesia can be maintained with a volatile agent. Muscle relaxation is paramount in avoiding any movements by the patient while the surgical instruments are within the abdominal cavity. An orogastric tube and a urinary bladder catheter are placed. Convective-air body warmers are applied whenever possible.

With the patient in the supine position, the patient is prepared and draped, and the abdominal cavity is insufflated with carbon dioxide (CO_2) to a pressure not to exceed 20 mm Hg. The trocar for the camera is placed manually. Incision ports for Nissen fundoplication and cholecystectomy are shown in Figures 76-8 and 76-9. The side cart robot is brought very close to the patient's head to engage the other trocars with visual guidance from the robotic camera. Because of the proximity of the side cart to the patient's head, there is limited access to the patient's airway and neck, and the head must be guarded against inadvertent collision with the robotic arms when moving.[18,19] After the robot is engaged, the patient's body position cannot be changed. The surgical team should be capable of rapidly disengaging the robotic device if an

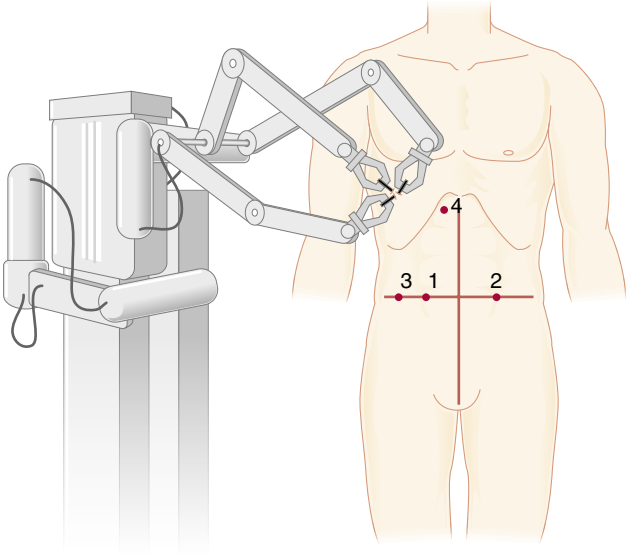

Figure 76-8 Numbered incision ports for Nissen fundoplication and location of the robotic arms.

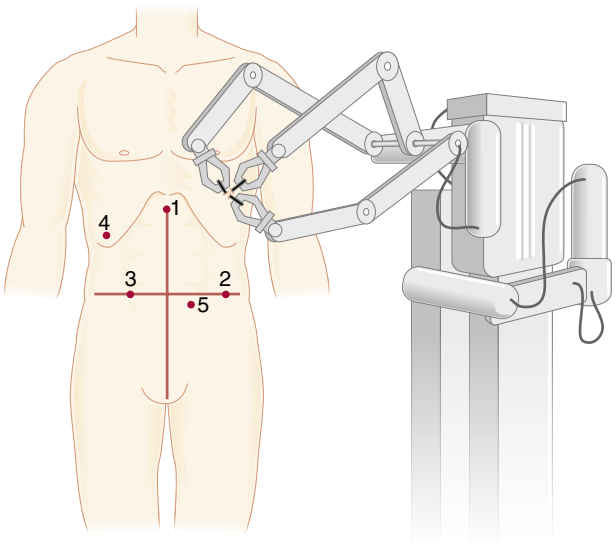

Figure 76-9 Numbered incision ports for cholecystectomy and location of the robotic arms.

airway or anesthesia emergency arises. As with any laparoscopic procedure that requires a pneumoperitoneum pressurized with CO_2, ventilator adjustments may be required to normalize the exhaled CO_2.[20] Some surgeons argue that the benefit of invasive arterial monitoring does not outweigh the risks.[19] This issue should be considered for each patient based on a risk/benefit analysis.

Cardiac Surgery

Application of conventional endoscopic instruments has paved the way for several cardiac procedures to be performed with robotic assistance (see Chapter 60). Internal mammary artery harvesting was successfully performed thoracoscopically in 1997 by Nataf.[21] In 1998, Loulmet and colleagues[22] reported the first totally endoscopic coronary artery bypass surgery. Cardiothoracic applications of robotically assisted surgery have expanded and include atrial septal defect closures,[23-25] mitral valve repairs,[26] patent ductus arteriosus ligations,[27] totally endoscopic coronary artery bypass grafting,[28,29] minimally invasive atrial fibrillation surgery,[30,31] and left ventricular pacemaker lead placement.[32]

Although technical advances in minimally invasive surgery have introduced techniques that are done through very small ports and may eventually make surgical sternotomy obsolete, surgeons still must be trained and prepared to convert to an open sternotomy if the need arises. Sternotomy alone carries a finite risk of morbidity from an inflammatory response, but it is less than that of exposure to cardiopulmonary bypass.[33-35]

Familiarity with and expertise in cardiac and thoracic anesthesia are imperative because both organ systems need to be managed safely. The ability to perform and maintain single-lung ventilation is mandatory, as is the management of the physiologic consequences (Table 76-1). Preoperative assessment of lung function is indicated if a patient has significant lung disease. Poor pulmonary function test results may be a contraindication to robotically assisted cardiac surgery because single-lung ventilation may be poorly tolerated. Robotic surgery may require unprecedented, prolonged one-lung ventilation, which challenges the extent of our understanding of respiratory physiology. Continuous monitoring of cardiac function with transesophageal echocardiography (TEE) has become a standard of care and has found a niche for several procedures required for safer robotically assisted surgery.

Mitral Valve Surgery and Anesthetic Implications

In 1997, two independent groups reported the first robotically assisted mitral valve repair.[36,37] In November 2002, the FDA approved the use of robot-assisted surgery for performing mitral valve repairs. Mitral valve repair, initially done through minithoracotomy incisions, could be done completely with a closed chest. Mitral valve replacements may still require a small thoracotomy, however, to introduce the new prosthetic valve.

Mitral valve surgery employing robotic devices is being done at a few cardiac centers in the United States and Europe. The anesthetic techniques and other relevant considerations have been described previously.[38] Patients are initially evaluated by cardiac catheterization to estimate the degree of coronary artery stenosis and to assess valve function. Severe mitral regurgitation is a mechanical problem that requires surgery for cure. Most patients are medically treated with afterload reducers, such as angiotensin-converting enzyme inhibitors if they are hypertensive. An enlarged left atrium is often susceptible to atrial fibrillation. Patients with persistent atrial fibrillation may be taking anticoagulants concomitantly with therapy for rate control. Chronic elevation of left atrial pressure may manifest with pulmonary hypertension, which may be exacerbated further by obstructive lung disease. Severe pulmonary hypertension renders a patient unsuitable for robotic surgery.[39]

Patients are provided with a large peripheral intravenous catheter. Light sedation with midazolam and local anesthesia is offered before the placement of bilateral radial arterial catheters. The patient is routinely monitored with electrocardiogram leads II and V_5, pulse oximetry, and a right radial arterial pressure catheter to exclude endovascular aortic balloon misplacement. Modern electrocardiogram monitors can provide automatic ST segment analysis for the detection of ischemia. After ample oxygenation, the patient is anesthetized with a combination of midazolam, fentanyl, and isoflurane, and a muscle relaxant is administered.

The trachea is intubated with a double-lumen endotracheal tube. Proper tube position is confirmed by bronchoscopy. A TEE probe is inserted to assess heart and valve function and to guide central line placement. A midesophageal, bicaval view at 90 degrees is used for guidance in positioning the superior vena cava (SVC) and inferior vena cava cannulas (Fig. 76-10). Initially, a left 9F introducer catheter is inserted by means of the Seldinger

Table 76-1 One-Lung Ventilation Strategy

1. Use $F_{IO_2} = 1.0$
2. Begin one-lung ventilation with pressure control ventilation, maintaining a plateau pressure of <30 cm H_2O
3. Adjust respiratory rate so that P_{aCO_2} approaches 40 mm Hg
4. Check arterial blood gas pressure
5. Apply continuous positive airway pressure to nonventilated lung
6. Apply positive end-expiratory pressure to ventilated lung

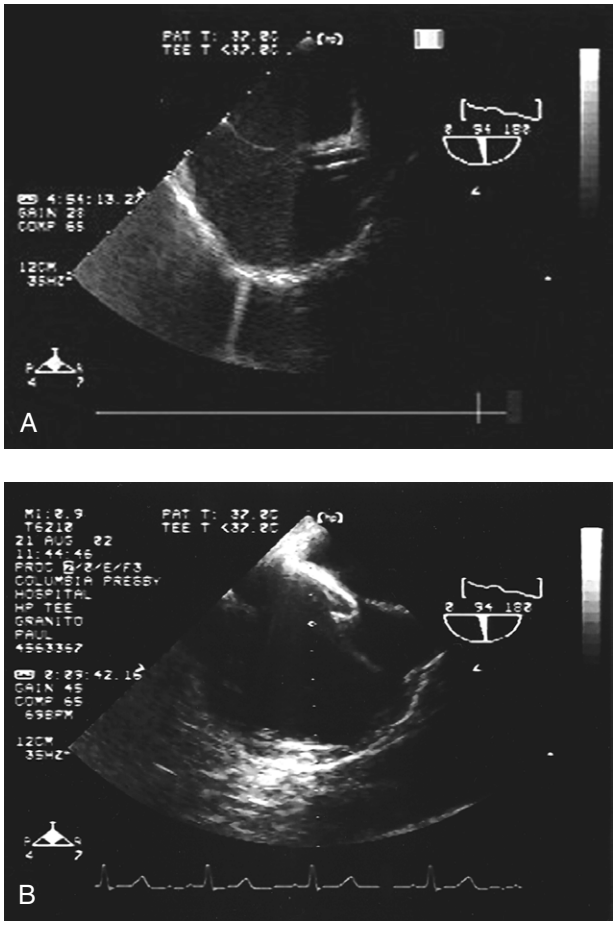

Figure 76-10 **A,** Ultrasound image of the superior vena cava cannula. **B,** Ultrasound image, bicaval view, depicting the inferior vena cava containing a J guidewire. Both views are helpful in correctly placing cardiopulmonary bypass venous cannulas.

technique, and an 8F pulmonary artery catheter is floated into the pulmonary artery. Next, the right neck is prepared for insertion of a percutaneous 17F Biomedicus cannula (Medtronics, Minneapolis, MN). It is inserted directly into the internal jugular vein using the Seldinger technique, and its proper placement is confirmed by TEE. Experience shows that the long transthoracic aortic cross-clamp may impinge and occlude the SVC. For this reason, an armored SVC neck cannula provides resistance to occlusion or kinking. At the time of insertion, the cannula is flushed with 5000 U of heparin to ensure its patency. The cannula is anchored with a purse-string suture at the skin and secured with Kerlix gauze wrapped around the patient's head.

After the patient's pelvis is positioned supine and the right shoulder is tilted 30 degrees to the left, transcutaneous defibrillation and pacing pads are applied. The surgeon can determine proper location for port access, which may vary according to a patient's body habitus.

After the right femoral vessels are exposed and left-sided, single-lung ventilation is established, a right-sided mini-thoracotomy incision is made. The heart is exposed after a pericardial opening is made. The pericardium is anchored open to the chest wall by two percutaneous stay sutures.

After the patient is heparinized according to an activated clotting time–guided protocol, the femoral vein and artery are cannulated in anticipation of femorofemoral cardiopulmonary bypass. First, the femoral vein is cannulated, and a 21F cannula is placed over a guidewire and passed into the inferior vena cava–radial artery junction with the aid of TEE. One end hole and 12 side holes resist collapse under the high negative pressure that is created by augmented venous return pumps. Likewise, the femoral artery is cannulated with a 24F cannula, and cardiopulmonary bypass is initiated with venous drainage from the femoral and jugular veins. Anterograde and retrograde cardioplegia cannulas are placed. Some surgical teams prefer to cannulate the ascending aorta using a Heartport Straight-shot (Heartport, Inc. Redwood City, CA).[39] A transthoracic aortic cross-clamp is passed percutaneously through the right axilla and applied to the ascending aorta. The robotic arms are engaged through their respective trocars lateral to the mini-thoracotomy incision, while the camera arm passes directly through the thoracotomy incision. The left atrium can be entered for mitral valve repair or replacement.

Before terminating cardiopulmonary bypass, TEE is used to evaluate the function of the mitral valve, to assess residual valvular regurgitation, and to confirm the disappearance of intracardiac air. The anterior leaflet of the mitral valve is inspected further for systolic anterior motion.

Patient selection is important for optimal results. Table 76-2 lists the risk factors that make patients unsuitable candidates for robotic mitral valve surgery.

Atrial Septal Defect Repair

Operations for atrial septal defects are similar to those for mitral valve repairs except that a mini-thoracotomy is not required. A closed-chest procedure is possible. Similar to all robotic procedures that demand entrance into the thoracic cavity, single-lung ventilation must be instituted during surgery. Atrial septal defect repairs also require opening the heart and preventing any blood from entering the heart; this is facilitated by jugular and femoral vein cannulation and snaring the inferior vena cava and SVC. Cardiopulmonary bypass with cardioplegia administration into the aortic root is used to arrest the heart. Methods of cardiopulmonary bypass using endovascular clamping are described in the section on coronary artery bypass grafting.

Internal Mammary Artery Harvest

Patients are monitored in the usual way for cardiac surgery. A central venous line and a radial artery cannula are placed on the same side as the harvested internal mammary artery. Single-lung ventilation with a double-lumen tube, a Univent tube, or a bronchial blocker is mandated; the position of the tube is confirmed by bronchoscopy. The patient is positioned supine, with the thorax rotated 20 degrees by placing a roll under the left scapula. External defibrillation and pacing pads are applied to the left posterior

Table 76-2 Exclusion Criteria for Robotically Assisted Mitral Valve Repairs

Severely calcified mitral annulus
Severe pulmonary hypertension
Ischemic heart disease
Surgery requiring multiple valve repairs
Previous surgery to right hemithorax
Severe aortic and peripheral atherosclerosis

Table 76-3 Exclusion Criteria for Robotically Assisted Endoscopic Coronary Artery Bypass Grafting

Contraindication to one-lung ventilation
Age >80 years
Ejection fraction ≤40%
Severe noncardiac health issues
Severe peripheral vascular disease
Myocardial infarction within last 7 days
Previous thoracic surgery, pleural adhesions, or emergency surgery
Calcified left anterior descending artery or diffuse disease
Intramyocardial left anterior descending artery
Morbid obesity (body mass index >32)
Large heart within left chest

chest and anterolateral right chest. Raising the left arm provides more exposure and stretches the skin overlying the left anterolateral chest. The opposite can be done to the right chest when harvesting only the right internal mammary artery.

CO_2 insufflation is needed to provide exposure and countertraction. CO_2 insufflation (5 to 10 mm Hg) into the left hemithorax pushes the mediastinal fat pad medially and enlarges the space between the sternum and heart to a small extent to provide a better view. For harvesting both internal mammary arteries, insufflation of the left hemithorax is sufficient to expose the right internal mammary artery because of the leftward position of the heart[40] and the improved angle of sight. Insufflation is begun in increments of 2 to 4 mm Hg. The insufflation flow rate is adjusted automatically to achieve a preset intrathoracic pressure limit. Caution should be exercised when insufflating the thorax in patients who have poor left ventricular function or are hypovolemic (central venous pressure <5 mm Hg).

Patients should have their volume status augmented before proceeding to full insufflation. CO_2 insufflation and one-lung ventilation increases central venous pressure and pulmonary artery pressure by a small amount.[41] Bilateral pneumothoraces are deliberately produced when doing bilateral internal mammary artery harvest. Most patients studied tolerate small bilateral pneumothoraces well for periods less than 1 hour.[42]

Coronary Artery Bypass Grafting

All patients undergoing coronary artery bypass grafting are evaluated preoperatively by TEE to exclude the possibility of persistent left SVC or patent foramen ovale. Table 76-3 lists the major exclusion criteria for robotic coronary artery bypass grafting. The iliac and femoral arteries also should be evaluated for their size by echo Doppler ultrasonography.

Patients are prepared and monitored for anesthesia in a manner similar to that for mitral valve surgery (see the section on mitral valve repair). Monitoring of the right radial artery pressure tracing is imperative with use of an endovascular balloon-occlusion catheter. After the patient is asleep, inspired oxygen tension and expired CO_2 are monitored. TEE is used routinely as the standard of care for determining cardiac function and for confirming catheter placement. Pulmonary artery catheters are used judiciously in the appropriate patient population, but the data that the catheter provide may be redundant when TEE data are available. The patient is positioned the same as for internal mammary artery takedown, and trocar positions are placed as depicted in Figure 76-11.

When cardiopulmonary bypass is anticipated, the left femoral artery is cannulated with a 17F or 21F Remote Access Perfusion catheter (Fig. 76-12) with an aortic occlusion balloon. Table 76-4 lists exclusion criteria for endovascular cardiopulmonary bypass. The Remote Access Perfusion catheter allows anterograde flow of 4 L/min or 5 L/min. The cannula has a separate lumen for delivering cardioplegia to the aortic root beyond the occlusion of the balloon. The aortic cannula is positioned in the ascending aorta, 2 cm above the aortic valve, with TEE guidance (Fig. 76-13). The endovascular balloon is inflated with a volume equal to the diameter (in milliliters) of the sinotubular junction of the aorta. A balloon pressure greater than 300 mm Hg usually provides complete occlusion of the aorta.[43] Residual flow around the balloon can be seen and monitored with color flow on TEE. The use of bilateral radial arterial lines is useful in detecting the migration of the occlusion balloon toward the innominate artery. Proximal migration of the balloon can be seen most easily with TEE, preventing balloon herniation through the aortic valve.

After full cannulation and being poised for cardiopulmonary bypass, the right lung is allowed to collapse, and left lung ventilation is begun. The ventilator is adjusted to provide an end-tidal CO_2 partial pressure of 35 to 40 mm Hg. Ports can be placed safely after the right-sided pneumothorax has formed. CO_2 is insufflated into the right hemithorax and continued at a pressure of 5 to 10 mm Hg; this allows the affected lung to collapse further and provides a larger visual field. It also may prevent mediastinal shifts during one-lung ventilation when large tidal volumes are used, such as in a patient with emphysematous lungs. Insufflation to produce a deliberate pneumothorax is ineffective at raising the sternum above the anterior surface of the heart. For this reason, some surgeons provide sternal lift retractors to increase the retrosternal space and provide better exposure.[44]

Robot-assisted, beating-heart coronary artery bypass grafting can be accomplished with appropriate patient selection. Articulating stabilizers passed through a subxiphoid port can stabilize the anterior surface of the heart to facilitate grafting.[45] Bilateral internal mammary artery grafting also has been accomplished using robotic assistance.

Atrial Fibrillation Surgery

Atrial fibrillation is a common rhythm disturbance encountered in clinical practice (see Chapter 61). The Cox maze procedure is often the first choice to treat medically resistant atrial fibrillation. Excellent long-term results have been reported with this procedure.[46] In this procedure, right and left atriotomies are combined

Table 76-4 Contraindications to Use of Endovascular Cardiopulmonary Bypass System

Major vascular disease of iliac, femoral, and abdominal aorta found by Doppler ultrasound imaging
Severe atherosclerosis
Aortic diameter >4 cm
Moderate to severe aortic valve incompetence

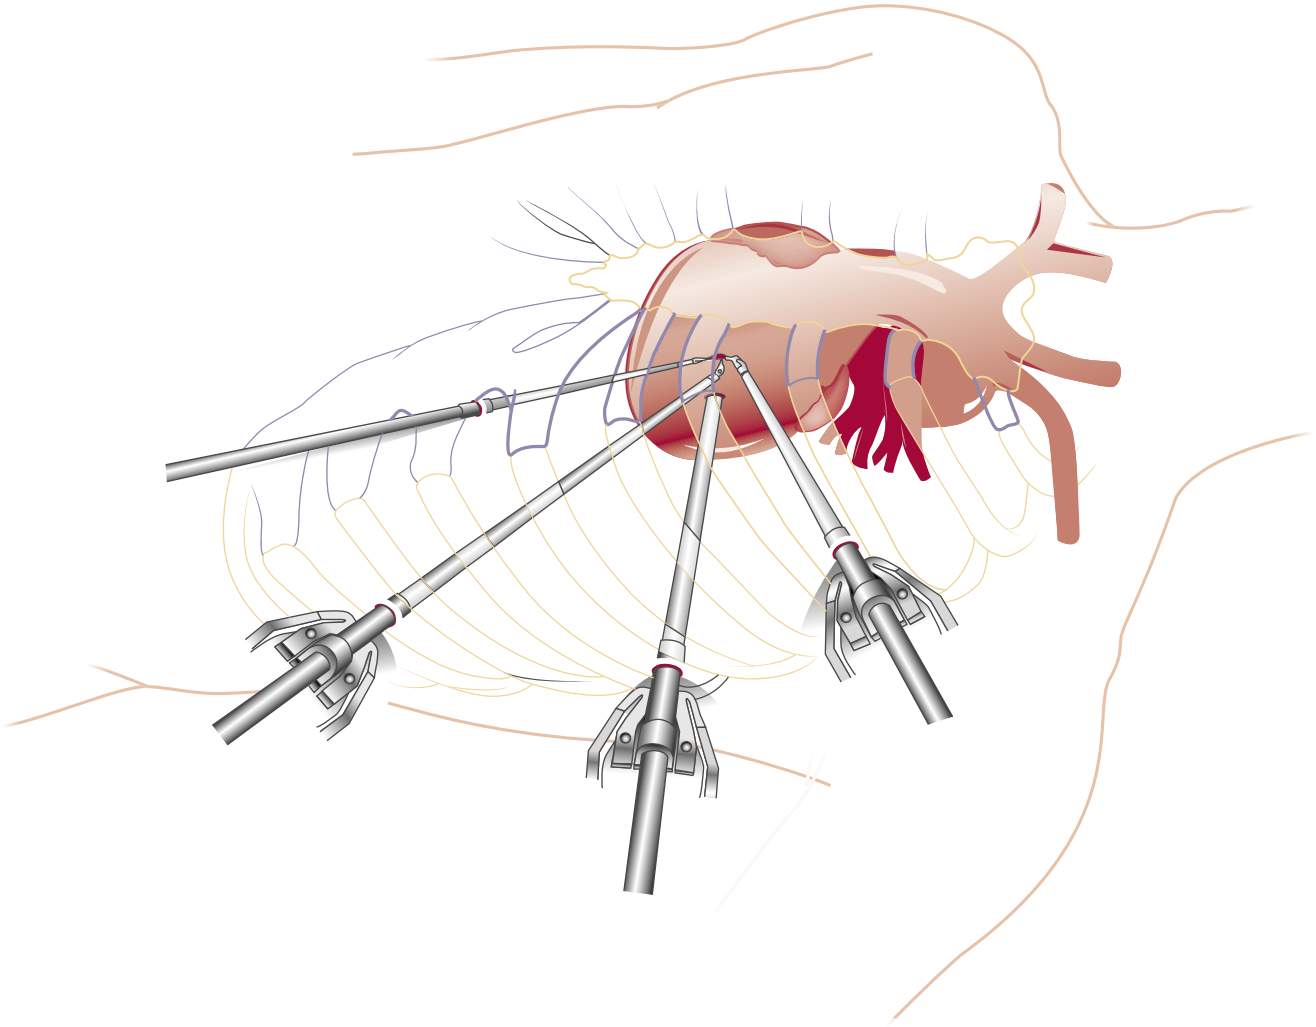

Figure 76-11 Incision ports for coronary artery bypass grafting. Trocars are placed in the third, sixth, and eighth intercostal spaces. Similar port positions are used for bilateral internal mammary artery dissection.

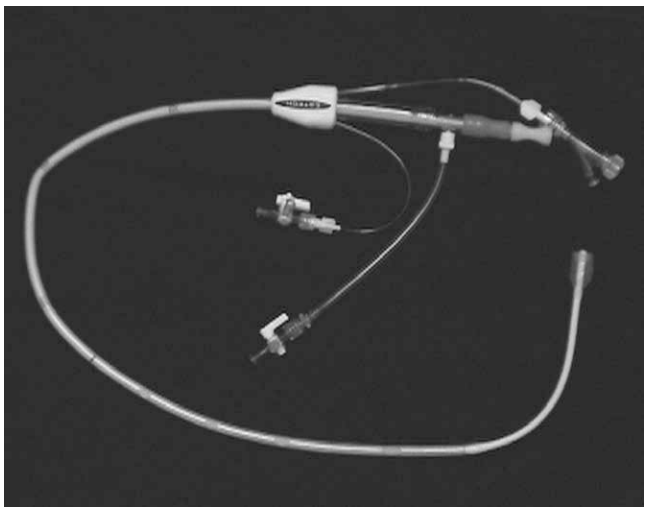

Figure 76-12 Remote Access Perfusion (Estech Systems, Inc, Plano, TX) catheter. The endovascular catheter has a cylindrical balloon for endovascular aortic clamping. The catheter provides anterograde perfusion of the aortic arch at a rate of 5 L/min and cardioplegia administration to the aortic root.

