When central neuraxis block techniques are utilized for ambulatory surgery, it is important to select the most appropriate local anesthetic-adjuvant combination to avoid prolonged local anesthetic effects that negatively impact on the patient's "readiness for discharge."[306] Prolonging subarachnoid-induced analgesia with fentanyl rather than epinephrine avoids the prolonged time to micturition[307] and reduces the time to discharge from the hospital.[308] However, the adjunctive use of the opioid increases the incidence of pruritus and PONV. As compared with conventional intrathecal doses of local anesthetics, use of so-called mini-dose lidocaine (10-30 mg), bupivacaine (3.5-7 mg), or ropivacaine (5-10 mg) techniques combined with a potent opioid analgesic (e.g., fentanyl, 10-25 μg, or sufentanil, 5-10 μg) results in faster recovery of sensory and motor function.[309-311] The mini-dose spinal technique involving lidocaine and fentanyl achieved comparable recovery times to monitored anesthesia care (MAC) after knee arthroscopy.[312] For outpatient laparoscopic gynecologic surgery, this combination technique has also been reported to offer significant advantages over both conventional spinal and general anesthetic techniques with respect to hemodynamic stability and speed of recovery.[310,313,314] However, surgical conditions may be inadequate for lower abdominal procedures, and postoperative side effects (e.g., pruritus, nausea) are increased due to the intrathecal opioid.

Short-acting local anesthetics (e.g., lidocaine and procaine) are clearly preferable to bupivacaine, ropivacaine, and tetracaine in achieving a rapid recovery. However, the use of lidocaine is controversial because of numerous reports of transient neuropathic symptoms (i.e., radicular nerve root pain).[315,316] As a result, investigators are recommending the use of either isobaric lidocaine alone or combinations of small-dose hypobaric lidocaine with fentanyl or sufentanil. Intrathecal fentanyl-induced pruritus is more severe with procaine than with lidocaine or bupivacaine.[317] However, use of droperidol (0.625 mg IV) or nalbuphine (4 mg IV) can decrease these side effects.[312] Intrathecal bupivacaine and ropivacaine should be reserved for ambulatory procedures with an anticipated duration of more than 2 hours because of their more prolonged recovery times.[318] With longer procedures, Korhonen and colleagues[319] reported comparable recovery times after spinal anesthesia with hyperbaric bupivacaine (5 mg) and general endotracheal anesthesia. Compared with bupivacaine, the duration of sensory blockade with ropivacaine was two thirds and the duration of motor block was half.[320] Hyperbaric ropivacaine also produces a faster onset of analgesia compared with isobaric

ropivacaine.[321] Outpatients should be allowed to fully recover motor function before discharge home. After complete recovery of motor function, residual sympathetic blockade and orthostatic hypotension are less likely to be a problem with ambulation. However, functional balance is frequently impaired for 150 to 180 minutes after spinal anesthesia.[322]

Epidural anesthesia is technically more difficult to perform, has a slower onset of analgesia and a greater potential for intravascular or intrathecal injection, and is associated with a higher increase of incomplete sensory blocks compared with spinal anesthesia. The use of 3% 2-chloroprocaine epidural anesthesia achieved discharge times comparable to those of small-dose lidocaine spinal anesthesia for outpatient knee arthroscopy while avoiding post–dural puncture headache and transient neurologic symptoms.[323] Another advantage of epidural anesthesia is the ability to extend the duration of anesthesia by placing a catheter. Use of the short-acting local anesthetic 2-chloroprocaine for outpatient epidural anesthesia was associated with a high incidence of back pain from muscle spasm as a result of the preservative ethylenediaminetetraacetic acid (EDTA).[1] However, the newer formulations are preservative free and are associated with discharge times comparable to those for general anesthesia.[324] Epidural 3% 2-chloroprocaine enables readiness for discharge home 1 hour earlier than epidural 1.5% lidocaine after knee arthroscopy.[325] The preservative-free formulation of 2-chloroprocaine (50 mg) also offers advantages over lidocaine when administered in the subarachnoid space for short (<60 minutes) outpatient procedures.[326] The use of combined spinal-epidural anesthesia allows for the reliability of spinal anesthesia with the flexibility of continuous epidural anesthesia.[327,328] The small initial dose of intrathecal drug results in a more rapid onset, reduced side effects, and faster recovery from the sensorimotor blockade. If necessary, the epidural catheter could be used to extend the block beyond the duration of the spinal anesthetic.

Given that similar postoperative analgesia can be achieve using a perineural catheter technique (e.g., continuous femoral or popliteal nerve blocks) as with epidural local analgesia without the attendant risk of epidural-related complications (e.g., inadvertent dural puncture, hematoma formation, hemodynamic instability), continuous peripheral neural blockade would appear to be preferable to epidural techniques for lower extremity surgery in the ambulatory setting. Use of epidural anesthesia and analgesia for major laparoscopic surgery only facilitated recovery of bowel function when a traditional (nonaccelerated) perioperative care program was used.[329] Recent advances in fast-track surgery techniques and the availability of peripheral mu-opioid antagonists[330] will likely lessen the role of epidural analgesia in the postoperative period.

Intravenous Regional Anesthesia

The intravenous regional anesthetic (IVRA) technique with 0.5% lidocaine is a simple and reliable technique for short superficial surgical procedures (<60 minutes) limited to a single extremity (see Chapter 52). Intravenous regional anesthesia has been reported to be a more cost-effective technique for outpatient hand surgery than general anesthesia.[331-333] Ropivacaine is alleged to provide longer-lasting analgesia after deflation of the tourniquet cuff than lidocaine.[334] The addition of a wide variety of adjuvants (e.g., ketorolac, 15 mg; clonidine, 1 μg/kg; dexmedetomidine, 0.5 μg/kg; gabapentin, 1.2 mg; dexamethasone, 8 mg) has been reported to improve the quality of intraoperative and postoperative analgesia after IVRA.[333-339]

Peripheral Nerve Blocks

If more profound and prolonged anesthesia of the upper or lower extremity is required, a major regional block of the brachial plexus (e.g., axillary, subclavicular, or interscalene block) or femoral-sciatic-popliteal nerves can be extremely valuable in the ambulatory setting (see Chapter 52).[339,340] As supplements to general anesthesia, peripheral nerve blocks (versus local infiltration) improve postdischarge analgesia and reduce opioid-related side effects, thereby facilitating the fast-track recovery process.[7,341]

The "three-in-one block" (i.e., femoral, obturator, and lateral femoral cutaneous nerves) performed with the use of a perivascular technique is useful for outpatient knee arthroscopy and anterior cruciate ligament repairs because it provides excellent postoperative analgesia. Use of a simple femoral nerve block with 0.25% or 0.5% bupivacaine improves postoperative analgesia after arthroscopic anterior cruciate repairs.[340] Ultrasound guidance can provide reliable blockade of the infrapatellar nerve for arthroscopic knee surgery, although concomitant blockade of the saphenous nerve may occur.[342]

Ankle blocks are also effective techniques for surgery on the foot. However, these blocks require multiple injections that increase patient discomfort. In contrast, popliteal fossae nerve blocks are simple to perform and provide excellent postoperative analgesia after foot and ankle surgery.[343] More importantly, these peripheral blocks can be extended by using continuous local anesthetic infusions.[344,345] Continuous perineural techniques can be administered at home after discharge.[344-348] The beneficial effects of these techniques have been demonstrated in a recent multicenter trial that utilized patient-controlled perineural local analgesia as an alternative to IV patient-controlled analgesia (PCA).[349] A recent meta-analysis confirmed the advantages of a peripheral catheter technique over parenteral opioid-based analgesic techniques for painful extremity procedures.[350] As the primary analgesic technique, peripheral nerve blocks are associated with shorter discharge times, improved analgesia and reduced need for opioid analgesics, enhanced patient satisfaction and mobility (i.e. activity), and fewer side effects when utilized for hand,[341,351] shoulder,[352-354] anorectal,[355] hernia repair,[356,357] and knee surgery.[358] For example, when compared with general anesthesia, use of a pudendal nerve block in hemorrhoidectomy was associated with reduced postoperative pain, shortened hospital stay, and earlier return to normal activities of daily living.[359] Not surprisingly, continuous peripheral nerve blocks are becoming increasingly popular for painful orthopedic procedures.[344-347,360,361] The use of disposable nonelectronic (elastomeric) pumps may offer advances over mechanical pumps in the ambulatory setting.[362] Patient-controlled regional anesthesia has also been used effectively for pain control outside the hospital after hand[363] and breast augmentation surgery.[364]

Other popular peripheral nerve blocks include combined deep and superficial cervical plexus blocks, which reduce pain and opioid requirements after thyroid surgery.[365] When compared with intravenous regional and general anesthesia for carpal tunnel surgery, distal nerve blocks at the wrist were found to be more cost effective because they were associated with improved intraoperative cardiovascular stability, fewer postoperative side effects, and earlier discharge home.[366] Paravertebral somatic nerve blocks

can be used as an alternative to ilioinguinal-hypogastric nerve block for inguinal herniorrhaphy.[367] However, the additional time and expertise required to perform this block, as well as the risk of serious side effects (e.g., pneumothorax), are concerns when using paravertebral blocks rather than simpler peripheral blocks for this common operation.[367]

In pediatric patients, peripheral nerve blocks can be performed immediately after induction of general anesthesia to reduce the anesthetic requirement and provide postoperative analgesia (see Chapter 81). Historically, caudal anesthesia has been the most popular technique to reduce postoperative pain in children undergoing lower abdominal, perineal, and lower extremity procedures. However, this central neuraxis block is associated with more side effects (e.g., urinary retention) and a longer recovery time than simple peripheral nerve blocks. Popular peripheral blocks for children include blockade of the ilioinguinal and iliohypogastric nerves to minimize postherniorrhaphy pain[368] and use of the dorsal penial nerve block and subcutaneous ring block for postcircumcision pain. Using ultrasound guidance for ilioinguinal and iliohypogastric nerve blockade significantly reduced the volume of local anesthetic injected, as well as the intraoperative and postoperative requirements for opioid analgesics.[369] Interestingly, simple wound infiltration (or instillation) with local anesthetics may be as effective as a caudal or ilioinguinal nerve block in reducing pain after inguinal hernia repair.[370] Other studies suggest that systemic ketorolac (1 mg/kg) is also as efficacious as caudal blockade and has a lower incidence of side effects when combined with local anesthetic wound infiltration.[371] Topical lidocaine ointment is a simple and effective alternative to both a peripheral nerve block and opioid analgesics for postcircumcision pain.

Local Infiltration Techniques

Of all the anesthetic techniques suitable for outpatients, local infiltration of the operative site with dilute solutions of local anesthetics is the simplest and safest approach to reducing postoperative pain and the need for postdischarge opioid-containing analgesics.[372] Infiltration of local anesthetics at the surgical incision site should be a component of all ambulatory anesthetic techniques.[373,374] Outpatient urologic procedures (e.g., vasovasostomy, orchiopexy, and hydrocele and spermatocele repairs) performed with local anesthesia can significantly decrease the overall cost or surgical care. Local infiltration anesthesia alone can provide adequate analgesia for superficial procedures (e.g., inguinal herniorrhaphy, breast and anorectal surgery, shoulder and knee arthroscopy) but is vastly underutilized in clinical practice.[312,375-377] Compared with spinal anesthesia for anorectal surgery, local anesthesia with sedation resulted in a shorter hospital stay, reduced cost, and fewer side effects.[378] Patient comfort can be improved if IV sedation-analgesia is used to supplement local anesthetic infiltration, particularly when the local anesthesia is not completely effective.[355,376] However, use of IV adjuvants can also increase side effects (e.g., ventilatory depression, PONV).[379,380]

The benefits of local wound infiltration in patients undergoing more invasive major surgical procedures have not been as extensively studied. Although there is very little evidence that "preemptive analgesia" involving local anesthetic injections at the surgical wound reduces the risk for developing persistent postoperative pain syndromes,[381] it does lessen both intraoperative and postoperative opioid requirements, as well as opioid-related side effects.[382] Many studies have demonstrated improved analgesia, greater patient satisfaction with pain management, and reduced PONV and hospital stay when local anesthetics are administered at the surgical incision site.[383] For example, patients receiving a continuous infusion of bupivacaine at the incision site not only experienced improved postoperative pain management but also were able to ambulate earlier.[383] Infiltration of local anesthetic at portal sites and the gallbladder bed improves postoperative analgesia after laparoscopic cholecystectomy.[384] Compared with neuraxial or general anesthetic techniques, local anesthetic infiltration techniques reduce the risk of postoperative urinary retention associated with anorectal surgery[355] and inguinal herniorrhaphy.[380,385,386] A combination of local infiltration and intercostal nerve blocks has also been used for lithotripsy. Careful patient (and surgeon) selection is important for operations performed using local infiltration or a field block techniques. When used as the primary anesthetic technique, local anesthesia facilitates postanesthesia care unit (PACU) bypass, thereby reducing recovery costs.[331,355,356,376,380,387] Local anesthetic supplementation during general and spinal anesthesia (e.g., infiltration with bupivacaine, 0.25% to 0.5%) will also decrease incisional pain in the postdischarge period.[388]

Monitored Anesthesia Care

The combination of local anesthesia and/or peripheral nerve blocks with intravenous sedative and analgesic drugs is commonly referred to as MAC and has become extremely popular in the ambulatory setting.[379,389] Compared with general endotracheal and central neuraxis anesthetic techniques for superficial (noncavitary) surgical procedures, MAC-based techniques can facilitate recovery in the ambulatory setting.[355,356] The *simplest* local anesthetic technique that provides adequate analgesia is recommended to minimize the risk of side effects and complications.[366] These local anesthetic-based techniques are also the most cost effective for ambulatory surgery (Tables 78-10 and 78-11).[355,356]

The primary objective in providing MAC is to ensure patient comfort, safety, and satisfaction during surgery. MAC is the term used when an anesthesiologist monitors a patient receiving local anesthesia or administers supplemental drugs to patients undergoing diagnostic or therapeutic procedures.[389] The ASA defines MAC as *instances in which an anesthesiologist has been requested to provide specific anesthesia services to a particular patient undergoing a planned procedure, in connection with which a patient receives local anesthesia or, in some cases, no anesthesia at all.*[390] In such a case, the anesthesiologist is in control of the patient's vital signs and is available to administer anesthetics and provide other medical care as appropriate. The standard of care for patients receiving MAC should be the same as for patients undergoing general or regional anesthesia and includes a standard preoperative assessment, intraoperative monitoring, and postoperative recovery care. Vigilant monitoring is required because patients may rapidly progress from a "light" level of sedation to "deep" sedation (or unconsciousness) and, thus, may be at risk for airway obstruction, oxygen desaturation, and even aspiration.

Anesthetic drugs are administered during procedures under MAC with the goal of providing analgesia, sedation, and

Table 78-10 Comparison of Anesthetic Techniques for Outpatient Inguinal Herniorrhaphy

	Local Anesthesia with Sedation	General Anesthesia	Spinal Anesthesia

anxiolysis and ensuring rapid recovery without side effects. Systemic analgesics are often used to reduce the discomfort associated with the injection of local anesthetics and prolonged immobilization[391] as well as procedure-related pain that is not amenable to local anesthesia (e.g., endoscopy). Sedative-hypnotic drugs are used to make procedures more tolerable for patients by reducing anxiety and providing a degree of intraoperative amnesia while allowing them to rest (or sleep) during the operation.[392] Patients often become restless, bored, or uncomfortable when forced to remain immobile for prolonged periods of time under local anesthesia. Perioperative anxiety can be reduced with benzodiazepines (e.g., midazolam, 2 mg IV), as well as by intraoperative verbal communication, keeping the patient warm and covered, and allowing him or her to listen to music during the procedure.[393]

Many different sedative-hypnotic drugs have been administered during MAC (including barbiturates, benzodiazepines, ketamine, and propofol) using a wide variety of delivery systems (e.g., intermittent boluses, variable-rate infusion, target-controlled infusion, and even patient-controlled sedation).[394,395] The most commonly used sedation technique is a propofol infusion at 50-100 μg/kg/min.[396-398] Methohexital has also been used during MAC when administered as intermittent boluses (10-20 mg) or as a variable-rate infusion (1-3 mg/min). Residual sedation is greater with methohexital compared with propofol. Nevertheless, discharge times were similar after infusions of methohexital (40 μg/kg/min) and propofol (50 μg/kg/min) during MAC.[399] Furthermore, the incidence of pain on injection is lower with methohexital.[205,218] Therefore, the short-acting barbiturate may be a cost-effective alternative to propofol for sedation during MAC.[399]

In women undergoing laparoscopic tubal sterilization with a MAC technique, anesthetic drug costs were significantly reduced in comparison with general anesthesia.[400] The MAC technique was also associated with less time in the operating room, a higher degree of "awakeness" on the evening of the day of surgery, and decreased postoperative pain and sore throat. Analogous to earlier studies involving patients undergoing unilateral hernia repair and anorectal surgery,[355,356] Patel and coworkers[401] reported that the use of MAC sedation resulted in a 6- to 7-minute decrease in operating room exit time when compared with general anesthesia, contributing to enhanced turnover of cases and improved operating room efficiency. This is an increasingly important consideration in the current practice environment that emphasizes "fast-tracking" after ambulatory surgery.[402]

Avramov and White[403] described the combined use of alfentanil (0.3 to 0.4 μg/kg/min) and propofol (25 to 75 μg/kg/min) infusions for MAC. Propofol produced a dose-related reduction in the opioid dose requirement (25% to 50%) and the incidence of PONV (0% to 17%) when compared with alfentanil alone (33%). Ketamine infusion has also been used as an alternative to the opioid analgesic.[404] Although an infusion of remifentanil, 0.05 to 0.15 μg/kg/min, can provide adequate sedation and analgesia during minor surgical procedures performed with the patient under local anesthesia, opioid-related side effects have limited the use of this drug as the primary IV adjuvant during MAC.[405] The addition of midazolam (2 to 4 mg IV) improved the quality of sedation and anxiolysis produced by remifentanil.[406] In

Table 78-11 Comparison of Anesthetic Techniques on Recovery Profile after Anorectal Surgery

	Local Anesthesia with Sedation	Spinal Anesthesia	General Anesthesia
Duration of anesthesia (min)	40 ± 15	72 ± 17	75 ± 19*
Duration of surgery (min)	26 ± 14	26 ± 13	26 ± 15

comparing the use of intermittent remifentanil boluses (25 μg) with a continuous variable-rate infusion (0.025 to 0.15 μg/kg/min) as part of a MAC technique consisting of midazolam (2 mg) and propofol (25 to 50 μg/kg/min), Sá Rêgo and colleagues[406] reported superior patient comfort when the remifentanil was administered by a variable-rate infusion. However, concomitant use of propofol and remifentanil infusions during MAC resulted in a higher incidence of episodic oxygen desaturation (30% versus 0%) compared with those given small intermittent boluses of remifentanil. When administered to spontaneously breathing patients in combination with propofol, remifentanil offered no benefits compared with propofol alone.[407] In a direct comparison of remifentanil and propofol infusions after premedication with midazolam (2 mg IV), a reduced level of sedation and a greater degree of respiratory depression were noted with remifentanil than with propofol.[408]