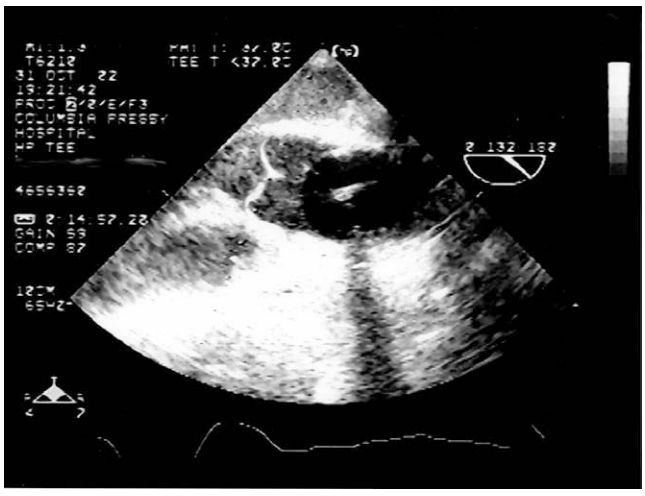

Figure 76-13 Ultrasound image of Remote Access Perfusion (Estech Systems, Inc, Plano, TX) catheter balloon in situ. Transesophageal echocardiography allows the anesthesiologist to keep track of migration of the catheter balloon. The balloon should be positioned in the ascending aorta 2 to 4 cm distal to the aortic valve. Right radial pressure catheter signal damping can detect balloon malposition when occlusion of the innominate artery occurs.

with cryoablation to interrupt re-entrant rhythms and restore sinus rhythm. Traditionally, this procedure has involved median sternotomy and cardiopulmonary bypass. With the evolution of technology such as cryotherapy, microwave, and radiofrequency, new hand-held devices have become available for use in minimally invasive surgery.

Many approaches have been used for minimally invasive atrial fibrillation ablation surgery. The approach employing the da Vinci system via right mini-thoracotomy with peripheral cannulation and cardiopulmonary bypass is the most commonly used approach.[30] A total endoscopic approach on a beating heart also has been described.[47]

This section describes the total endoscopic approach on a beating heart. The patient is placed in a supine position. In addition to the standard monitors, invasive arterial and central venous pressures are monitored. A pulmonary artery catheter can be used in appropriate patients. After induction of anesthesia, the trachea is intubated with a double-lumen endotracheal tube. The position of the tube is confirmed by a fiberoptic bronchoscope. A TEE probe is inserted for intraoperative cardiac monitoring and to rule out a clot in the left atrial appendage. External defibrillator pads are applied to the chest. One-lung (left) ventilation is instituted, the right lung is excluded, and the right hemithorax is insufflated with CO_2. Three 1-cm port access incisions are made at the level of the third, fourth, and fifth intercostal space on the anterior axillary line for the robotic arms and the endoscope. The heart is exposed after dissecting the pericardium. Using a microwave probe (Flex10, Boston Scientific, Natick, MA), a continuous circular lesion is produced encircling the pulmonary veins. Arrhythmias in the early postoperative period are treated with amiodarone and β-blocker therapy.[47,48]

Left Ventricular Lead Placement

Numerous patients with heart failure exhibit cardiac dyssynchrony secondary to delay in activation of the left ventricular free wall; this can result in a further decrease in ventricular function. This dyssynchrony may worsen mitral regurgitation and increases mortality.[49] Ventricular resynchronization has been shown to improve ventricular function, exercise capacity, and quality of life.[50] Standard biventricular pacing is done by inserting transvenous, right atrial, and ventricular endocardial leads. An epicardial left ventricular lead is inserted by cannulating the coronary sinus in the right atrium and advancing the lead via venous tributaries of coronary sinus to the ventricular surface. This approach has a failure rate of 15% to 20% because of inability to cannulate the coronary sinus. Left ventricular lead dislodgment also can contribute to a late failure rate of 5% to 10%.[32] In these patients, the only option is to place an epicardial lead via a left mini-thoracotomy. A mini-thoracotomy is associated with increased morbidity. Some surgical groups have developed a total endoscopic robotic approach.[51-53]

The total endoscopic approach is described in this section. After application of standard monitors and insertion of an arterial line, general anesthesia is induced, and the trachea is intubated with double-lumen endotracheal tube. The position of the endotracheal tube is verified with a fiberoptic bronchoscope. Subsequently, a TEE probe and a pulmonary artery catheter are inserted. The patient is placed in a posterolateral thoracotomy position. One-lung (right) ventilation is instituted. The left lung is excluded, and the left hemithorax is insufflated with CO_2 at a pressure of 8 to 10 mm Hg.

Robotic arms are inserted by incisions in the fifth and ninth intercostal spaces in the posterior axillary line, and the camera is inserted in the seventh intercostal space. The pacing lead is introduced through a working port and attached between the first and second obtuse marginal between the base and the apex. A second pacing lead is attached near the second obtuse marginal, and the pericardium is closed over the leads. Both leads are tunneled to an incision in the axilla and retested for threshold pacing requirements. The lead with the best threshold is connected to the pacemaker, whereas the other lead is capped and secured to the fascia for future use. If a right-sided pacing lead is needed, it is inserted transvenously at this time and connected to the biventricular pacemaker. This approach allows for reliable entry into the chest for left ventricular lead insertion, while allowing complete cardiac access for mapping.

Thoracic Surgery

Although video-assisted thoracoscopic surgery (VATS) is well established, its use is limited to simple procedures (see Chapter 59). Few centers perform complex procedures such as pulmonary lobectomies and thymectomies using VATS.[54] It is hoped that robotic surgery will be able to overcome some of the limitations of conventional VATS.

Compared with minimally invasive surgery performed in other regions of the body, robotic thoracic surgery presents a different set of challenges. The surgical challenges include rigidity of the chest wall and movement of heart, lungs, and mediastinum. The anesthesia-related challenges include prolonged one-lung ventilation and hemodynamic instability associated with CO_2 insufflation of the hemithorax.

Patient positioning plays a major role in exposing otherwise inaccessible areas because mediastinal structures are heavy and mobile, and change position in response to gravity. Supine or slight lateral decubitus (raising one side 15 to 30 degrees) position is ideal for anterior mediastinum pathology. A 90-degree lateral position may be optimal for hilar masses and lobectomies. A nearly prone position may create better exposure for posterior mediastinal masses.[55] CO_2 insufflation also has a big role in achieving adequate exposure by pushing the mediastinum to the opposite site, while compressing the lung away from the operative site. It also reduces fogging and removes cautery smoke. The disadvantage of CO_2 insufflation is hemodynamic instability.

As the use of robotics in surgery has increased, its role in thoracic surgery has evolved over the last few years. The procedures being performed include multiple esophageal procedures, including Heller myotomy, resection of esophageal masses,[56] and esophagectomy.[57] Other procedures being performed include resection of mediastinal masses and thymectomy.[54]

Neurosurgery

From the late 1980s to 1993, neurosurgeons investigated the use of robots to position resection probes and devices precisely within neural parenchyma to provide minimally invasive surgery and to protect normal tissue (see Chapter 63). Stereotactic navigation during neurosurgery has provided an image-guided system for real-time tracking of surgical instrument tips.

CyberKnife (Accuray, Inc, Sunnyvale, CA) is an image-guided frameless, stereotactic radiosurgery system for treatment of spinal tumors. A major potential benefit of radiosurgical treatment of spinal lesions is that this can be performed in an outpatient setting, with rapid recovery.[59] NeuroMate stereotactic robot (Renishaw plc, Gloucestershire, UK) is a frameless system that uses MRI data for treatment of movement-based disorders.[60] MRI-compatible robotic systems also have been developed for neurosurgery.

Medical robotics has yet to gain prominence in neurosurgery. The integration of various disciplines, such as robotics, machine intelligence, nanotechnology, and sophisticated computational networking, could revolutionize the practice of neurosurgery.

Urologic Surgery

The first use of robotics in urology began in the late 1980s, when a robotic frame was developed for transurethral resection of the prostate (see Chapter 65). The frame was constructed to support the six axes Unimate Puma robot (initially designed by Unimation, Inc., Danbury, CT). The safety of this device is derived from the steel circular frame that restricts and confines the robot to a precise arc of resection. Procedures can be done more quickly with a robotic instrument, and because hemostasis is required only once at the end of the procedure, there is less time for absorption of irrigation fluid. The Puma robot has been used to resect prostate tissue safely.[61]

The percutaneous access robot (PAKY-RCM) (URobotics, Baltimore, MD) was developed in 1996, and was later replaced by Tracker in 2003. This is used with fluoroscopy or CT guidance to improve the accuracy of needle placement in percutaneous nephrolithotomy and tissue biopsy. The AESOP system (see earlier) also has been used successfully in laparoscopic urologic surgery. The most advanced systems currently being used in urology are master-slave systems, such as the da Vinci Robotic Surgical System. The procedures that have been performed using da Vinci systems include radical prostatectomy,[62] radical cystectomy,[63] radical and simple nephrectomy, live donor nephrectomy, pyeloplasty, and adrenalectomy.[64]

Radical Prostatectomy

Guillonneau and Vallancien[65] were the first to show the feasibility and efficacy of laparoscopic radical prostatectomy. Since then, several centers have shown the feasibility of a robotically assisted radical prostatectomy (RAPR). RAPR has become the most common procedure performed with robotic assistance. Between 2000 and 2004, 5200 RAPRs were performed, and in 2005, more than 8000 procedures were performed.[66]

The learning curve seems to be much shorter with RAPR compared with the laparoscopic approach. The most common technique used for RAPR seems to be the transperitoneal and antegrade approach, developed by Ficarra and colleagues[62] at Vatikutti Institute of Urology in Detroit, Michigan. Outcome data, such as the transfusion rate, positive surgical margin rate, urinary continence recovery, and erectile function with RAPR, compare favorably with those for laparoscopic or traditional retropubic approaches.[67-69] The operating times also can be similar to the traditional retropubic technique after the operator has learned the technique.

After inducing anesthesia, an arterial line may be placed for frequent phlebotomy. An additional, large-bore intravenous line may be considered when the potential for large blood losses are foreseen. The patient is positioned in a supine lithotomy position with 30 degrees of Trendelenburg incline. The thighs are spread far enough apart to allow the approach of the robotic system between them. Patients shorter than 6 feet are not placed in a lithotomy position and have their legs in a frog-leg position. The prolonged Trendelenburg position may be relatively contraindicated in patients with history of stroke or cerebral aneurysm. Because of the long procedure, silicone gel pads are placed at every pressure point. Some surgeons advocate tucking the patient's arms while the patient is awake to maintain optimal comfort and avoidance of neurapraxia.[70] After a 14F Foley catheter is inserted, the body is prepared and draped. A pneumoperitoneum is created through an umbilical puncture needle, and the maximum pressure is set to 15 mm Hg. The trocar is inserted according to the standardized Heilbronn approach using a semilunar five-trocar arrangement, with a sixth in the suprapubic area.[71] A procedure with some modification of the Montsouris technique is used.[70]

Radical Cystectomy

The advantage of using the laparoscopic approach to perform radical cystectomy is decreased blood loss, improved postoperative pain control, and decreased length of hospital stay.[63] The drawback of the laparoscopic approach is that it is a technically challenging procedure requiring a high degree of surgical skill, and currently there is a paucity of data on long-term oncologic outcomes. The robotic approach might be able to bridge the gap between the open and laparoscopic approach. The first case series of robotic radical cystectomy was described in 2003. Since then, other case reports and small case series have been published.[72]

An arterial line may be placed depending on the comorbidities. The trachea is intubated with a single-lumen endotracheal tube. An additional, large-bore intravenous line may be considered when the potential for large blood losses is foreseen. Anesthesia can be maintained with a volatile agent. Muscle relaxation is paramount in avoiding any movements by the patient while the surgical instruments are within the abdominal cavity. An orogastric tube and a urinary bladder catheter are placed. Convective-air body warmers are applied whenever possible. The patient is positioned in an extended lithotomy position with 45 degrees of Trendelenburg incline. Because of the long procedure, silicone gel pads are placed at every pressure point.

Using the six-port approach and the da Vinci system, pelvic lymphadenectomy and cystoprostatectomy are performed. The specimen is removed in a bag through a 5- to 6-cm suprapubic incision. Through this incision, the bowel is exteriorized, and a neobladder is created extracorporeally. Subsequently, urethroneovesical anastomosis is performed with robotic assistance.[73] Compared with open radical cystectomy, the advantage of the robotic approach seems to be decreased blood loss and shorter hospital length of stay.

Gynecologic Surgery

Robotic surgery in gynecology was first described in 1999 for fallopian tubal anastomoses[74,75] after sterilization or tubal ligation. Subsequently, there have been small case series describing the use of robotic assistance in gynecology. The procedures that have

been performed with robotic assistance include sacral colpopexy, myomectomy, treatment of endometriosis, simple and radical hysterectomy, salpingo-oopherectomy, ovarian cystectomy, and repair of vesicovaginal fistula.[76,77] The advantages of robotic assisted surgery include three-dimensional visualization of surgical field, improved dexterity, and greater surgical precision. The disadvantages include increased cost and added operating room time for assembly of robotic equipment.

Orthopedic Surgery

Total Hip Arthroplasty

The first medical application of robotics was in orthopedic surgery (see Chapter 70). In 1992, Paul,[78] a veterinarian who worked in collaboration with International Business Machines (IBM), developed a robotic system that could be used for hip replacement in dogs. The research collaboration resulted in the first surgical robot—ROBODOC (Integrated Surgical Systems, Davis, CA). In this procedure, the femoral implant is placed into an axial canal of the proximal shaft of the femur. The femoral component can be glued or pressed into the femoral shaft as a tight fit. Long-term radiographs after hip replacement surgery have shown that adhesives are prone to cracking and loosening, with consequent osteolysis, which leads to surgical failure of the prosthetic hip. Modern femoral implants have a porous surface that allows for bone growth into the surface, promoting better hip longevity. For this reason, a tight fit of the implant into the femoral canal is essential.

This femoral canal is formed with higher precision by a robot than by the visual cues that are used in the manual method. The cavity it creates is 10 times more accurate than is achieved by manual methods.[78] The robot obtains its visual or coordinate cues from image-based information, such as from an MR image or CT scan. The accurate registration of the femoral coordinates in three-dimensional space is essential for precise bone milling of the femoral canal so that it can accommodate the surgical implant. Titanium pins are placed in the femoral condyles and the greater trochanter. The patient's leg is imaged by CT, and three-dimensional data about the femoral bone and registration pins are recorded in a computer.

In the operating room, the surgeon removes the native femoral head and places the acetabular cup into its place in the routine manual procedure. The femur is rigidly clamped and secured by the robot fixator. The robot is allowed to recognize the three titanium registration pins and compares their location relative to the data obtained from CT. In this manner, the robot has a perfect sense of where the femur lies in three-dimensional space and can perform precise milling of the femoral canal. The remainder of the surgery proceeds manually.

Four systems are commercially available for robotic orthopedic surgery, including the Acrobot system (Acrobot Co Ltd, London, UK), the ROBODOC system, the Pi galileo nav system (Precision Implants AG, Aarua, Switzerland), and the CASPER system (Ortho-Maquet/URS, Schwerin, Germany). The first randomized multicenter study compared the ROBODOC system with a control (manual) group for hip replacement. It showed that the ROBODOC group had fewer gaps between the prosthesis and bone, with no intraoperative femoral fractures.[79] The amount of blood loss and surgical time were significantly higher in the ROBODOC group. In 2001, the FDA approved the second multicenter U.S. trial of the ROBODOC system using the pinless system. The aim of this trial was to prove the efficacy of the pinless system and to decrease surgical time and blood loss associated with ROBODOC-assisted surgery. In the cases performed, there was a significant decrease in blood loss and surgical time[80] compared with the first multicenter trial.[79]

A more recent study[81] showed a higher rate of dislocations (18% in the ROBODOC group versus 4% in the control group) and revisions (13% in ROBODOC group versus 0% in the control group) in ROBODOC-assisted primary total hip arthroplasty compared with manual arthroplasty. These complications were thought to be due to injury to the abductor muscles. These complications have been attributed to human error because such a high rate of dislocations was not reported in the initial multicenter trial,[79] and has not been reported in the ongoing U.S. multicenter trial.[80]

Knee Replacement

Most total knee replacements depend on a jig system to guide bone sawing. The placement of the jig is based on the surgeon's visual cues from the exposed bone surfaces. These inaccuracies can produce patellofemoral pain and limited flexion in 40% of patients when conventional approaches are used.[82] Displacements of 2.5 mm can produce a 20-degree alteration in the range of motion of a joint.

Robotic surgical assistants have been developed to increase the accuracy of prosthetic joint alignment. For the robot to recognize specific landmarks, the pelvis and the ankle must be fixed to the surgical table. Osseous material is less likely to deform under pressure and can keep its shape. Small trials have shown increased accuracy of robotic systems in knee surgery.[83,84]

Ophthalmologic Surgery

The challenge of creating a robot that is accurate and has an extremely high level of dexterity and precision was mandated for laser retinal surgery (see Chapter 75). Because blood vessels in the retina are only 25 µm apart, high precision is necessary. Collaboration between Charles and the NASA Jet Propulsion Laboratory developed a Robot-Assisted Microsurgery System.[85] It is capable of performing laser microsurgery with 10-µm accuracy. The unaided human eye can discern an increment of only 200 µm. The Robot-Assisted Microsurgery System provides a 200-Hz gating system for eye tracking, and it eliminates the saccades of the eye, allowing the eye to appear perfectly still to the observer. The system also provides a 100:1 scaling that allows for 10-µm incremental movements. Tremor is filtered out between 8 and 14 Hz to eliminate inaccuracy.

The ability to work at such small scales is the robot's strength. Newer robotic devices intended for microsurgical application have an accuracy of 5 µm. This accuracy would be inconceivable without the dexterity of robotic technology.

Summary

The use of robots in surgery is likely to increase because of enhanced precision and control. Because of the minimally invasive nature of robotic surgery, the stress response, overall pain,

tissue trauma, and length of hospital stay are reduced; recovery from surgery is hastened; and cosmetic results are improved.[86]

Anesthesiologists need to be aware of this fast-changing field and how it affects anesthetic techniques and their delivery. Initially, robotically assisted surgical thoracic procedures increased the duration of required general anesthesia. Concomitantly, the duration of one-lung ventilation has been taken to new time extremes, which has given us insight into the respiratory physiology of prolonged one-lung ventilation. As surgeons gain expertise with robotically assisted surgery, operative times are expected to decrease dramatically to the point of traditional open surgery. The inability to move the patient while the robot is engaged with the patient is a challenge when attempting to alter cardiac filling pressures by gravity, causing pharmacologic agents to be used more often.

Anesthesiologists have experienced working in locations that are remote from the patient's airway. It should come as no surprise that robotically assisted surgery of the upper body also presents that challenge. Improved monitoring methods are needed to make remote anesthesia safe and practical. Perhaps the "minimally invasive" revolution will advocate earlier patient recovery and the increased implementation of regional anesthetic techniques. The extent of the surgical stress response may be attenuated, ultimately minimizing the inflammatory response.

We have entered a new age of practical robotic applications that ultimately will improve surgical care. In the future, the robot will be regarded less as a mechanical device and more as an information system to be used with other information systems. The latest innovation in robotics is that of image-guided surgery, in which a surgeon is able to see in real time the scanner images superimposed on the surgical field. The human anatomy will be rendered translucent, and the exact location of any vital structure will be clearly visible. Preoperative diagnostic imaging in combination with virtual reality simulators will allow the surgeon to rehearse the complex procedures in advance and program the robot to avoid any vital structures during the surgery. Visualization systems are being developed that will improve surgery on mobile structures, such as the beating heart. Advances in motion gating technology will allow the heart to appear as if it were standing still. A properly timed strobe light that is synchronized with the heart rate will achieve the proper virtual image of a heart standing still or of virtual stillness.[2]

Another area in which development in medical robotics may occur is nanotechnology. More recently, the world's smallest untethered robot was shown to measure 250 × 100 μm.[1] In the future, nano-scale robots will be used to deliver targeted gene therapy or chemotherapy to remote locations in the body. As with all new innovations, we make progress with optimistic caution.

77 Anesthesia for Laser Surgery

Key Points

1. The energy of a photon depends on its frequency. Higher-frequency photons (toward ultraviolet) have more energy than lower-frequency photons (toward infrared).
2. Stimulated emission is the basis for laser phenomena. Stimulated emission creates a chain reaction leading to the creation of many photons of the same energy.
3. The biomedical application of laser light involves its ability to focus intense energy in a small area. Focus is determined by monochromicity, collimation, and phase synchrony, all of which are superior in laser light than in ordinary light.
4. Carbon dioxide (CO_2) lasers pose a high risk of remote fires. CO_2 laser light is invisible infrared and usually is transmitted to the surgical site in a beam through free air.
5. Potassium titanyl phosphate (KTP)–type lasers are not usually transmitted through air. These lasers are conducted by fiberoptics to a direct contact tip that creates heat from light, coagulating adjacent tissue.
6. Infrared laser light at 10.6 μm is strongly absorbed by water molecules. This frequency of laser light, generated by CO_2 lasers, explosively converts water to steam.
7. Different laser sources require different eye protection. Any glass or plastic lens can block CO_2 laser light, but other lasers require type-specific protection.
8. All nonmetal endotracheal tubes have the potential to burn in the airway.
9. Nitrous oxide should not be used to dilute the fraction of inspired oxygen (F_{IO_2}) during airway surgery. Nitrous oxide supports combustion similar to oxygen.
10. If possible, the F_{IO_2} should be held at less than 40% during airway surgery.

The word *laser* is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation, and laser technology is one consequence of Nobel prize–winning developments in quantum mechanics, which are among the most important in 20th century physical sciences. In essence, lasers provide the ability to transfer large quantities of energy rapidly to remote locations. Applications in medicine have been sought since the creation of the laser. About 30 years later, lasers are an accepted and often preferred member of the surgical armamentarium. The rapid proliferation of this technology has been accompanied occasionally by severe complications, however, making it imperative that anesthesiologists understand the potential threat to their patients and themselves and be prepared to respond properly. This chapter reviews relevant highlights of the fundamental physics of lasers and laser light, rationales for the various lasers in clinical use, and important anesthesia-related concerns during laser surgery. Table 77-1 is a glossary of terms relevant to this topic.