Given the increased risk of ventilatory depression when potent opioid analgesics are combined with sedative-hypnotics, a variety of nonopioid analgesics have been evaluated during MAC.[391] Ketorolac has been used as an analgesic supplement to propofol sedation during local anesthesia. The use of ketorolac was associated with a lower incidence of pruritus, nausea, and vomiting when compared with fentanyl.[126,409,410] However, ketorolac-treated patients required higher intraoperative dosages of propofol and more supplemental opioid analgesia.[126,391] Low-dose ketamine (0.25 to 0.5 mg/kg) combined with either midazolam or propofol has also been administered to outpatients undergoing cosmetic surgical procedures with local anesthesia.[226,411,412] Ketamine has the advantage over both opioid analgesics and NSAIDs because it produces less ventilatory depression and PONV than the opioid compound while providing more effective intraoperative analgesia than NSAIDs.[413] Small doses of either midazolam and propofol can be administered to attenuate the adverse psychomimetic reactions produced by ketamine.[229,411,412,414,415]

The α_2-agonists clonidine and dexmedetomidine reduce central sympathetic outflow and have been shown to produce anxiolysis and sedation. Kumar and associates[416] demonstrated that oral clonidine (300 μg) provided effective anxiolysis for elderly patients undergoing ophthalmic surgery under local anesthesia while also decreasing the incidence of intraoperative hypertension and tachycardia. Dexmedetomidine (1 μg/kg IV) significantly decreased anxiety levels and reduced the requirements for supplemental analgesic medications when given before intravenous regional anesthesia for hand surgery.[417] In comparing dexmedetomidine with midazolam for sedation, Aho and colleagues[418] reported faster recovery from sedation when dexmedetomidine was followed by reversal with the specific α_2-antagonist atipamezole. However, the slower onset and recovery from dexmedetomidine-induced sedation, as well as the occurrence of bradycardia, has limited its use for MAC in the ambulatory setting.[417-419]

Facilitating the Recovery Process

Cerebral Monitoring

The impact of monitoring the level of consciousness during general anesthesia in the ambulatory setting remains controversial (see Chapter 39).[420] Monitoring patient vital signs remains the most useful method for determining the "depth of anesthesia" during surgery. Although the value of cerebral monitoring as an adjuvant to monitoring autonomic responses to noxious surgical stimuli is limited, several studies have reported that the use of cerebral monitoring can improve early recovery after general anesthesia in the ambulatory setting because of its ability to minimize both "overdosing" and "underdosing" with both intravenous (e.g., propofol) and inhaled anesthetic (e.g., sevoflurane and desflurane) drugs during the maintenance period.[421-425] A meta-analysis confirmed that more precise dosing of intravenous and inhaled anesthetics during ambulatory surgery significantly reduced anesthetic consumption, the incidence of PONV, and the time in the recovery room.[426]

Several different electroencephalographic (EEG)-based algorithms have been evaluated in an attempt to improve the correlation between EEG-derived indices, anesthetic drug concentrations, and clinical signs of the depth of anesthesia.[427] The bispectral index (BIS), physical state index (PSI), spectral and response entropy, auditory evoked potential (AEP) index, and cerebral state index (CSI) are all processed variables derived from the EEG that have been used to quantify the sedative and hypnotic effects of anesthetic drugs on the central nervous system (CNS).[426] The BIS, PSI, and CSI values are dimensionless numbers that vary from 0 to 100, with values less than 60 associated with "adequate" hypnosis under general anesthesia and values greater than 75 typically observed during emergence from anesthesia.[428] In contrast to the BIS, PSI, and CSI monitoring devices, the AEP monitor uses the middle latency auditory evoked potential (MLAEP) response to assess the depressant effects of anesthetic drugs on the CNS. Studies suggest that the AEP index changes in a consistent and dose-dependent manner with the administration of sedative-hypnotic and volatile anesthetics but not with opioid analgesics.[428,429]

Despite the introduction of these cerebral monitoring devices, there is still no universally accepted "gold standard" for measuring the depth of anesthesia. For a monitor to be of the most clinical utility, it should display a strong correlation between the observed variable (index) and the patient's state of consciousness and physiologic responses (e.g., blood pressure, heart rate, catecholamine levels) to noxious stimuli during surgery independent of the anesthetic technique and with minimal interpatient variability. For example, the CSI failed to reliably predict autonomic or somatic responses to surgical stimuli.[430] In studies involving nonparalyzed patients, electromyographic activity has been found to interfere with the ability of these monitors to obtain reliable EEG-based index values. In their editorial on cerebral monitoring, Kalkman and Drummond[420] suggested that all of the currently available devices have deficiencies in monitoring "depth of anesthesia." This is hardly surprising because these monitoring devices only measure the hypnotic component of anesthesia.

The reported indices of the cerebral monitors are generally lower (reflecting "deeper" levels of sedation-hypnosis) in patients when using standard monitoring practices than in cerebral-monitored patients.[424,428,431] These data suggest that patients are maintained at a "lighter" level of anesthesia (or hypnosis) when the anesthesiologist has access to the information provided by one of these cerebral monitoring devices. The information provided by a cerebral monitor influences the anesthesiologist's use of not only volatile anesthetics but also opioid analgesic and

sympatholytic drugs during the maintenance period. As a result of the anesthetic and/or analgesic-sparing effects, monitored patients are able to more rapidly achieve surrogate recovery end points (e.g., fast-track eligibility) and to satisfy PACU discharge criteria (e.g., Aldrete score of 10), resulting in a 30- to 90-minute reduction in the length of the PACU stay and/or the time to discharge home after ambulatory surgery.[424] When cerebral monitoring is used to administer isoflurane, the speed and quality of recovery was similar to sevoflurane after outpatient gynecologic surgery.[432]

One of the concerns in "minimizing" the use of anesthetics relates to the possibility that patients may experience more purposeful movement during surgery (i.e., less optimal operating conditions) and even awareness. It has further been suggested that the use of cerebral monitors to minimize the administration of anesthetic and analgesic drugs may result in increased autonomic (stress) responses and adverse clinical outcomes (e.g., myocardial ischemia). Previous studies have demonstrated that patient outcome is similar whether supplemental general anesthetic, opioid analgesic, or sympatholytic drugs were used to control acute autonomic responses during surgery.[433,434] A study by Monk and colleagues[435] suggested that there was a correlation between the length of time during anesthesia that the BIS value was less than 45 and the incidence of adverse clinical outcomes in elderly surgical patients. Despite the emphasis on rapid recovery after ambulatory anesthesia, outpatients do not appear to be at increased risk for awareness when compared with inpatients receiving general anesthesia.[436] From the perspective of the patient, the quality of recovery appears to be improved with cerebral monitoring versus traditional monitoring practices.[424,431]

Optimal Anesthetic Techniques

In the ambulatory setting, the optimal anesthetic technique would provide for excellent operating conditions and rapid "fast-track" recovery to full activity without postoperative side effects or complications.[7] In addition to improving the quality and minimizing the cost of anesthetic services, the ideal anesthetic technique would also optimize operating room efficiency (e.g., turnover times) and provide for an earlier discharge home. Local anesthesia with intravenous sedation (i.e., MAC techniques), regional (peripheral) blocks, spinal anesthesia, and general anesthesia can all be used for ambulatory surgery. Opinions differ regarding the "best" anesthetic technique, even for superficial surgical procedures.[309,355,356,437-440] Rather than simply generalizing about the best anesthetic technique for ambulatory surgery, it would be far better to individually analyze each surgical procedure (i.e., procedure-specific approach).[306]

In the current cost-conscious environment, it is important to also examine the impact of anesthetic techniques on the perioperative process because prolonged recovery times and reduced efficiency contribute to the increased cost of surgical care.[355,356,387] In addition, patient satisfaction with the perioperative experience and quality of recovery is improved when the anesthetic technique chosen for the procedure is associated with a low incidence of postoperative side effects. For example, the routine use of prophylactic antiemetic drugs during general anesthesia has been found to increase patient satisfaction in "at-risk" outpatient surgical populations (e.g., nonsmoking women with a history of PONV or motion sickness).[140] Furthermore, the use of local anesthetic infiltration and/or peripheral nerve blocks decrease postoperative pain after ambulatory surgery procedures irrespective of the actual anesthetic technique.[402,441,442]

The time required to achieve a state of home readiness (i.e., "fitness" for discharge home) is influenced by a wide variety of surgical and anesthetic factors.[443,444] However, the major contributors to a delay in discharge after ambulatory surgery are nausea, vomiting, dizziness, pain, and prolonged sympathetic and motor blockade. Although the incidence of PONV can be decreased by the use of prophylactic antiemetic drugs,[402] it remains a common side effect after general anesthesia and prolongs discharge after ambulatory surgery.[138] The primary factor delaying discharge after spinal anesthesia is recovery from the residual motor and sympathetic blockade, which contributes to delayed ambulation and an inability to void. These side effects can be minimized by use of the so-called minidose lidocaine-fentanyl spinal anesthetic technique.[110,440] Other concerns with spinal anesthesia include back pain, post–dural puncture headache, and transient radicular irritation.[445,446] Although MAC is associated with the lowest incidence of postoperative side effects,[355,356] the possibility of transient nerve palsy is a concern when peripheral nerve block techniques are used.[447-449] Another issue relates to the fact that many patients simply prefer to "be asleep during the operation."

Use of the modern general anesthetics with an LMA for airway management combined with antiemetic prophylaxis and nonopioid analgesic techniques can achieve recovery times that compare favorably with MAC techniques.[450,451] Studies have demonstrated that outpatients undergoing hernia repair and breast surgery were able to ambulate within 30 minutes and were discharged within 60 minutes after general anesthesia. When tracheal intubation is required (e.g., laparoscopic procedures, risk factors for aspiration [e.g., diabetics, morbidly obese, esophageal dysfunction]), the use of minimally effective doses of a short-acting opioid analgesic (e.g., remifentanil) or sympatholytic (e.g., esmolol, labetalol) can facilitate the early recovery process and allow patients to achieve earlier discharge times after ambulatory surgery.[117,276,452]

Table 78-12 Effects of Intravenous Anesthetic and Cardiovascular Drugs on the Duration of Electroconvulsive Therapy–Induced Seizure Activity

	Increased	No Change	Decreased
Anesthetic Drugs	Etomidate	Methohexital,* ketamine, alfentanil,† remifentanil†	Thiopental, thiamylal, lorazepam, midazolam, propofol
Cardiovascular Drugs	Aminophylline, caffeine	Clonidine, esmolol, labetalol, dexmedetomidine, nifedipine, nicardipine, nitroglycerin, trimethaphan, nitroprusside	Diltiazem, lidocaine

*When compared with saline, methohexital decreases the seizure duration of electroconvulsive therapy.
†Increases seizure time because of an anesthetic-sparing effect.

The cost savings associated with the newer anesthetic techniques are lost if institutional practices mandate minimum lengths of stay in the recovery units (i.e., PACU or "step-down" unit). Claims of reduced total costs with earlier discharge are commonly based on the assumption that there is a linear relationship between the cost of a clinical service and the time spent providing it. Because personnel costs are semifixed rather than variable, an additional 15- to 30-minute stay in the PACU may not be associated with increased cost to the institution unless the facility is working at or near its capacity.[453] Fast-tracking does not, however, reduce the overall nursing workload and the associated costs after ambulatory surgery.[454]

The relationship between decreasing costs and bypassing the PACU ("fast-tracking") appears to be much closer because the major factor in recovery care cost relates to the peak number of patients admitted to the PACU at any given time.[453] Fast-tracking can lead to the use of fewer nurses and a mix of less highly trained, lower-wage nursing aides and fully qualified recovery room nurses and, therefore, reduces "overtime" personnel costs for busy ambulatory surgery units. Shorter anesthesia times, the ability to bypass the PACU, and a decreased length of stay in the day-surgery unit will reduce total institutional costs.[455] Studies have demonstrated that "fast-tracking" ambulatory surgery patients can decrease the time to actual discharge.[456,457]

The combination of low cost and high patient satisfaction suggests that the highest-quality (cost/outcome) anesthetic may be achievable with a MAC technique if the surgical procedure is amenable to this anesthetic approach (e.g., superficial surgical and endoscopic procedures). However, the success of MAC techniques is dependent not only on the anesthesiologist but also on the skills of the surgeon in providing effective local anesthetic infiltration and gentle handling of tissues during the intraoperative period. Superficial operations can be performed under local anesthesia without any monitoring or intravenous adjuvants (so-called unmonitored local anesthesia) in situations in which the local anesthesia is able to provide complete analgesia and patients do not object to being awake and aware of events in the operating room.[458] However, in a prospective, randomized comparison of local infiltration with spinal and general anesthesia,[459] surgeons in Sweden suggested that technical difficulties and patient pain were "more intense" during surgery under local anesthesia alone.

Fast-Tracking Concepts

Ambulatory anesthesia is administered with the dual goals of rapidly and safely establishing satisfactory conditions for the performance of therapeutic or diagnostic procedures while ensuring rapid, predictable recovery with minimal postoperative sequelae. If careful titration of short-acting drugs permits safe transfer of patients directly from the operating room suite to a less labor-intensive recovery area, many outpatients can be discharged home within 1 hour after surgery, thereby resulting in cost savings to the institution.[450,460] Bypassing the PACU has been termed "fast-tracking" after ambulatory surgery.[461] In addition, fast-tracking can be accomplished directly from the PACU ("PACU fast-tracking") by creating a specialized area within an existing PACU where recovery procedures are organized along the lines of a step-down unit.[462] This approach represents a key component of the "total care" package for ambulatory surgery.[463]

The criteria used to determine fast-track eligibility (see Table 78-7) have been made even more stringent than the standard PACU discharge criteria to reduce the need for nursing interventions in areas with less nursing personnel.[464] The use of anesthetic techniques associated with more rapid recovery will result in fewer patients remaining deeply sedated in the early postoperative period[457,465] and decrease the risk for airway obstruction, episodes of oxygen desaturation, and cardiovascular instability, thereby reducing the number of nursing interventions.[457,466] By using anesthetic techniques associated with faster emergence times from anesthesia, it should be possible to reduce the need for "intensive" nursing care in the early postoperative period.[467] Therefore, a well-organized fast-tracking program may permit an institution to use fewer nurses in the recovery areas and could lead to significant cost savings.

The fast-track concept is gaining wider acceptance for outpatients of all ages.[468,469] Fast-tracking children after ambulatory surgery is feasible and beneficial (e.g., shorter recovery time) when specific selection criteria are used.[455] Similarly, elderly outpatients can be fast-tracked after general anesthesia if short-acting drugs are used.[465] The vast majority of outpatients no longer require admission to a conventional PACU recovery facility after ambulatory surgery.[470] Bypassing the PACU after outpatient knee surgery was associated with fewer unplanned hospital admissions.[471] The primary anesthetic-related cause of failure to fast-track outpatients after laparoscopic surgery was residual sedation on emergence from anesthesia (propofol > sevoflurane > desflurane).[457] Other important reasons included residual muscle weakness (due to nondepolarizing muscle relaxants) and surgical misadventures. If common side effects cannot be effectively prevented, bypassing the PACU may result in more nursing interventions in the day-surgery step-down unit.[471]

Improved titration of anesthetic drugs with the use of EEG-based cerebral monitors can lead to faster emergence from general anesthesia,[421,422] and by predicting the time required to achieve fast-track eligibility,[472] they may actually reduce discharge times.[424] Whereas the availability of more rapid and shorter-acting anesthetic drugs has clearly facilitated the early recovery process after general anesthesia, the "preemptive" use of nonopioid analgesics[126] and antiemetics[140] will reduce postoperative side effects and accelerate both the immediate and late recovery phases after ambulatory surgery. When compared with a conventional recovery pathway, fast-tracked patients are eligible to be discharged home 30 to 90 minutes earlier without compromising patient safety or satisfaction with their surgical experience.[452]

Multimodal Approaches to Minimizing Side Effects

As more complex procedures are performed utilizing minimally invasive surgical approaches (e.g., laparoscopic adrenalectomy and nephrectomy, arthroscopic knee and shoulder reconstructions), the ability to effectively control postoperative side effects such as pain and PONV may make the difference between performing a given procedure on an inpatient or ambulatory basis. The introduction of multimodal approaches to perioperative care has led to improved surgical outcomes.[473]

For preventing PONV, the most cost-effective antiemetic combination consists of droperidol (0.625-1.25 mg IV), dexame-

thasone (4-8 mg IV),[155,156] and generic ondansetron (4-8 mg IV).[474] Outpatients at the highest risk of PONV may also benefit from the addition of a long-acting 5-HT_3 antagonist (e.g., palonosetron, 75 µg IV), an NK-1 antagonist (e.g., aprepitant), a transdermal scopolamine patch, or an acu-stimulation device (e.g., SeaBand, ReliefBand).[159,161,166] Use of nonopioid analgesics (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], cyclooxygenase-2 [COX-2] inhibitors, acetaminophen, α_2-agonists, glucocorticoids, ketamine, and local anesthetics) as part of a multimodal analgesic regimen will minimize opioid-related side effects and enhance patient satisfaction.[139,382,475] In a study comparing ketorolac with the glucocorticoid steroids when administered as adjuvants during ambulatory surgery, the parenteral NSAID not only provided more effective postoperative analgesia but also was superior in preventing PONV in the early recovery period. However, the adjunctive use of dexamethasone does prolong the analgesic effects of NSAIDs.[476] In addition to using multimodal antiemetic and nonopioid analgesic therapy,[382,477] ensuring adequate hydration will minimize nausea and other side effects (e.g., dizziness, drowsiness, thirst) during the postoperative period.[180-183]

A multimodal (or "balanced") approach to providing postoperative analgesia is essential in the ambulatory setting.[4,35,478] Not surprisingly, pain has been found to be a major factor complicating recovery and delaying discharge after ambulatory surgery.[233] The addition of low-dose ketamine (75-150 µg/kg) to a multimodal analgesic regimen improved postoperative analgesia and functional outcome after painful surgical procedures.[229,414,479] In addition to effective multimodal analgesic regimens, nonpharmacologic factors can also influence control of postoperative pain. For example, when compared with the conventional CO_2 insufflation technique, reduced pain and shorter convalescence were achieved after mini-laparoscopic cholecystectomy simply by using a gasless technique.[29] Use of nitrous oxide for pneumoperitoneum and heated insufflation gases were also associated with less postoperative pain than the standard insufflation technique.[191,480]

After ambulatory surgery, pain must be controllable with simple oral analgesics (e.g., acetaminophen, ibuprofen, acetaminophen with codeine) when patients are discharged from the surgery facility. Although the potent rapid-acting opioid analgesics (e.g., fentanyl, sufentanil, remifentanil) are commonly used to treat moderate-to-severe pain in the early recovery period, these compounds increase the incidence of PONV and may contribute to delayed discharge after ambulatory surgery.[126,233] As a result of the concern regarding opioid-related side effects, interest has increasingly focused on the use of parenteral NSAIDs (e.g., diclofenac, ketorolac, parecoxib), which can effectively reduce the requirements for opioid-containing oral analgesics after ambulatory surgery and lead to an earlier discharge home.[481] However, less expensive oral nonsteroidal analgesics (e.g., ibuprofen, naproxen)[482,483] are also highly effective in the postdischarge period. The perioperative use of the oral COX-2 inhibitors has become more popular because they are devoid of adverse effects on platelet function (Tables 78-13 and 78-14).[122] Oral celecoxib (400 mg/day) is a simple and cost-effective approach to improving pain control and decreasing discharge times after ambulatory surgery.[127,129,484-486] A recent study demonstrated that the use of celecoxib, 400 mg/day, on the day of surgery and for the first 3 postoperative days can lead to significant improvements in clinically relevant patient outcome measures (e.g., gastrointestinal function, resumption of physical activities, patient satisfaction).[485] Furthermore, the addition of a glucocorticoid (e.g., dexamethasone, 4-8 mg IV) can prolong the duration of analgesia when

using a multimodal analgesic regimen that included an NSAID and local anesthesia.[130] Finally, acetaminophen is a cost-effective alternative to the traditional NSAIDs if an effective dose (40 to 60 mg/kg orally or rectally) can be given before the end of surgery.[487-489] A parenteral formulation of acetaminophen (1 g IV) has been developed and has quickly become a valuable adjuvant to standard multimodal analgesic regimens.