Physics of Laser Light

Visual light is electromagnetic radiation, as are radio waves, x-rays, and gamma rays. These different classes of electromagnetic radiation are similar phenomena that occur at very different wavelengths. In 1864, Maxwell[1] explained that light is an electromagnetic wave with combined electric and magnetic oscillations that propagates at 299,792,458 m/sec. Planck[2] subsequently discovered the photoelectric effect: Light of a certain color (e.g., blue) causes metal to eject electrons at a rate proportional to the brightness of the light, whereas intense light of other colors (e.g., red, orange, yellow) cannot. Planck's discovery was the first step toward laser physics, because explaining the photoelectric effect required a new conceptual framework. Einstein[3] developed this framework, quantum mechanics, in 1905, establishing the theoretical basis for laser action. He explained that all electromagnetic

Table 77-1 Glossary of Laser Terminology

Ablation	Removal of tissue by vaporization
Absorption	The transformation, by interaction with matter, of radiant energy to a different form of energy
Active medium	A material that acts as a laser with the proper excitation
Aiming beam	A very low-powered laser beam that is collimated with the high-powered, often invisible therapeutic beam to illuminate the target site
Ångstrom unit (Å)	10^{-10} m
Anode	The positive terminal in a gas discharge laser
Attenuation	The reduction in beam energy by absorption or scattering as it passes through matter
Brewster windows	Transparent windows at the ends of a gas laser discharge tube set at such an angle to the optical axis of the tube (Brewster angle) as to provide maximum light transmission
Coherent light	Light in which the photons all have the same wavelength and maintain a constant in-phase relationship with each other
Collimation	The property of a light beam that describes the degree to which the constituent photons move in a single direction; highly collimated beams do not spread in diameter as they move away from the source
Continuous wave (CW) mode	A mode of operation in which the laser discharge is continuous
Diffraction	The modulation in intensity and apparent bending exhibited by photons as they pass through an opaque body
Dopant	A chemical added to a crystal matrix to serve as an active laser constituent
Energy density	The amount of energy per unit area arriving at a surface, usually expressed in joules per square centimeter
Excimer	Excited dimer; a type of laser based on the transition states of a diatomic molecule (e.g., ArF, KrF, XeCl); these lasers produce photons of very high energy
Extinction length	The thickness of a specified medium that absorbs 98% of the incident beam intensity (expressed as wave number in cm^{-1})
Infrared	Electromagnetic radiation whose wavelengths lie in the band 0.7 μm to 1 mm (i.e., longer than visible light, but shorter than microwaves or radio waves)
Interference	The phenomenon in which photons of like wavelength but different phase combine constructively and destructively to modulate the resulting intensity
Joule (J)	A unit of energy (1 joule = 1 watt-second)
Micrometer (μm)	10^{-6} m
Mode	A description of the intensity cross-section of a laser beam
Monochromatic light	Light of a single wavelength or color
Nanometer (nm)	10^{-9} m
Neodymium (Nd)	A rare earth metal, frequently chosen as a laser material within a substrate of glass or yttrium-aluminum-garnet (YAG)
Output power	Rate of energy discharge, usually measured in watts or joules per second
Photon	A quantum of electromagnetic energy possessing both wavelike and particle-like properties; photons travel at a constant speed of approximately 300 million m/sec
Power density	The amount of power (energy per second) per unit area arriving at a surface, usually expressed in watts per square centimeter
Pulsed mode	A mode of operation in which the laser delivers discrete (usually quite brief) bursts of photons
Pump	The means of including an electron population inversion so that stimulated emission may occur
Resonator	The combination of laser material and mirrors necessary to support laser activity
Spontaneous emission	The emission of a photon when an excited orbital electron decays back to its ground-state energy
Stimulated absorption	The process by which an orbital electron captures the energy of a colliding photon and is boosted to a higher-energy orbital
Stimulated emission	The process by which an electron in a high-energy orbital, if struck by an appropriate photon, emits a new photon of wavelength, phase, and direction equal to those of the original, colliding photon
Tunable laser	A laser that can be adjusted to provide a selected output wavelength from a range of possibilities
Ultraviolet	Electromagnetic radiation having wavelengths shorter than visible light, 0.01 to 0.38 μm
Wavelength	The distance from peak to peak of a photon wave; the usual units for light waves are nanometers (nm) or micrometers (μm)
YAG	A synthetic crystalline matrix composed of yttrium, aluminum, and garnet, with the chemical formula $Y_3Al_5O_{12}$

radiation (e.g., light, radio, x-ray) consists of photons, which may be described as follows:

1. Their properties are consistent with particles and waves.
2. They propagate in a vacuum, without diminishing, at a constant speed of 299,792,458 m/sec.
3. Their energy is proportional to their vibrational frequency, as follows:

$$E(J) = h\upsilon$$

In this equation, h is the Planck constant, 6.63×10^{-34} (joule-seconds), and υ is the frequency of the photon in Hertz.

4. Their wavelength (λ) can be calculated as follows:

$$2.998/\lambda(m) \times 10^8\ m/sec = \upsilon(Hz)$$

What we perceive as color is a property of the wavelengths of visible light, which ranges from 385 to 760 nm (nanometer = 10^{-9} m); shorter wavelengths are ultraviolet, and longer wavelengths are infrared. Einstein also explained that the photoelectric effect is independent of the number of photons present, occurring even if only one photon at a time struck the metal surface. Frequency is the key: Only photons of high enough energy (i.e., high enough frequency and short enough wavelength) can provide the energy necessary to stimulate electron emission; lower-energy photons, even arriving in large numbers at a given time (i.e., brightness), cannot. These findings precipitated the development of laser light.

Some additional aspects of quantum physics provide greater insight into the origin and nature of laser light. Electrons circling the nuclei of atoms are constrained to a few specific orbital patterns and radii (Fig. 77-1). Each orbital is associated with a specific energy level; the only way an electron can move from one orbital to another of higher or lower energy is to absorb or emit an amount of energy exactly equal to the difference in energy between the two orbitals. The process by which a photon's energy is captured by an electron, vaulting the electron into a higher-energy orbital, is called *stimulated absorption* (Fig. 77-2); the converse process, by which an electron drops to a lower orbital in the process sending out a photon to carry away the excess energy, is called *spontaneous emission*. In 1917, Einstein predicted that stimulated emission, the key to laser action,[4] also could occur. For this process, a photon of a particular wavelength (i.e., energy) must collide with an atom ready for spontaneous emission at that wavelength (i.e., having an electron already in the higher-energy orbital), stimulating immediate photon emission and electron descent to a lower orbital. The colliding photon leaves the electron with the emitted photon, with both photons having the identical wavelength, phase, and direction.

The energy differences between electron orbitals are specific to different atoms and are responsible for the fingerprint-like emission (i.e., absorption spectra) used in chemical identification. Under normal circumstances of thermodynamic equilibrium, most of a substance's electrons are in the lowest available (ground-state) energy orbitals. Normally, an electron is much more likely to engage in spontaneous than in stimulated emission (by a factor of 10^{33}:1). The key to the creation of the laser was the achievement of a population inversion, in which many electrons are "pumped up" to the higher orbital, waiting for a photon to come along and start a chain reaction (i.e., amplification) of stimulated emission. In 1958, the technology for pumping up electrons to achieve stimulated emission was introduced.[4] A method was found for enclosing the laser medium between parallel mirrors, so that laser-frequency photons could traverse the medium repeatedly and maximize the number of stimulated emissions. When one of the mirrors is partly transparent, a beam of laser light eventually exits through that mirror.

Laser light differs from ordinary light in three ways. First, it is highly monochromatic. It consists of photons that have a well-defined, very narrow band of wavelengths, whereas ordinary light contains a wide spectrum of wavelengths. Second, laser light is coherent, a property that implies that the electromagnetic fields of all photons in the laser beam oscillate synchronously (in identical phase). In ordinary light, the electromagnetic fields are phased randomly even at the same wavelength. Third, directed beams of laser light are collimated (i.e., have minimal dispersion). The light remains in a narrow, collimated beam, whereas ordinary light beams spread out in all directions from a point source. These three characteristics allow lasers to generate intensely powerful light beams, to send such beams efficiently and accurately through lenses, and to deliver intense energy to small target sites.

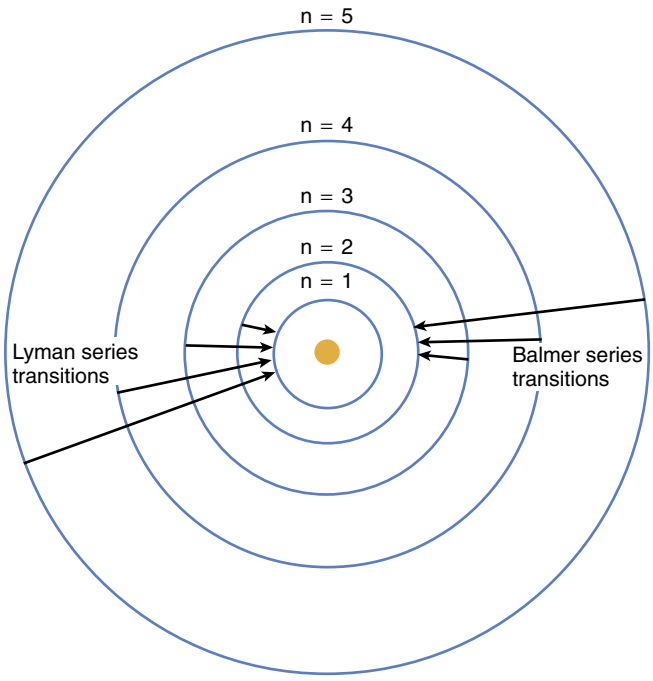

Figure 77-1 Electronic orbitals and energy levels are shown in this schematic diagram of the Bohr model of the hydrogen atom. The circular electron orbitals are a simplification of the probabilistic electron cloud structure. Superimposed on the electron orbitals are the energy transitions responsible for two of the line series in the emission spectrogram of hydrogen. The Lyman series of spectral lines occurs when electrons release photons as they jump down to the lowest energy orbital; the Balmer series of lines represents jumps to an orbital just above the lowest. The wavelength of the resulting photons is inversely proportional to the size of the jump. In the Balmer series, the jump from the n = 3 orbital to the n = 2 orbital releases a photon of wavelength 656.3 nm, whereas the jump from n = 5 to n = 2 is more energetic, releasing a 434-nm photon.

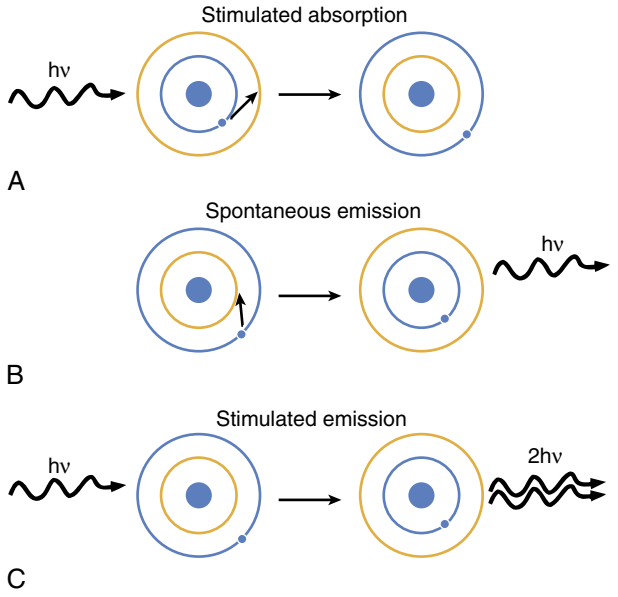

Figure 77-2 Absorption, emission, and stimulated emission. Photons may interact with orbital electrons in three ways. **A,** A photon striking an electron may transfer its energy to the electron, pushing the electron into a higher energy orbit. This interaction is known as absorption. **B,** An electron in an orbit higher than the ground (i.e., minimal energy) state may spontaneously lose energy in the form of an emitted photon. **C,** An incoming photon may interact with an electron that is already in a high-energy orbit, with the result that two perfectly coherent, collimated photons leave the electron; this is known as stimulated emission.

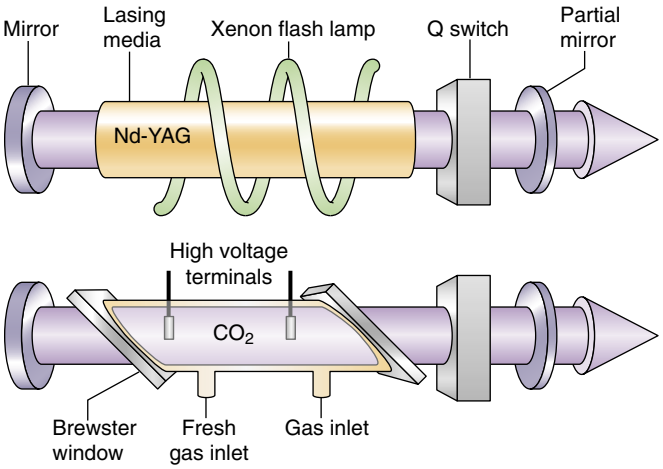

Figure 77-3 Generic laser hardware. A laser system consists of several components, regardless of whether the laser is a solid-based, liquid-based, or gas-based device. The central component is the laser medium itself, which may be a solid crystal of yttrium-aluminum-garnet (YAG) with a small concentration of neodymium as dopant, or may be a tube containing carbon dioxide (CO_2). The energy pump provides the means of obtaining a population inversion of orbital electrons; it may consist of a xenon flash lamp or an electric spark generator. A pair of axial mirrors permits repeated passes of collimated photons through the medium, allowing maximum amplification by stimulated emission. The mirror on the right is not 100% reflective, allowing the beam to escape eventually. The optional Q switch increases the efficiency of pulsed lasers by allowing a small delay to increase the pumping.

Laser System Hardware

The essential components of a laser system include a laser medium containing the atoms whose electrons create the laser light, resonating mirrors to boost laser efficiency, and an energy source to excite or pump the atoms of the laser medium into producing laser light (Fig. 77-3). The different types of lasers applied in clinical practice use a variety of laser media and energy pumps. Some clinical lasers use a gaseous medium, such as carbon dioxide (CO_2), argon, krypton, or helium-neon, and are pumped by electric discharge through the gas. Gas lasers may produce a continuous or an intermittently pulsed beam output. Other lasers use solid rods of laser-passive material containing small quantities of ionic impurities, known as dopants, which are the actual laser materials. Dopants commonly used for their laser potential include chromium (as in the ruby laser), neodymium (Nd), and holmium (Ho). A synthetic gem crystal known as yttrium-aluminum-garnet (YAG) is commonly used as a passive host matrix, but even glass has been used. Solid lasers usually are pumped by high-energy photons from a xenon flash lamp and produce a pulsed beam. Lasers also are made from dyes in liquid media and semiconductors, but these technologies have yet to appear to a significant extent in surgical practice. Table 77-2 summarizes medically relevant laser media and their respective output wavelengths.

Because lasers are inefficient at converting electricity into light, they require a large power supply. A laser with a 10-W output requires greater than 1000 W of alternating current from a wall socket; consequently, some laser systems may require special wiring for the high current load. This electrical energy is converted to very high voltages (5000 to 30,000 V) to drive the gas discharge or a xenon flash lamp. Many laser systems also require running water for cooling. Some power supply units contain nonmedical compressed gas (e.g., argon, krypton, CO_2) as a laser medium or as a coolant.

Frequency doublers convert laser light to a different wavelength, enhancing therapeutic flexibility. A beam of laser light passed through a crystal of potassium titanyl phosphate (KTP) emerges with a mixture of light of the original wavelength and light of a wavelength that is one half of the original (i.e., double the original frequency). In medical lasers, KTP is most often used with Nd:YAG. Truly "tunable" or frequency-adjustable lasers exist, but they are still low-powered devices. A light guide directs the laser beam to the surgical site, as illustrated in Figure 77-4. Fiberoptic bundles provide a convenient, flexible conduit for visible and near-infrared wavelengths. Wavelengths outside this range, such as the long infrared from a CO_2 laser, require an articulated arm containing front-surface mirrors at each joint or newly developed exotic materials in a fiberoptic bundle. After the laser beam is delivered in proximity to the surgical site, it is focused to the site by the lens of an operating microscope, or the shape of the beam is intentionally altered by passing it through a contact probe directly on the tissue to be ablated.

An operating microscope accurately aims a laser by directing a low-power (about 1-mW) visible beam (usually from a low-power helium-neon gas laser) through the same optical path as the surgical laser. Some surgical lasers can be focused

Table 77-2 Laser Media Wavelengths

Laser Medium	Color	Wavelength (nm)	Typical Application
Carbon dioxide	Far infrared	10,600	General, cutting
Erbium:YAG	Infrared	2930	Dental, arthroscopy
Holmium:YAG	Infrared	2060	Angioplasty
Neodymium:YAG	Near infrared	1064	General, coagulation, with fiberoptics
Ruby	Red	694	Tattoos, nevi
Krypton	Red	647	
Helium-neon	Red	632	Aiming beam
Gold (vapor)	Red	632	
Organic dye (liquid)	Red	632	Phototherapy
Organic dye (liquid)	Yellow	585	Dermatology, ophthalmology
Copper (vapor)	Yellow	578	
Organic dye (liquid)	Yellow	577	
Krypton	Yellow	568	Retina
KTP:neodymium-YAG	Green	532	General, pigmented lesions
Krypton	Green	521	
Argon	Green	514	Vascular, pigmented lesions
Copper (vapor)	Green	510	
Organic dye (liquid)	Green	504	
Argon	Blue	488	Vascular, pigmented lesions
Xenon fluoride	Ultraviolet	351	Cornea, angioplasty
Xenon chloride	Ultraviolet	308	Cornea, angioplasty
Krypton fluoride	Ultraviolet	248	Cornea, angioplasty
Krypton chloride	Ultraviolet	222	Cornea, angioplasty
Argon fluoride	Ultraviolet	193	Cornea, angioplasty

KTP, potassium titanyl phosphate; YAG, yttrium-aluminum-garnet.

to a spot size of 30 µm (0.030 mm), creating very-high-power densities.

For surgical procedures that do not require a "no-touch" technique, there are special heat-resistant (sapphire), direct-contact probes[5] (see Fig. 77-4) that are interchangeable and whose shapes can be designed as needed for sharp cutting or diffuse coagulation. These probes require active cooling, however, in the form of a compressed gas or liquid jet, a feature that has contributed significantly to laser-related morbidity and mortality.[6] The mechanism of action of the contact probe is probably a combination of thermal conversion of most of the laser energy within the sapphire (heating the surface to >800°C) and transmission of perhaps 20% of the near-infrared energy to the surrounding tissue.[7]

Clinical Applications

Lasers used as scalpels and electrocoagulators have some unique advantages. Lasers allow highly precise microsurgery, even in confined or difficult-to-reach sites. Two examples of procedures using the ability of a laser system to reach remote sites effectively are percutaneous diskectomy[8] and endovascular angioplasty.[9] The ability to focus laser beams on small target areas concentrates the intensity or power per area enormously. A 10-W beam, originally with an area of 1 cm^{-2}, has a power density of 10,000 W/cm^2 when focused on a target area of 0.001 cm^{-2}. This power density delivers approximately 2500 kcal/sec to the target site, producing heating at a rate of many thousand degrees per second, depending on the volume of energy absorption. This heating allows precise, rapid vaporization of tissue and most other materials. Even metals and ceramics are susceptible to high-energy lasers. Lasers do not increase the energy of a particular photon, but they place more photons at a given place and time than other light sources. Laser surgery is relatively "dry," providing near-instantaneous sealing of small blood vessels and lymphatics, even in the presence of clotting abnormalities. Early claims for faster-than-normal healing (see later) and lower infection rates have not been convincingly validated, however.[10]

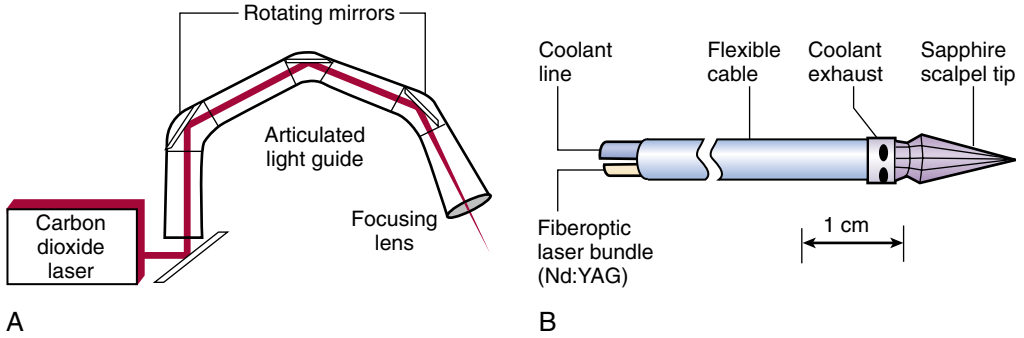

Figure 77-4 Light guides. **A,** Schematic representation of a carbon dioxide laser guide such as may be found in an operating microscope or a hand-held wand. The guide consists of rigid hollow tubes with hinged, aligned mirrors, which reflect the beam from its source through the focusing lens. **B,** Schematic of a flexible fiberoptic guide with a sapphire contact scalpel and a coaxial cooling system.

Biologic Effects of Laser Light

Living tissue is a complex aqueous solution containing a variety of molecules that absorb light. When an atom interacts with a photon whose energy does not exactly match a possible electron transition, the photon's energy may be translated into atomic vibrations that we recognize as heat. The degree to which a particular wavelength of light is absorbed and converted to heat in the target tissue determines its effect on that tissue.

Long infrared wavelengths are absorbed with great efficiency by water, the main constituent of tissue. Long-wavelength laser light, such as that from CO_2 (operating at 10,600 nm), is completely absorbed by water in the first few layers of cells. With powerful, focused CO_2 beams, this results in explosive vaporization of the surface tissue of the target with little damage to underlying cells. Excimer lasers have an extremely precise effect because they produce ultraviolet light that is absorbed more intensely by water and other molecules. These lasers are of great value in office-based refractive surgery. Near-infrared light from an Nd:YAG laser at 1064 nm is less absorbed by water, and the beam diffuses through several millimeters, scattering through a volume of tissue 100 to 1000 times the volume through which a CO_2 beam diffuses. Consequently, the energy of an Nd:YAG beam is more widely disseminated (Fig. 77-5), producing less vaporization and more thermal coagulation (i.e., a cooking effect). Some of the effects of this bulk coagulation may not be apparent for hours or days after exposure.

Nd:YAG or holmium laser energy delivered via a thin fiberoptic bundle has begun to replace traditional electrodessication in transurethral resection of the prostate. The anesthetic implication of this new modality includes the reduced incidence of transurethral resection of the prostate syndrome because saline irrigant can be used.[111] Some authors advocate the use of topical anesthesia with a digitally guided transperineal prostate block[112] in place of the more traditional subarachnoid block. Another area more recently developed around fiber-delivered Nd:YAG laser energy is office-based resection of laryngeal papillomatosis and dysplasia using only topical anesthesia.[113] Another application for outpatient surgery in the airway is the laser uvulopalatoplasty, which is at least moderately effective in reducing the symptoms of obstructive sleep apnea. The absence of an endotracheal tube in these outpatient cases would diminish the likelihood of an airway fire; however, risk of igniting drapes remains (see Chapter 78).

The red light produced by a ruby laser (694 nm) is poorly absorbed except by cells containing dark pigment. The green and blue light produced by argon (514 nm and 488 nm) or krypton (476 nm, 521 nm, and 568 nm) gas lasers is transmitted by water, but is intensely absorbed by hemoglobin, providing the ability to penetrate skin or ocular structures and selectively coagulate vascular or pigmented regions. Although lasers that produce infrared or visible light have exclusively thermal effects on tissue, the photons produced by ultraviolet excimer lasers are energetic enough to disrupt chemical bonds directly and cause ionization, which might result in mutation and carcinogenesis.

Excimer laser light, despite the high energy per photon, is very highly absorbed and capable of extremely fine focus, providing the exquisitely controlled vaporization and coagulation necessary for photorefractive surgery of the cornea. Photorefractive keratectomy and, more recently, laser-assisted in situ keratomileusis are now widely performed in outpatient clinics with only topical anesthesia, such as proparacaine or oxybuprocaine. Occasionally, children with severe refractive pathology also require laser keratoplasty, necessitating general anesthesia. In 2001, an interaction was discovered in such a case in which nitrous oxide leaking from a facemask absorbed a sufficient quantity of argon-fluoride beam at 193 nm to abort the photorefractive repair.[114]

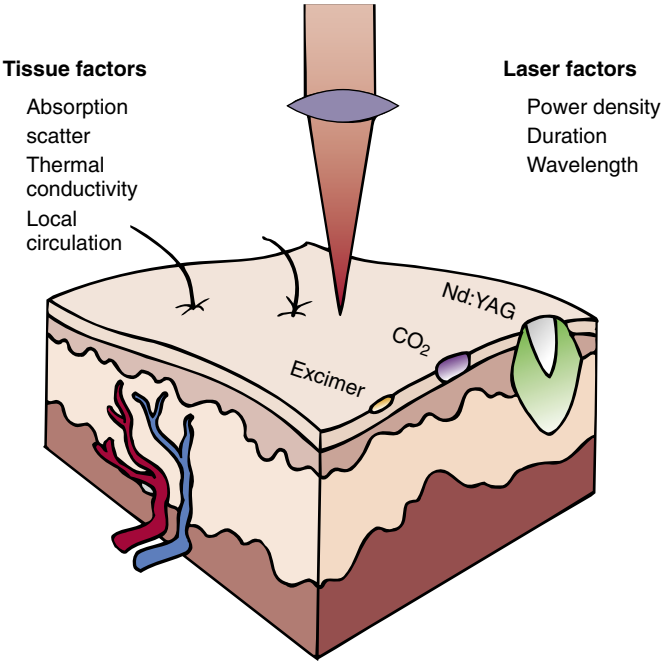

Figure 77-5 Different wavelengths of laser light cause different patterns of tissue destruction. The destructive effect of laser light on tissue depends on laser parameters and tissue factors.

Low-level laser irradiation has been posited for many years to increase the rate of wound healing as a result of hypothetical stimulation of immune function and fibroblast proliferation. A critical review of the relevant literature by the Agency for Healthcare Research and Quality found little evidence of clinical efficacy.[107] Laser light also has been studied as an analgesia-inducing stimulation of skin, over either painful areas or identified acupuncture sites. At best, the evidence for efficacy is mixed.[108]

Another application of laser light is in the use of an erbium:YAG (2930 nm) beam to disrupt the cutaneous diffusion barrier and enhance the delivery of topically applied drugs.[109] Singer and colleagues[110] showed that a single pulse from a hand-held laser followed by a 5-minute application of 4% lidocaine cream reduced pain associated with intravenous line placement by nearly two thirds over placement after sham laser plus the same exposure to lidocaine cream.

Risks of Laser Use: Standards and Regulations

Because lasers are potentially dangerous technologic devices, their clinical use is subject to some degree of federal regulation

and to voluntary consensus standards to minimize possible risks. The U.S. Food and Drug Administration (FDA) controls the manufacture and marketing of medical laser equipment. There are no mandatory federal safety precautions or regulations governing the clinical use of lasers, however. Institutions using lasers clinically should subscribe to the standards published in the American National Standard for the Safe Use of Lasers in Health Care Facilities (Z136.3-1988) by the American National Standards Institute (ANSI). ANSI Z136.3-1988 is available from ANSI (1430 Broadway, New York, NY 10018) or from the Laser Institute of America (5151 Monroe Street, 102W, Toledo, OH 43623). These standards reflect a consensus of governmental, industrial, and professional opinions on the methods used to define and control the risks of laser use, define and standardize training, and assess and ensure safety. The FDA also has suggested a set of regulations that have been adopted and modified by several states.[11] The safety guidelines proposed by ANSI and the FDA should be followed to the maximal extent possible.

Although patients are at most risk from the surgical use of lasers, injuries to staff members have occurred. The Occupational Safety and Health Administration is empowered to intervene if the medical use of lasers threatens the health of employees. Data regarding the true incidence of laser-related injury are limited. Manufacturers are required to report unusual incidents or injuries as they become aware of them. Until more recently, clinical reporting has been voluntary, however, except when complications of laser use occur in the course of a premarketing testing protocol. The passage by Congress of the Safe Medical Devices Act of 1990 requires reporting by clinicians of all serious injuries and should provide more accurate data regarding the prevalence of such injuries.

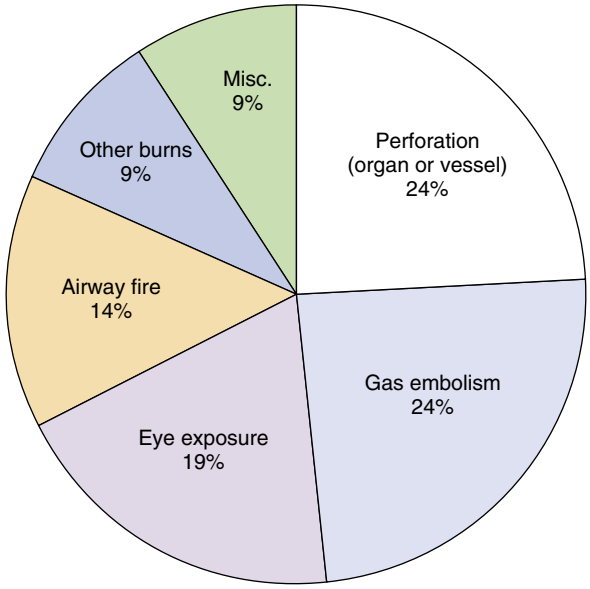

Figure 77-6 Distribution of laser injury type reported to the U.S. Food and Drug Administration from January 1989 to June 1990. *(Data from U.S. Food and Drug Administration: Special report: Laser safety. Laser Nurs 4:3, 1990.)*

Laser Hazards

The hazards associated with laser use can be divided into four major categories: atmospheric contamination, perforation of a vessel or structure, embolism, and inappropriate energy transfer. Twenty-one injuries were reported to the FDA—2 minor, 12 serious, and 7 fatal.[12] The distribution by type of injury is illustrated in Figure 77-6.

Atmospheric Contamination: Laser Plume

Vaporization of tissue, whether by electrosurgery or laser radiation, produces a plume of smoke and fine particulates (mean size 0.31 µm; range 0.1 to 0.8 µm),[13] sized within the range of particles that are efficiently transported and deposited in the alveoli. Many people find the odor of this plume objectionable, and sensitive persons have described headaches, tearing, and nausea as a consequence of inhalation. Deposition of laser plume particulates in rat lung seems capable of producing interstitial pneumonia, bronchiolitis, reduced mucociliary clearance, inflammation, and emphysema.[14,15]

Potentially, the laser plume also may be mutagenic,[16,17] teratogenic, or a vector for viral infection. In vitro, the mutagenic potential of laser condensate is one half that of electrocautery,[17] and the total mutagenic potential from 1 g of tissue is comparable to smoking three to six cigarettes. The role of the smoke plume as a viral vector is controversial. Viral DNA has been detected in plume from condylomas[18,19] and skin warts,[20] but not from laryngeal papillomas.[21] Human immunodeficiency virus (HIV) was not detected in electrosurgical smoke plume[22] in one study, and only noninfectious DNA fragments were found in a CO_2 laser plume from HIV-infected tissue pellets.[23] Competent transmission of any viral infection by a smoke plume has yet to be shown.[24] The laser plume does not seem to contain viable eukaryotic cells (i.e., tumor cells),[25,26] but it may contain viable bacterial spores.[27,28] CO_2 lasers seem to produce the most smoke because of vaporization of tissue, and Nd:YAG contact probes produce much less.

The most effective means of preventing dissemination of the plume is to use an efficient smoke evacuator at the surgical site.[29,30] Ordinary surgical masks efficiently filter particles only down to 3 µm, and special high-efficiency masks (e.g., The Protector II; Anago, Fort Worth, TX) are required to catch laser plume particulates. The high-efficiency masks are less effective when wet and may need to be changed periodically.

Tissue and Vessel Perforation

Misdirected laser energy may perforate a viscus[31-34] or a large blood vessel (vessels >5 mm are not coagulable by laser). Laser-induced pneumothorax has been reported after a laryngeal procedure.[35] With an Nd:YAG system, the depth of damage is impossible to assess accurately or immediately, and perforation and bleeding may not occur until edema and necrosis have become maximal several days postoperatively.

Embolism

The Nd:YAG laser system has been associated with venous gas embolism. Embolization has been a particular problem during

hysteroscopic surgery with Nd:YAG contact probes when the gas coolant for the sapphire probe tip has accidentally inflated the uterine cavity. In 1989, this technique resulted in five widely publicized cases involving four deaths.[6] In another report, uterine insertion of a sheathed quartz fiber (with coaxial coolant gas running) produced an immediate, massive, and fatal gas embolism.[36] The laser and its contact probe were not directly responsible for the injury, but a liquid (saline) coolant is strongly preferred during hysteroscopy. If a coolant gas must be used, CO_2 produces less damage after embolization than nitrogen or air. If uterine distention is achieved with saline rather than with gas, a fluid overload similar to that seen during transurethral prostate surgery is possible.[37]

Venous gas embolization also has been reported during Nd:YAG resection of tumor in the trachea,[38,39] and during various types of laparoscopic and endoscopic procedures.[40,41] A laser coolant malfunction during laparoscopic ablation of endometriosis at the University of California, San Francisco, resulted in complete subcutaneous air emphysema, from which the patient recovered after a benign course. During laparoscopic surgery with CO_2 insufflation, mechanical hyperventilation should be instituted and adjusted to compensate for intra-abdominal CO_2 absorption and cephalic displacement of the diaphragm. Continuous airway CO_2 monitoring is highly recommended for detection of embolization or hypercapnia.

Energy Transfer to an Inappropriate Location

All available medical laser wavelengths are transmitted transparently through air and are well reflected by smooth metal surfaces. Pressing the laser control trigger at the wrong time can deliver damaging laser light across the wound to sites at which surgical ablation was not desired or across the operating room into colleagues' eyes. Potentially tragic situations include laser ignition of surgical drapes[42,43] and, of special concern for anesthesiologists, accidental irradiation of an endotracheal tube during airway surgery.

Eye Protection

The ANSI standards and common sense dictate that the eyes of the operating room staff and the patient be protected during laser surgery (see Chapter 75). Errant infrared energy from a CO_2 laser can quickly cause a serious corneal injury,[44] whereas argon, KTP:Nd:YAG, or ruby lasers may burn the retina.[45] The lids of patients' nonoperated eyes should be taped closed and then covered with an opaque, saline-soaked knit or metal shield.[46-48] Operating room personnel must wear safety goggles or lenses specific for the specific laser wavelength in use. Using the wrong filter provides no protection. Safety goggles should provide wraparound protection from reflected light. For CO_2 lasers, any clear glass or plastic lenses suffice because they are opaque to far infrared. Regular eyeglasses may be sufficient, but contact lenses are not. Other lasers require color filters whose wavelength specificity and optical density are regulated. Nd:YAG lasers require special green-tinted goggles, which make assessment of patient skin color difficult, or clear lenses (Nd:YAG Protection Glass; Surgical Laser Technologies, Malvern, PA), which have a special coating opaque to near infrared. Argon or krypton lasers require an amber-orange lens filter, and KTP:Nd:YAG lasers require a red filter. Because lasers other than the far-infrared CO_2 produce beams that pass through glass, all windows into the operating room should be covered during laser procedures, and specific, specially designed warning signs should be posted as described in ANSI Z136.3.

Endotracheal Tube Fires

A feared complication of laser use during airway surgery is endotracheal tube fire. The estimated incidence of this complication during such operations is 0.5% to 1.5%.[49,50] Although a survey of otolaryngologists did not provide an incidence for fires, it did show that laser-induced ignition of endotracheal tube, cuff, or cottonoids was responsible for most (41%) perioperative complications, followed by postoperative laryngeal web (19%) and laser-related or laser-induced facial burns (11%).[51] The largest published (retrospective) series of CO_2 laser airway procedures documented 6 airway fires in 4416 cases (0.14% incidence),[52] confirming it as the most frequent laser-related complication in patients undergoing this type of procedure. Given the proximity of the endotracheal tube to surgical sites around the larynx, the potential for fire or other airway complications is clear. Electrosurgical devices also have caused airway fires when leaks from the breathing circuit raise the oxygen concentration in proximity to the cautery. Many of these fires, when appropriately handled, result in minimal or no harm to the patient,[49,53,54] but catastrophic consequences are possible.[55,56]

With the energy delivery rates described earlier, any hydrocarbon material, including tissue, plastic, or rubber, can ignite and burn, particularly in an oxygen-enriched atmosphere. Fires can result from direct laser illumination, reflected laser light, or incandescent particles of tissue blown from the surgical site.[57] Initially, most fires are located solely on the external surface of the endotracheal tube, where they can cause local thermal destruction. If a fire is unrecognized and burns through to the interior of the tube, the oxygen-enriched gas combined with the to-and-fro gas flow owing to ventilation produce a blowtorch-like flame, blowing heat and toxic products of combustion down to the pulmonary parenchyma (Fig. 77-7). Puncture and unrecognized deflation of the tube cuff also may permit oxygen-enriched gas to flood the operative site and increase the chance of a devastating fire after a laser burst.

Three strategies are used to reduce the incidence of airway fire: reduction of the flammability of the endotracheal tube, removal of flammable materials from the airway by using a metallic Venturi jet ventilation cannula or intermittent extubation with or without apnea, and reduction of the available oxygen content to the minimum required for reasonable arterial saturation. Each of these strategies is discussed next.

Relative Flammability: Effect of Tube Composition

Because all common endotracheal tubes are potentially flammable, the relative risks of the various types of construction material

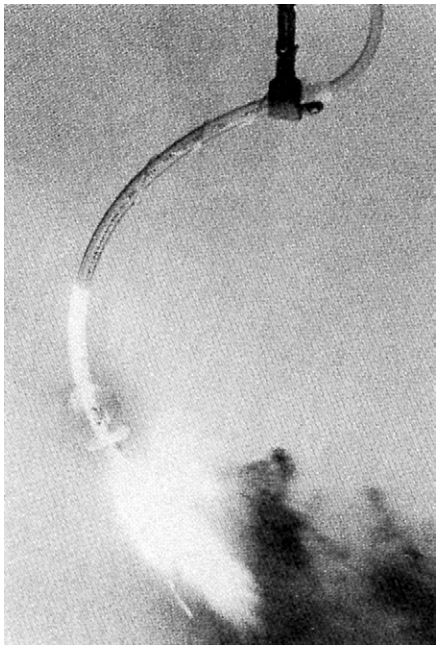

Figure 77-7 Blowtorch ignition of an endotracheal tube. *(From Emergency Care Research Institute: Airway fires: Reducing the risk during laser surgery. Health Devices 19:109, 1990.)*

have been well studied. For many years, reusable red rubber tubes were commonplace, but these were supplanted by clear polyvinyl chloride (PVC) plastic tubes. Modern PVC strongly absorbs far-infrared light and is very sensitive to CO_2 laser energy. PVC tubes seem to be ignited much more easily by CO_2 lasers than red rubber tubes[52,58,59] and to produce more toxic combustion products. In vitro, PVC is transparent and immune to Nd:YAG and visible laser light; however, a thin coating of mucus or blood in vivo can absorb energy and restore the hazard.[60] Commercially available tubes fabricated of PVC without opaque lettering or a barium stripe make claims of laser resistance based on the in vitro tests—however, *caveat emptor* (i.e., let the buyer beware).

Two studies of the effects of Nd:YAG laser energy on common types of tubes, including tubes designed to be resistant to laser irradiation, revealed that endotracheal tubes of all materials are quite vulnerable.[61,62] Ossoff and colleagues[58] compared the extent of acute damage to the trachea from blowtorch-type ignitions in dogs ventilated with 1% halothane and 70% nitrous oxide (balance oxygen) through PVC, rubber, or silicone endotracheal tubes. PVC ignited and developed intense flame the soonest, resulting in widespread deposit of carbonaceous debris and significant ulceration and inflammation of the trachea on postmortem analysis. Red rubber tubes were more resistant to ignition, and produced less debris and inflammation. Silicone tubes were the most resistant to ignition, but they produced copious white silica ash, suggesting the potential for late development of silicosis.

Ossoff[63] subsequently measured the time to intraluminal ignition during exposure CO_2 laser energy to determine resistance to ignition and reversed the ranking of silicone and red rubber, with PVC remaining the most vulnerable. He also found that addition of 2% halothane vapor retarded ignition. After ignition occurs, the index of flammability is the minimum inspired oxygen fraction (F_{IO_2}) necessary to maintain combustion. Wolf and Simpson[64] report that PVC is less flammable than silicone or red rubber, having a flammability index of 0.26 versus 0.19 for silicone and 0.19 for red rubber. When nitrous oxide was used as the oxidant, PVC retained the highest index (0.46), followed by silicone (0.41) and red rubber (0.37).

Despite the conflicting data, many physicians recommend the use of red rubber endotracheal tubes during laser surgery of the aerodigestive tract, and base this suggestion on criteria of resistance to ignition and least toxic combustion products. At the University of California, San Francisco, one surgeon has performed more than 4000 microdirect laryngoscopies using a CO_2 laser, incurring only two fires (0.005%), and no significant fire-related morbidity (H. H. Dedo, personal communication, 1992) with aluminum-taped PVC endotracheal tubes and moistened pledgets (discussed later). Regardless of the tube substrate, there are additional safety considerations and maneuvers to consider, as outlined later.

Effect of Respiratory Gas Mixture

The mixture of airway gases becomes an important issue when any type of potentially flammable endotracheal tube is used. Combustion is more vigorous when excess oxidizer is present, and most clinicians recognize the need to reduce the F_{IO_2} to less than 0.40 or to the minimum concentration consistent with patient oxygenation. That nitrous oxide also is a powerful oxidizer is less well recognized, but adding nitrous oxide as a diluent for oxygen is just as dangerous as having a high F_{IO_2}.[64] Use of an air-oxygen mixture seems to be acceptable. Some investigators prefer helium as a diluent to nitrogen because helium has a higher thermal conductivity, which may delay the ignition of an endotracheal tube for a few seconds.[63,65] Helium also has a lower density, allowing the use of a smaller endotracheal tube without turbulence and high flow resistance.[67-69] The index of flammability is reduced by only 1% to 2%, however, when oxygen-helium is substituted for oxygen-nitrogen.[66]

The volatile anesthetics used in clinical practice are nonflammable and nonexplosive in clinically relevant concentrations.[70,71] During an airway fire, they may undergo pyrolysis to potentially toxic compounds.[72] On this theoretical basis, the ANSI Z136.3 standard recommends not using volatile anesthetics during airway laser surgery. This is an extremely conservative stance given the low concentration of anesthetic gas compared with the products of combustion from an endotracheal tube, and the lack of evidence of toxicity because of the pyrolytic products. When Venturi ventilation is used, administration of volatile agents usually is not practical.

Protection of the Endotracheal Tube

After the possibility of endotracheal tube ignition was raised, extrinsic protection of the tubes was suggested.[73] Patil and colleagues[74] suggested wrapping tubes with moistened muslin. If allowed to dry, however, muslin becomes flammable. Kumar and Frost[75] suggested coating the vulnerable portion of the exterior of the tube with dental acrylic. This approach renders the tube rigid with a rough surface, however, which may traumatize the mucosal

surfaces. The most popular approach to the problem has been wrapping the tube with metallized foil tape.[50,59,61,63,73,76,77]

Three types of tape have been used: aluminum foil with adhesive backing, copper foil with adhesive backing, and plastic tape thinly coated with metal on one side and adhesive on the other. These tape products are widely available from electronics, arts and crafts, and building supply shops. Lead foil (commonly used on windows for burglar alarms) is similar in appearance, but is toxic and should never be used in the airway.

The aluminum and copper tapes have been evaluated for protection of different types of endotracheal tubes with various lasers. Although taping does not provide protection of the inflatable cuff portion of an endotracheal tube, these metal tapes do offer a measure of protection against inadvertent, brief, or unfocused far-infrared CO_2 laser hits to the taped portion of the tube shaft. Metallic tapes are a less certain shield, however, against the near-infrared beam from Nd:YAG. The solid copper (1-mm foil; Venture Tape Corp, Rockland, MA) and aluminum (no. 425 or no. 433; 3M Corp, Industrial Tape Division, St. Paul, MN) tapes were able to withstand at least 60 seconds of direct Nd:YAG laser exposure without penetration or ignition.[77] An Emergency Care Research Institute (ECRI) study[78] found that the 3M aluminum tape provided protection against CO_2 and KTP:Nd:YAG, but it did allow ignition of a PVC tube at the highest power setting of an Nd:YAG laser. Copper tape (no. 1181; 3M Corp, Electrical Products Division, St. Paul, MN) provided ignition protection from all three lasers. Sosis and Dillon[77] found that metallized plastic tape (Radio Shack no. 44-1155, Fort Worth, TX) was more easily ignited by Nd:YAG than an unwrapped red rubber tube, with a time to ignition of 6 seconds versus 13 seconds for the unwrapped control. The ECRI[78] also found that although the metallized plastic tape was most pliant and least likely to abrade the larynx, it provided protection only against CO_2 lasers, not against Nd:YAG or KTP:Nd:YAG.

Applying a protective metal foil wrap to an endotracheal tube requires some care. A clean tube should be wiped with alcohol to remove residue that could interfere with adhesion and then optionally wiped lightly with Mastisol or tincture of benzoin. The end of the tape should be cut at an angle of about 60 degrees, and the cut edge should be aligned with the proximal end of the cuff junction (Fig. 77-8). Tape should be wrapped in a spiral, with about 30% overlap, to the exit point of the cuff pilot tube. Wrinkles should be eliminated to avoid abrading the tracheal mucosa. The result should eliminate bare tubing or areas of exposed tape adhesive (which is quite flammable). Rewiping the wrapped tube with alcohol provides a degree of cleanliness before tracheal intubation.

Although this use is well supported in the medical literature, none of these metal foils has FDA approval because their manufacturers have not sought it. Physicians who devise a wrapped endotracheal tube using such tapes incur some product liability risk as a noncertified "manufacturer" should injury occur, especially because there are FDA-approved commercial products that claim laser resistance.

The Merocel Laser Guard (Medtronic Xomed Merocel Corp, Mystic, CT) is a commercial, FDA-approved endotracheal wrap consisting of an adhesive metal foil laminated to a synthetic sponge surface. Properly placed on an endotracheal tube and kept moist, the Merocel product provides protection against CO_2, argon, and KTP:Nd:YAG lasers, but not YAG lasers.[78] The manufacturer recommends this product only for use with CO_2 lasers. The shield material adds almost 2 mm to the diameter of the endotracheal tube. Similar to the nonapproved tapes, Laser Guard can be applied only to the shaft of the tube and provides no protection for the cuff.

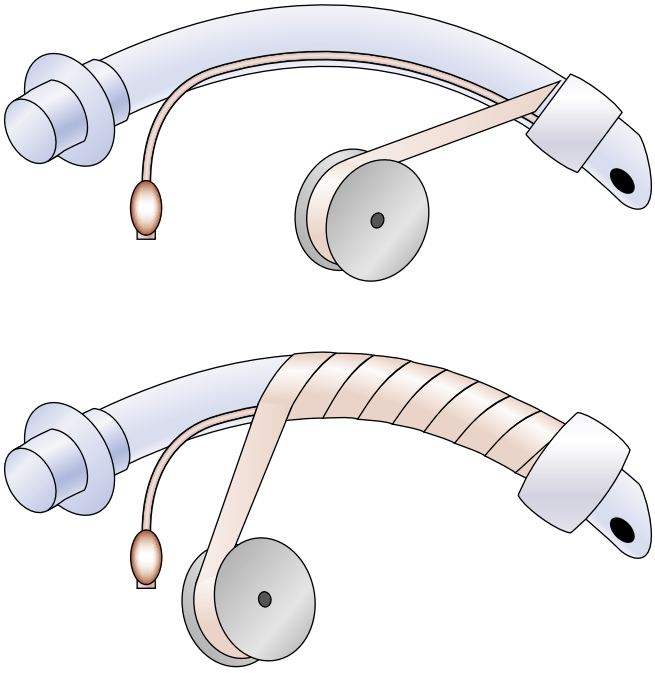

Figure 77-8 Cuff wrapping technique. If a wrapped endotracheal tube is the chosen method for laser protection, the technique for wrapping is crucial in ensuring protection from ignition and foil-induced mucosal abrasions. It is often helpful first to paint the tube sparingly with a medical adhesive, such as benzoin or Mastisol. The end of the tape should be cut with a scalpel to approximately 60 degrees. Wrapping is begun by aligning the cut end of the tape with the junction of the tube and the proximal end of the cuff and is done in a spiral with a 30% to 50% overlap between layers. Wrapping should include the inflation tube for the cuff and should be continued until just short of the pilot balloon, with care taken not to wrinkle the tape at any point.

The FDA also has approved the use of an integral laser-resistant coating in the manufacture of endotracheal tubes. The commercially available Xomed Laser shield tube (Medtronic Xomed, Jacksonville, FL) is fabricated from silicone with an outer layer of finely divided aluminum powder in silicone; the aluminized layer extends over the inflatable cuff. This tube is specified for use only with CO_2 lasers, a beam power density of less than 4900 W/cm^2, and an F_{IO_2} of less than 25%.

Although more resistant to far-infrared radiation than PVC or red rubber tubing,[79,80] the Laser Shield nonetheless burns vigorously when ignited in vitro,[63] producing friable silica dust. It also may ignite under typical surgical conditions, failing the ECRI flammability test.[78] In at least one case, an airway fire involving this tube occurred,[56] resulting in serious injury attributed to an intraluminal fire caused by laser penetration of the cuff; the laser power settings were within specified limits, but the respiratory gas mixture included an excessive F_{IO_2} and nitrous oxide. A newer version, the Laser Shield II, is approved for use with CO_2 or KTP lasers. The construction of this version includes a silicone-based tube that is smoothly wrapped by a coated aluminum

tape. The cuff is made of unshielded silicone elastomer, designed to be expanded with saline, and includes methylene blue dye to tint the saline. The tube wrap is specified to withstand (in vitro) 35,000 W/cm^2 of CO_2 laser energy or 11,000 W/cm^2 of KTP energy for 3 minutes. Blood or mucus on the tube can be expected to reduce its tolerance to laser irradiation by approximately 60%.