One of the keys to facilitating the recovery process is the routine use of local anesthesia as part of a multimodal regimen.[126,479] The use of local anesthetics for perioperative analgesia during MAC, as well as adjuncts to general and regional anesthesia, can provide excellent analgesia during the early recovery and postdischarge periods.[441,442] Even simple wound infiltration and instillation techniques have been shown to improve postoperative analgesia after a variety of lower abdominal, peripheral extremity, and even laparoscopic procedures. A wide array of peripheral extremity blocks have also been used to minimize postoperative pain;[340,490] however, the beneficial effects of local anesthetic blocks on patient outcomes are limited unless the local analgesia can be extended into the postdischarge period.[491] The use of continuous local anesthetic delivery systems has been found to improve pain control after major ambulatory orthopedic surgery by extending peripheral nerve blocks into the postdischarge period.[344,346,347]

For laparoscopic procedures, abdominal pain can also be minimized by the use of a local anesthetic at the portals and topical application at the surgical site. Shoulder pain is also common after laparoscopic surgery, and this pain has been reported to be reduced with subdiaphragmatic instillation of local anesthetic solutions. Topical intra-abdominal application at the surgical site (e.g., gallbladder bed, fallopian tubes) can also reduce both pain and PONV.[492] After arthroscopic knee surgery, instillation of 30 mL of 0.5% bupivacaine into the joint space reduces postoperative opiate requirements and permits earlier ambulation and discharge.[493] The addition of adjuvants (e.g., morphine, 1-2 mg; ketorolac, 15-30 mg; clonidine, 0.1-0.2 mg; ketamine, 10-20 mg; triamcinolone, 10-20 mg) to intra-articular local anesthetics can further reduce pain after arthroscopic surgery.[494-497] Novel compounds such as capsicum (the active ingredient in chili peppers!) have been found to produce analgesic effects because of their ability to alter nociceptive input at peripheral nerve ending.[498] Finally, simple electroanalgesic techniques (e.g., transcutaneous electrical nerve stimulation [TENS]) can also be used as a nonpharmacologic component of a multimodal analgesic regimen.[499] Future growth in the complexity of surgical procedures being performed on an ambulatory basis will necessitate further improvements in our ability to provide effective postoperative pain relief away from the surgical facility.

Bisgaard[500] suggested that "opioids should only be used when these other nonopioid analgesic techniques fail." Although so-called preemptive analgesic techniques have been postulated to provide superior analgesia by preventing the establishment of central sensitization,[501] this approach does not appear to offer any clinically significant advantages over simple preventative multimodal regimens administered immediately after surgery.[502] Administration of celecoxib after plastic surgery was as effective as administering the drug both before and after the operation.[503] Interestingly, perioperative administration of IV lidocaine improved patient outcomes after major laparoscopic surgery.[504] Safer, simpler, and more efficacious analgesic drug delivery systems are still needed to provide cost-effective pain relief in the postdischarge period as more major surgery is performed on an ambulatory basis in the future.[473,505]

Special Considerations

Office-Based Anesthesia

Office-based anesthesia is simply a variant of ambulatory anesthesia that has attracted growing attention around the world.[506] Ralph Waters opened the first office-based anesthetic practice (the Downtown Anesthesia Clinic) almost 100 years ago in Sioux City, Iowa. In response to an occasional call from a dentist for anesthesia, Dr. Waters set up "a modest office with a waiting room and a small operating room with an adjoining room containing a cot on which a patient could lie down after his anesthetic before going home."[20] In a series involving over 30,000 office-based ENT procedures with 72% receiving "deep sedation" or general anesthesia, the complication rate was only 1.3% and only two patients required overnight hospitalization.[507] In a review of over 4,000 consecutive patients who had undergone office-based surgery with MAC techniques, postoperative complication rates were less than 0.1% and only two patients required overnight hospitalization.[508]

For many years, simple minimally invasive surgical procedures have been performed in physicians' offices. Certified registered nurse anesthetists, dental anesthesiologists, and, increasingly, practicing anesthesiologists have been active in office-based surgery. It is currently estimated that only 5% to 10% of outpatient surgical procedures are performed in the office setting, and this number is anticipated to approach 20% by 2010. Both the numbers and the types of surgical procedures are steadily increasing. As pressure from third-party payers to reduce the overall cost of surgical procedures continues to increase, surgeons and anesthesiologists are moving cases to facilities where they have more direct control over costs. For example, a cost comparison of laparoscopic inguinal herniorrhaphy was performed by Shultz, who reported that the total cost for this procedure in the hospital was $5494 versus $1534 in an office facility.[509] Similarly, the hospital-based fee for a conventional "open" inguinal herniorrhaphy was $2237 versus $895 in an office facility.

Office-based facilities have lower overhead than hospital or freestanding ambulatory surgical centers and are often more comfortable and convenient for patients. It is important to select patients appropriately and to adhere to the usual guidelines for safe anesthetic care. The preoperative workup should be guided by the same clinical acumen and common sense that drives the decision-making process at freestanding surgery centers (i.e., coexisting diseases must be under good control). Patients with potentially difficult airways are not good candidates for office-based anesthesia. The selection criteria for patients should also consider the invasiveness of the surgical procedure.

The optimal anesthetic techniques for office-based surgical procedures are similar to those used for hospital-based and freestanding ambulatory surgery procedures. Most procedures involve the use of local anesthesia supplemented with intravenous sedation (e.g., propofol infusion) or "light" general anesthesia and an LMA or facemask for airway management.[450,451,510] Propofol is used for providing sedation, as well as for induction and mainte-

nance of anesthesia, along with sevoflurane and desflurane. Nitrous oxide was shown to decrease the propofol requirement and allow patients to be discharged within 60 minutes after office-based procedures without increasing the incidence of PONV. The use of larger doses of opioid analgesics has been found to enhance cardiorespiratory depression without improving the quality of perioperative patient comfort.[511] Most office suites do not have stretchers or recovery beds, and patients have to be able to get up from the operating room table and transfer themselves (with assistance) to a reclining chair or ambulate to an area where they can rest until they are ready to get dressed and go home.

Although the modern practice of office-based anesthesia is relatively new in the United States, a similar practice of office-based dental anesthesia has been in place for several decades in the United Kingdom. After a review of anesthetic deaths in dental offices in the United Kingdom, it was recommended that all anesthetics be administered by accredited anesthesiologists whose training included specific experience in dental anesthesia.[510] There were also recommendations regarding resuscitation equipment and the availability of drugs needed for emergency use. In the years after publication of the Poswillo report, the number of dental offices offering general anesthesia for office-based procedures significantly decreased.[512] The high cost required to equip and maintain such locations was the main reason for this change of practice. Based on the U.K. experience, it is obvious that if office-based anesthesia is going to be successful in North America, issues other than cost must be considered.[23]

Office-based surgery practice guidelines established by the ASA, the American Association of Nurse Anesthetists, and the Joint Commission on the Accreditation of Healthcare Organizations include the following:

1. Employment of appropriately trained and credentialed anesthesia personnel
2. Availability of properly maintained anesthesia equipment appropriate to the anesthesia care being provided
3. As complete documentation of the care provided as that required at other surgical sites
4. Use of standard monitoring equipment according to the ASA policies and guidelines
5. Provision of a PACU or recovery area that is staffed by appropriately trained nursing personnel and provision of specific discharge instructions
6. Availability of emergency equipment (e.g., airway equipment, cardiac resuscitation)
7. Establishment of a written plan for emergency transport of patients to a site that provides more comprehensive care should an untoward event or complication occur that requires more extensive monitoring or overnight admission of the patient
8. Maintenance and documentation of a quality assurance program
9. Establishment of a continuing education program for physicians and other facility personnel
10. Safety standards that cannot be jeopardized for patient convenience or cost savings

Beyond their responsibility to provide safe anesthesia care in the office, modern-day office-based anesthesiologists have an opportunity to expand their role as perioperative physicians. This practice has the potential to heighten public awareness of the vital role of anesthesiologists in the ambulatory setting and enhance the professional image of our specialty.[512] Patients and caregivers must be confident that the office setting adheres to the same standards of care required in a hospital-based or a freestanding ambulatory surgery facility.

Anesthesia for Procedures outside the Operating Room

Anesthesiologists are being called on to provide anesthetic care for an increasing number of procedures in remote locations (see Chapter 79). The most common of these procedures are electroconvulsive therapy (ECT), extracorporeal shock waves lithotripsy (ESWL), and neuroradiologic procedures, including magnetic resonance imaging (MRI) and computed tomography (CT). The anesthetic machines and monitors used in these locations may be old or unfamiliar models, and the monitoring equipment and supplies may be more limited in comparison to the operating room. Experienced assistants may be unavailable, and nursing staff members in these locations are frequently unaccustomed to the anesthetic drugs, equipment, and procedures used by anesthesiologists. Consequently, the anesthesiologist must be vigilant when checking the anesthetic machine and must know where to locate emergency resuscitation drugs and equipment.

As with any ambulatory or office-based surgical procedure, patients must be carefully selected and evaluated before any procedure involving the administration of anesthetic drugs if performed outside the operating room. The anesthetic techniques used for these procedures should provide for prompt recovery with minimal side effects, and patients must fulfill the same discharge criteria as those undergoing procedures in an operating room facility. Many of these procedures have specific anesthetic considerations and well-known complications. The anesthetic techniques used for ESWL procedures have changed dramatically over the past several years. With the development of newer lithotriptors, the water bath is no longer required and targeting is more precise, so fewer shocks are required. These improvements have essentially eliminated the use of general or epidural regional anesthesia, and the majority of these procedures can be performed with IV sedation-analgesic techniques.[482,512,513] These MAC techniques reduce anesthesia and recovery times without compromising patient safety and satisfaction.[514] MAC techniques involving midazolam-alfentanil, midazolam-ketamine, and fentanyl-propofol have been used for ESWL procedures with excellent patient satisfaction.[514,515] In addition, PCA with alfentanil and remifentanil has been described for lithotripsy of gallstones and urinary tract calculi.[516,517] A MAC technique involving midazolam (2 mg), propofol infusion (25 to 50 μg/kg/min), and a continuous infusion of remifentanil (0.025 to 0.15 μg/kg/min) has also been described.[406] Intercostal nerve blocks may improve patient comfort during ESWL. Even electro-acupuncture has been reported to produce sedation-analgesia during an ESWL procedure.[518]

In summary, nonoperating room anesthesia requires anesthesia providers to deliver sedation and anesthesia in a wide variety of venues (including radiology suites, cardiac and neurologic catheterization laboratories, and diagnostic centers) in addition to office-based facilities.[519] Nonoperating room anesthesia claims had a higher severity of inquiry and more substandard

care than operating room claims.[520] Inadequate oxygenation and an inability to adequately ventilate were the most common mechanisms of patient injury. Therefore, maintenance of minimum monitoring standards and airway management training should be required of all staff members involved in the administrations of sedative analgesic medications. When properly conducted, office-based surgery is both safe and highly cost effective.[521]

Magnetic Resonance Imaging

MRI has become an increasingly popular noninvasive radiologic diagnostic procedure because of the high-quality images provided. MRI requires that patients be confined for 30 to 60 minutes in a magnetic, closed noisy space. Because of their age, altered mental state, or pain, some patients cannot fully cooperate for this length of time and require either general anesthesia or intravenous sedation-analgesia to obtain a high-quality image. Patient movement during any part of the examination can compromise the quality of the image. Therefore, anesthesiologists are increasingly becoming involved in patient care for MRI and spectroscopy. Special anesthetic considerations are necessary for MRI because of the high magnetic field and the specialized rooms and buildings for housing the MRI scanners.[522-524] Problems in monitoring patients undergoing MRI include the following:

1. Ferromagnetic equipment must be removed from the magnetic field, including credit cards, key chains, paper clips, pins, and pens, as well as conventional monitoring devices.
2. While in the scanner, access to the patient and viewing of the patient are limited.
3. Malfunction of monitoring equipment or interference produced by the changing magnetic field (e.g., syringe infusion pumps) can occur.
4. Stray radiofrequency current produced by the monitoring equipment can degrade the quality of the images.

These issues make it difficult to achieve an adequate balance between meeting the ASA standards for monitoring during anesthesia and acquiring high-quality images.[522] Newer anesthesia machines and nonferrous pumps and monitoring equipment are available. Because the older monitors may have to be located far from the patient (e.g., outside the room), the chance of disconnection and kinks in the intravenous tubing, anesthesia breathing circuit, and monitoring leads is increased. The ideal situation is to have two anesthesia personnel: one close to the patient and an assistant outside the room with the monitoring equipment. Unfortunately, the personnel costs of this type of arrangement would be higher than most institutions are willing to accept.

Gastroenterology Suite

For many years, endoscopists have used conscious sedation techniques for gastroenterology procedures. Sedation improves not only patient comfort during the examination but also patient acceptance of follow-up examinations. Specific monitoring guidelines and sedation techniques for assisting the endoscopist are available.[525-527] However, situations arise that can benefit from the services of an anesthesiologist, such as endoscopic procedures performed on unruly patients with complex coexisting medical conditions or situations in which previous attempts at performing the procedure using operator-administered sedation were unsuccessful.

An important consideration in the planning of an anesthetic technique is the position of the patient during the examination. Patients undergoing endoscopic procedures are often positioned lateral or prone to facilitate the examination, and these positions may pose difficulty should resuscitative efforts be required due to cardiorespiratory depression. During upper endoscopic procedures or endoscopic retrograde cholangiopancreatography, the endoscope is inserted orally, which necessitates sharing the patient's airway with the endoscopist. Cooperation and a team approach by the endoscopist, the radiology staff, and the anesthesiologist are essential for the safe and expeditious performance of these procedures.

Electroconvulsive Therapy

The use of ECT to provoke a generalized epileptic seizure was first described in 1938 and was performed without anesthesia for almost 30 years. At the present time, the number of ECT procedures performed each year under general anesthesia in the United States exceeds the number of coronary revascularization, appendectomy, and herniorrhaphy procedures. ECT has assumed an increasingly important role in the treatment of acute and medication-resistant chronic depression and mania, as well as the management of schizophrenic patients with affective disorders, suicidal drive, delusional symptoms, vegetative dysregulation, inanition, and catatonic symptoms.[528] ECT is both extremely safe and highly effective in a wide variety of high-risk patient populations. Typically, the acute phase of ECT is performed three times a week for 8 to 12 treatments. Maintenance therapy can be performed at progressively increasing intervals from once a week to once per month.

Anesthetic management for ECT typically involves the use of an induction dose of an intravenous anesthetic (e.g., methohexital, thiopental, etomidate, or propofol), followed by a short-acting muscle relaxant (e.g., succinylcholine or mivacurium).[529] Although the overall recovery profiles are similar with all the intravenous anesthetics, methohexital remains the drug of choice because of longer seizure times (versus propofol), shorter awakening times (versus thiopental), and fewer side effects (versus etomidate). Of interest, patients who received propofol for anesthesia required a longer acute course of ECT.[530] However, if patients are experiencing excessively long seizures (>100 seconds), propofol may be a useful alternative to methohexital.[531] In situations in which the intravenous anesthetic precludes an adequate seizure (<30 seconds), adjunctive use of remifentanil (50 to 100 μg IV) can prolong the seizure duration because it produces an anesthetic-sparing effect[532] and has no direct effect on the ECT-induced seizure duration.[533] A wide variety of cardiovascular drugs (e.g., esmolol, labetalol, nicardipine) are commonly used to minimize the acute hemodynamic changes produced by the electrical stimulus and the resultant seizure activity (Table 78-12).

Standard noninvasive monitors are used during the procedure, and the airway is typically managed with a facemask and reusable airway circuit. An antisialagogue (e.g., glycopyrrolate) is administered to decrease oral secretions, and a Guedel airway device may be used in patients prone to upper airway obstruction (e.g., sleep apnea syndrome, morbid obesity). An LMA is an excellent option for airway management when fitting a facemask is difficult.[534] Tracheal intubation is rarely performed (e.g., late

pregnancy, obese diabetics). The availability of cerebral monitors may improve the ability of anesthesiologists to titrate anesthetic drugs and to optimize the timing of the ECT-induced seizure stimulus in refractory cases.[535,536]

The optimal dosage of anesthetic, muscle relaxant, and sympatholytic drugs requires careful titration to the needs of the individual patient, and further adjustments during the course of a series of ECT treatments should be based on the patient's earlier responses. Although a simple "modal" approach to anesthesia for ECT was advocated by Kellner,[537] patients vary widely in their sensitivity to these drugs, depending on their age, body habitus, concurrent drug therapy, and underlying medical conditions. Given the large number of elderly patients with underlying cardiovascular disease (e.g., hypertension, coronary artery disease, peripheral vascular disease), careful titration of the commonly used sympatholytic drugs (e.g., labetalol, esmolol, nicardipine, clonidine) is also important to maintain hemodynamic stability and obtain the best possible outcome with ECT. Anesthesiologists should be aware of anesthetic factors that influence the duration of seizure activity because the clinical effectiveness of ECT is predicated on achieving an adequate seizure at each treatment session.