Protection of the Endotracheal Tube Cuff

The thin plastic envelope of a standard high-volume, low-pressure endotracheal cuff is extremely susceptible to misdirected laser energy. Although combustion is possible, simple puncture may be more common. Unrecognized cuff punctures lead to oxygen enrichment of the gas surrounding the surgical site and endotracheal tube and increase the likelihood of a catastrophic airway fire. Cuffs with significant laser resistance that maintain the mechanical properties necessary to minimize tracheal trauma are unavailable. Many physicians recommend filling the standard Hi-Lo cuff with colored saline to signal a puncture more clearly and potentially to quench a small cuff fire. The cuff should be placed as far distal in the trachea as possible, and the surgeon should completely cover the visible cuff with moistened cotton pledgets. The cotton strings attached to the pledgets should be replaced by uninsulated wire, and the pledgets should be remoistened as needed. The utility of moistened pledgets in preventing or delaying cuff ignition from CO_2 laser exposure has been confirmed.[81]

Metal Endotracheal Tubes

In 1978, Norton and De Vos[82] introduced a nonflammable endotracheal tube constructed as an interlocking stainless steel spiral coil, resembling electric cable armor (Baxter Healthcare Corp, Niles, IL). The manufacture of this endotracheal tube has been discontinued. Its walls were not airtight, and although this property allowed a cooling gas flow to the exterior surface, it could make ventilation difficult in patients with noncompliant lungs, particularly because the tube had no inflatable cuff. Jet ventilation with a modified Sanders Venturi coupler was suggested as a means to overcome this problem,[83] as was the use of a separate, slide-on cuff, but these are all flammable and pose an ignition risk.

Two other metal endotracheal tubes are commercially available and are approved for use with specific lasers. The Laser Flex tube (Mallinckrodt Inc, St. Louis, MO) is an airtight stainless steel spiral with two distal, saline-inflatable PVC cuffs (redundant in case of puncture of the proximal cuff). This tube is resistant to CO_2 and KTP laser energy,[84] but not the Nd:YAG laser.[78] The Bivona Fome-Cuf (Smith's Medical, Kent, UK) is an aluminum spiral tube with an outer covering of silicone and a unique, self-inflating foam sponge-filled cuff, which prevents deflation after puncture. This feature allows continued positive-pressure ventilation and segregation of airway gases from the operative site, but it may lead to injury if a puncture of the cuff or of the filling tube prevents deflation before removal. The Fome-Cuf is approved for use only with pulsed CO_2 lasers.

The use of laser-resistant endotracheal tubes requires particular care to prevent mucosal abrasions because these tubes tend to be bulkier and more rigid than conventional tubes. Surgeons should ensure that laser energy is not reflected from smooth metal surfaces and directed at sensitive structures. Use of a metal endotracheal tube does not imply absolute protection from ignition; 50 W of an Nd:YAG beam focused to 0.68 mm has been reported to ignite a Laser Flex tube in 6 seconds.[85]

Jet Ventilation

Some physicians contend that optimal surgical conditions and patient safety can be obtained with jet ventilation. This technique takes advantage of Bernoulli's principle to augment the ventilation produced by a narrow, high-speed gas stream in a Venturi tube. In practice, jet ventilation uses an intermittent high-pressure oxygen supply, directed at the glottis through a small metal tube, such as a ventilating bronchoscope or even a 12-gauge blunt needle.[86-91] A retrospective review of 942 cases of microdirect laryngoscopy using endolaryngeal jet ventilation found only four complications.[92] Jet ventilation with air also has been used through a bronchoscope when resecting distal tracheal and bronchial tumors.[93-96] It has been suggested that patients undergoing laser resections of airway tumors during jet ventilation may absorb carbon monoxide from entrained laser smoke in the pharynx. The carbon monoxide can result in an overestimate of arterial oxygen saturation by pulse oximetry. Goldhill and colleagues[95] found neither a significant increase in carboxyhemoglobin during Nd:YAG bronchoscopy nor a difference in pulse oximetry reading versus in vitro carbon monoxide–oximeter measurement of arterial oxygen saturation.

Although jet ventilation generally provides adequate ventilation without introducing flammable material or a large obstacle to the surgical field, potential disadvantages include the risk of barotrauma, pneumothorax, or crepitus; the restriction to use of intravenous anesthetic agents; gastric distention; and the relative requirement for compliant lungs. In the presence of papillomas, a common indication for laryngeal laser surgery, jet ventilation could cause distal bronchial seeding with active virus. Shikowitz and associates[92] found no evidence, however, of this phenomenon in 96 patients who had multiple laser procedures and were followed over time. Cozine and colleagues,[97] in a survey of 58 institutions (15,701 cases) performing CO_2 laser airway surgery, found a higher rate of ventilatory complications with jet ventilation than with a standard endotracheal tube (Fig. 77-9), but the only fatality was caused by an endotracheal tube fire.[97] The investigators concluded that no single mode of ventilation proved superior during laser surgery.

To reduce obstruction of the surgical field by ventilatory instrumentation even further, several researchers have advocated complete removal of such instrumentation combined with the technique of spontaneous ventilation or intermittent apnea, with general anesthesia provided by nasal insufflation or bronchoscopic delivery of a potent inhaled anesthetic[7,72,98,99] or use of an intravenous anesthetic.[100] Cohen and associates[101] and Hawkins and Joseph[102] advocated modest hyperventilation followed by intermittent tracheal extubation by the surgeon for periods of 90 to 120 seconds, during which the laser is used. Pulse oximetry adds a measure of safety by confirming adequate oxygenation from a denitrogenated pulmonary residual capacity during apnea.

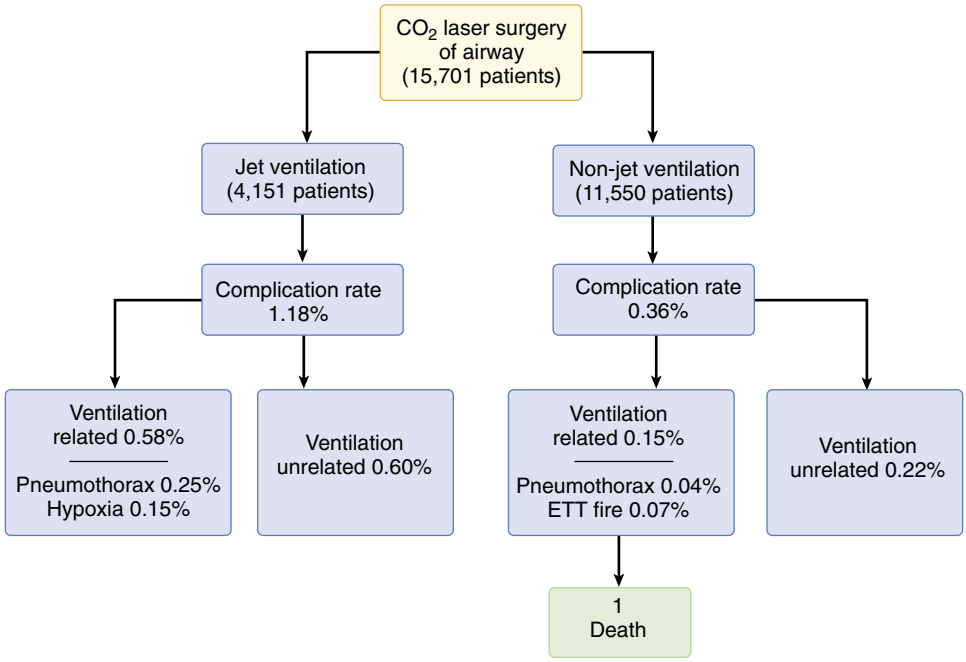

Figure 77-9 Complications of laser airway surgery. Pneumothorax was common with jet ventilation, but potentially lethal airway fires occurred with endotracheal intubation. ETT, endotracheal tube. *(Data from Cozine K, Stone JG, Shulman S, et al: Ventilatory complications of carbon dioxide laser laryngeal surgery. J Clin Anesth 3:20, 1991.)*

Other Considerations

Although not specifically related to laser procedures in the airway, vagal hyperactivity often occurs during instrumentation of the trachea. Immediate recognition and treatment are important. The paraneoplastic syndrome, occasionally observed with small cell and other types of endobronchial tumors, may lead to prolonged weakness after administration of neuromuscular relaxants.[103]

Airway Fire Protocol

If an airway fire or explosion occurs, the surgeon and the anesthesiologist must act quickly, decisively, and in a coordinated fashion. This may not be easy after an explosion because the event may be so traumatic as to incapacitate the operating room staff temporarily. Clear communication and emergency practice (at least a mental drill of the emergency procedure) are key to managing such a crisis. Schramm and coworkers[104] provided a useful review of the ensuing pathologic features and suggested emergency management.

A surgeon who detects an endotracheal or other source of airway fire should remove the source as quickly as possible and simultaneously inform the anesthesiologist, who should immediately, despite reflexive training to the contrary, stop ventilation. Temporarily disconnecting the breathing circuit from the anesthesia machine may be useful. These maneuvers remove the flame and the retained heat in the tube and stop the flow of oxygen-enriched gas. The flaming material should be extinguished in a bucket of water, which should always be available during laser surgery. Ventilation with 100% oxygen should be provided by mask, and anesthesia should be continued.

Direct laryngoscopy and rigid (Venturi-ventilating) bronchoscopy should be performed to survey damage and to remove debris. If the fire was of the "interior blowtorch" type, gentle bronchial lavage may be indicated, followed by fiberoptic assessment of the more distal airways. If any airway damage is apparent, the patient should be reintubated. Small fires involving only the exterior of the tube may not cause appreciable damage. If the damage is severe, a low tracheotomy may be indicated.

The pattern of damage in interior fires tends to be worst in the upper airway and diminishes as the surgeon approaches and passes the carina. The patient's oropharynx and face should be assessed, and a chest radiograph should be obtained. Pulmonary damage due to heat or smoke inhalation, or both, may necessitate prolonged intubation and mechanical ventilation. A brief course of high-dose steroids may be helpful.[105,106]

Summary

Lasers provide a useful tool in the surgical armamentarium, one for which anesthesiologists must prepare, with increasing frequency, their patients and themselves. Although some of the potential threats posed by clinical lasers are unique, most are extensions of the risks posed by the previous generation of surgical tools. As with most potentially dangerous procedures, the risks of laser use can be minimized by common sense and preconsidered contingency plans.

78 Ambulatory (Outpatient) Anesthesia

Key Points

1. The continued growth in ambulatory surgery is related to expansion in minimally invasive surgical techniques and office-based procedures.
2. Pre-existing medical conditions are rarely an exclusionary criterion for ambulatory surgery.
3. Routine laboratory testing is not recommended before ambulatory surgery.
4. The choice of anesthetic technique has a significant effect on postoperative side effects and discharge time. The use of local anesthesia with sedation, so-called monitored anesthesia care, is associated with the fewest side effects and the shortest time to discharge home.
5. The use of propofol for induction or maintenance of anesthesia (or both) is associated with a reduced incidence of postoperative nausea and vomiting (PONV).
6. The use of desflurane or nitrous oxide (or both) in conjunction with antiemetic prophylaxis will facilitate the "fast-track" recovery process.
7. The use of potent opioid analgesics (e.g., fentanyl, sufentanil) in combination with local anesthetics will decrease the time to discharge home after spinal anesthesia.
8. Multimodal ("balanced") analgesic and antiemetic regimens will allow most outpatients to be fast-tracked after ambulatory surgery under general anesthesia.
9. Fast-tracking after ambulatory surgery is accomplished by taking the patient directly from the operating room to the day-surgery step-down unit ("bypassing the PACU") or simply discharging the patient home from the PACU ("PACU bypassing").
10. Outcomes after ambulatory (and office-based) surgery are no different than after inpatient (hospital-based) surgery procedures. Recent data suggest that for elderly patients the surgical outcome may be improved.

Over the past 4 decades, ambulatory surgery has grown from less than 10% to over 70% of all elective surgical procedures.[1] Ambulatory surgery has progressed from the practice of performing simple procedures on healthy outpatients to encompassing a broad spectrum of major procedures in outpatients with complex preexisting medical conditions. Formal development of ambulatory anesthesia as a respected subspecialty occurred with establishment of the Society for Ambulatory Anesthesia (SAMBA) in 1984 and the subsequent development of postgraduate subspecialty training programs recognized by the American Society of Anesthesiologists (ASA).

The expanding number of freestanding diagnostic and surgical treatment centers around the world reflects the global interest in reducing the need for hospitalization after elective surgery.[2] However, the growth in ambulatory surgery would have not been possible without the development of improved anesthetic and surgical techniques.[3] The availability of rapid, shorter-acting anesthetic, analgesic, and muscle relaxant drugs has clearly facilitated the recovery process after surgery, and the development of minimally invasive surgical techniques allowed more extensive procedures to be performed on an ambulatory basis, irrespective of the patient's preexisting medical conditions.[4]

The range of acceptable ambulatory surgical procedures continues to expand, and patients are presenting for outpatient surgery with increasingly complex medical problems. As a result, anesthesiologists must play a more active role in the preoperative assessment and preparation of these patients to avoid costly delays and last-minute cancellations.[5] The role of the anesthesiologist has evolved from that of a physician primarily concerned with providing optimal surgical conditions and minimizing pain immediately after the operation to that of a perioperative physician responsible for ensuring that patients with coexisting medical conditions are optimally managed before, during, and after surgery (Table 78-1).[6,7] In modern ambulatory facilities, complex surgical procedures can be safely performed without sacrificing quality while minimizing use of hospital resources.[8] In an era of cost containment, the savings inherent in providing increased ambulatory surgical services ensures that the number of outpatient surgical procedures will continue to grow in the 21st century.[1]

Table 78-1 Key Elements of Perioperative Anesthetic Management for Facilitating a Fast-Track Recovery after Elective Ambulatory Surgery

Preoperative Period
- Stabilize coexisting diseases (e.g., hypertension, diabetes) and encourage prehabilitation exercise program and smoking cessation.
- Optimize patient comfort by minimizing anxiety and discomfort.
- Ensure adequate rehydration by replacing fluid deficits.
- Use appropriate prophylactic therapies to prevent postoperative complications (e.g., nausea, vomiting, pain, ileus).

Intraoperative Period
- Utilize anesthetic techniques that optimize surgical conditions, while ensuring a rapid recovery with minimal side effects.
- Administer local analgesia via peripheral nerve blocks, wound infiltration, and/or instillation.
- Apply multimodal analgesia and antiemetic prophylaxis (including use of glucocorticoid steroids).
- Minimize use of nasogastric tubes and surgical drains, and avoid excessive fluid administration.

Postoperative Period
- Allow patients who meet discharge criteria to be fast-tracked (i.e., discharged earlier from recovery units).
- Ensure adequate pain control in the postdischarge period utilizing nonopioid analgesics to minimize need for opioid-containing analgesics.
- Encourage early ambulation and resumption of normal activities of daily living.

Modified from White PF, Kehlet H, Neal JM, et al: The role of the anesthesiologist in fast-track surgery: From multimodal analgesia to perioperative medical care. Anesth Analg 104:1380-1396, 2007.

Rationale for Ambulatory Surgery

Ambulatory surgery can offer a number of advantages for patients, health care providers, third-party payers, and even hospitals (Table 78-2). Most patients actually prefer to have their surgical procedures performed as outpatients because it decreases separation from their familiar home environment. Postoperative cognitive dysfunction was less frequent in elderly patients undergoing minor surgery on an ambulatory basis,[9] confirming that hospitalization should be avoided whenever possible. A survey of patient satisfaction after ambulatory surgery reported that 97% of the respondents would choose to have day surgery for a future surgical procedure.[1] Unlike inpatient surgery, ambulatory surgery does not depend on the availability of a hospital bed, and patients thus have a greater degree of flexibility in scheduling the timing of their operation.

Outpatient surgery has been performed safely with a remarkably low incidence of both minor and major morbidity.[10] Studies have shown that unanticipated admission to the hospital and return visits to the hospital occur in less than 3% of patients after ambulatory surgical procedures.[11-13] The majority of readmissions (and emergency department visits) were related to surgical complications.[12] Of the surgical subspecialties, otolaryngology had the highest, and gynecology the lowest, incidence of unanticipated admissions. The lower infection rate associated with outpatient surgery is particularly beneficial to pediatric, geriatric, and immunocompromised patients.[1] Risk factors associated with an increase in surgical site infections were the use of postoperative antibiotics and prolonged surgical times.[14] Finally, there is evidence that the incidence of respiratory complications (i.e., pulmonary embolus and pneumonia) also may be decreased.[15] Even outpatients with obstructive sleep apnea syndrome were not found to have an increased incidence of respiratory complications or unanticipated hospital admissions.[16]

Minimally invasive ambulatory surgery has clear economic benefits. For example, when compared with conventional "open" procedures, the use of minimally invasive surgical techniques can reduce overall hospital costs by almost 50%.[17] Another cost-saving benefit relates to the greater efficiency of ambulatory centers, which results in higher operating room utilization and faster turnover times.[8] The ability to care for larger volumes of patients can lead to reduced surgical waiting lists. When compared with similar procedures performed in hospitalized patients, less preoperative laboratory testing is ordered for ambulatory surgery and the patients have a reduced demand for postoperative medications. These factors all contribute to the 25% to 75% reductions in overall cost for most operations performed in the outpatient (versus inpatient) setting. However, procedures requiring specialized postoperative care (e.g., extensive physical therapy or complex pain management techniques) may be more costly when performed on an outpatient basis.[18] Patients who require postoperative blood transfusions or intravenous antibiotics and parenteral opioid analgesics are best handled as 23-hour admissions. Recent improvements in home health care and outpatient physical therapy may enable these services to be performed in the patient's home. Importantly, studies comparing minimally invasive (versus open) procedures have reported that patients can resume activities of daily living several days or even weeks earlier.[19] Assuming that the number of available hospital beds continues to decline in the future, the growth of ambulatory surgery will lead to an increased return on investment of the health care dollar.

Table 78-2 Benefits of Ambulatory Surgery

- Patient preference, especially children and the elderly
- Lack of dependence on the availability of hospital beds
- Greater flexibility in scheduling operations
- Low morbidity and mortality
- Lower incidence of infection
- Lower incidence of respiratory complications
- Higher volume of patients (greater efficiency)
- Shorter surgical waiting lists
- Lower overall procedural costs
- Less preoperative testing and postoperative medication

Modified from Snyder DS, Pasternak LR: Facility design and procedural safety. *In* White PF (ed): Ambulatory Anesthesia and Surgery. London, WB Saunders, 1997, p 61.

Facility Design and Safety

Ambulatory surgical facilities need to be well-designed to ensure efficient delivery of surgical services at the lowest possible cost. The first freestanding outpatient surgical facility was built and managed by an anesthesiologist, Wallace Reed, to provide surgical care to patients whose operations were deemed too demanding for a surgeon's office yet did not require overnight hospitalization.[20] Since that time, outpatient surgical facilities have continued to grow and evolve.[21] The prototypical ambulatory surgical units have four basic designs[1]:

1. *Hospital integrated:* Ambulatory surgical patients are managed in the same surgery facility as inpatients. Outpatients may have separate preoperative preparation and recovery areas.
2. *Hospital-based:* A separate ambulatory surgical facility within a hospital handles only outpatients.
3. *Freestanding:* These surgical and diagnostic facilities may be associated with a hospital or medical center but are housed in separate buildings that share no space or patient care functions. Preoperative evaluation, surgical care, and recovery occur within this autonomous unit.
4. *Office-based:* These operating and/or diagnostic suites are managed in conjunction with physicians' offices for the convenience of patients and health care providers.

Patient volume, types of patients (e.g., children, elderly), types of diagnostic and therapeutic procedures, organizational structure, and radiologic and laboratory testing requirements must all be considered during the initial planning of a new facility. To be optimally efficient, it is recommended that all the outpatient services be organized in one dedicated area. Designs that place the waiting room, preoperative evaluation area, preanesthesia room, operating suites, and recovery areas in close proximity have many advantages.[20] Surgeons and anesthesiologists are able to visit the patient and family before and after the operation without losing valuable time in transit. Patient transportation time is also reduced to a minimum, and extra personnel are unnecessary because the circulating nurse (or anesthesiologist) can transport the patient to and from the operating room (Fig. 78-1). In most office-based facilities, the patients can walk in and walk out of the operating room.

Quality assurance and total quality improvement are helpful in maintaining high standards for outpatient care and ensuring patient safety. Quality standards are set and enforced either by government regulation, through a licensing process, or by accreditation by private organizations such as the Accreditation Association for Ambulatory Health Care (AAAHC). The AAAHC is an independent accreditation organization whose principal activities are to develop standards, conduct surveys, and confer accreditation on ambulatory health care providers. In the United States and Canada, hospital-based ambulatory surgical facilities receive accreditation through The Joint Commission on Accreditation of Healthcare Organizations, which is the primary accreditation agency for hospitals. As a result of heightened public and practitioner concern over the safety and quality of office-based surgical procedures, the AAAHC has established new quality standards for office-based and so-called mobile or itinerant anesthesia organizations.[22] It has been recommended that all facilities where surgery is performed, as well as the health care providers, be accredited to ensure that patient safety is not being compromised.[23]

The ASA also provides guidelines for ambulatory surgical facilities. The availability of personnel and equipment for unexpected emergencies or a delayed return to the operating room is essential. In-service training of all staff members regarding skills that are infrequently required should be given regularly, including advanced cardiac life support, management of airway complications, emergency tracheotomy, and treatment of malignant hyperthermia (MH).[1] All facilities in which anesthesia is administered require a portable crash cart and suction device. General support services for routine laboratory tests, an electrocardiography (ECG) machine, and access to a blood supply should also be available. A mechanism should be in place for obtaining an emergency MH kit in locations where general anesthesia is performed.

Patient Selection Criteria

Selection of Procedures

Surgical procedures suitable for ambulatory surgery should be accompanied by minimal postoperative physiologic disturbances and an uncomplicated recovery.[24] The primary predictors of prolonged stay or unanticipated admission after day-case surgery are related to the type of surgical procedure and associated complications (e.g., blood loss, incisional pain, postoperative nausea and vomiting [PONV]).[25,26] With advances in surgical technologies and the rapid growth in minimally invasive surgical techniques, an even wider variety of operations can now be performed on an outpatient basis (Table 78-3). Many published reports have demonstrated that minimally invasive outpatient procedures such as parathyroidectomy and thyroidectomy, laparoscopically assisted vaginal hysterectomy, removal of ectopic tubal pregnancy, and ovarian cystectomy, as well as laparoscopic cholecystectomy and fundoplication, offer advantages over conventional "open" approaches.[27-31] In addition, procedures such as laparoscopic adrenalectomy, splenectomy, and nephrectomy, lumbar microdiscectomy, and video-assisted thoracic surgery significantly improve recovery and reduce costs compared with open procedures.[32,33] For superficial procedures (e.g., mastectomy), reductions in both cost and perioperative complications have been observed when these procedures are performed on an outpatient basis.[34]

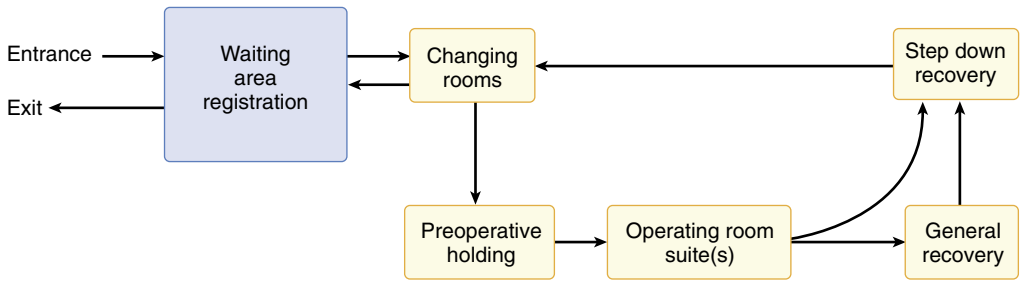

Figure 78-1 Essential components related to patient flow in an ambulatory surgery facility. (*Redrawn with modification from Snyder DS, Pasternak LR: Facility design and procedural safety. In White PF [ed]: Ambulatory Anesthesia and Surgery. London, WB Saunders, 1997, p 61.*)

Table 78-3 Operative Procedures Suitable for Ambulatory Surgery

Specialty	Types of Surgical Procedures
Dental	Extraction, restoration, facial fractures
Dermatology	Excision of skin lesions
General	Biopsy, endoscopy, excision of masses, hemorrhoidectomy, herniorrhaphy, laparoscopic cholecystectomy, adrenalectomy, splenectomy, varicose vein surgery
Gynecology	Cone biopsy, dilatation and curettage, hysteroscopy, diagnostic laparoscopy, laparoscopic tubal ligations, uterine polypectomy, vaginal hysterectomy
Ophthalmology	Cataract extraction, chalazion excision, nasolacrimal duct probing, strabismus repair, tonometry
Orthopedic	Anterior cruciate repair, knee arthroscopy, shoulder reconstructions, bunionectomy, carpal tunnel release, closed reduction, hardware removal, manipulation under anesthesia and minimally invasive hip replacements
Otolaryngology	Adenoidectomy, laryngoscopy, mastoidectomy, myringotomy, polypectomy, rhinoplasty, tonsillectomy, tympanoplasty
Pain clinic	Chemical sympathectomy, epidural injection, nerve blocks
Plastic surgery	Basal cell cancer excision, cleft lip repair, liposuction, mammoplasty (reductions and augmentations), otoplasty, scar revision, septorhinoplasty, skin graft
Urology	Bladder surgery, circumcision, cystoscopy, lithotripsy, orchiectomy, prostate biopsy, vasovasostomy, laparoscopic nephrectomy and prostatectomy

Modified from White PF (ed): Ambulatory Anesthesia and Surgery. London, WB Saunders, 1997.

Patients undergoing procedures that are likely to be associated with major postoperative surgical complications (e.g., bleeding) or major fluid shifts (e.g., extensive plastic surgery) should be admitted to the hospital overnight. Although autologous blood transfusions are used for extensive outpatient plastic surgery (e.g., reduction mammoplasty, liposuction), after lengthy procedures associated with excessive fluid shifts, patients should be admitted to an overnight (23-hour) recovery facility. Similarly, operative procedures requiring prolonged immobilization and parenteral opioid analgesic therapy are more ideally suited to a 23-hour stay. However, the availability of newer analgesic therapies (e.g., continuous local anesthetic infusions, nonparenteral opioid analgesic delivery systems), as well as ambulatory patient-controlled analgesic techniques (e.g., subcutaneous, intranasal, transcutaneous), is allowing more patients undergoing painful orthopedic procedures to be discharged home on the day of surgery.[35-37]

Duration of Surgery

The duration of surgery in the ambulatory setting was originally limited to procedures lasting less than 90 minutes because early investigators found that the operating and anesthesia times were strong predictors of postoperative complications (e.g., pain, emesis)[38] and delayed discharge,[25] as well as unanticipated admission to the hospital after ambulatory surgery.[11,38-40] However, surgical procedures lasting 3 to 4 hours are now routinely performed on an ambulatory basis.

Patient Characteristics

Originally, the majority of patients treated in ambulatory surgical facilities were classified as ASA physical status I or II. However, improved anesthesia and surgical care has allowed increasing numbers of medically stable ASA physical status III (and even some IV) patients to undergo operations away from conventional medical centers.[1] In a large, prospective outcome study by Warner and coworkers,[10] 24% of ambulatory surgical patients were ASA physical status III, and these patients had the same low incidence of morbidity as ASA I and II patients (Table 78-4). Other studies have shown that patients with preexisting medical conditions do not have an increased incidence of perioperative complications or unexpected admissions.[41] The comparable incidence of complications in outpatients of differing ASA status was attributed to prudent patient selection, careful preoperative evaluation, and close communication among surgeons, anesthesiologists, and primary care physicians.

The risk of complications can be minimized if preexisting medical conditions are stable for at least 3 months before the scheduled operation. Therefore, the ASA physical status should not be considered in isolation because the type of surgical procedure, the anesthetic technique, and a multitude of medical and social factors can also influence decisions regarding a patient's suitability for ambulatory surgery.[42] Even morbid obesity (body mass index >40 kg/m^2) is no longer considered an exclusionary criterion for day-case surgery.[43,44] However, morbidly obese patients with preexisting cardiovascular (e.g., hypertension, congestive heart failure, angina) and respiratory (e.g., asthma, chronic obstructive pulmonary disease) conditions had a higher incidence of perioperative morbidity than did healthy outpatients undergoing similar procedures on an ambulatory basis.[25] Elderly obese patients were more likely to experience natural oxygen desaturation and episodic airway obstruction after ambulatory surgery.[45] As expected, heavy smoking was associated with an increased risk of respiratory complications and postoperative wound infection in patients undergoing ambulatory surgery.[46]

Table 78-4 Relationship between American Society of Anesthesiologists Physical Status and Postoperative Morbidity and Mortality

ASA Physical Status	No. Patients (%)	Major Morbidity (No.)
I (healthy patient)	14,609 (32)	6
II (mild systemic disease)	19,614 (43)	17*
III (severe systemic disease with functional limitation)	10,867 (24)	8
IV (severe systemic disease, constant threat to life)	0	—
V (moribund, unlikely to survive 24 hr)	0	—

*A total of four deaths were reported within 30 days of the surgical procedure (two were related to motor vehicle accidents).
From Warner MA, Shields SE, Chute CG: Major morbidity and mortality within 1 month of ambulatory surgery and anesthesia. JAMA 270:1437, 1993. Copyright 1993, American Medical Association.

Yet, the presence of obstructive sleep apnea syndrome was not associated with an increased risk of unanticipated admission to the hospital.[16]

Susceptibility to Malignant Hyperthermia

MH-susceptible patients can be successfully managed with nontriggering anesthetics (e.g., local anesthesia) in the outpatient setting (see Chapter 37). The decision to admit a patient postoperatively should be based on clinical criteria because admission solely on the basis of MH susceptibility is no longer considered appropriate.[47] If the anesthesia and surgery were uneventful, MH-susceptible patients can be safely discharged home on the day of surgery. Patients at risk for MH and their families should be advised about the signs and symptoms of MH, in addition to the usual postoperative instructions.

Extremes of Age

Age alone should not be considered a deterrent in the selection of patients for ambulatory surgery (see Chapters 71 and 82). However, there is recent evidence to suggest that the rate of admission or death within 7 days of outpatient surgery increases with increased age.[48] Even the "elderly elderly" patient (>100 years) should not be denied ambulatory surgery solely on the basis of age.[49] In fact, elderly patients experience less postoperative pain, dizziness, and emetic symptoms than their younger counterparts.[50] A study found that elderly patients experienced less postoperative cognitive dysfunction and disorientation after ambulatory (versus inpatient surgery).[8] Nevertheless, elderly outpatients may experience a higher incidence of perioperative cardiovascular events, and recovery of fine motor skills may be slowed with increasing age. Furthermore, elderly outpatients may require a greater degree of supervision after discharge than their younger counterparts. Social factors, including lack of transportation, a responsible escort, and a caretaker at home, may make it difficult for some elderly patients to undergo ambulatory surgery procedures on a same-day basis.

At the other extreme, ex-premature infants (gestational age < 37 weeks) recovering from minor surgical procedures under general anesthesia have an increased risk for postoperative apnea. Controversy exists regarding the postconceptual age after which no further risk remains.[51] Most studies suggest that the risk is greatest in premature infants younger than 46 weeks' postconceptual age.[51,52] However, some authors have reported that the risk of apnea may persist until the 60th postconceptual week.[53] In addition, anemia (hematocrit < 30%) independently increases the risk of postoperative apnea in former preterm infants less than 60 weeks' postconceptual age.[54] Treatment with IV caffeine may prevent prolonged apnea and desaturation in this patient population.[55] There was no relationship between apnea and intraoperative use of opioid analgesics or muscle relaxants.[56]

Contraindications to Outpatient Surgery

Patients with the following conditions may be at increased risk for postoperative complications and should be offered the option of overnight hospitalization[24]:

1. Potentially life-threatening chronic illnesses (e.g., brittle diabetes, unstable angina, symptomatic asthma)
2. Morbid obesity complicated by symptomatic cardiorespiratory problems (e.g., angina, asthma)
3. Multiple chronic centrally active drug therapies (e.g., use of monoamine oxidase inhibitors such as pargyline and tranylcypromine) and/or active cocaine abuse
4. Ex-premature infants less than 60 weeks' postconceptual age requiring general endotracheal anesthesia
5. No responsible adult at home to care for the patient on the evening after surgery

Preoperative Assessment

Preoperative assessment of outpatients has become increasingly important because patients are presenting for ambulatory surgery with more complex medical conditions and may be taking multiple chronic medications (see Chapter 34). It is essential to develop an effective method of screening these patients preoperatively to avoid costly delays and last-minute cancellations.[5] Preoperative screening may be accomplished by means of a telephone interview by a trained nurse[57] or a visit to a preoperative evaluation clinic.[58,59] The use of a computerized questionnaire can also be a time-saving and efficient practice. Computerized questionnaires are more accurate in listing positive and negative historical information than a physician interview and can be used to guide preoperative laboratory testing.[60] Clinical studies suggest that these computerized questionnaires allow for more appropriate and cost-effective use of preoperative laboratory testing.

The use of a preoperative questionnaire along with a telephone screening interview was highly effective in reducing cancellations and surgical delays.[61,62] However, when the preoperative assessment is performed 1 to 2 weeks before surgery in a preadmission clinic, it was reported to provide a benefit for less than 10% of patients.[63] A trained nurse using a rule-based computer program in which the identified medical problems and abnormal laboratory findings were reviewed by an anesthesiologist was found to reduce cancellation from 5% to 2%.[64] It would appear that the quality of information obtained from the preanesthetic visit is improved by using computer-based standardized questionnaires.[65]

Preoperative Evaluation

The primary objective of the preoperative assessment is to identify patients who have concurrent medical problems requiring further diagnostic evaluation or active treatment before elective surgery. Patients with specific anesthetic concerns (e.g., difficult airway, active cardiac disease, MH susceptibility) and those at increased risk for perioperative anesthetic and surgical complications should be identified so that steps can be taken to prevent postoperative complications. Preexisting medical conditions that may be associated with adverse events include hypertension (e.g., perioperative cardiovascular events); obesity, asthma, and smoking (e.g., perioperative respiratory events); and gastroesophageal reflux disease (e.g., intubation-related events).[46,66] Of the three primary components of a preoperative assessment (i.e., history, physical examination, and laboratory testing), the patient's

medical history is clearly the most valuable.[67] Evaluations of medical consultations demonstrated that 86% of diagnoses depended entirely on the information obtained from the patient's history. A further 6% of diagnoses were discovered by careful physical examination, and only 8% were determined by additional laboratory investigations. Routine preoperative laboratory testing of patients before ambulatory surgery is unjustified and extremely wasteful of valuable health care resources.

For outpatients undergoing superficial surgical procedures (e.g., biopsy, dilatation and curettage, herniorrhaphy, arthroscopy, vein stripping), no laboratory tests appear to be indicated in males, and only a hemoglobin (or hematocrit) test is indicated for adult females of child-bearing age. Obviously, patients with chronic diseases (e.g., hypertension, diabetes) require additional laboratory studies (e.g., electrolytes, glucose). Patients with an unexplained hemoglobin concentration of less than 10 g/dL should be considered for further evaluation before elective outpatient surgery because a low hemoglobin level may be associated with diseases that could influence perioperative mortality and morbidity. Eliminating routine preoperative testing (even in elderly outpatients) will allow cost savings without compromising the safety or the quality of patient care.[68-71]

Preoperative assessment 1 to 2 weeks before surgery was found to reduce preoperative anxiety when compared with assessment on the evening before surgery.[72] In addition to the anesthesiologist's evaluation, the preoperative visit could be used by the nursing staff to assess, prepare, and educate the patient; by the facility's business office to perform a financial interview; and to familiarize the patient and family with the center's operating procedures. To avoid unexpected delays resulting from an incomplete assessment, all paperwork (including the consent form, history and physical examination, and laboratory test results) should be reviewed before the patient arrives for surgery. A well-planned and smooth-functioning ambulatory surgery program can yield many benefits to patients and their families, as well as to surgeons and nursing personnel. Appropriate patient preparation before the day of surgery can prevent unnecessary delays, absences ("no shows"), last-minute cancellations, and substandard perioperative care.

Preoperative Preparation

Optimal preoperative preparation of outpatients makes ambulatory surgery both safer and more acceptable for patients and the hospital staff (see Chapter 34). The preparation process is aimed at reducing the risks inherent in ambulatory surgery, improving patient outcome, and making the surgical experience more pleasant for the patient and their family. Simple procedures such as topical warming of an extremity before venous cannulation reduce both the time and number of attempts required.[72] Preoperative preparation should attempt to minimize patient anxiety using both pharmacologic (e.g., benzodiazepines) and nonpharmacologic (e.g., relaxation therapies) approaches. Patients should be encouraged to continue all their chronic medications up to the time that they arrive at the surgery center. Oral medications can be taken with a small amount of water up to 30 minutes before surgery. Practitioners need to be aware of the fact that an increasing number of outpatients are using nutraceuticals,[73] some of which may cause adverse effects during the perioperative period.[73]

Nonpharmacologic Preparation

The anticipation of undergoing anesthesia can cause psychological stress that is commonly manifested as acute anxiety. Preoperative anxiety has been shown to rise at least 1 week before surgery and return to normal levels in the postoperative period only after an uneventful recovery is ensured. The cause of patients' preoperative anxiety is multifactorial, but most commonly it is related to concerns about intraoperative awareness, not awaking after surgery, or postoperative pain and nausea. Not surprisingly, previous surgery reduces the degree of preoperative anxiety.[74] High levels of stress preoperatively are associated with slower recovery and greater analgesic and antiemetic requirements after surgery, but it can be effectively reduced by careful preoperative preparation (Fig. 78-2). Overall, well-informed patients tend to recover faster and experience less pain and fewer postoperative complications.

Nonpharmacologic preparation has many desirable characteristics. These methods are economic, lack undesirable side effects, and are associated with high patient acceptance. More than 40 years ago, Egbert and colleagues demonstrated that the anesthetist's preoperative visit was more effective than a sedative premedicant in relieving preoperative anxiety. Postoperative pain can also be reduced by preoperative educational programs. The timing of the preoperative interview is also important because anxiety is significantly decreased only when the interview takes place outside the operating room immediately before surgery.[75] Many centers have shown encouraging results with the use of instructional preoperative videotapes that offer a complete explanation of the events surrounding surgery.[76] Outpatients who listen to music before surgery reported significantly lower anxiety levels.[77] Self-hypnotic relaxation techniques have proved beneficial during invasive medical procedures.[78] Hypnosis and imagery may also have a positive effect in reducing pain and anxiety, as well as improving hemodynamic stability during the perioperative period.

The use of play-oriented preoperative teaching, books, pamphlets, and video programs are beneficial for pediatric patients.[79] Separation anxiety and postoperative behavioral changes (prominent in children 1 to 4 years of age) may be diminished when preparation programs are utilized. In the modern ambulatory surgery center, both psychological and pharmacologic means should be available to alleviate patients' anxiety and decrease postoperative morbidity.[80] Preoperative preparation should also include written and verbal instructions regarding arrival time and place, fasting instructions, and information concerning the postoperative course, effects of anesthetic drugs on driving and cognitive skills immediately after surgery, and the need for a responsible adult to care for the patient during the early postdischarge period (<24 hours).

Pharmacologic Preparation

The use of premedication in the outpatient setting has been a subject of considerable debate over the past 30 years. The primary indications for preoperative medication include anxiolysis, sedation, analgesia, amnesia, and prophylaxis against postoperative emesis and aspiration pneumonia.[81] Despite these well-recognized indications, benzodiazepine premedication is not routinely used at many ambulatory surgery facilities in the United States[1] because of concern that these drugs will prolong the recovery period. Interestingly, prospective studies have not found recovery to be prolonged after the use of appropriate doses of sedative

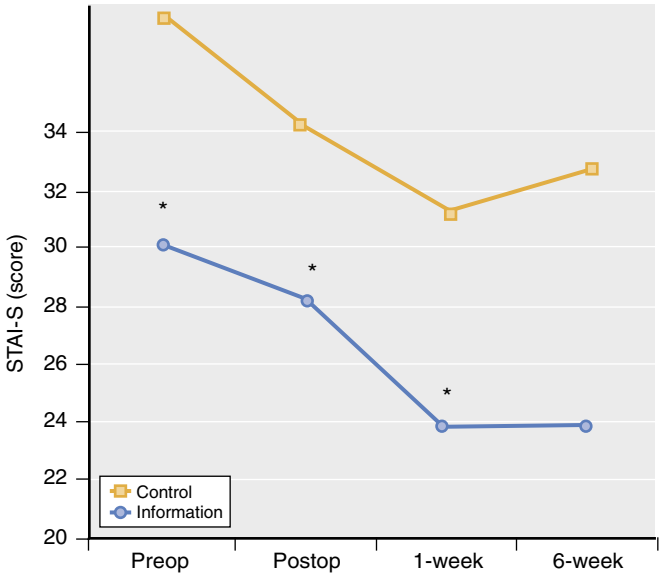

Figure 78-2 Preoperative psychological preparation reduces stress before and up to 1 week after surgery, as measured by the Spielberger state anxiety score. * = $P < .05$. (*Redrawn with modification from Wallace LM: Psychological preparation as a method of reducing the stress of surgery. J Hum Stress 10:62, 1984. premedication in the outpatient setting (e.g., midazolam, 1-2 mg intravenously [IV]).[82,83] Van Vlymen and associates[84] found that premedication with a small dose of a benzodiazepine actually improved outcome in women undergoing needle-localized breast biopsies without delaying recovery. Midazolam premedication not only decreases preoperative anxiety but may also be associated with a reduction in postoperative pain.[85]

Anxiolysis and Sedation

Traditionally, the most widely used premedicants have been barbiturates and benzodiazepines. These drugs produce dose-related anxiolysis, sedation, and ultimately, unconsciousness (see Chapter 26). Barbiturates are not commonly used as premedicants in the outpatient setting because of residual sedation, which makes them less cost beneficial than nonbarbiturate sedative drugs (e.g., midazolam, propofol).[86] Methohexital and ketamine have been used for rectal premedication in children. However, side effects of ketamine (e.g., confusion, vivid dreams) are frequent unless this drug is combined with midazolam.[87] Melatonin has also been reported to produce sedation and anxiolysis comparable to oral midazolam when administered for premedication.[88]

Benzodiazepines

The amnesic and anxiolytic properties of small doses of benzodiazepines are also useful in the outpatient setting (Table 78-5). Oral diazepam, 0.1 mg/kg, given 60 to 90 minutes before surgery was found to reduce stress hormone levels after day-case surgery.[89] Diazepam was the most commonly used benzodiazepine; however, midazolam has become the drug of choice because its shorter elimination half-life and its anesthetic sparing effects and lack of significant side effects facilitate the recovery process after ambulatory surgery.[90-92] In addition to its well-known anxiolytic properties, midazolam may be effective in reducing postoperative nausea and improving patient satisfaction.[93] Although larger doses of midazolam are required when it is administered orally because of first-pass metabolism, it is a highly effective in both adults and children.[80,94] Midazolam (0.5 mg/kg PO) allowed children to be separated from their parents as early as 15 minutes after oral ingestion, without prolonging recovery even after brief surgical procedures.[81,94,95] Larger doses (1.0 mg/kg) of oral midazolam delay early recovery (emergence) but not discharge time after ambulatory surgery.[96] In geriatric patients, premedication with midazolam (0.5-1.0 mg IV) did not adversely affect mental and psychomotor recovery, even after brief ambulatory procedures.[97]

Temazepam and alprazolam also are effective oral premedicants for outpatient surgery.[94,98] Although oral triazolam can produce effective sedation and amnesia, it is less effective than diazepam or midazolam in decreasing preoperative anxiety. Lorazepam, because of its long duration of amnesia, is not recommended in the ambulatory setting. If a patient expresses significant anxiety during the preoperative interview, an oral benzodiazepine should be prescribed to be taken at home in the evening before or in the morning 1 to 2 hours before surgery or

Table 78-5 Use of Anxiolytic-Sedative Drugs for Outpatient Premedication

	Dosage Range	Onset (min)	Key Points
Benzodiazepines			
Midazolam	7.5-15 mg PO	15-30	Large first-pass effect
	5-7 mg IM	15-30	Water soluble, nonirritating
	1-2 mg IV	1-53	Rapid onset, excellent amnesia
Diazepam	5-10 mg PO	45-90	Long-acting metabolites
Temazepam	15-30 mg PO	15-40	Comparable anxiolysis to midazolam
Triazolam	0.125-0.25 mg PO	15-30	Prominent sedation
Lorazepam	1-2 mg PO	45-90	Prolonged amnestic effect
α2-Adrenergic Agonists			
Clonidine	0.1-0.3 mg PO	45-60	Prolonged sedative effect
Dexmedetomidine	50-70 μg IM	20-60	Bradycardia and hypotension
	50 μg IV	5-30	Reduced anesthetic/analgesic requirements

Modified from White PF: Ambulatory anesthesia and surgery: Past, present, and future. *In* White PF (ed): Ambulatory Anesthesia and Surgery. London, WB Saunders, 1997.

both. When significant anxiety develops after admission to the day surgery center, intravenous midazolam (1-3 mg IV) is the most useful drug.

α-Adrenergic Agonists

Premedication with α_2-adrenergic agonist drugs produce sedation and anxiolysis while also decreasing the heart rate and blood pressure during anesthesia and opioid requirements after surgery.[99] Oral clonidine, the prototypical α_2-agonist, has been successfully used for ambulatory premedication and may reduce intraoperative blood loss,[100] as well as the anesthetic and analgesic requirements. Dexmedetomidine is a more highly selective α_2-agonist that has a shorter duration of action than clonidine.[101] Because of its high potency and selective agonist action on α_2-receptors, dexmedetomidine may gain more widespread acceptance in outpatient anesthesia. Although the acute hemodynamic effects of this IV drug may limit its use for premedication, dexmedetomidine could prove to be a valuable adjunct during surgery because of its anesthetic and analgesic sparing effects and ability to decrease postoperative pain.[102]

When compared with oral midazolam, clonidine was less effective in reducing anxiety but produced greater anesthetic- and analgesic-sparing effects in children.[103,104] Interestingly, clonidine was also effective in decreasing emergence delirium after sevoflurane anesthesia.[105] In adults, adjunctive use of intravenous clonidine during general anesthesia reduced emetic symptoms after breast surgery.[106] Clonidine has also been found to facilitate glycemic control in type-2 diabetic patients[107] and reduce postoperative myocardial ischemia in patients with preexisting cardiac disease.[108]

β-Blockers

The role of β-adrenergic blockers appears to be increasing in ambulatory surgery because of their ability to control acute autonomic responses during surgery while minimizing the need for opioid analgesics.[109,110] Recent studies[110,111] have demonstrated improved postoperative pain control when esmolol is used as an adjuvant during ambulatory surgery. β-Blockers (e.g., atenolol, esmolol) suppress surgery-induced increases in circulating catecholamines and prevent untoward perioperative cardiovascular events in the elderly and patients with preexisting coronary artery disease undergoing noncardiac surgery.[112] Although labetalol has not been studied, it possesses both α-adrenergic and β-blocking properties and is highly effective in both the prevention and control of acute autonomic responses during ambulatory surgery procedures.

Preemptive (Preventative) Analgesia

Improving pain control after ambulatory surgery can accelerate normalization of activities of daily living and improve functionality.[113-115] Multimodal analgesic regimens involving the use of a combination of nonopioid analgesics to minimize the need for opioid analgesics after ambulatory surgery can optimize the recovery process and allow patients to resume normal activities more promptly after discharge home.[116] Although the value of preemptive analgesia has been questioned, the use of perioperative multimodal analgesia is helpful in facilitating a faster emergence from anesthesia and an earlier discharge.