Discharge Criteria

Discharge after General Anesthesia and Monitored Anesthesia Care

The three stages of recovery after ambulatory surgery are the early, intermediate, and late recovery phases (see Chapter 85). The early and intermediate recovery stages occur in the ambulatory or office-based surgical facility, whereas late recovery refers to the resumption of normal daily activities and occurs after the patient has been discharged home. Early recovery is the time interval during which patients emerge from anesthesia, recover control of their protective reflexes, and resume early motor activity. During this phase of recovery, patients are cared for in the PACU and day-surgery unit, where their vital signs and oxygen saturation are carefully monitored, and supplemental oxygen, analgesics, or antiemetics can be readily administered if necessary. The modified Aldrete or White score is commonly used to assess the fitness of patients to be transferred to the day-surgery recovery area.[464,538] Ideally, the vast majority of outpatients would complete the early recovery criteria in the operating room and be able to satisfy the White fast-track criteria.[539]

During the intermediate recovery period, patients are usually cared for in a reclining chair and progressively begin to ambulate, drink fluids, void, and prepare for discharge (see Fig. 78-1). The choice of anesthetic technique, as well as the appropriate use of postoperative analgesic and antiemetic drugs, all have an impact on the duration of the intermediate recovery period. Analogous to the use of IV caffeine in the past, a preliminary study[540] suggested that modafinil, a wakefulness promoting drug, could reduce postoperative fatigue and improved alertness in patients recovering from general anesthesia. A prolonged early (emergence) and intermediate recovery can significantly increase the overall cost of the patient's operation. Factors that predict a more prolonged stay in the day-surgery unit include female gender, advanced age, longer operations, large blood loss, use of opioid and nondepolarizing muscle relaxants, episodes of oxygen desaturation, postoperative pain and PONV, and spinal anesthesia.[25,541,542]

The late recovery period starts when the patient is discharged home and continues until complete functional recovery is achieved and the patient is able to resume normal activities of daily living. Although anesthetics, analgesics, and antiemetics can affect the patient's early and intermediate recovery, the surgical procedure itself has the highest impact on late recovery (i.e., the patient's ability to resume normal activities of daily living). Guidelines for safe discharge from an ambulatory surgical facility include stable vital signs, return to baseline orientation, ambulation without dizziness, minimal pain and PONV, and minimal bleeding at the surgical site.[47] The major accreditation bodies in the United States and Canada require that all ambulatory surgical patients receiving sedative and anesthetic drugs have an escort to transport them home, and they must receive written postoperative instructions, including advice on whom to contact if a problem develops in the postdischarge period.

A more objective discharge scoring system has been developed to evaluate and document the patient's readiness for discharge.[541,543] The so-called postanesthetic discharge scoring (PADS) system is a simple cumulative index that measures the patient's home readiness; it is based on five major criteria: (1) vital signs, including blood pressure, heart rate, respiratory rate, and temperature; (2) ambulation and mental status; (3) pain and PONV; (4) surgical bleeding; and (5) fluid intake/output.[538] Patients who achieve a score of 9 or greater and have an adult escort are considered fit for discharge (or "home ready"). The requirement for patients to drink and void before discharge is no longer considered mandatory. A modified postanesthetic discharge scoring system was developed that eliminated input and output as discharge criteria and resulted in earlier discharge for up to 20% of the outpatients studied (Table 78-15).[47]

Delays in discharge are typically related to persistent symptoms such as pain, PONV, hypotension, dizziness, unsteady gait, or the lack of an escort.[543] Excessive postoperative pain and emetic symptoms are the most common causes of delayed discharge from ambulatory surgical facilities and can lead to unexpected hospital admissions.[233] The highest incidence of moderate-to-severe pain occurred in patients undergoing orthopedic, general, and plastic surgery procedures.[373]

Discharge after Regional Anesthesia

Patients recovering from regional anesthesia must meet the same discharge criteria as patients recovering from general anesthesia. However, these outpatients must also fulfill additional criteria to ensure safe ambulation if they were administered a central neuraxis blockade or a major nerve block involving a lower extremity. With spinal or epidural anesthesia, it is generally accepted that motor and sensory function returns before sympathetic nerve function. Residual blockade of the sympathetic nerve supply to the bladder and urethra can cause urinary retention. It is advisable after spinal and epidural anesthesia for outpatients to void before discharge. Therefore, long-acting local anesthetics (e.g., bupivacaine, ropivacaine, tetracaine) should be avoided in the ambulatory setting. The use of shorter-acting local anesthetics (e.g., lidocaine, procaine) with the addition of a potent opioid

Table 78-15 Modified Postanesthesia Discharge Scoring (PADS) System

Vital Signs

analgesic can provide spinal anesthesia without significantly prolonging the time to discharge.[310,313] Before ambulation, patients receiving a central neuraxis block should have normal perianal (S4-5) sensation, have the ability to plantarflex the foot, and have proprioception of the big toe. Discharge criteria after spinal and epidural anesthesia should include the return of normal sensation, muscle strength, and proprioception, as well as the return of sympathetic nervous function.

Controversies Related to Discharge Criteria

There is still controversy regarding the requirement for all outpatients to tolerate fluids and void before discharge from an ambulatory surgical facility. It is clearly unacceptable to discharge a patient who is actively vomiting and unable to tolerate oral fluids. Interestingly, Schreiner and Nicolson[174] found that requiring children to drink before discharge actually increased the incidence of vomiting (>50%) and delayed discharge. On the other hand, children are more likely to vomit after discharge than during their stay at the surgical facility, and, therefore, tolerating clear fluids before discharge may prevent dehydration at home after discharge. At the Children's Hospital of Philadelphia, more than 20,000 day-surgery patients have been discharged home without requiring intake of oral fluids and there have been no readmissions for dehydration.[174] All these children (except those undergoing myringotomy tube placement) received the equivalent of 8 hours of intravenous fluid replacement during their hospital stay. Well-hydrated outpatients can be safely discharged home without demonstrating an ability to tolerate oral fluids after surgery.

The requirement to void before discharge has also been challenged.[544] The inability to void may be caused by pain (which inhibits normal bladder detrusor function) and opioid analgesics, spinal or epidural anesthesia, and anticholinergic drugs.[47] Patients may be discharged earlier if voiding is not a discharge requirement. Delaying discharge for voiding after spinal or epidural anesthesia with short-acting local anesthetics is unnecessary in low-risk patients (e.g., age < 70 years; no hernia, rectal, or urologic surgery; no history of voiding problems).[544] However, appropriate measures must be in place for urinary catheterization if the inability to void persists after discharge home. The use of ultrasound bladder monitoring before discharge may reduce voiding problems after discharge.[544]

Before leaving the outpatient facility, patients should have their dressings checked and be given both verbal and written instructions regarding their postoperative care. Most postoperative symptoms (e.g., pain, PONV, dizziness, headache, and myalgias) resolve within 24 hours. However, if these symptoms persist, the patient should be encouraged to contact the facility regarding appropriate follow-up care. All patients should be discharged from the surgical facility in the company of a responsible adult and should be aware of the recommendations regarding appropriate activities after discharge. Patients should be warned about the potential dangers of operating complex machinery, driving a car, or making important decisions for up to 24 hours after anesthesia.[545] However, when short-acting anesthetic drugs are used for 1- to 2-hour procedures, return of fine motor skills can occur in less than 4 hours.

It is important to have an efficient mechanism in place for admitting outpatients to the hospital if the need arises. Most well-organized outpatient facilities have an unanticipated hospital admission rate of less than 1%.[11,12] However, transfer rates are higher in ambulatory centers with a larger proportion of neonates, elderly (>80 years), and ASA physical status III patients. The Federated Ambulatory Surgery Association multicenter survey suggested that 70% of all perioperative complications occurred after discharge from the ambulatory surgery center.[1] This finding emphasizes the importance of providing clear, written discharge instructions and the availability of a responsible adult to monitor the patient at home. Most practitioners recommend that out-of-town patients spend their first postoperative night within a reasonable distance from the surgical facility. All outpatient facilities should also have a mechanism in place for collecting follow-up information regarding patient well-being after discharge (e.g., telephone interview or postcard questionnaire).

Outcome Measures

As outpatient surgery continues to grow and the types of surgical procedures become more complex, ambulatory surgical centers must develop methods to evaluate patient outcome during both the early and late recovery periods (see Chapter 33).[546] The overall risk of major morbidity and mortality is very low after ambulatory surgery. A large, retrospective study of more than 45,000 ASA I to III outpatients found that only 31 patients (1:1455) experienced major morbidity.[10] Four patients died, 2 as passen-

gers in automobile accidents within the first 48 hours and 2 of myocardial infarctions more than 48 hours after surgery. In a multicenter survey performed in the 1980s involving over 50 freestanding ambulatory centers in the United States, an increased risk of perioperative complications was reported in patients who had preexisting cardiovascular diseases.[1] A four-center prospective study involving 6,914 Canadian outpatients also found that patients with underlying medical conditions (e.g., hypertension, diabetes, and gastrointestinal disorders) were at higher risk for adverse events in the perioperative period.[547] No deaths were reported during the study period, and major morbid events were extremely rare. In a more recent analysis, ASA III outpatients undergoing ambulatory surgery demonstrate no significant difference in unplanned admission rates or complications in the first 24 hours after discharge compared with ASA I and II outpatients.[548]

Although the incidence of major morbidity is extremely low, minor complications remain problematic after ambulatory surgery, in particular, in the postdischarge period. In a survey of anesthesiologists,[549] the clinical anesthesia outcomes that were thought to be most important to avoid in the ambulatory setting were incisional pain, nausea, vomiting, preoperative anxiety, and discomfort from insertion of the intravenous line. One study found that 35% of outpatients discharged from freestanding surgical centers experienced PONV severe enough to prevent their return to normal daily activities.[550] Half these patients had not experienced PONV in the recovery room and became symptomatic only after they were discharged home. Incisional pain, PONV, drowsiness, dizziness, headache, and fever are the most frequent minor symptoms that occur after surgical outpatients are discharged home.[551] The type of surgical procedure clearly influences the occurrence of postdischarge symptoms, with laparoscopic, general, and orthopedic surgical procedures having the highest incidence and minor gynecologic and ophthalmologic procedures having the lowest incidence of postdischarge symptoms. Outpatients experiencing other postdischarge symptoms experienced delays in returning to their usual daily activities. Despite the frequent occurrence of minor morbidity after ambulatory surgery, patient satisfaction is remarkably high and most would choose to have their surgery performed on an outpatient basis in the future.[1]

Delayed discharge and unexpected hospital admission after outpatient surgery are the most commonly identified outcome measures after ambulatory anesthesia (Table 78-16). Not only does hospital admission add to the expense of the procedure, but it is also disruptive for the patient and the surgical facility. Ambulatory surgery facilities should have admission rates of less than 1%.[11-13] Orthopedic (3.2%), general surgery (3.1%), otolaryngology (3.1%), and urology (29%) have the highest rates of unanticipated hospital admissions.[15] However, freestanding and office-based units tend to have lower unanticipated hospital admission rates (<0.1%) because of differences in the types of patients and procedures, as well as the relative ease of admitting outpatients from hospital-based facilities.[12] The most common reasons for unexpected admission are pain, bleeding, intractable vomiting, surgical misadventure (e.g., bowel or uterine perforation), more extensive surgery than expected, urinary retention, or lack of an escort.[11]

The likelihood of an unexpected hospital admission is related more to the type of surgery performed than to specific patient characteristics or the type of anesthetic technique.

Table 78-16 Factors Alleged to Delay Discharge and Lead to Unanticipated Admissions after Ambulatory Surgery

Delayed Discharge

Preoperative

- Female gender
- Increasing age
- Congestive heart failure

Intraoperative

- Long duration of surgery
- General anesthesia
- Spinal anesthesia

Postoperative

- Postoperative nausea and vomiting
- Moderate-to-severe pain
- Excess drowsiness
- No escort

Unanticipated Admissions

Surgical

- Pain
- Bleeding
- Extensive surgery
- Surgical complications
- Abdominal surgery
- Otorhinolaryngology and urology surgery

Anesthesia

- Nausea and vomiting
- Somnolence
- Aspiration

Social

- No escort

Medical

- Diabetes mellitus
- Ischemic heart disease
- Sleep apnea

Modified from Awad IT, Chung F: Factors affecting recovery and discharge following ambulatory surgery. Can J Anaesth 53:858-72, 2006.

The frequency of return hospital visits after discharge from ambulatory units is another useful outcome measure. One early study found that 3% of patients returned to the hospital after discharge after ambulatory surgery,[13] with bleeding at the surgical site accounting for 42% of the patients who requested emergency medical care. Interestingly, patients undergoing varicocelectomy and hydrocelectomy were eight times more likely to return to the hospital. However, 77% of the outpatients who sought medical attention in the emergency department were treated and subsequently discharged home. These findings suggest that better preoperative and postoperative education may have prevented a return visit to the hospital in many of these cases.

Future Perspectives

Advances in anesthetic and surgical practices have facilitated the rapid growth in ambulatory surgery throughout the world.[505] With the availability of rapid, short-acting anesthetic, analgesic, sympatholytic, and muscle relaxant drugs, as well as improved cerebral monitoring techniques, it has been possible to minimize the adverse effects of anesthesia on the recovery process. Improvements in perioperative care has allowed surgeons to perform an increasing array of more invasive surgical procedures on outpatients with complex medical conditions on an ambulatory (day-case) basis.

Major surgical procedures (e.g., extensive knee and shoulder reconstruction, laparoscopically assisted vaginal hysterectomy, gastric fundoplication, nephrectomy, splenectomy, and adrenalectomy) are routinely performed at ambulatory centers. Even patients undergoing carotid endarterectomy, pulmonary lobectomy, prostatectomy, and minor craniectomy procedures are being discharged on a 23-hour admission basis. Although it is commonly assumed that the primary reason for the continued expansion in ambulatory surgery is related to pressure from third-party payers and governmental agencies to reduce health care costs, there may be other less obvious benefits for patients and their families. More aggressive rehabilitation leads to faster recovery of organ function, fewer surgical and anesthetic complications, reduced mental and physical disability, and, most importantly, earlier resumption of normal activities (e.g., return to work). For patients "at risk" for hospital-acquired infections (e.g., immunosuppressed patients), ambulatory surgery may also reduce postoperative infectious complications.

As perioperative physicians, anesthesiologists can play an important role in facilitating ambulatory (and short-stay) surgery by actively becoming involved in the preoperative, intraoperative, and postoperative care of this expanding patient population. To achieve the desired outcome, careful consideration must be given to each phase of the ambulatory surgical process. First, it is important to ensure that all patients are in "optimal" medical condition before their elective operation. Changes in NPO policies[552] have allowed patients to continue taking chronic medications and avoid the uncomfortable symptoms of dehydration, hypoglycemia, and caffeine withdrawal. In addition, oral premedication with preventive analgesics (e.g., NSAIDs, COX-2 inhibitors) can improve pain control during the postoperative period. The use of small doses of sedative-anxiolytic drugs (e.g., midazolam) for premedication has been found to improve the perioperative experience of patients without adversely affecting the early recovery process.

Second, the use of anesthetic techniques that optimize intraoperative surgical conditions while providing for rapid early recovery has assumed increased importance in the current health care environment.[464] The introduction of more rapid- and shorter-acting volatile anesthetics and opioid analgesics has allowed practitioners to improve titration and more consistently achieve a recovery profile that facilitates the "fast-tracking" process. Use of cerebral monitoring can further improve the titration of maintenance anesthetics. However, in spontaneously breathing (nonparalyzed) patients, the value of cerebral monitoring in facilitating the recovery process is limited.[553] Importantly, recent studies confirm that modern general anesthesia causes minimal delayed cognitive impairment.[554] Increasingly, practitioners are turning to MAC as an alternative to both general and spinal anesthesia. The availability of drugs such as propofol, remifentanil, and dexmedetomidine has clearly improved the intraoperative conditions for patients undergoing more extensive surgical procedures with local anesthesia-based techniques.

Third, preventing postoperative pain and other untoward side effects (in particular PONV) is critical to successfully implementing a fast-track program in the ambulatory setting and facilitating earlier resumption of normal activities of daily living.[555] The use of a multimodal approach to preventing postoperative pain will decrease the dependence on opioid analgesics. Importantly, NSAIDs (e.g., ketorolac, diclofenac, COX-2 inhibitors) and other nonopioid analgesics (e.g., local anesthetics, gabapentin, acetaminophen, ketamine, clonidine) have assumed an increasingly important role in controlling pain in the ambulatory setting. Similarly, the routine use of prophylactic antiemetic drugs is also extremely helpful in facilitating the recovery process and improving patient satisfaction. Multimodal strategies for minimizing side effects have assumed even greater importance because of rapid expansion in the variety of surgical procedures performed in the ambulatory setting.[424]

Finally, streamlining the recovery process and providing patients and their families with information on how to avoid problems after discharge will also facilitate the rehabilitation process.[462,505] The importance of discussing the implications of undergoing surgical procedures on an ambulatory basis with the patient and family before the operation will also increase acceptance and patient satisfaction with an early ("fast-track") discharge. As perioperative physicians, anesthesiologists will be required to assume an increasingly important role in minimizing postoperative pathophysiologic changes and facilitating the rehabilitation process. To optimize patient outcome, a care team approach involving the patient, the patient's family, the nursing staff, the surgeon, and the anesthesiologist is essential.[556] It has recently been reported that an anesthesiologist-led management team improved OR efficiency (resulting in a 48% reduction in "gap time" between cases) when defined scheduling policies were supported by surgeons, nurses, and hospital administrators.[557] In addition, the implementation of a multidisciplinary approach to minimizing common postoperative side effects can lead to a reduced recovery room and hospital stay as well as enhanced patient satisfaction after surgery.[558] As more extensive surgical procedures are performed on an ambulatory basis, more innovative "multimodal" approaches to providing postdischarge recovery care will assume increased importance.[7,556]

In summary, ambulatory surgery has become the predominate mode of surgical care delivery in both North America and Europe. However, the benefits of ambulatory anesthesia and surgery are yet to be appreciated in the developing countries around the world. The expanded use of ambulatory surgery has the potential to (1) increase patient access to surgical care in locations remote from major medical centers; (2) reduce surgery "waiting list" at public institutions; (3) provide basic surgical services at a reduced cost to patients, third party payers, and governmental agencies; (4) enhance patient satisfaction with their perioperative experience; (5) allow greater involvement of the patient's family in their postoperative care; and (6) facilitate an earlier resumption of normal activities of daily living, including returning to work. Therefore, the challenge for practitioners in the future will be to facilitate the practice of ambulatory surgery throughout the world to improve health care and optimize the use of increasingly limited healthcare resources.