Opioid (Narcotic) Analgesics

Use of opioid analgesics for premedication is not recommended unless the patient is experiencing acute pain (see Chapter 27). Opioid premedication can increase the incidence of PONV and urinary retention, which can contribute to a delayed discharge after ambulatory surgery.[82] Traditionally, fentanyl and its newer analogs have been given before induction of anesthesia because they can decrease the anesthetic requirement and minimize the hemodynamic response to airway stimulation and the surgical incision.[117] It is unclear whether the newer, shorter-acting fentanyl analogs (alfentanil and remifentanil) offer any significant advantages over the traditional compounds with respect to reducing perioperative side effects.[118-120] However, remifentanil may offer a significant advantage in situations in which rapid resumption of spontaneous ventilation is desirable.[121]

Nonopioid Analgesics

Controversy surrounds the preoperative use of the classic nonsteroidal anti-inflammatory drugs (NSAIDs) because of their side effect profile (e.g., antiplatelet effect) and limited efficacy in controlling acute postoperative pain.[122] Nevertheless, newer NSAIDs have proved to be valuable analgesic adjuvants as a result of their long-lasting opioid-sparing actions and lack of effect on platelet function. When administered as part of a balanced ("multimodal") analgesic technique in combination with local anesthetics and acetaminophen, NSAIDs can facilitate early recovery, decrease side effects, and reduce discharge times.[4,123] For many outpatient procedures, use of NSAIDs and local anesthetics for 2 to 3 additional days after surgery can eliminate the need for opioid analgesics postoperatively.[124] Ketorolac, a parenterally active NSAID, was more effective than acetaminophen with codeine in preventing pain after outpatient procedures in children.[125]

To achieve the optimal benefit of NSAIDs in the ambulatory setting, they should be administered on a "fixed" dosing schedule beginning in the preoperative period and extending into the postdischarge period.[126] To minimize the potential for operative site bleeding, as well as gastric mucosal and renal tubal toxicity, the more selective cyclooxygenase-2 (COX-2) inhibitors can be used as alternatives to the nonselective NSAIDs during the perioperative period. Perioperative celecoxib (400 mg) reduces pain and the opioid analgesic requirement in the postoperative period, thereby leading to improved patient satisfaction with the quality of recovery after ambulatory surgery.[127-129] The addition of dexamethasone to a COX-2 inhibitor leads to a further improvement in postoperative analgesia.[130] Gabapentin has also shown to offer a significant analgesic benefit in the ambulatory setting when administered for premedication.[131]

Prevention of Nausea and Vomiting

PONV remains a common problem after general anesthesia and contributes to patient dissatisfaction with their ambulatory surgery experience (see Chapter 86).[1,132] When patients undergoing a preanesthetic evaluation were asked which postoperative side effects were of greatest concern, PONV accounted for 49% of the responses.[132] Over 70% of patients considered avoidance of PONV to be very important, and patients were willing to pay a significant amount of money out-of-pocket to avoid PONV.[133] Emetic symptoms can delay discharge and result in unplanned overnight hospital admission.[11,25,134,135] The type of surgery, choice of anesthetic technique, and use of opioid analgesics can all influence the incidence of PONV (Table 78-6). Additional factors influence the incidence of PONV and include preexisting medical conditions (e.g., motion sickness), gender, smoking status, preg-

Table 78-6 Common Factors Associated with Nausea, Vomiting, and Retching during the Perioperative Period

Premedication
Opioid analgesics
Induction and maintenance anesthetics
Reversal (antagonist) drugs
Gastric distention
Inadequate hydration
Residual sympathectomy
Surgery-Related Factors
Operative procedure
Length of surgery
Blood in the gastrointestinal tract
Forcing oral intake
Opioid analgesics
Premature ambulation (postural hypotension)
Pain

Data from Watcha MF, White PF: Postoperative nausea and vomiting: Its etiology, treatment, and prevention. Anesthesiology 77:162, 1992.

nancy, phase of the menstrual cycle, preoperative hydration status, and postoperative hypotension (due to residual sympathectomy, premature ambulation).[136] The incidence of emesis is low in infants, gradually increases toward adulthood, and then decreases again at advanced age (e.g., the elderly). The phase of the menstrual cycle may influence the incidence of PONV, with the highest incidence reported during the ovulatory and luteal phases of the woman's cycle.

A variety of risk scoring systems have been developed in an attempt to improve the use of antiemetic therapies.[137] These scores and the treatments are more fully discussed in Chapter 86, although studies specific to the outpatient setting are described here. Although the use of propofol for induction and maintenance of anesthesia significantly reduces the incidence of PONV after ambulatory surgery,[138,139] the cost-effective combination of droperidol, dexamethasone, and ondansetron is increasingly being used for antiemetic prophylaxis of outpatients undergoing a wide variety of surgery procedures.[140]

Butyrophenones

Droperidol is a butyrophenone neuroleptic drug with antiemetic properties as a result of its antagonistic effects at central dopamine receptors. Larger doses of droperidol (>20 μg/kg) enhance postoperative sedation and may prolong recovery and discharge in ambulatory surgical patients without improving on its antiemetic efficacy. In children undergoing strabismus surgery, droperidol, 80 μg/kg, was most effective in reducing emetics without prolonging time to discharge.[141] However, larger doses of droperidol can produce unwanted side effects, including dyskinesia, restlessness, and dysphoric reactions. Since the effect of droperidol in prolonging the QT interval appears to be dose-related, the lowest effective dose should be administered after induction of anesthesia.[141,142]

Phenothiazines

The antiemetic action of phenothiazines also results from their ability to block dopamine receptors in the chemoreceptor trigger zone of the brain.[143] Prochlorperazine suppositories are frequently used for treating PONV occurring after discharge. Premedication with phenothiazines can produce intraoperative hypotension along with significant residual sedation after surgery. In addition, these compounds may produce extrapyramidal effects ranging from restlessness to oculogyric crisis.[141] Therefore, this class of antiemetic is rarely used for prophylaxis in the outpatient setting.

Anticholinergics

Anticholinergic drugs (e.g., atropine, glycopyrrolate, and scopolamine) have traditionally been used for their antisialagogue and vagolytic properties. However, transdermal scopolamine (TDS), a centrally active anticholinergic, with potent anti–motion sickness properties has recently been found to be comparable to both droperidol and ondansetron when used for antiemetic prophylaxis in the ambulatory setting.[144] Preoperative placement of a TDS patch can reduce the incidence of severe PONV in both the early and late postoperative periods. However, when administered before outpatient gynecologic laparoscopy, transdermal scopolamine was associated with a higher incidence of adverse effects (including dry mouth, somnolence, mydriasis, and dizziness).

Antihistamines

Dimenhydrinate and hydroxyzine are antihistaminic compounds that also act on the central vomiting center and vestibular pathways to prevent PONV. These compounds are particularly useful for the prophylaxis and treatment of motion-induced emesis in outpatients undergoing middle ear and strabismus surgery.[145] A long-acting formulation of dimenhydrinate compared favorably with droperidol in reducing vomiting for up to 24 hours without delaying discharge from the ambulatory facility.[146]

Serotonin Antagonists

Given the important role of 5-hydroxytryptamine (5-HT) in the pathophysiology of drug-induced emesis, it is hardly surprising to learn that specific 5-HT antagonists are highly effective in the treatment and prevention of PONV. Ondansetron, granisetron, dolasetron, and palonsetron are all highly selective 5-HT_3 receptor antagonists that lack the sedative, dysphoric, or extrapyramidal effects of other commonly used antiemetics.[147-150] However, these compounds appear to produce headache and may be less effective in preventing nausea than other antiemetic drugs. Palonsetron is a 5-HT3 antagonist with a long half-life and a high receptor binding affinity[151] that may prove to be advantageous in the postdischarge period.

Neurokinin-1 Antagonists

The neurokinin-1 (NK-1) antagonists are effective in both the treatment[152] and prevention[153] of PONV. Preliminary studies suggest that NK-1 antagonists may have longer-lasting antiemetic properties than ondansetron.[152,153] In addition, these compounds may act synergistically with 5-HT_3 antagonists.[153] Premedication with oral aprepitant was comparable to IV ondansetron in preventing PONV in the early postoperative period and offered

an advantage in the postdischarge period.[154,155] Studies examining the cost-benefit of using an NK-1 antagonist as part of a multimodal antiemetic prophylactic regimen are clearly needed.[156]

Nonpharmacologic Techniques

Recent studies suggest that nontraditional therapies may be useful additions to the traditional antiemetic drug therapies.[157,159] Acupuncture, acupressure, and transcutaneous electrical nerve stimulation at the P-6 acupoint have all been used for the prevention of PONV.[136,158-161] Korean hand acupressure has been shown to be superior to ondansetron in reducing PONV in both adults and children.[158,162-164] In outpatients undergoing laparoscopic cholecystectomy procedures,[165] acupressure compared favorably with ondansetron (4 mg IV) in preventing PONV. Transcutaneous electrical acupoint stimulation at the P-6 acupoint with the ReliefBand device compared favorably to ondansetron, and the combination was more effective than either modality alone.[161] Compared with antiemetic drugs, most studies have suggested that the use of electro-acupoint stimulation is more effective in preventing nausea than vomiting (or emesis).[161,166,167]

Prevention of Aspiration Pneumonitis

Outpatients may have an increased risk of aspiration based on the observation that a larger percentage of patients had a residual gastric volume greater than 25 mL with a pH less than 2.5. However, carefully controlled studies have found no increased risk of aspiration in "fasted" outpatients (versus inpatients) undergoing elective surgery. Therefore, routine prophylaxis for acid aspiration is no longer recommended. However, outpatients with predisposing risk factors for pulmonary aspiration (i.e., pregnancy, scleroderma, hiatal hernia, nasogastric tubes, severe diabetics, morbid obesity) may benefit from the use of an H_2-receptor blocking drug or proton pump inhibitor in the preoperative period.

H_2-Receptor Antagonists and Proton Pump Inhibitors

H_2-receptor antagonists are effective in increasing gastric pH and decreasing gastric volume by reducing gastric acid secretion. Ranitidine offers an advantage over cimetidine because of a more prolonged period of protection and fewer side effects. When compared with fasted patients who did not receive ranitidine, patients who received oral fluids in combination with ranitidine 2 to 3 hours before induction of anesthesia had lower residual gastric volumes and higher gastric pH values and were less thirsty.[168,169] The use of effective doses of metoclopramide in combination with an H_2-receptor blocking drug has been advocated to decrease postoperative emesis and reduce the potential risk for aspiration pneumonitis in high-risk surgical populations (e.g., diabetics, the morbidly obese). Other studies have failed to demonstrate a significant advantage of this drug combination over an H_2-receptor antagonist alone. Premedication with the rapid-acting proton pump inhibitor pantoprazole (40 mg IV) was less effective than use of ranitidine (50 mg IV) in reducing gastric volume and increasing pH.[170]

NPO Guidelines

Prolonged fasting does not guarantee an empty stomach at the time of induction. Therefore, several investigators have questioned the value of even a 4- to 5-hour fast before elective surgery.[168,171-173] Due to short half-life of clear fluids in the stomach (10-20 minutes), residual gastric volume after 2 hours is less in patients ingesting small amounts of clear fluids than in fasted patients.[174] After an overnight fast, 50% and 44% of outpatients complained of moderate-to-severe hunger and thirst, respectively. More importantly, 14% of young female outpatients arriving at the operating room in the early afternoon after an overnight fast had a serum glucose concentration less than 45 mg/dL.[175] Drinking 150 mL of water 2 hours before surgery significantly decreased the severity of thirst without increasing gastric volume in fasted outpatients.[176] Furthermore, the ingestion of 150 mL of either coffee or orange juice 2 to 3 hours before induction of anesthesia had no significant effect on residual gastric volume or pH even in obese adults.[176,177] Similarly, preoperative ingestion of apple juice, 3 mL/kg, decreased gastric volume, thirst, and hunger in children and had no adverse effect on gastric contents.[178]

Arbitrary restrictions prohibiting outpatients from drinking fluids on the day of surgery are completely unwarranted. A national survey in the United States demonstrated that 69% of anesthesiologists had changed their NPO guidelines to allow the ingestion of clear fluids for children and 41% had changed their guidelines for adults.[179] Unless outpatients have delayed gastric emptying (e.g., diabetics), the requirement for a prolonged fast is not justified. Importantly, adequate hydration (e.g., allowing oral intake of clear liquids up to 2 to 3 hours before surgery and/or IV hydration before induction of anesthesia) is associated with a decreased incidence of postoperative side effects, including pain, dizziness, drowsiness, thirst, and nausea (Fig. 78-3).[38,180] Several recent studies[181-183] have confirmed the importance of ensuring adequate hydration. Liberal (versus restrictive) fluid administration during laparoscopic surgery also led to improved patient outcomes. Preoperative administration of glucose-containing fluids prevents postoperative insulin resistance and attenuates the catabolic responses to surgery while replacing fluid deficits.[184,185] However, effects of glucose-containing solutions on clinical outcomes including the length of hospital stay, incidence of PONV, muscle strength, and subjective well-being remains controversial.[186,187]

Basic Anesthetic Techniques

Quality, safety, efficiency, and the cost of drugs and equipment are all important considerations in choosing an anesthetic technique for ambulatory surgery. The ideal outpatient anesthetic should have a rapid and smooth onset of action, produce intraoperative amnesia and analgesia, provide optimal surgical conditions and adequate muscle relaxation with a short recovery period, and have no adverse effects in the postdischarge period. Ambulatory surgery requires the same basic equipment as inpatient surgery for delivery of anesthetic drugs, monitoring, and resuscitation. Standard intraoperative monitoring equipment for outpatient operations should include an electrocardiogram, blood pressure cuff, temperature probe, pulse oximeter, and capnograph. If nondepolarizing muscle relaxants are used, a neuromuscular monitor should also be available. The availability of a cerebral monitor can be useful for patients with a history of intraoperative recall and for improving the titration of anesthetic drugs, thereby facilitating a faster emergence from anesthesia.[188]

The choice of anesthetic technique depends on both surgical and patient factors. For many ambulatory procedures, general anesthesia remains the most popular technique with both patients

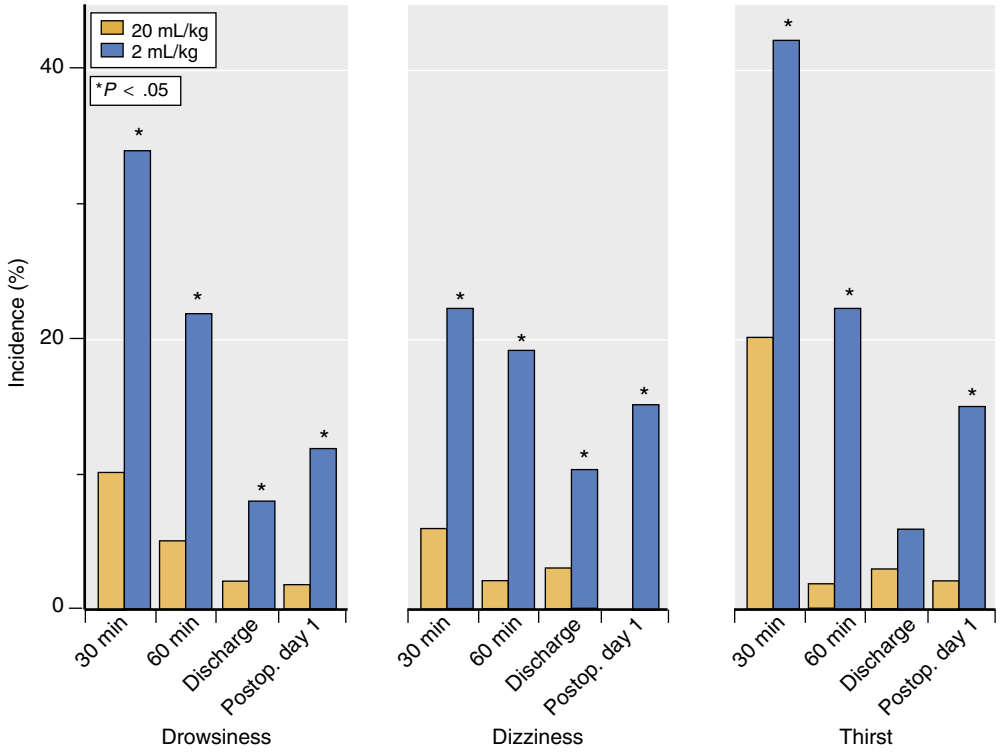

Figure 78-3 Preoperative hydration of 20-mL/kg versus 2-mL/kg decreases in postoperative morbidity in outpatients. (*Redrawn with modification from Yogendran S, Asokumar B, Cheng DC, et al: A prospective randomized double-blinded study of the effect of intravenous fluid therapy on adverse outcomes on outpatient surgery. Anesth Analg 80:682, 1995.*)

and surgeons despite the well-known advantages of local and regional anesthetic techniques. Although spinal and epidural anesthesia (i.e., central neuraxis blockade) has traditionally been used for lower extremity and abdominal-perineal procedures, its use in the ambulatory setting can delay discharge because of residual motor and sympathetic blockade. Local anesthesia and peripheral nerve blocks facilitate the recovery process by reducing postoperative pain and minimizing the need for opioid analgesics. Therefore, an increasing number of ambulatory cases are being performed using local anesthetic infiltration and/or nerve blocks in combination with intravenous sedation-analgesia (so-called monitored anesthesia care [MAC]). Although there is no single ideal anesthetic drug or technique for outpatients, a knowledge of the options available for each type of operation is critically important to produce the desired surgical conditions with an optimal fast-track recovery (Table 78-7).

General Anesthesia

The ability to deliver a safe and cost-effective general anesthetic with minimal side effects and rapid recovery is critical in a busy outpatient surgery unit. Despite a higher incidence of side effects than local or regional anesthesia, general anesthesia remains the most widely used anesthetic technique for ambulatory surgery. Effective use of ancillary equipment (e.g., protective padding, heated airway humidifiers,[189] blankets, forced air warmers,[190] passive heat and moisture exchangers, minimally invasive airway devices) will enhance patient comfort after general anesthesia. For example, devices that heat and humidify insufflation gases may improve maintenance of core body temperature while reducing pain after laparoscopic surgery.[191] Using a forced air warming device with standard cloth hospital blankets was found to be a cost-effective alternative to commercial forced air heating blankets in maintaining body temperature during surgery.[192] However, for ambulatory procedures lasting less than 90 minutes, forced warming devices are unlikely to be cost effective.[190]

Tracheal intubation causes a more frequent incidence of postoperative airway-related complaints, including sore throat, croup, and hoarseness than a facemask or laryngeal mask airway (LMA) (see Chapter 50). Most outpatients undergoing superficial procedures under general anesthesia do not require tracheal intubation unless they are at an increased risk for aspiration. The LMA device was introduced in 1983 as an alternative to tracheal intubation and the face mask for airway management. When compared with a facemask and oral airway, patients with an LMA had fewer desaturation episodes, fewer intraoperative airway manipulations, and fewer difficulties in maintaining a patent airway.[193] The incidence of postoperative sore throat after ambulatory surgery was 18% with an LMA compared with 45% with a tracheal tube and 3% with a facemask.[194] The LMA also frees the anesthesiologist's hands for record keeping, monitoring, and drug administration and avoids hand fatigue.

The LMA can be easily positioned without direct visualization or neuromuscular blocking drugs, and patients can ventilate spontaneously throughout the procedure if muscle relaxants are not needed.[195] Although desflurane is more pungent than sevoflurane or isoflurane, the LMA is equally well tolerated during the maintenance period with all volatile anesthetics.[196] However, coughing is more frequent with desflurane during the emergence

Table 78-7 Criteria Used to Determine Fast-Track Eligibility after Ambulatory Anesthesia

Criteria	Score
Level of Consciousness	
Awake and oriented	2
Arousable with minimal stimulation	1
Responsive only to tactile stimulation	0
Physical Activity	
Able to move all extremities on command	2
Some weakness in movement of the extremities	1
Unable to voluntarily move the extremities	0
Hemodynamic Stability	
Blood pressure < 15% of the baseline MAP value	2
Blood pressure between 15% and 30% of the baseline MAP value	1
Blood pressure > 30% below the baseline MAP value	0
Respiratory Stability	
Able to breathe deeply	2
Tachypnea with good cough	1
Dyspneic with weak cough	0
Oxygen Saturation Status	
Maintains value > 90% on room air	2
Requires supplemental oxygen (nasal prongs)	1
Saturation < 90% with supplemental oxygen	0
Postoperative Pain Assessment	
None or mild discomfort	2
Moderate to severe pain controlled with IV analgesics	1
Persistent severe pain	0
Postoperative Emetic Symptoms	
None or mild nausea with no active vomiting	2
Transient vomiting or retching	1
Persistent moderate to severe nausea and vomiting	0
Total score	14

A score over 12 with no individual score less than 1 is required for fast-tracking.
MAP, mean arterial pressure.

period.[197] Use of an LMA in children with a recent upper airway infection was also associated with increased coughing, laryngospasm, and oxygen desaturation.[198] When compared with tracheal intubation, insertion of the LMA causes minimal cardiovascular responses and is better tolerated at lighter levels of anesthesia. The incidence of sore throat is also reduced when an LMA is used as an alternative to a tracheal tube.[199] In the ambulatory setting, LMA devices can be re-used up to 200 times,[200] thus making the LMA a cost-effective alternative to other airway devices. The LMA does not completely protect the patient from having foreign material introduced into the airway and should not be used in patients at high risk of aspiration. If positive airway pressure is required for maintaining the airway or assisting ventilation, the risk of gastric dilatation and subsequent aspiration may be increased.[201] A variety of supraglottic devices are available as alternatives to the LMA (e.g., cuffed oropharyngeal airway [COPA]). Even though these devices are easy to insert after induction without muscle relaxants, their ability to maintain an obstruction-free airway is less adequate than other currently used airway devices.[202] Although supraglottic airway devices have been used in paralyzed patients undergoing laparoscopic surgery,[203,204] most practitioners in North America still prefer tracheal intubation in these situations to minimize the risk of gastric distention and aspiration for patients in the Trendelenburg position.

Anesthetic Drugs

Induction of general anesthesia is typically accomplished with a rapid-acting intravenous anesthetic (see Chapter 26). Propofol has replaced the barbiturates for induction of anesthesia in the ambulatory setting because of its favorable recovery profile.[205] However, the most popular technique for maintenance of anesthesia is a combination of a volatile anesthetic with or without nitrous oxide. The extremely low solubility of nitrous oxide and the newer volatile anesthetics (i.e., sevoflurane and desflurane) contributes to a more rapid recovery from general anesthesia. Although nitrous oxide can produce emetic symptoms, its clinical importance is questionable because nitrous oxide's anesthetic and analgesic-sparing effects offset its emetogenic potential.[206-209] Total intravenous anesthesia (TIVA) utilizing a combination of propofol and remifentanil (or alfentanil) has become extremely popular outside North America owing in large part to the availability of target-controlled, computer-based drug delivery symptoms.[210] Studies suggest that TIVA is as effective as spinal anesthesia for ambulatory surgery with the advantage of earlier home readiness.[211] When compared with a target-controlled infusion of propofol for maintenance of anesthesia, the use of desflurane or sevoflurane produced similar anesthetic conditions with shorter emergence times and lower drug costs.[212-215]

Barbiturates

Thiopental (3 to 6 mg/kg) was the prototypical intravenous induction drug because of its rapid onset and relatively short duration of hypnotic action (see Chapter 26). However, thiopental can impair fine motor skills for several hours after surgery and can produce a "hangover" effect.[216] Methohexital is associated with shorter emergence times, but complete recovery of fine motor skills may still require 2 to 4 hours after an induction dose.[217] When compared with thiopental, methohexital is associated with a higher incidence of pain on injection, involuntary muscle movement, and hiccoughing. Although propofol is associated with a faster emergence from anesthesia and a lower incidence of PONV than methohexital when used for both induction and maintenance of general anesthesia,[205] the barbiturate compared favorably with propofol when used for induction only in procedures lasting longer than 30 minutes.[218]

Benzodiazepines

Although midazolam (0.2 to 0.4 mg/kg IV) has been used for induction of anesthesia in outpatients, its onset of action is slower and recovery is prolonged in comparison to the barbiturate compounds and propofol.[219] When combined with nitrous oxide and a potent opioid analgesic, lower doses of midazolam (0.1-0.15 mg/kg IV) can be used to induce general anesthesia. If midazolam is used for induction and flumazenil, a specific benzodiazepine antagonist, is administered at the end of surgery, prompt recovery can be achieved after outpatient surgery.[220] Yet when compared with propofol, recovery after flumazenil antagonism of midazolam anesthesia offered no clinically significant advantages. Recurrence of sedation is a concern when flumazenil is used to facilitate emergence from anesthesia.

Etomidate

Etomidate (0.2 to 0.3 mg/kg) has also been used for induction and maintenance (1 to 3 mg/min) of general anesthesia during short outpatient procedures.[221] Recovery tends to be faster than after thiopental and compares favorably with methohexital. Disadvantages of etomidate include pain on injection, a high incidence of PONV, myoclonic movements, and transient suppression of adrenal steroidogenesis.[221,222] Given its side effect profile, the use of etomidate is restricted to clinical situations in which its hemodynamic stability offers a distinctive advantage over the other available induction drugs (e.g., elderly outpatients with clinically significant coronary artery or cerebrovascular disease).