79 Anesthesia at Remote Locations

Key Points

1. Standards of anesthesia care and patient monitoring do not vary with the anesthetizing location.
2. Open communication between anesthesiologists and physicians working in non–operating room anesthetizing locations is key to efficient and timely provision of anesthetic care to patients in these areas.
3. Anesthesiologists working in areas where radiology equipment is in use need to be knowledgeable regarding radiation safety and take adequate precautions to ensure their own safety.
4. The iodinated contrast media used in the radiology and neuroradiology suites, as well as the cardiac catheterization laboratory, may cause significant adverse reactions, and patients receiving contrast media require close monitoring.
5. The unique nature of the magnetic resonance imaging suite with its powerful magnetic fields mandates special care and training to avoid disastrous adverse events.
6. Provision of quality anesthetic management in the cardiac catheterization laboratory requires an understanding of the patient's underlying condition and the procedure to be performed.
7. Electroconvulsive therapy has profound physiologic effects that must be understood and dealt with by anesthesiologists providing care to patients undergoing such therapy.
8. Provision of anesthesia services in areas where therapeutic radiation is used requires further understanding of radiation safety and is facilitated by the installation of devices to allow remote monitoring of patients under general anesthesia.

Hospital-based anesthesiologists increasingly provide anesthetic care to patients at locations outside the operating suite. Such locations include radiology suites, cardiac catheterization laboratories, and psychiatric units. Care must be provided in these locations because of patient need and the logistic constraints of specialized equipment available only in these areas of the hospital, such as computed tomography (CT) and magnetic resonance imaging (MRI) machines. When providing care at such locations, anesthesiologists must maintain the same high standard of anesthetic care provided in the operating suite.[1] The anesthetizing location must be surveyed by the anesthesiologist to determine whether anesthetic care can be delivered safely in that location before delivery of that care.[2] The requirements for anesthesia and the patient's underlying condition do not vary merely because of location, but the conditions under which the anesthetic care is delivered may vary greatly because of the space and equipment available in these locations. Large, mobile pieces of radiologic equipment, radiation hazards, intense magnetic fields, paramedical personnel not familiar with the anesthesia team, and other factors may make the delivery of quality anesthetic care problematic. Despite the promulgation of detailed guidelines, a recent analysis of closed anesthesia claims demonstrated greater injury severity and more substandard care than seen with operating room closed claims.[3]

Guidelines for anesthetic care delivered outside the operating suite have been developed by the American Society of Anesthesiologists (ASA).[4] The 1994 Guidelines for Non–Operating Room Anesthetizing Locations include recommendations for (1) a reliable oxygen source with backup; (2) a suction source; (3) waste gas scavenging; (4) adequate monitoring equipment to meet the standards for basic anesthetic monitoring and, in addition, a self-inflating hand resuscitator bag; (5) sufficient safe electrical outlets; (6) adequate illumination of the patient and anesthesia machine with battery-powered backup; (7) sufficient space for the anesthesia care team; (8) an emergency cart with a defibrillator, emergency drugs, and other emergency equipment; (9) a means of reliable two-way communication to request assistance; and (10) compliance of the facility with all applicable safety and building codes. It is the responsibility of the anesthesiologist providing care to ensure that the anesthetizing location in which that care is delivered meets all applicable standards.

Monitoring

Appropriate patient monitoring is a universal requirement for delivery of safe anesthetic care (see Chapter 38). The ASA has

developed and published standards for basic anesthetic monitoring requiring that qualified anesthesia personnel be present throughout conduct of the course of anesthesia and that the patient's oxygenation, ventilation, circulation, and temperature be continually evaluated.[5] Provision is made for the absence of anesthetic personnel from the immediate vicinity of the patient if required for safety (i.e., in the presence of radiation hazards), provided that adequate patient monitoring is continued despite the physical separation of the anesthesiologist from the patient. Oxygen concentrations of inspired gas should be monitored with the use of a low-concentration alarm, blood oxygenation should be monitored with pulse oximetry, and ventilation should be monitored by observation of the patient. When present, the position of the endotracheal tube must be verified by observation and by detection of end-tidal carbon dioxide. Continuous end-tidal carbon dioxide analysis should be performed. When mechanical ventilation is used, a disconnect alarm with an audible signal must be present. Circulation is monitored by continuous display of the electrocardiogram, as well as by measurement of arterial blood pressure at a minimal interval of 5 minutes, in addition to other assessments such as auscultation, palpation of pulse, invasive blood pressure monitoring, or oximetry. When changes in body temperature are anticipated or suspected, patient temperature should be assessed.

Facilities and Equipment

Many features of non–operating room anesthetizing locations may render delivery of quality anesthetic care difficult (see Chapter 100). Such features may include an awkward layout from the perspective of the anesthesiologist, unfamiliar anesthetic equipment, the anesthetic implications of the procedure performed, the remoteness of available assistance, and personnel less familiar than the usual personnel in the operating suite with the anesthetic aspects of patient care.

Anesthetizing locations outside the operating suite are frequently designed for their primary role, with provision for the requirements of anesthesia being a seeming afterthought. Access to the patient for anesthetic care is hampered by diagnostic and therapeutic equipment such as C-arms, other angiographic equipment, ultrasound machines, and other devices. Space for anesthesia equipment and drugs may be limited and not conveniently located. Advance planning and communication with involved personnel are key to providing safe anesthetic care to patients in such locations.

Piped-in gases, suction, and isolated power are not always available in non–operating room anesthetizing locations. Anesthesia personnel must be familiar with the gas cylinder supply for anesthesia machines. The machines themselves may be older models relegated from the operating suite to areas where their use is less frequent. The ASA has developed and published "Guidelines for Determining Anesthesia Machine Obsolescence."[6] These guidelines have not been reviewed or approved as a practice parameter, but they are practical, instructive, and worthy of review. Briefly, the anesthesia machine should have essential safety features such as a minimum gas ratio device and oxygen failure alarm, not have unacceptable features such as measured flow vaporizers, and be maintained and serviced. Anesthesia machines that do not meet these standards should not be used in any anesthetizing location. Anesthesia personnel must perform standard machine checks before delivering anesthesia and should be familiar with operation of the machine, which may be quite different from the familiar operating room anesthesia machines. Ideally, familiarization and machine checks should be performed before the procedure. Grounded power outlets are a minimum electrical requirement.

Personnel and Staffing

Nonanesthesia personnel involved in patient care in non–operating room anesthetizing locations, including circulating nurses and radiology technicians (see Chapter 2), are frequently less familiar with the management of patients under anesthesia than their counterparts who care for patients in the operating suite. Consequently, they may be unable to provide the skilled assistance that anesthesia personnel may take for granted in other areas. Open communication between care teams is essential because skilled assistance for the anesthesia care team may be some distance away. Thus, the presence of an adequate number of anesthesia personnel in the immediate vicinity of the care site is vital. Educational programs for personnel in non–operating room anesthetizing locations may be helpful in this regard.

Many procedures in non–operating room anesthetizing locations may be performed with conscious sedation provided by practitioners not specialized in anesthesiology. The ASA has published "Practice Guidelines for Sedation and Anesthesia by Non-Anesthesiologists."[7] Numerous recommendations are provided. Patients must be evaluated before the procedure by qualified personnel to ensure that they are not compromised by coexisting medical conditions, are appropriately fasting, and have given informed consent. During the procedure, the level of consciousness, ventilation, oxygenation, and hemodynamics are to be monitored. The standard monitoring practice discussed earlier should be used. A designated individual, not the person performing the procedure, should be present to monitor the patient and ensure maintenance of an adequate level of sedation and analgesia. This designated individual should be trained to recognize complications of analgesia and sedation, and at least one individual trained in basic life support skills should be present continuously when moderate or deep sedation is used. Supplemental oxygen should be used for moderate and deep sedation, and emergency equipment, including pharmacologic antagonists, should be available. Defibrillators should be on hand for at-risk patients undergoing moderate sedation and for all patients undergoing deep sedation. Adequate recovery care should be provided, with the patient observed in an adequately staffed and equipped recovery area. The patient should be released only when acceptable discharge criteria have been met.

Efficient assignment of anesthesia personnel to multiple locations in the hospital is complex. Many factors come into play, including patient need, requirements for adequate preanesthetic evaluation by personnel working in multiple areas, and minimization of "downtime" during room turnover or waiting for the next patient. Organization of the anesthesia department to provide services both within and outside the operating suite is key to efficient provision of patient care. Specific recommendations for such organization are extremely dependent on the health care system under consideration. Non–operating room anesthetic

locations with predictable high utilization might have full-time assignment of anesthetic personnel. Areas with lower utilization may require block assignments of anesthesia times and centralized scheduling with the anesthesiology group to provide care in a timely, yet efficient manner. Benefits include optimal use of assigned anesthesia personnel and release of personnel who would be underused to areas that would otherwise be understaffed.[8] Additionally, provision of adequate anesthesia personnel to provide necessary services allows growth of these practices, with additional opportunities to benefit patients.[9]

Medications

Anesthesia techniques used in non–operating room anesthetizing locations range from no anesthesia; to minimal, moderate, or deep sedation/analgesia; to general anesthesia. The choice of personnel to deliver the anesthesia care depends on the desired level of anesthesia, the patient's underlying medical condition, and the procedure to be performed. Medications used to provide sedation/analgesia result in a continuum of depth of sedation ranging from anxiolysis to general anesthesia.[7] Sedation/analgesia is defined as the level of anesthesia at which patients are able to tolerate unpleasant procedures through relief of anxiety, discomfort, or pain and at which uncooperative patients are able to tolerate procedures requiring that they not move. Moderate sedation/analgesia is defined as the level of anesthesia at which the patient retains purposeful responses to stimulation, requires no airway intervention, and can maintain adequate ventilation and cardiovascular function. Nonanesthesia personnel may care for patients undergoing procedures that require minimal to moderate sedation/analgesia, provided that they are trained to rescue patients from deep sedation/analgesia. Deeper levels of sedation, general anesthesia, or complex underlying patient conditions require the presence of adequately trained anesthesia personnel. Most procedures conducted in non–operating room anesthetizing locations can be performed under minimal to moderate sedation/analgesia.

Combinations of sedative and analgesic medications, such as benzodiazepines and opioids, provide effective moderate sedation (also see Chapter 78).[7] It is recommended that the drugs be administered individually and the doses carefully titrated to achieve the desired effect in a given patient while recognizing that combinations of sedative and analgesic agents may cause more than additive respiratory depression. Patients receiving intravenous sedation/analgesia should have intravenous access maintained throughout the procedure. Otherwise, the need for intravenous access needs to be individually assessed according to the patient's condition, as well as the procedure planned. When oral agents are used (e.g., benzodiazepines, chloral hydrate), adequate time must be given to allow complete drug uptake before supplementation can be considered. Repeat nonintravenous dosing of sedatives/analgesics is specifically not recommended because of variability in drug absorption. Combinations of benzodiazepines (e.g., midazolam, diazepam) and opiates (e.g., alfentanil or remifentanil) have been the mainstay of intravenous sedation/analgesia. These drugs are titratable, and antagonists are available: flumazenil for antagonism of benzodiazepine-induced sedation and naloxone for antagonism of opiate effects. These antagonists should be reserved for emergency use only because their administration can result in patient discomfort, as well as adverse side effects. The ASA has noted that the use of barbiturates or propofol for analgesia/sedation can result in rapid onset of general anesthesia and that these agents are best reserved for the use of trained anesthesia personnel. Because ketamine may alter the signs of anesthetic depth, as well as cause airway obstruction and pulmonary aspiration, this agent should also be reserved for the use of anesthesia personnel.

Recovery Care

Frequently, anesthesia provided in remote locations requires transport of the patient over longer distances to the recovery location than similar care provided in the operating suite does (also see Chapter 85). The patient must be medically stable before transport. The patient must be accompanied to the recovery area by the individual providing the anesthesia or sedation/analgesia care, and monitoring commensurate with the patient's medical condition must be maintained. Provision of oxygen delivery and monitoring while the patient is on the transport cart may be required. Appropriate recovery facilities and staff must be provided.[7,10] In the recovery area, the patient's condition must be documented and continually assessed. Immediate availability of personnel trained in advanced cardiac life support should be ensured. Patients should not be discharged until they have met specific discharge criteria.

Radiology Suite

Radiologic procedures that may require sedation/analgesia include a number of imaging modalities such as radiology, ultrasonography, CT, and MRI, as well as various interventions that may be directed by the imaging modalities. Such interventions include percutaneous drain placement, nephrostomy tube placement, percutaneous placement of feeding tubes, placement of intravascular access catheters, thrombolysis, dilation of stenotic vessels, embolization of tumors or arteriovenous malformations (AVMs), and many other interventions. Tissue biopsy specimens may be obtained under radiologic guidance with the aforementioned techniques. For example, some solid tumors may be treated by guided tissue ablation.[11] Painful metastases may be treated by guided radiofrequency (RF) ablation.[12] Cerebrovascular lesions may be treated endovascularly with guidance by digital subtraction angiography.[13] Advances in imaging capability, as well as the availability of advanced endovascular devices and RF probes, have increased the use of radiology suites and the demand for anesthesia services in these areas.

General Considerations

In diagnostic and, especially, in therapeutic radiologic procedures, the patient must often remain immobile for prolonged periods. Most procedures may be accomplished with minimal to moderate sedation/analgesia.[14] Cooperative patients may be able to undergo procedures with no or minimal sedation, but obtunded patients or children will require, at a minimum, sedation/analgesia. In

some instances, however, cooperative patients may not tolerate the procedure because of anxiety or claustrophobia. Patients in the radiology suite may have severe underlying medical conditions such as cardiovascular, pulmonary, or neurologic disease. Indeed, they may be in the radiology suite, as opposed to the operating suite, precisely because their severe underlying disease precludes operative intervention. Finally, anesthesiologists may be summoned relatively late in the care episode, after failure of sedation/analgesia administered by the radiologist or nonanesthesia personnel. Clearly, this situation is undesirable, and open communication between the departments of radiology and anesthesiology is essential.

The work environment in the radiology suite is frequently ill adapted to safe anesthetic care of patients. The rooms may be crowded, especially in older radiology suites or those in which anesthesiologists were not consulted during the design phase. Patients and equipment are frequently moved during the procedures to facilitate imaging, and if such movement is not coordinated with the anesthesia team, airway devices or intravascular access may become dislodged, and the patient, or even the anesthesia provider, may be injured. High-voltage equipment or the presence of intense magnetic fields may result in current leakage being conducted to the patient by electrically conductive monitoring leads. Lack of gas scavenging may limit the options of the anesthesiologist should general anesthesia prove necessary for the procedure. Familiarity of the anesthesia personnel with the environment in the anesthetizing location is essential to provide safe patient care.

Radiation Safety

A unique hazard in the radiology suite is radiation exposure (see Chapter 101). Radiation exposure is potentially harmful in terms of its somatic effects during an exposed individual's lifetime (e.g., production of leukemia) and in terms of genetic injury resulting in fetal abnormalities caused by damage to gonadal cells or the developing fetus. In the environment of the radiology suite, anesthesia personnel must be aware of radiation safety and take precautions when possible to avoid radiation exposure. Dosimeters should be worn to monitor exposure. In the United States, the maximal permissible radiation dose for occupationally exposed persons is 50 millisieverts (mSv) annually, a lifetime cumulative dose of 10 mSv × age, and monthly exposure of 0.5 mSv for pregnant women.[15] Radiation exposure can be limited by wearing appropriate lead aprons and thyroid shields, using movable leaded glass screens, and applying innovative techniques such as video monitoring and remote mirroring of monitor data to allow remote conduct of anesthesia when appropriate and required for the safety of anesthesia personnel. Open communication and adequate warning of initiation of imaging by the radiology team allow the anesthesia personnel to take appropriate precautions in a timely fashion.

Iodinated Contrast Media

Iodinated contrast agents are often used in diagnostic and therapeutic radiologic procedures to assist imaging. Soluble contrast agents use iodine (atomic number 53) to absorb x-rays. Older ionized contrast media were hyperosmolar and relatively toxic.[16] Nonionized contrast media feature low osmolality, have improved side effect profiles, and are being used with increasing frequency.[17] Adverse reactions to contrast media range from mild to immediately life threatening, and causes include direct toxicity, idiosyncratic reactions, and allergic reactions, either anaphylactic or anaphylactoid (Table 79-1). Predisposing factors include a history of bronchospasm, history of allergy, underlying cardiac disease, hypovolemia, hematologic disease, renal dysfunction, extremes of age, anxiety, and medications such as β-blockers, aspirin, and nonsteroidal anti-inflammatory drugs.[18] Prompt recognition plus treatment of contrast media reactions is important to prevent progression of less severe reactions and lessen the impact of severe reactions. Treatment is symptomatic, for example, oxygen and bronchodilators to treat bronchospasm. Severe or resistant bronchospasm may require treatment with epinephrine. Typically, corticosteroids and antihistamines are given to symptomatic patients under the assumption that the cause is immunologic. Patients who have had previous reactions to contrast media may benefit from pretreatment with prednisolone, 50 mg 12 and 2 hours before a procedure requiring contrast media, and diphenhydramine, 50 mg immediately before the procedure.[17,19] Protocols should be in place both for treatment of acute contrast media reaction and for prophylaxis in patients with a history of such reactions.

Contrast-induced nephropathy is a significant complication of radiologic procedures and a leading cause of hospital-acquired acute renal failure.[18,20] High-osmolality contrast agents are associated with greater nephrotoxicity than low-osmolality agents are. Most cases of new or worsened renal function related to contrast media are self-limited and resolve within 2 weeks. However, some patients may progress to the point of requiring dialysis. Prevention of renal dysfunction related to contrast media has been based on hydration before, during, and after the procedure and the use of low-osmolality contrast media. Recent studies have demonstrated a reduction in contrast media–related nephrotoxicity by the administration of acetylcysteine[21-23] or ascorbic acid.[24] Life-threatening lactic acidosis may develop in non–insulin-dependent diabetic patients who are receiving metformin and have preexisting renal dysfunction if their renal function declines further.[18,25] Extra care is needed when patients taking metformin receive radiologic contrast media.

Anesthesia in the Radiology Suite

It is obvious from the preceding discussion that delivery of anesthesia care in the radiology suite is not to be undertaken

Table 79-1 Reactions to Iodinated Contrast Media

Mild	Severe	Life Threatening
Nausea, retching	Vomiting	Glottic edema/bronchospasm
Perception of warmth	Rigors	Pulmonary edema
Headache	Feeling faint	Life-threatening arrhythmias
Itchy rash	Chest pain	Cardiac arrest
Mild urticaria	Severe urticaria	Seizures/unconsciousness
	Bronchospasm, dyspnea	
	Chest pain	
	Abdominal pain/diarrhea	
	Arrhythmias	
	Renal failure	

lightly. Ideally, the anesthesiologist should be involved at the earliest possible stage in planning the delivery of such care. Careful communication with radiologists and early consultation with the anesthesiologist will maximize efficient operation of both departments by providing timely, quality anesthetic care and minimizing delays or cancellation of necessary procedures. The development of sedation/analgesia guidelines, as well as training of involved personnel, is an important step in providing quality anesthetic care.[7] Nonanesthesiologist providers of sedation/analgesia who know and understand the guidelines regarding sedation/analgesia become adept at recognizing patients who are at higher risk for either failure of sedation or complications and are thus able to provide more timely notification of appropriate anesthesia personnel that assistance is required.

In the past, much variability was noted in adherence to the modern guidelines regarding provision of anesthesia care, including lack of preoperative evaluation, lack of informed consent, and lack of sufficient dedicated personnel to monitor pediatric and adult patients during sedation/analgesia.[26,27] It would be hoped that increased involvement by anesthesiologists in this arena will improve the delivery of care.

A number of anesthesia techniques are used in the radiology suite. Minimal to moderate sedation/analgesia is the technique used for most patients undergoing these procedures.[14,27] For most adults, combinations of intravenous benzodiazepines and opioids (e.g., titration of midazolam and fentanyl) are sufficient to ensure comfort during the procedure. As noted earlier, the use of more potent anesthetic agents such as propofol, barbiturates, and ketamine is best reserved for specialists in anesthesia.[7] The patient's condition, the anticipated level of stimulation, and patient position during the procedure are all important considerations. As an example, a patient undergoing ultrasound-guided hepatic biopsy might have ascites, which would render that patient prone to aspiration if sedated, and penetration of the hepatic capsule by the biopsy needle would be anticipated to be quite painful. Such a patient might benefit from general anesthesia rather than sedation/analgesia. Procedures that might be anticipated to last several hours may best be performed with general anesthesia at the outset rather than late conversion after failure of sedation/analgesia, when patient access might be limited by catheter placement and radiologic equipment. Certain procedures performed in the radiology suite may necessitate specific anesthetic techniques for maximum patient benefit. It was found that patients undergoing RF ablation of painful osteolytic lesions seem to benefit from continuous regional anesthesia after the procedure, which is usually performed under general anesthesia.[12] The role of regional anesthetic techniques may be expected to grow in nonoperative anesthetizing locations as further advances in treatment modalities occur (also see Chapters 51 and 52).

Pediatric patients merit special consideration (see Chapter 82).[28] Some radiologic procedures require patients to remain still for prolonged periods, which may not be possible for infants and children, even with sedation/analgesia. When it is thought that the procedure can be performed with sedation/analgesia, healthier infants and children frequently receive chloral hydrate orally for radiologic procedures (25 to 50 mg/kg for infants younger than 4 months, 50 mg/kg for older children) (also see Chapter 82). Interventional procedures of longer duration or those that require more dermal punctures than placement of a single intravenous catheter may necessitate more intensive anesthetic regimens ranging from deeper sedation/analgesia to general anesthesia, with or without endotracheal intubation. Additionally, the patient's underlying medical condition may merit more intensive anesthesiology involvement than might otherwise be the case. Children's Hospital Boston has developed criteria to assist radiology nurses carrying out preprocedure evaluations to determine the necessity for anesthesiology referral before the planned procedure. Patient characteristics necessitating anesthesiology referral at that institution include a history of apnea, age younger than 1 month, respiratory compromise, Pierre Robin syndrome, Apert's or Crouzon's syndrome, severe gastroesophageal reflux, poor oral muscle development, sedative/analgesic allergy, new-onset illness, a history of cardiac disease, and mitochondrial or metabolic disease.[29] The development of similar referral triggers at other institutions seems prudent, to provide timely, quality anesthetic care and to avoid unnecessary cancellation or postponement of potentially beneficial procedures. The availability of anesthesia personnel familiar with the pediatric patient plus the availability of equipment for provision of pediatric anesthesia in all areas where pediatric anesthesia may be delivered is essential.

Patients with difficult airways, whether anticipated or not, can be problematic in settings outside the operating suite (also see Chapter 50). It is recommended that anticipated difficult endotracheal intubations be performed in the operating suite because of its greater availability of skilled assistants and specialized equipment. As soon as the airway is controlled, the patient can be transported to the site of the planned procedure, should it be necessary to perform the procedure outside the operating suite. Unanticipated difficult airways can place an anesthesiologist outside the operating suite in a difficult position.

Computed Tomography

CT is commonly used for diagnostic purposes, for example, to evaluate the status of a neoplastic process in the thorax or abdomen. It has proved valuable in studies of vascular malformations and tumors. Caregivers involved in imaging patients undergoing this examination should be mindful that some patients have limited reserve because of their disease process (e.g., compression of the upper airway or vena cava by a neoplastic process). CT is occasionally also used for invasive therapeutic procedures instead of fluoroscopy, such as to visualize drainage of a liver abscess. Contrast media are often used in conjunction with CT to enhance the quality of the image. If contrast media are to be introduced into the gastrointestinal system in patients who are sedated or anesthetized, it is usually done by nasogastric tube. When the airway is not protected in this situation, there is a risk of aspiration. It has also been suggested that the incidence of adverse sequelae associated with the use of contrast media is higher in patients undergoing CT than other types of radiologic studies because of limited access to the patient and consequent compromised monitoring and treatment if reactions do occur.[17]

Issues confronting anesthesiologists requested to anesthetize patients undergoing CT include inaccessibility of the patient during the procedure and control of movement artifact. Monitoring interference is not a problem in CT, however, as it is with MRI, as discussed later. With anesthetized patients, care needs to be taken to ensure that the sides of the scanning tunnel do not occlude or dislodge the breathing circuit or monitoring leads during the procedure. As with other radiographic procedures,

exposure to ionizing radiation occurs during CT scans. The patient can be monitored visually through a lead glass window, supplemented if necessary by closed-circuit television. Should the patient's condition merit closer monitoring by the anesthesiologist, radiation-monitoring badges and protective lead aprons and thyroid shields must be worn.

The anticipated procedure may necessitate special anesthetic techniques. Ablation of bony metastases may be conducted under CT guidance, and continuous postprocedure regional analgesia may be beneficial, as noted previously. Selection of the regional anesthetic technique and timing of placement of the catheter (if a catheter-based technique is selected) are dependent on the patient's condition, as well as the available space and equipment. For example, the CT room is not typically a suitable location for placement of an epidural catheter. If a recovery room or preanesthetic area is available in the radiology suite, it might be a convenient, safe location for placement of a regional anesthetic catheter. If such areas are not conveniently located or sufficiently equipped, these techniques might have to be performed in the operating suite before or after the CT-guided procedure.

Certain pulmonary neoplasms, usually metastases not suitable for surgical resection, are amenable to CT-guided RF ablation.[30,31] These procedures have been performed under both sedation/analgesia and general anesthesia. Reported complications of RF ablation of pulmonary masses include pleural effusion, pneumothorax, pneumonia, acute respiratory failure, and massive hemoptysis.[32,33] It may be desirable that these procedures be performed under general anesthesia. Some of the procedures, depending on perceived risk, have been conducted via one-lung ventilation with the use of double-lumen endotracheal tubes. Whatever the anesthetic method, anesthesia personnel caring for these patients must be vigilant for the occurrence of complications, which are not infrequent.

Magnetic Resonance Imaging

MRI can reveal subtle differences between areas of dissimilar anatomy, physiology, and pathology that are not possible with other imaging techniques. Other advantages include the following:

1. Unlike conventional radiographs and CT, MRI can obtain images in any plane (transverse, sagittal, coronal, or oblique).
2. MRI provides excellent soft tissue contrast.
3. It may provide intravascular contrast without the need for intravenous contrast media.
4. Very little patient preparation is required.
5. MRI does not produce ionizing radiation, is noninvasive, and does not in itself produce biologically deleterious effects.

Principles of MRI

A number of detailed descriptions of the technical aspects of MRI have been published.[34-37] Briefly, atomic nuclei with an odd number of protons or neutrons have the potential to act as magnetic dipoles. This property is possessed by all paramagnetic elements (^{1}H, ^{13}C, ^{19}F, ^{23}Na, and ^{31}P). Biologic tissues have a high water content. Thus, ^{1}H is present in high concentrations, and its detection is the basis of MRI. The single-proton ^{1}H can be understood to behave like a tiny bar magnet with north and south poles. Absent a strong magnetic field, the hydrogen protons are oriented randomly and do not exhibit any net magnetic field. If they are placed in a strong external magnetic field, the hydrogen protons will align themselves parallel or antiparallel to the applied magnetic field, and the tissue itself will exhibit slight net magnetism, with the magnetic vector aligned with the MRI field. This tissue magnetism results from the nuclei that are aligned antiparallel to the external magnetic field; they are in a slightly higher energy state than those aligned parallel to the field. This energy difference increases with the strength of the applied magnetic field. In MRI, tissue magnetized by the powerful static magnetic field is suddenly exposed to a second, transient magnetic field aligned perpendicular to the static field. This second magnetic field is generated by a pulse of RF energy. The RF pulse deflects the magnetic vector of ^{1}H by altering proton alignment. When the transient RF pulse is terminated, the nuclei return to their original alignment within the static magnetic field, which causes a weak transient RF signal as the protons return to their previous energy state. The RF signal emitted by the tissues is detected by an RF coil placed in close proximity to the patient. The intensity of the signals received is plotted in gray scale, and an image is built up by sophisticated computers. The characteristics of decay of the emitted signal, which is called "relaxation," provide most of the information for generating the image. Relaxation time is measured in two ways: T1 relaxation is the time taken to return to the resting magnetic vector, whereas T2 is the time taken to return to resting axial spin. Different tissues demonstrate different relaxation characteristics. Multiple, sequential RF pulses within the static field can thus be used to emphasize particular tissues or abnormalities by taking advantage of the difference in relaxation between tissues.

The magnetic field strength used in MRI scanners is measured in tesla units. One tesla (T) equals 10,000 gauss, with the strength of the earth's magnetic field at its surface being between 0.5 and 1.0 gauss. Field strengths used in most clinical MRI examinations vary from 0.05 to 2.0 T, but the use of 3-T units is increasing, and research units with 8 T or greater are in use.[38] The advantage of weaker-field MRI scanners is that more open construction can be used, and the advantage of scanners with stronger fields is that they produce better image quality. Stronger-field MRI scanners generally use cryogenic magnets with superconductive coils operating in liquid helium (4°K).

Hydrogen proton density and relaxation dynamics as detected by MRI vary in different tissues in accordance with the tissue's physical and chemical properties. Because the differences in water content and proton environment in gray and white matter are greater than the differences in electron densities as measured by CT, MRI can produce better resolution between gray and white matter, and the same is also applicable to soft tissue examinations. MRI permits evaluation of blood flow, cerebrospinal fluid flow, contraction and relaxation of organs, and because calcium does not emit a signal in MRI, images of tissues surrounded by bone. This lack of a calcium signal, however, prevents MRI from detecting pathologic calcification in soft tissue tumors and pathologic changes in cortical bone.[39]

The RF signal used during MRI scanning is of very low intensity and is subject to interference from stray high-frequency

electronic radiation such as FM radio signals and electromagnetic emissions from electronic equipment or monitoring devices.[34] For this reason, the scanning area is enclosed in an RF shield incorporated into the structure of the MRI suite. Preventing interference from monitoring devices situated within the RF shield can be challenging. Attempts have been made to overcome this problem by using isolated power sources or battery power, filtering, enclosing the monitoring device in its own small RF shield, or any combination of these measures. The implications of this problem for the anesthesiologist are obvious.

Limitations and Hazards of MRI

MRI scanning has a number of limitations. Imaging is time consuming, and individual scans may take up to 20 minutes, with an entire examination lasting more than 1 hour. Any patient movement, even that resulting from physiologic motion (e.g., cardiac and vascular flow pulsations, cerebrospinal fluid flow and pulsation, respiratory excursion, and peristalsis in the gastrointestinal tract), can produce artifacts on the image. To optimize information when imaging the cardiovascular system, the signal acquisition is synchronized or "gated" with phases of the cardiac cycle (electrocardiographic [ECG] R wave) to virtually freeze cardiac motion. The magnet generating the large static magnetic field has a small-diameter hollow bore, typically 50 to 65 cm in diameter. Obese patients cannot be examined in this small magnetic bore, and patients otherwise suitable for examination may not tolerate long periods inside the confines of the magnet. Switching the RF generators on and off produces loud noises (>90 dB). Hearing protection is mandatory for both the patient and health care personnel who must be present in the scanning room. Heating resulting from the RF energy of nonferromagnetic prosthetic devices has not proved to be a problem.[40] Body surfaces do absorb this RF energy, but it is unlikely that the patient's temperature will increase by more than 1°C.

Direct adverse biologic effects of the MRI field are not believed to exist. Nonetheless, a number of serious hazards are attributable to the intense magnetic fields necessary for MRI.[41] Although heating of the whole patient is not generally a concern, the potential exists for generation of heat within monitoring wires as a result of electromagnetic induction, circuit resonance, or an "antenna effect." Thermal injury in the area of ECG electrodes and pulse oximeter probes has been reported.[42] Recommendations for avoiding thermal injury include keeping monitoring wires straight (avoid loops), avoiding having conductors touch the patient at more than one location, and inspecting monitor wires before each use to avoid the use of worn or frayed wires.

The most significant risk posed in the MRI suite is the effect of the magnet on ferrous objects.[34,39-42] Dislodgement and malfunction of implanted biologic devices or other objects containing ferromagnetic material are also real possibilities. Such items include shrapnel, vascular clips and shunts, wire spiral endotracheal tubes, pacemakers, automatic implantable cardioverter-defibrillators (ICDs), mechanical heart valves, and implanted biologic pumps. Potential problems with cardiac pacemakers and ICDs include heating of leads by induced current, inhibition of the pacemaker output of rapid pacing, reed switch malfunction, ICD malfunction, or torque on the pacemaker pack.[43,44] Patients with such devices should not undergo MRI examination. Tattoo ink may contain high concentrations of iron oxide. Burns at tattoo sites have been reported after exposure to the magnetic fields of MRI, but such incidents are very rare and the presence of, for example, permanent eyeliner should not exclude the patient from MRI examination.[45,46] Intraocular ferromagnetic foreign bodies may migrate within the MRI field, and MRI examination of patients with suspected ferromagnetic ocular foreign bodies should not be undertaken.[47]

Death from torque of a vascular clip within the MRI field has been reported.[48] Manufacturers of some implantable devices, such as the clips used in vascular surgery and neurosurgery, are now trying to use alloys that have low ferromagnetic properties and are safe in the MRI suite. Clips with low ferromagnetic properties are safe in MRI systems with magnetic fields of 1.5 T or less. MRI systems of up to 3 T, which are increasingly being used, mandate that the clips be nonferrous (e.g., titanium) to avoid movement of the clip within the scanning magnet.[49] Before MRI examination, the radiologist and the surgeon who placed the vascular clip must confer, and a positive determination of the MRI safety of the particular clip implanted in the patient must be made. In the absence of positive knowledge of the exact composition of the clip in question, MRI examination should not be performed.

Although potentially significant, the relatively small movements of implanted ferromagnetic devices and local damage caused by heat generation within lead systems are overshadowed in the popular and medical literature by the large, rapid movements possible when iron-containing items are brought into the vicinity of the magnetic field of the MRI machine. Typical objects include scissors, pens, keys, and gas cylinders. When such objects are brought into the vicinity of the MRI scanner, the intense magnetic field may attract them into the scanner bore at high velocity. The result when a patient is present in the scanner bore may be fatal.[50,51] Even in the absence of a patient, health personnel, maintenance workers, or visitors to the MRI suite might be injured by objects flying at high velocity toward the scanner.[51] For this reason, ferromagnetic items must never be allowed in the vicinity of the MRI magnet.

Because of the numerous, severe hazards related to MRI, recommendations regarding MRI safety have been developed by the American College of Radiology.[41] To summarize, recommendations include the development of formal policies and procedures regarding MRI, which should be present at every MRI site. These policies should be under the direction of formally appointed competent personnel, and review mechanisms should be in place to ensure quality care. Importantly, the recommended policies include restriction of access to the site within the MRI suite. The MRI suite should be divided into four zones. Zone I is the public zone with free access. Zone II is the interface between the public zone and the MRI suite, where all movement by non-MRI personnel is supervised by MRI personnel. Zone III is the area within which the introduction of ferromagnetic objects may form a hazard. Zone II should be separated from zone III by physical restriction (locked doors). MRI personnel are responsible for controlling all movement into zone III by any personnel, including patients, the public, health care workers, maintenance workers, hospital administration, security, and fire department personnel. Note that this restriction specifically includes non–MRI-trained physicians. Zone IV is the scanner room itself, which should be further separated from zone III and clearly marked with lighted signs. Formal training programs are to be put in place for MRI personnel. No one is to be considered "MRI personnel" until they

have completed the formal training program. MRI personnel will screen all non-MRI personnel who request access to zone III and beyond and closely supervise their activities. It is important that anesthesiologists caring for patients understand the restrictions in place on access to the MRI suite and the reasons for these restrictions. Anesthesia personnel who may be called on to provide patient care in the MRI suite should complete the formal training program to become recognized MRI personnel.

Intraoperative MRI

Safety guidelines have been developed for "freestanding" MRI areas. The increasing use of intraoperative MRI complicates this picture further. Not only must the anesthesia team provide anesthesia for a potentially complex surgical procedure, but they must also intermittently provide an MRI-compatible anesthetic during episodes of intraoperative imaging. In addition to radiology and anesthesia personnel, intraoperative use of MRI means that a complete surgical team will also be in the vicinity of the MRI machine. All personnel on these teams must understand the special hazards associated with MRI and must be "MRI qualified." Radiology personnel must continue to monitor all involved staff to ensure compliance with safety guidelines, especially because anesthesia and operating room staff may be distracted by the surgical procedure and not be as cognizant of MRI safety requirements as they would be in a freestanding MRI area. In addition, anesthesia personnel must deal with moving anesthetized patients intraoperatively into the MRI torus, perhaps multiple times. Anesthesiologists must be involved from the beginning in the design of the MRI operating room to ensure that the needs of anesthetized patients can be met safely.[28]

Anesthetic Management for MRI

Patient acceptance of MRI examination is generally high. Most adults and small babies (if recently fed and well wrapped) tolerate the procedure without sedation/analgesia. Sedation/analgesia may be required in older children and adults who cannot cooperate. Sedation/analgesia is usually administered by radiologists and nurses in the MRI suite. This practice generally works well, as long as it conforms to the ASA recommendations for sedation by nonanesthesiologists.[7] The likelihood that a child can undergo the examination successfully under sedation/analgesia is enhanced if the child is deprived of sleep for several hours the previous night. All patients receiving sedation/analgesia need supplemental oxygen and standard monitoring. Anesthesia personnel become involved in these patients' care in the MRI suite when sedation fails, when it is impossible to control patient movement without general anesthesia, and when it is necessary to protect the patient's airway and control ventilation.