Ketamine

Ketamine is a unique sedative-analgesic that can be used for both induction and maintenance of general anesthesia.[223] However, ketamine compares unfavorably with both the barbiturates and propofol for minor surgical procedures because of its prominent psychomimetic effects and higher incidence of PONV during the early postoperative period.[224] Use of the more potent S(+)-isomer of ketamine may decrease some of the adverse effects associated with the racemic mixture in the ambulatory setting.[87,225] Premedication with a benzodiazepine (e.g., midazolam, 0.05 mg/kg IV) and/or concomitant administration of propofol decreases the incidence of ketamine-induced emergence reactions.[223] Smaller doses of ketamine (10 to 20 mg IV) have been used as an alternative to potent opioid analgesics during induction of anesthesia with propofol,[226,227] as well as for sedation-analgesia in combination with propofol.[228] Furthermore, adjunctive use of 75-150 µg/kg intravenously during ambulatory surgery produced an opioid-sparing effect after painful orthopedic procedures.[229,230]

Propofol

Propofol is an intravenous anesthetic with an extremely high metabolic clearance rate (see Chapter 26).[231] Recovery after propofol anesthesia is superior to that from all other intravenous anesthetics in the outpatient setting.[232] Although propofol is more costly than the barbiturate anesthetics, the use of propofol may contribute to significant savings because of decreased recovery costs.[81] Recovery after induction of anesthesia with propofol is faster than with the barbiturate compounds, irrespective of the maintenance anesthetic (Fig. 78-4).[135,217,233] When compared with methohexital, use of propofol was associated with fewer perioperative side effects (e.g., hiccoughs, nausea, and vomiting) and faster overall recovery times.[205] The faster intermediate recovery with propofol may also yield savings with respect to nursing costs (e.g., less overtime).

The use of propofol is associated with less PONV and a decreased requirement for antiemetic medications.[205,234-237] When propofol was administered in subhypnotic doses (10-20 mg IV) to treat PONV, 81% of patients showed improvement compared with only 35% in the control group.[238] Unfortunately, 28% of patients experienced a relapse of their symptoms within 30 minutes. Small doses of propofol administered after a volatile anesthetic can reduce emesis in the early postoperative period.[239] Subhypnotic concentrations of propofol can produce other central effects, including perioperative mood alterations.[240] Patients emerging from propofol anesthesia were more likely to exhibit sensation-seeking tendencies (e.g., adventurous, daring, energetic) and to report feeling elated or even euphoric. IV administration of propofol is associated with a high incidence of venous pain and discomfort. Administration of lidocaine (40 mg IV) immediately before propofol injection (or mixed with propofol) reduces the incidence and severity of pain when it is injected into small hand veins.[241] Use of a bisulfite-containing formulation of propofol may also be associated with less pain on injection.[242] On the other hand, the low lipid formulation of propofol (Ampofol) is associated with more pain on injection.[243]

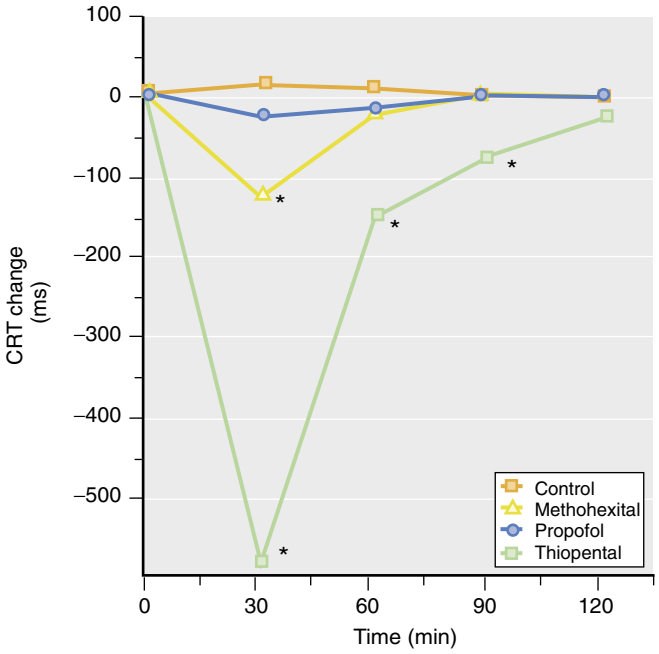

Figure 78-4 Comparison of mean changes in choice reaction time (CRT) postoperatively in untreated controls and outpatients who received thiopental, methohexital, or propofol for induction of anesthesia. * = $P < .5$. Br J Anaesth 57:725, 1985.*)

Inhaled Anesthetics

Volatile anesthetics are most commonly used for maintenance of ambulatory anesthesia (see Chapters 20, 21, 24, 25). Changes in the depth of anesthesia can be achieved readily because of the rapid uptake and elimination of these anesthetics. The rapid elimination of anesthetic vapors also provides for fast recovery and potentially earlier discharge from the outpatient facility. Although a similar spectrum of pharmacologic activity is produced by all of the available volatile anesthetics, halothane and isoflurane have largely been replaced by the less soluble sevoflurane and desflurane because of their superior recovery profiles. Studies involving pediatric patients have reported that sevoflurane (versus halothane) is associated with a higher incidence of postoperative complications (e.g., emergence delirium).[244,245] A single dose of propofol (1 mg/kg) at the end of surgery is effective in preventing agitation during emergence from sevoflurane without delaying discharge in children.[244]

Sevoflurane is widely used for inhaled induction in the outpatient setting because of its lack of pungency and more favorable recovery profile compared with halothane (Table 78-8).[1,246] However, when desflurane is used for maintenance of anesthesia, emergence (awakening) was significantly faster than with sevoflurane or other available agents (Table 78-9).[247-251] However,

intermediate and late recovery after sevoflurane and propofol is similar to that after desflurane (Fig. 78-5).[252] Compared with the volatile anesthetics, propofol anesthesia offered the advantage of a lower incidence of PONV (Fig. 78-6).[252,253]

Early comparative studies of propofol, sevoflurane, and desflurane were performed before the introduction of fast-track recovery paradigms involving the routine use of multimodal analgesic and antiemetic therapies for minimizing pain and emesis, respectively. As a result of its extremely low tissue solubility, desflurane is associated with the most rapid recovery of both cognitive and psychomotor function.[253-257] In morbidly obese outpatients, both emergence and intermediate recovery times were consistently more rapid after desflurane than after propofol.[258] In addition, desflurane was associated with better postural control than propofol in the early recovery period.[259] Desflurane can produce significant autonomic stimulation when administered at high inspired concentrations,[255,256,260] and its pungency precludes its use for routine induction of anesthesia.[261] However, sevoflurane's impressive lack of airway irritation makes it a very useful alternative to propofol for induction of anesthesia in both adults and children.[262-265] In the elderly, induction with sevoflurane was also associated with better hemodynamic stability compared with induction with propofol.[266]

Volatile anesthetics are associated with a more frequent incidence of vomiting in the early recovery period than propofol-based anesthetic techniques.[15,267] However, no difference in emesis was observed in the later recovery period because delayed (post-discharge) PONV is most commonly associated with oral opioid-containing analgesics. From a cost-minimization point of view, maintenance with a volatile anesthetic compares favorably with a propofol-opioid (i.e., TIVA) technique.[211] The use of nitrous oxide as an adjuvant during outpatient anesthesia significantly reduces the requirements for intravenous and volatile anesthetics and opioid analgesics during the maintenance period. Therefore,

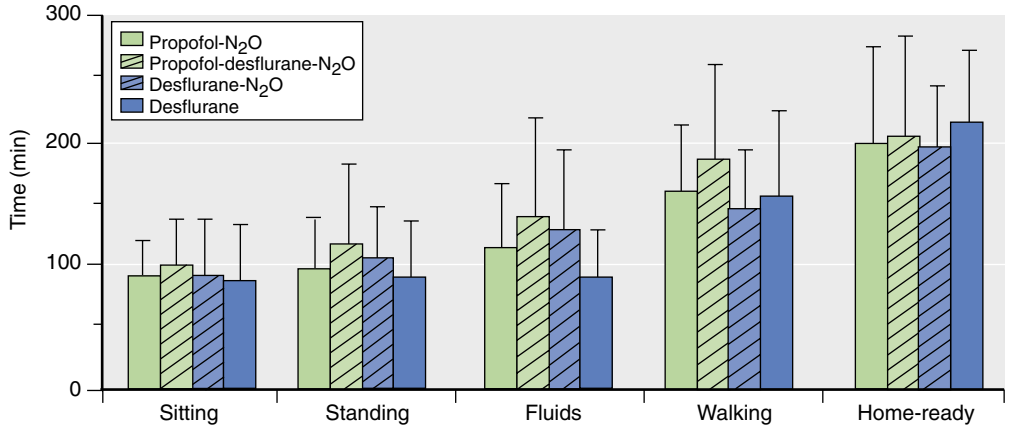

Figure 78-5 Intermediate recovery after propofol, desflurane, and propofol-desflurane anesthesia. (*Redrawn from Van Hemelrijck, J, Smith I, White PF: Use of desflurane for outpatient anesthesia: A comparison with propofol and nitrous oxide. Anesthesiology 75: 197, 1991.*)

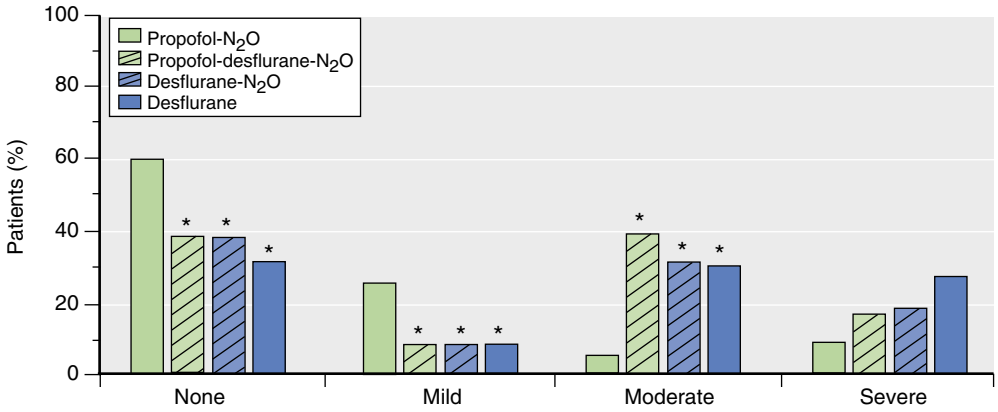

Figure 78-6 Postoperative nausea after propofol, desflurane, and propofol-desflurane anesthesia. (*Redrawn from Van Hemelrijck, J, Smith I, White PF: Use of desflurane for outpatient anesthesia: A comparison with propofol and nitrous oxide. Anesthesiology 75: 197, 1991.*)

recovery is faster and the cost of anesthesia is reduced when nitrous oxide is used as an adjuvant.[267,268]

Opioid Analgesics

Opioid compounds are frequently administered during anesthesia to suppress autonomic responses to tracheal intubation and painful (noxious) surgical stimuli (see Chapter 27). Opioids can also reduce the dosage requirements for sedative-hypnotic and volatile anesthetic drugs, thereby decreasing recovery times. Potent opioid analgesics have been shown to decrease the incidence of pain on injection and involuntary motor activity associated with intravenous methohexital, etomidate, and propofol. Fentanyl also reduces tachycardia observed during inhalational induction with desflurane and decreases emergence agitation after sevoflurane.[269]

Small doses of potent opioid analgesics (e.g., fentanyl, 1-2 µg/kg, alfentanil, 15-30 µg/kg, sufentanil, 0.15-0.3 µg/kg, or remifentanil, 0.5-1 µg/kg) can effectively attenuate the transient cardiostimulatory response to laryngoscopy and intubation, as well as skin incision. These drugs are also useful supplements to inhaled anesthetics during the maintenance period. Compared with inhaled anesthesia (i.e., volatile agents with nitrous oxide), adjunctive use of fentanyl or one of its newer analogs improves intraoperative conditions and provides for a more rapid emergence from anesthesia.[270,271] When a sufentanil infusion was compared with fentanyl for maintenance of outpatient anesthesia in combination with nitrous oxide, use of the more potent analog was associated with less nausea and postoperative pain. Because alfentanil has a more rapid onset and shorter duration of action than fentanyl does, emergence and recovery of psychomotor function are faster after an anesthetic technique based on alfentanil (versus fentanyl).[271] Alfentanil has also been alleged to cause less emesis than equipotent doses of fentanyl or sufentanil.[272]

Remifentanil is an ultrashort-acting opioid analgesic with potency similar to that of fentanyl but with a much shorter duration of action because it is rapidly metabolized by nonspecific tissue esterases. This metabolic process allows for rapid systemic elimination, with a half-life of 8 to 10 minutes and a context-sensitive half-life (the time for a 50% decrease in its effect site concentration after discontinuing an infusion) of 4 minutes regardless of the duration of infusion (Fig. 78-7).[273] In contrast, the context-sensitive half-life of alfentanil is 58 minutes because it depends on its small volume of distribution rather than metabolism for the rapid termination of its clinical effect.[273] When remifentanil was compared with alfentanil as part of a TIVA technique, remifentanil provided more effective suppression of acute autonomic responses and a faster emergence from anesthesia. However,[274] it can prolong postoperative recovery due to increased postoperative pain.[274] Studies involving the use of remifentanil in combination with the less-soluble volatile anesthetics suggest that a low-dose infusion (0.05-0.2 µg/kg/min) can produce a significant anesthetic-sparing effect and thereby contribute to a faster emergence from anesthesia.[275,276] Furthermore, bolus doses of remifentanil (0.5-1 µg/kg) were more effective than a standard dose of fentanyl in suppressing the acute

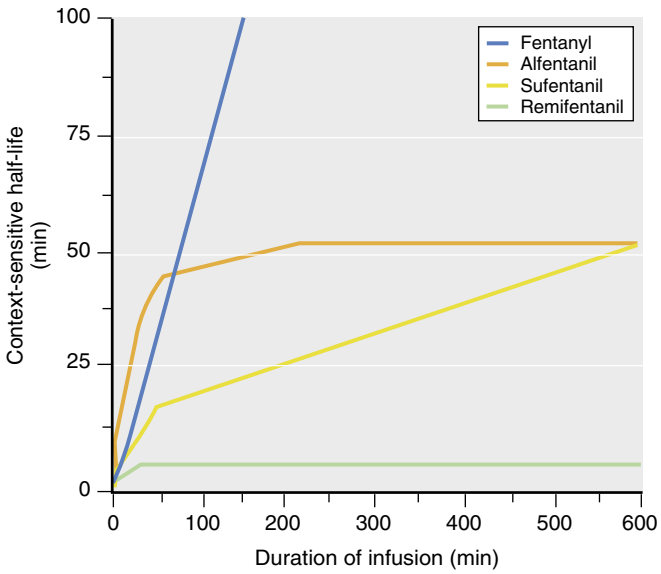

Figure 78-7 Computer simulation of the "context-sensitive" half-life (CSHT) for remifentanil (3.65 minutes), alfentanil (58.5 minutes), sufentanil (240 minutes), and fentanyl (262.5 minutes). Note that remifentanil's CSHT is independent of the duration of infusion. (*Redrawn with modification from Egan TD, Lemmens JH, Fiset P, et al: The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. Anesthesiology 79:881, 1993.*)

hemodynamic response to laryngoscopy and tracheal intubation in outpatients undergoing laparoscopy procedures.[117] Smaller doses of remifentanil (0.25 μg/kg) have been used to facilitate placement of an LMA device.[277] However, remifentanil is less cost-effective than either fentanyl or alfentanil when administered as an adjuvant to general anesthesia unless drug wastage is minimized.[278,279]

Morphine, hydromorphone, oxymorphone, and meperidine have all been used in outpatient anesthesia. However, these classic opioid compounds are less popular than the more potent, rapid, and short-acting opioid analgesics because motion-induced emesis is a concern when morphine and its older congeners are used in the ambulatory setting. When intraoperative morphine and fentanyl were compared in ambulatory surgical patients, higher postoperative pain scores and greater oral analgesic use in the postdischarge period was reported in the fentanyl group.[280] However, morphine was associated with increased nausea and vomiting.

The opioid agonist-antagonist compounds (e.g., butorphanol, nalbuphine, dezocine, tramadol) have a theoretical advantage over the potent opioid compounds as adjuvants during general anesthesia because of their limited potential to produce severe ventilatory depression. Unfortunately, there is also a "ceiling effect" with respect to their analgesic efficacy. Although intraoperative use of dezocine provided significantly longer postoperative analgesia than fentanyl, it increased postoperative nausea and delayed discharge after outpatient anesthesia.[281] When nalbuphine (0.3-0.5 mg/kg) was compared with fentanyl (1.5 μg/kg) during outpatient surgery, it was found to produce more unpleasant dreaming during surgery and greater postoperative anxiety, drowsiness, and emetic symptoms.[120]

Muscle Relaxants

Many superficial outpatient surgical procedures do not require the use of neuromuscular relaxants. However, muscle relaxants are commonly used during laparoscopic surgery, ophthalmologic ("open globe") and ear/nose/throat procedures and operations performed in the prone position (see Chapter 29). When remifentanil is used in combination with propofol for induction of anesthesia, tracheal intubation can often be performed without any muscle relaxants.[282] Nevertheless, muscle relaxants are still commonly used to facilitate tracheal intubation and to optimize surgical conditions while minimizing the use of anesthetic and analgesic drugs.

Succinylcholine remains a commonly used muscle relaxant to facilitate tracheal intubation in the ambulatory setting because it has a rapid onset and its short duration of action obviates the need for reversal drugs. Prior to the introduction of short and intermediate-acting nondepolarizing muscle relaxants,[283] an infusion of succinylcholine was the most frequently used muscle relaxant technique during outpatient laparoscopic surgery. Although the administration of succinylcholine has been reported to cause myalgia after surgery, use of mivacurium or vecuronium as alternatives to succinylcholine failed to lower the incidence or severity of muscle pain after outpatient laparoscopy.[283,284] Pretreatment with small doses of rocuronium before succinylcholine also failed to reduce the incidence or severity of postoperative myalgia and is not recommended because it may cause uncomfortable muscle weakness before loss of consciousness.[285]

Use of the short-acting nondepolarizing muscle relaxants (e.g., mivacurium) allows spontaneous reversal of neuromuscular blockade even after relatively brief surgical procedures.[286] An intubating dose of mivacurium (0.15-0.20 mg/kg) has approximately twice the duration of action of succinylcholine (20-30 min) but a significantly more rapid spontaneous recovery profile than atracurium, vecuronium, or rocuronium.[287,288] A cost-effective technique involves the use of succinylcholine for tracheal intubation followed by small bolus doses of mivacurium during the maintenance period. This relaxant technique minimizes the need for muscle relaxant reversal drugs after short laparoscopic procedures.[283] The availability of sugammadex, a novel cyclodextrin compound, should allow for rapid reversal even from a "deep" block when a steroid-based muscle relaxant is used.[289] Compared with the standard reversal combinations of edrophonium-atropine and neostigmine-glycopyrrolate, use of sugammadex produced a more rapid and complete reversal of rocuronium-induced blockade.[290]

Antagonist (Reversal) Drugs

Pharmacologic antagonists (i.e., drugs that compete with agonists at specific receptor sites) may be useful in facilitating the recovery process after ambulatory anesthesia. However, antagonists frequently produce unwanted side effects (e.g., dizziness, headaches, nausea, vomiting). If the duration of action of the antagonist is shorter than the agonist (e.g., naloxone, flumazenil), a "rebound" agonist effect may occur later in the recovery period. This latter effect is a concern in the ambulatory setting because patients are frequently discharged home within 2 hours after surgery.

Opioid-induced rigidity and respiratory depression can be treated with small incremental boluses of naloxone. However, naloxone has its own intrinsic side effects (e.g., nausea and vomiting, hypertension, pulmonary edema, and arrhythmias); therefore, it is preferable to carefully titrate the opioid to achieve the desired effect during surgery without the need for the reversal drug. For treating opioid-induced muscle rigidity, small doses of succinylcholine (5 to 10 mg IV) are highly effective without adversely affecting the opioid's analgesic action.

The central effects of benzodiazepines (e.g., residual sedation and amnesia) can be promptly reversed with flumazenil (0.2-0.5 mg IV). Although flumazenil is a specific benzodiazepine antagonist, its use also leads to an increase in side effects. As with opioids, it is far more cost-effective to carefully titrate a benzodiazepine to the desired clinical effect rather than to rely on flumazenil to reverse the residual central depressant effects. Re-sedation can occur 1 to 2 hours after reversal because the elimination half-life of flumazenil (90 minutes) is shorter than that of any of the benzodiazepine agonists.

Intermediate-acting neuromuscular drugs are usually reversed at the end of an ambulatory surgery procedures using neostigmine and edrophonium in combination with an anticholinergic drug. Several studies have reported that the dosage of the reversal drug influences the frequency of PONV in the ambulatory setting.[283] When compared with patients receiving no reversal drugs, patients receiving neostigmine-glycopyrrolate had an increased frequency of PONV in the early postoperative period.[291] Mivacurium may be advantageous for use during the maintenance period because reversal is seldom required if the drug is properly titrated.[283] The novel cyclodextrin compound sugammadex[289] is capable of facilitating reversal of steroid-based, nondepolarizing neuromuscular blockers without uncomfortable anticholinergic side effects.[290] Use of this reversal agent may also

lead to earlier tracheal extubation after laparoscopic surgery procedures.

Pediatric Considerations

In unruly, frightened, or mentally retarded children, preoperative sedation is required before taking the patient into the operating room (see Chapter 82). Because of the aversion of children to needles, oral or rectal premedicants are more popular. Midazolam remains the most commonly used anxiolytic premedication for pediatric outpatients. After receiving oral midazolam, children can be separated from their parents within 30 minutes and dosages of 0.25 to 0.75 mg/kg do not prolong the discharge time even after short ambulatory procedures.[81] Use of rectal methohexital (20 to 30 mg/kg) for premedication before a volatile anesthetic can prolong recovery. Rectal etomidate (6 mg/kg) and ketamine (5 to 10 mg/kg) both produce a rapid onset of hypnosis without cardiorespiratory depression in children undergoing outpatient procedures. Although ketamine (2-4 mg/kg IM) can be an extremely useful drug for induction of anesthesia in an uncooperative or mentally retarded child, home readiness is delayed when larger doses of ketamine (>5 mg/kg) are administered before a volatile anesthetic.[292]

The practice of allowing parents to be present during induction of anesthesia is becoming more common. An informal survey indicated that 50% of pediatric anesthesiologists allow parents to be present during induction of anesthesia.[293] If the parents are calm and supportive, the number of upset children during the preinduction and induction periods is significantly decreased. Parents must be told exactly what to expect and must agree to leave immediately if asked to do so by the anesthesiologist. Unduly anxious or hysterical parents should not be encouraged to be present for induction because they will increase the child's anxiety.[294]

Regional Anesthesia

Regional anesthesia can offer many advantages for the ambulatory patient population (see Chapters 51 to 53). In addition to limiting the anesthetized area to the surgical site, common postoperative side effects of general anesthesia (e.g., nausea, vomiting, dizziness, lethargy) can be minimized.[295] Regional anesthesia offers advantages over general anesthesia with respect to speed of early recovery,[296] but recent data suggest that there are no significant differences in long-term outcomes after ambulatory surgery.[297] However, regional anesthesia can decrease the need for nursing care if it can provide more effective analgesia in the early postoperative period.[298] Simple regional anesthesia techniques (e.g., IVRA, peripheral nerve blocks) may be more cost effective in the outpatient setting because of the lower incidence of side effects and improved recovery profile compared with general and spinal/epidural anesthesia. Proper patient selection along with the skill and enthusiasm of the surgical and anesthesia teams will allow an even wider variety of procedures to be performed using regional anesthetic techniques in the future. While obesity is associated with higher block failure and complication rates,[299] use of newer ultrasound techniques may improve the success rates in this patient population.[300,301] Another important factor to successful implementation of a regional anesthesia program for ambulatory surgery is the availability of an induction room to perform the block before the patient enters the operating room.[302]

Spinal and Epidural Anesthetic Techniques

Spinal anesthesia is probably the simplest and most reliable regional anesthetic technique (see Chapter 51). Unfortunately, the incidence of side effects is surprisingly high and early recovery times are longer when subarachnoid block techniques are used in the ambulatory setting. The most troublesome complications of outpatient spinal anesthesia are related to residual effects of the block on motor, sensory, and sympathetic nervous system function. These residual effects can contribute to delayed ambulation, dizziness, urinary retention, and impaired balance.[303] Although the incidence of post–dural puncture headache can be minimized with the use of small-bore, 25-gauge pencil-point needles, the incidence of failed blocks appears to be higher.[304] When compared with general anesthesia, the use of spinal anesthesia with small doses of short-acting local anesthetics is also associated with a much higher incidence of backache (35% versus 14%).[303,305]