Several articles have discussed anesthetic management of patients undergoing MRI.[52-56] As might be inferred from the preceding discussion, provision of anesthesia in the MRI suite poses several unique problems, including the following:

1. Limited patient access and visibility, especially when the patient must be placed head first into the magnet (Fig. 79-1)

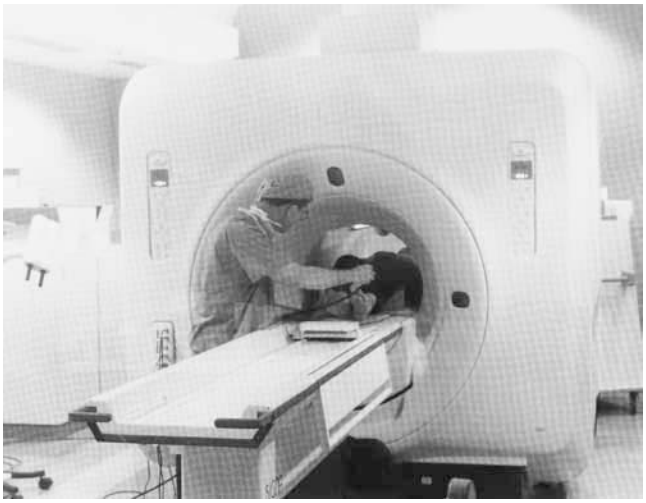

Figure 79-1 View of a magnetic resonance scanner through the window from the control desk. Note the limited patient access. The photograph appears grainy because of the radiofrequency shield embedded in the window. *(From Mackenzie RA, Southorn PA, Stensrud PE: Anesthesia at remote locations.* In *Miller RD* [*ed*]*: Anesthesiology, 5th ed. Philadelphia, Churchill Livingstone, 2000, p 2248.)*

2. Absolute need to exclude ferromagnetic components
3. Interference/malfunction of monitoring equipment produced by the changing magnetic field and RF currents
4. Potential degradation of the imaging caused by the stray RF currents produced by the monitoring equipment and leads
5. The necessity to not move the anesthetic and monitoring equipment when the examination has started to prevent degradation of magnetic field homogeneity
6. Limited access to the MRI suite for emergency personnel in accordance with the recommended policies noted earlier

Anesthesiologists must be involved in the planning and construction of MRI suites, as well as administration of the operation of these suites, to minimize the aforementioned issues. Satisfactory performance of the anesthetic and monitoring equipment and ensuring that this equipment does not interfere with the scanning need to be confirmed before clinical use. A common approach now is to induce anesthesia in an induction area adjacent to the MRI suite outside the magnetic field by using conventional equipment with the patient on a dedicated MRI transport table that is not ferromagnetic. This transport table is then used to bring the patient into the MRI suite, where anesthesia and monitoring are continued with MRI-compatible devices. The MRI transport table is also used to remove the patient rapidly from the scanner should an emergency arise. This is important because the ferromagnetic equipment used for patient resuscitation by the code team and others must never be brought into the MRI scanner room.[41]

Several manufacturers make MRI-compatible anesthetic machines.[56] Various breathing circuits have been used successfully in the MRI suite. They can be used to deliver breaths generated by an MRI-compatible mechanical ventilator or by manual inflation of an anesthesia bag. Because the patient's airway is not

easily accessed during the MRI scan and because patient assessment and communication are limited by both the magnet bore in which the patient is placed and the loud noise associated with MRI scanning, deep sedation/analgesia is not advisable. Patients requiring more than moderate sedation/analgesia are probably most safely administered a general anesthetic with airway control by either endotracheal intubation or a laryngeal mask airway (LMA). Endotracheal tubes and LMAs and their connections to the breathing circuit must contain no ferromagnetic material. Because conventional zinc batteries are strongly ferromagnetic, if a laryngoscope is needed in the MRI suite, it should be of plastic construction and equipped with lithium batteries and aluminum spacers. As noted, most emergency situations in the MRI scan room itself should be treated with basic life support techniques while the patient is rapidly moved out of the scanner vicinity for definitive treatment.

Given the patient's inaccessibility in the MRI scanner, observation of the patient by the anesthesiologist is limited (see Fig. 79-1). Chest excursion will probably be observable, but this is not guaranteed. A peripheral pulse will probably be amenable to palpation, but again, this is not guaranteed. Specific problems and solutions for monitoring each physiologic parameter in the MRI environment can be summarized as follows[52]:

1. Electrocardiography: Voltage induced by blood flow in the aorta when the patient is in a static magnetic field produces T- and ST-wave abnormalities. In addition, the rapidly changing magnetic fields can induce artifacts in the ECG trace. Furthermore, as noted previously, the patient may be subject to heating and thermal injury. ECG wires must be kept straight and contact of the wires with the patient must be minimized.
2. Pulse oximetry: The "antenna effect" in conventional pulse oximetry wires has resulted in thermal injury.[42] Typically, MRI-compatible pulse oximeters use fiberoptic signal linking between the sensor and monitor.
3. Noninvasive blood pressure monitoring: Such monitoring can be successfully accomplished, provided that the connections of the blood pressure cuff and hoses are plastic.
4. Precordial and esophageal stethoscopes: These instruments do not function well because of interference created by the noise of the scanner during operation.
5. Capnography: This monitor usually functions satisfactorily, but the length of the sample tube may cause a significant time delay in signal transduction.
6. Temperature: Temperature monitoring is not generally a problem if temperature probes with RF filters are used.

Meeting all the ASA recommendations for standard monitors in the MRI suite is thus problematic. Pulse oximetry should be used on all patients receiving sedation/analgesia or anesthesia, with the probe placed as far from the scanning site as possible to limit the potential for thermal injury, which still exists despite the use of nonferromagnetic connections.[56] Noninvasive blood pressure monitoring should likewise be used in all anesthetized patients. Capnography should be performed in all applicable cases. ECG monitoring in the MRI scanner should probably be limited to patients deemed to be at particularly high risk, if it is used at all, with precautions taken to limit the potential for thermal injury.[41]

No specific anesthetic technique is required for MRI. Most cooperative patients, as noted, will tolerate MRI with either no sedation or light to moderate sedation/analgesia. MRI is not painful, and the medication regimen may thus be biased toward sedation unless the patient's underlying condition or the long period in the scanner in the supine position requires analgesia. Patients with critical neurologic and cardiac problems, including congenital cardiac conditions, are frequently and safely anesthetized for MRI. Should the patient undergo sedation/analgesia, the anesthesia provider should be present in the scanner room. Hearing protection is mandatory for anesthesia providers if they must remain in the scan room. Critically ill patients, uncooperative adults, and children older than 3 years, who may not respond favorably to chloral hydrate, may best be managed with general anesthesia. Because patient access is limited during the scan, it has been suggested that the airway be secured with either an endotracheal tube or LMA and ventilation controlled. General anesthesia is induced in an induction area adjacent to the MRI room after standard monitors are placed and the airway is secured. Particular care is taken to ensure removal of the ECG electrodes before transfer to the scan room, as well as all other non–MRI-compatible monitoring devices. The patient is then transferred to the adjacent scan room, ventilation is resumed, and function of the airway device is reassessed. Airway disconnection is typically limited to 15 to 30 seconds. Anesthesia can be maintained with volatile anesthetics or propofol. MRI-compatible monitors are placed, and the examination proceeds. It is not mandatory that the anesthesia provider remain in the scan room during general anesthesia, assuming that remote mirroring of the monitors and direct observation of the anesthesia machine are feasible from the immediately adjacent control room. If such observation is not feasible, the anesthesia provider will need to remain in the scanner room with the patient. At the end of the examination, the patient is transferred back to the induction area and awakened there, where conventional monitoring may be resumed and conventional management of any untoward event can take place. At any point in the examination, the patient may be transferred on an emergency basis to the induction area for management of an emergency situation. After emergence from anesthesia, the patient is transferred to an appropriate recovery room and monitored. Patients are discharged when they are documented to have met conventional discharge criteria.

Anesthesia for Interventional Neuroradiology

The advances in interventional neuroradiology over the past 25 years have been remarkable (see Chapter 63).[57] Procedures that were once highly experimental are now routinely performed at many centers. Relatively commonly performed interventional neuroradiologic procedures include embolization of cerebral and dural AVMs, coil embolization of cerebral aneurysms, angioplasty of atherosclerotic lesions, and thrombolysis of acute thromboembolic stroke.[58] Interventional neuroradiologic procedures are sophisticated diagnostic and therapeutic endeavors involving complex manipulation of patient conditions to provide optimal operative outcomes. These procedures may involve deliberate

hypotension, deliberate hypercapnia, or deliberate cerebral ischemia as part of the procedure; a requirement for rapid transition between deep sedation/analgesia and the awake, responsive state; and severe potential procedural complications.[58] Accordingly, involvement of experienced anesthesiologists is valuable to ensure an optimal outcome.

Interventional neuroradiology (or endovascular neurosurgery) is the radiologically guided endovascular approach to lesions of the central nervous system or its related circulatory structures to deliver therapeutic devices or agents.[58] The development of digital subtraction angiography was the basis for growth in this field.[57] By the 1990s, microcatheters suitable for placement in intracranial blood vessels were available, as well as interventional devices such as detachable balloons and coils, and the horizons of interventional neuroradiology began to expand rapidly.[57]

Methods

High-resolution fluoroscopy and digital subtraction angiography are combined to obtain real-time images of the patient's vascular anatomy, through which catheters can be guided. Vascular access for the neuroradiologist is usually obtained through the femoral artery, but the carotid or brachial arteries may be used as well. The site of sheath placement is typically infiltrated with local anesthetic to minimize patient discomfort. Radiologic contrast media are used, with attendant potential complications. It must be noted that digital subtraction angiography delivers greater radiation doses than even fluoroscopy does; attention to radiation safety policies in the neuroradiology suite is therefore essential.[58] Blood pressure may need to be increased or decreased at various points during the procedure to facilitate the intended therapy. When the catheter or catheters have been placed in the vicinity of the lesion, the definitive procedure commences.

Many cerebral aneurysms are amenable to endovascular treatment. Current practice is to embolize the aneurysm with Guglielmi detachable metallic coils.[59] Middle cerebral artery aneurysms are difficult to treat endovascularly. Conversely, aneurysms of the posterior circulation or the cavernous segment of the internal carotid artery are more amenable to embolization. Aneurysms with large necks or large neck-to-aneurysm size ratios are more favorably treated surgically. Aneurysms associated with large intraparenchymal hematomas may be approached surgically to allow concomitant decompression.[59] Patients with unruptured aneurysms may undergo procedures electively or be seen on an emergency basis for repair after rupture with subarachnoid hemorrhage. Patients with subarachnoid hemorrhage may suffer further rupture, hydrocephalus, or cerebral vasospasm.[59-61] Anesthesiologists managing patients during these procedures must be prepared for aneurysm rupture at any time, and tight postprocedural blood pressure control will be essential to reduce the potential for rupture or rerupture after the procedure.[58,59] Rupture of an aneurysm may be treatable with further embolization.

Brain AVMs are another lesion amenable to endovascular therapy.[62] Techniques used to obliterate AVMs include coil embolization, detachable balloons, particulate material, and glue. Frequently, the endovascular approach to intracranial AVMs is combined with a surgical approach, with initial embolization followed by subsequent surgical resection.[63,64] Multiple episodes of embolization are often necessary to limit the occurrence of hemorrhagic complications. Complications of AVM embolization include embolization of foreign material to undesired locations, cerebral edema, and intracranial bleeding.[58] As in the case of rupture of cerebral aneurysms, hemorrhage may be treatable by further embolization.

Intracranial and extracranial vessels with stenotic atherosclerotic lesions have been treated with balloon angioplasty.[58,65,66] Increasingly, patients with extracranial carotid artery stenosis are undergoing carotid angioplasty/stenting rather than conventional carotid endarterectomy. However, at present, indications for selection of carotid angioplasty/stenting over carotid endarterectomy are not clear, and the results of definitive comparative outcome trials remain some years away. A notable feature of carotid angioplasty/stenting is that profound bradydysrhythmias often occur at the time of balloon inflation. Placement of transvenous pacing wires or a pulmonary artery catheter with the ability to accept pacing wires before the procedure may be reasonable in some patients.[58] Movement attributable to external temporary cardiac pacing is undesirable in the face of the ongoing endovascular procedure. Intracranial arterial angioplasty/stenting has been performed, but at this time the procedure remains risky, with complication rates reported to be 12% to 28%.[67,68]

Treatment of acute occlusive stroke, performed in timely fashion, may result in reversal of neurologic deficits. A single, controlled trial has demonstrated improved neurologic outcome after thrombolytic therapy for acute stroke (thrombolysis within 3 hours of the onset of stroke).[69] A meta-analysis of other studies confirmed improved neurologic outcome after prompt thrombolytic treatment of acute stroke.[70] Complications of thrombolytic stroke therapy include low recanalization rates with major occlusion and increased risk for symptomatic intracerebral hemorrhage.[70] Risk factors for complications after thrombolysis of acute stroke include severe hemispheric stroke, extended early infarction signs on preprocedural CT, delay in treatment of more than 3 hours, uncontrolled hypertension, aspirin use, diabetes mellitus, and old age.[71] Current endovascular approaches to ischemic stroke include intra-arterial thrombolytic treatment with tissue plasminogen activator, possibly combined with intravenous administration. Increasingly, thrombolytic therapy is being combined with mechanical disruption or removal of thromboemboli.[70]

Anesthetic Management

Preprocedure anesthetic evaluation is similar to that before neurosurgical procedures. Airway examination is important inasmuch as airway manipulation during the procedure is not possible because of interference with head positioning for imaging. Patients judged to be at special risk for airway compromise might benefit from early securing of the airway and general anesthesia. Particularly important is a history of previous experience with radiologic procedures and any history of contrast media reaction. Because blood pressure management is essential for these procedures, preoperative evaluation for hypertension is important, as is good preoperative control of existing hypertension.

As in other areas outside the operative suite, communication between anesthesiologists and interventional neuroradiologists is essential to ensure optimal patient management. Some

procedures may require awake neurologic assessment during the procedure. Superselective injection of sodium amobarbital into a limited area of the cerebral circulation may be used to assess functional dependence in an awake patient.[72-74] Alternatively, temporary balloon occlusion of vessels that may be embolized may be used to assess functional dependence in an awake patient. Clearly, management of patients during cases involving midprocedure neurologic assessment can be particularly challenging because the patient must remain completely immobile during all critical portions of these long procedures, yet be awake and responsive during neurologic testing. Preoperative training can assist in patient management. Patients who do not require neurologic testing during anesthesia may be managed with either sedation/analgesia or general anesthesia. General anesthesia may provide improved images (less motion artifact), afford better airway control, given the neutral head position required, and facilitate control of blood pressure.[58,65]

Whatever anesthetic technique is selected, standard anesthesia monitoring is established. Two intravenous catheters are placed, one for drug infusions and one for fluid administration and drug boluses. Invasive arterial blood pressure monitoring may be obtained through the side port of the neuroradiologist's introducer sheath, but if postprocedure blood pressure control is considered important, placement of a radial arterial catheter is reasonable for ongoing monitoring. A urinary catheter is placed because of the frequent use of large amounts of radiologic contrast media and administration of osmotic diuretic agents. Careful attention is paid to padding all pressure points to ensure patient comfort and to avoid positioning injury during a potentially long procedure. Sedation may be accomplished with a number of drugs alone or in combination: benzodiazepines, opiates, dexmedetomidine, or propofol. General anesthesia may likewise be accomplished by a number of techniques, from volatile to total intravenous anesthesia, always keeping in mind the desirability of prompt, gentle emergence to allow neurologic evaluation and avoid complications.[58]

Heparin is commonly administered during these procedures, with a target activated clotting time (ACT) of 2 to 2.5 times the baseline value. Deliberate hypotension is frequently used during embolization of AVMs to decrease flow to feeding vessels, as well as during some trial balloon occlusions. Agents such as esmolol, labetalol, or sodium nitroprusside are all useful in this situation. Deliberate hypertension is called for during cerebral ischemia in an attempt to maximize collateral flow. Phenylephrine is generally used, both as a bolus and as an infusion titrated to increase systolic blood pressure 30% to 40% above baseline. Vasopressin may be a superior alternative to phenylephrine in these cases and should be considered. Close monitoring of ECG parameters for signs of myocardial ischemia is critical during induced hypertension, especially in patients likely to have concomitant coronary artery disease (see Chapter 42). Smooth emergence from anesthesia is important because these patients may be prone to migration of the device or intracranial hemorrhage. Administration of antiemetics before emergence is certainly reasonable, and precautions to avoid coughing and "bucking" should be taken.[58]

Anesthetic management of patients undergoing interventional neuroradiologic procedures is challenging. The anesthesia care team must remain vigilant for the occurrence of complications and act decisively and in concert with the procedural team as complications occur.

Interventional Cardiology

Like interventional neuroradiology, interventional cardiology continues to be a rapidly expanding field. Interventional cardiology procedures include coronary angiography and cardiac catheterization, coronary artery angioplasty/stenting, valvotomy, endovascular closure of intracardiac defects, endovascular cardiac valve replacement, electrophysiologic studies with pathway ablation, and cardioversion. These procedures, both diagnostic and therapeutic, may benefit from the involvement of anesthesia personnel in terms of both procedural outcome and patient comfort. Anesthesiologists caring for these patients must be familiar with the patient's medical condition, as well as the planned procedure, to develop a coherent anesthetic plan. Whereas many procedures performed in the cardiac catheterization laboratory may be performed with mild to moderate sedation, others will require advanced anesthetic care and sedated patients may require emergency conversion to general anesthesia because of complications incurred. Consequently, staffing of this area by an anesthesiology group or department must account for potential sudden changes in staffing requirements.

The environment of the cardiac catheterization laboratory is not optimized for anesthetic management. The rooms, like other radiologic procedure rooms, are frequently darkened to allow better visualization of fluoroscopic images, and they are crowded with equipment and personnel. Radiation safety is as much a concern in the cardiac catheterization laboratory as it is in other areas where x-ray devices are used. Like other radiologic suites, the cardiac catheterization laboratory is frequently some distance from the operating suite. It is critical that the requirements for anesthetic equipment and monitoring discussed earlier be met and that the anesthesiologist remain vigilant for rapid changes in the patient's condition, which frequently occur in this distracting environment.

Coronary Angiography and Percutaneous Coronary Intervention

The coronary vasculature may be visualized with the use of radiographic contrast media to allow identification of coronary anatomy, precise determination of the presence and location of coronary artery stenoses, and detection of coronary vasospasm.[75] The American College of Cardiology and the American Heart Association have developed guidelines for the practice of coronary angiography.[76] Although other procedures, such as CT and MRI, may allow determination of the presence of coronary artery disease (and as noted, also possibly require anesthetics administered away from the operating suite), coronary angiography remains the "gold standard" for this diagnosis. In addition, percutaneous coronary intervention (PCI) to improve coronary blood flow may be performed as part of the same procedure.[77] Some patients undergoing diagnostic procedures may be inpatients, but many are outpatients, and the anesthetic plan must take this possibility into account. It is at present controversial whether PCI should be performed in the outpatient setting.

Coronary angiography and cardiac catheterization carry a less than 2% risk of significant complications.[76] Risks include complications related to vascular access, such as hemorrhage, infection, or ischemia; cardiac ischemia in patients with coronary

artery disease; catheter-related complications such as coronary dissection and thromboembolic events (including stroke); and contrast media–related reactions. The risk of significant complications is increased in patients with cardiogenic shock, acute myocardial infarction, unstable angina, renal failure, cardiomyopathy, valvular heart disease, congestive heart failure, hypertension, or inpatient hospital status.[76,78] Very ill, unstable patients considered at high risk of requiring cardiac surgery should be transferred to institutions with immediate cardiac surgical backup available.[76]

Coronary angiography is performed by passing a catheter in retrograde fashion through the arterial tree to the aortic root for the selective injection of contrast media into the ostia of the coronary arteries. Usually, the catheter has been inserted through the femoral artery, but occlusive arterial disease or cardiologist and patient preference may indicate access via the brachial, radial, or ulnar arteries. Increasingly, access is electively gained through the radial artery, with improvement in patient satisfaction and decreased cost.[79,80] Supplemental oxygen is administered, typically by nasal cannula, and standard ASA monitors are used. Arterial blood pressure can be directly transduced from the arterial introducer, and noninvasive blood pressure can be monitored as well. The ECG tracing must be scrutinized and the patient watched closely for the presence of angina or heart failure. Local anesthesia is used at the catheter insertion site to limit patient discomfort related to vascular access. Peripheral intravenous access is necessary for the administration of cardiac medications and sedative/analgesics. The usual anesthesia management is by sedation/analgesia, with general anesthesia reserved for failure of sedation, uncooperative patients, or those who require airway control to manage respiratory failure or other major complications. Anesthetic agents used commonly include fentanyl and midazolam, sometimes supplemented with propofol or dexmedetomidine. Sedation and analgesia are helpful in reducing the discomfort associated with injection of contrast material and remaining motionless and supine during long procedures. Sublingual and intravenous nitroglycerin should be readily available for administration if myocardial ischemia develops, and emergency resuscitation drugs and equipment must be immediately accessible. Heparin is frequently administered, even for diagnostic catheterization, and the effects are often reversed with protamine. Typical heparin doses range from 2500 to 5000 IU intravenously. For interventional procedures, higher heparin doses (i.e., 10,000 IU intravenously) are given, with a target ACT of greater than 300 seconds. Patients must be monitored carefully after protamine administration to detect the predictable peripheral vasodilation, as well as the less predictable anaphylactic and anaphylactoid reactions or the rare catastrophic pulmonary vasoconstrictive crisis associated with protamine administration. Care must also be taken to carefully monitor the patient for reaction to the contrast media. Finally, the patient must be observed closely after the procedure for bleeding or hematoma at the catheter site, as well as for ischemia of the limb distal to the site. Recovery should take place in a fully equipped and staffed recovery area, with the patient discharged only after meeting standard discharge criteria.

Platelet aggregation inhibitors and low-molecular-weight heparin are frequently administered during interventional cardiac catheterization and have resulted in improved outcomes despite the reduction in heparin dose.[81] Platelet aggregation inhibitors used have included abciximab, ticlopidine, and clopidogrel. Numerous studies have shown the benefits of antiplatelet therapy in acute and chronic coronary syndromes.[82-85] A notable side effect of abciximab is elevation of the ACT independent of heparin.[86]

Coronary artery disease is assessed by detection of stenoses after injection of contrast medium selectively into each main coronary artery. Stenoses greater than 50% to 70% of the normal arterial diameter are considered hemodynamically significant, although lesser stenoses may be clinically important. Coronary artery disease is classified as one-, two-, or three-vessel disease or left main coronary disease. An additional cause of myocardial ischemia is coronary arterial spasm. When the patient has typical symptoms without significant atherosclerotic disease at cardiac catheterization, coronary vasospasm should be investigated. Provocative agents, including ergonovine maleate, methylergonovine maleate, or intracoronary acetylcholine, may be given to provoke spasm while contrast medium is injected into the coronary artery. Intracoronary vasodilators such as nitroglycerin may be required when provocative agents are administered. Intracoronary diltiazem may be used to treat resistant vasospasm.[87,88]

When the presence and location of coronary artery stenoses are confirmed, interventional cardiologists can use a variety of methods to improve myocardial blood flow directly. Heparin is administered before the procedure, as noted earlier. Percutaneous transluminal coronary angioplasty (PTCA) involves traversing the stenotic area with a balloon-tipped catheter and compressing the stenosis with the balloon, thereby opening the coronary artery.[89] Transient coronary artery occlusion occurs during balloon inflation, and the patient's hemodynamic status must be monitored closely. Further analgesia may be necessary because angina may develop during this time. The obligate ischemia initially limited the stenotic sites that may be treated with this technique to the distal coronary vasculature and, usually, to one- or two-vessel coronary artery disease. These limitations changed as the technology of angioplasty, coronary stents, and extracorporeal circulation allowed treatment of more severely affected patients in the catheterization laboratory, as discussed later. More recently, PTCA has been supplemented by various techniques that remove rather than compress the atheromatous plaque causing coronary arterial stenosis, as well as by placement of coronary stents to improve long-term patency. Coronary atherectomy may be performed either with atherectomy catheters that "shave" the plaque or with the excimer laser.[90]

During ischemia and frequently during reperfusion after dilation of the stenotic coronary artery, ventricular arrhythmias may develop and require treatment. Hemodynamically significant premature ventricular contractions and nonsustained ventricular tachycardia should be initially treated with amiodarone. More severe arrhythmias may require cardioversion with the patient under general anesthesia. Rupture of the coronary artery may result in hemopericardium and pericardial tamponade. Pericardial tamponade must be treated promptly with emergency pericardiocentesis, typically guided by transthoracic echocardiography, and it may require emergency operative intervention. Another rare complication of PTCA is coronary artery occlusion, which may result from coronary artery dissection, thrombus within the coronary artery, or vascular spasm caused by dysfunctional coronary artery endothelium. Vascular spasm may often be relieved by the injection of 200 μg of nitroglycerin through the coronary artery. Thrombosis of the coronary artery may require multiple therapeutic approaches.[91] Thrombus formation is

retarded by prior administration of heparin. When a thrombus has formed, intracoronary injection of thrombolytic agents, such as urokinase, may dissolve the thrombus. Bleeding complications may result from thrombolytic therapy, especially if the patient requires an emergency surgical procedure. Platelet aggregation inhibitors will probably be administered during stenting, as discussed earlier. Again, bleeding disorders may result and complicate postprocedure care and management during emergency surgery. These patients may require relatively massive autologous platelet transfusions should emergency cardiac surgery be necessary.[92] It should be anticipated that further developments will continue to occur in regulation of the hemostatic system to reduce acute occlusion and chronic reocclusion. Acute coronary occlusion may not respond to transluminal treatment in the catheterization laboratory and may require emergency coronary artery bypass grafting (CABG). The anesthesiologist must be prepared to manage a very unstable patient if this should occur. The patient may have angina, hypotension, and arrhythmias and may benefit from the insertion of an intra-aortic balloon pump. In addition, the patient may require inotropic support and endotracheal intubation. Nitroglycerin is administered in an effort to improve collateral coronary flow and reduce preload. Adequate preload must be ensured, and monitoring of central pressures may be helpful. If the stenotic or dissected area can be traversed with a guidewire, the cardiologist may be able to leave a perfusing catheter in place to allow some coronary blood flow and limit myocardial ischemia pending surgical revascularization.[93] Great care must be taken in transport so that this catheter is not dislodged. Time is critical when the patient requires emergency CABG in this situation. The patient must be expeditiously transported to the operating suite and placed on cardiopulmonary bypass as soon as possible for maximal myocardial salvage. Multidisciplinary examination of institutional systems may result in streamlining of the procedure for rapid transport of the patient to the operating suite, thus improving patient outcomes.[94] Because these patients may be very hemodynamically unstable, their cardiovascular and respiratory status must be monitored. continuously.

Results after PTCA and atherectomy procedures are initially excellent. However, restenosis of the dilated coronary arteries has occurred in as many as 30% to 40% of patients and is due to both neointimal thickening and remodeling.[95] Expandable metallic stents are used to maintain coronary artery patency, with improvement in patency rates. The stents are placed across the area of stenosis after PTCA or atherectomy and remain in place after the procedure.[96] Current research is focused on further reducing the restenosis rate, including the use of novel mechanical strategies, new systemic drugs to inhibit neointimal proliferation, and drug-coated and drug-eluting stents.[97] Anesthesiologists caring for patients undergoing cardiac catheterization laboratory procedures must be aware of the current protocols for pharmacologic regulation of hemostasis and intimal proliferation for the various procedures performed at their institution because they are evolving constantly.

The use of intracoronary radiation therapy to prevent instent restenosis has anesthetic implications. The radiation is believed to prevent neointimal proliferation by breaking DNA strands and hence blocking mitosis.[98] Multiple trials have demonstrated the effectiveness and complication profile of coronary brachytherapy.[99] From an anesthesia perspective, the therapy has a significant implication. Because of concerns of radiation safety, during deployment of the radiation probe, which is otherwise shielded in a lead-lined case, personnel may be required to leave the intracoronary radiation room. Provision for remote monitoring needs to be ensured, similar to that for MRI discussed earlier and similar to the remote monitors for intraoperative radiation therapy (IORT) discussed later.

Patients with acute coronary syndromes benefit from thrombolytic therapy, from antiplatelet therapy, and possibly from PCI to restore myocardial blood flow.[97] Such treatment must be administered rapidly to maximize myocardial viability and reduce morbidity and mortality. Delays in PCI reperfusion of patients with acute coronary syndromes are monitored by the Joint Commission on Accreditation of Health Care Organizations (JCAHO) and the Center for Medicare and Medicaid Services (CMS) as a component of institutional quality assessment. These patients may have full stomachs and may be hemodynamically unstable. General anesthesia has been successful in patients who cannot tolerate the procedure because of pain, anxiety, or dyspnea.[100]

Developments in perfusion technology have increased the portability of temporary ventricular assist devices. Use of these devices maintains hemodynamic stability during procedures that would otherwise result in unacceptable degrees of hemodynamic instability, such as PCI of the left main coronary artery or interventional procedures performed on patients in cardiogenic shock. Currently, this procedure is most frequently performed on patients who are not otherwise candidates for CABG surgery, such as those with unacceptably poor ventricular function or distal coronary artery disease that would preclude CABG.[101,102] However, the use of these devices is expanding to other cardiac catheterization procedures such as complex endocardial and epicardial RF ablation.[103] Extracorporeal circulation is established through the femoral artery or vein (or both, depending on the machine technology used) after induction of general anesthesia and systemic heparinization. Monitoring is the same as for CABG in the operating suite and typically involves placement of arterial and central venous or pulmonary artery catheters. Transesophageal echocardiography is also used for ventricular monitoring, as well as cannula placement. Given the often tenuous nature of these patients' condition, a case can be made for awake placement of these invasive monitors. The induction and maintenance techniques should, of course, take into account the patients' underlying condition. After the procedure, extubation is performed as soon as the patient's condition allows. The anesthetic technique chosen must provide hemodynamic stability and the potential for early extubation. A balanced anesthetic regimen of fentanyl and a volatile agent with neuromuscular blockade provides these conditions. Patients must be closely monitored for bleeding complications because heparinization is frequently continued after the procedure. Platelet aggregation inhibitors are generally administered. Should complications occur in these patients, who are supported by extracorporeal circulation but are not surgical candidates, ethical dilemmas may occur. The possibility of complications and the potential treatment options, or lack thereof, must be clearly understood by the patient and by all medical personnel caring for the patient before undertaking such procedures. Clear and open communication is essential in this setting.

Cardiac Catheterization

Placement of transvenous and transarterial catheters into the heart and great vessels (cardiac catheterization) allows determi-

nation of cardiac anatomy, ventricular function, valvular anatomy, and pulmonary vascular anatomy. Pressure measurements in cardiac chambers and vascular structures may be made with these catheters. Injection of contrast medium allows radiologic visualization of various structures, and injection of an indicator with distal sampling allows determination of flow according to the Fick principle. In addition, blood samples may be withdrawn from various areas for determination of oxygen saturation to detect the presence and location of shunts. Although much (but by no means all) of this information can be obtained with echocardiography, cardiac catheterization remains the "gold standard" for detailed diagnosis of complex cardiac anatomic anomalies. It must be noted that because multiple measurements and samples are necessary for the complete cardiac catheterization procedure, the measurements cannot be performed simultaneously. For the hemodynamic and shunt calculations to be valid, a relatively constant cardiovascular and respiratory state is necessary.[104,105] The arterial pressure of oxygen (Pa_{O_2}) and CO_2 (Pa_{CO_2}) must be "normal" for the patient being studied and must remain so during the measurement periods. The anesthetic techniques used in a given institution should be consistent so that the cardiologist does not have to account for differences in anesthetic techniques when interpreting diagnostic data. These constraints can make anesthetic management of these patients extremely difficult.

Cardiac catheterization in adults is frequently performed in conjunction with coronary angiography. Access to the right side of the heart (pulmonary circulation) is through the venous system and usually involves placement of a catheter in the femoral vein. The left side of the heart (systemic circulation) is accessed as the coronary arteries are accessed, through the brachial, radial, or more commonly, the femoral arteries. Complications related to vascular access are similar to those outlined for coronary angiography. Because catheters are placed within the cardiac chambers, supraventricular and ventricular arrhythmias are common during this procedure. The procedure is usually performed under local anesthesia, but patients benefit from systemic analgesia and sedation. Medications frequently used for this purpose include fentanyl and midazolam, sometimes supplemented with propofol or dexmedetomidine. Oxygen is administered as needed, but care must be taken to maintain "normal" (for the patient) arterial blood gas values if pulmonary hemodynamics is to be measured during the procedure. As with coronary angiography, the anesthesiologist must be prepared to deal with acute hemodynamic and respiratory instability in patients who may have severe valvular and myocardial dysfunction.

Pediatric Cardiac Catheterization

Anesthetic management for cardiac catheterization in pediatric patients can be uniquely challenging (see Chapter 83). These patients range in age from premature neonates to the upper limits of the pediatric age group. Cardiac anomalies vary from relatively simple atrial septal defects to complex congenital cardiac anomalies such as hypoplastic left heart syndrome. Shunts may be present at multiple levels, and patients may be profoundly cyanotic. Ventricular dysfunction may be severe. Patients may also have coexisting noncardiac congenital abnormalities. In addition, these young patients may be uncooperative, and their parents may be severely stressed and thus of limited assistance. Neonatal studies are frequently performed on an emergency basis, and these patients are often deeply cyanotic and critically ill. Diagnosis of the cardiac anomaly is usually made by echocardiography before cardiac catheterization, but determination of surgical treatment or possible catheter-based intervention is dependent on the results of cardiac catheterization.

Anesthetic techniques used in these cases range from sedation and analgesia to general anesthesia. Again, it must be remembered that a "steady state" must be maintained for diagnostic accuracy. In general, older, cooperative patients are readily managed with intravenous sedation and analgesia. Even in cyanotic patients, supplemental oxygen is not administered unless oxygen saturation falls below baseline levels. Care must be taken to maintain ventilation and Pa_{CO_2} within normal physiologic limits to avoid alterations in pulmonary vascular resistance.[106] Medications administered for sedation include fentanyl, midazolam, propofol, and ketamine. Premedication with midazolam, 0.5 mg/kg orally, can be particularly helpful. Some evidence has indicated that ketamine can increase oxygen consumption, so care must be taken to ensure that it does not impair diagnostic accuracy.[107] Even small infants have been sedated in this manner for these procedures.

That said, infants and small children frequently cannot tolerate the procedure under intravenous sedation and are more readily managed with general anesthesia. As with intravenous sedation for these procedures, premedication with oral midazolam, 0.5 mg/kg, can be very helpful. If intravenous access is not present, induction with inhaled nitrous oxide, oxygen, and a volatile anesthetic such as sevoflurane is performed, and intravenous access is obtained after the patient is anesthetized. Alternatively, intravenous induction with thiopental, ketamine, etomidate, or propofol is performed. A nondepolarizing neuromuscular relaxant is administered, and endotracheal intubation is carried out when the patient is fully relaxed. Correct endotracheal tube position is confirmed by end-tidal CO_2 measurement, and position above the carina is readily confirmed with fluoroscopy. Anesthesia is maintained with volatile anesthetics and controlled ventilation with room air, as long as oxygen saturation does not fall below baseline levels. Controlled ventilation avoids the increases in Pa_{CO_2} frequently seen with levels of intravenous sedation adequate to allow performance of this invasive procedure in pediatric patients. Controlled ventilation has not been found to affect the diagnostic accuracy of cardiac catheterization.[104] Minute ventilation and the respiratory rate are adjusted to maintain normal Pa_{CO_2} based on analysis of arterial gases from blood drawn by the cardiologist from the arterial catheter. The end-tidal CO_2 determination can be used to subsequently adjust ventilation, but it must be remembered that physiologic dead space is highly variable in these patients. Infiltration of local anesthetic at vascular access sites limits postprocedure discomfort. Small amounts of an opioid such as fentanyl (i.e., 1 to 2 μg/kg intravenously) or midazolam may be administered to provide postprocedure sedation, thus allowing the patient to remain still and avoid bleeding complications at the femoral vascular access sites. As an alternative to a volatile anesthesia–based technique, the patient can be managed with total intravenous anesthesia using various combinations of opioids, benzodiazepines, propofol, and ketamine.[108-113] Again, steady-state conditions are essential, and the anesthetic plan at any institution should be consistent from patient to patient to provide reproducible patient conditions for the cardiologists and cardiac surgeons who must interpret the diagnostic data.

Close monitoring of these patients is required. Especially in neonates, deterioration can be rapid. These patients may be very sensitive to anesthetics, and hemodynamic instability may ensue. Repeated blood gas analysis is necessary because metabolic acidosis may be the initial sign of a low cardiac output state. Even mild degrees of metabolic acidosis should be treated in critically ill patients, and inotropic therapy may be necessary. Hypocalcemia and hypoglycemia may develop in neonates and require treatment. Hypothermia can be a problem in young patients, especially those under general anesthesia. The room may need to be warmed. In addition, inspired gases may need to be warmed and humidified, and a warming blanket or forced-air warming system should be available. Rectal temperature may need to be monitored in small patients because an esophageal or axillary probe may intrude into the cardiologist's imaging area. Blood loss during the procedure is less well tolerated than in larger patients because the loss may represent a significant fraction of a smaller patient's blood volume. Hematocrit must be monitored carefully and anemia must be treated appropriately. Deeply cyanotic patients tend toward polycythemia as they age, and sufficient fluids must be administered to balance the osmotic effects of contrast media, which could result in hemoconcentration and microembolic events.

Complications of cardiac catheterization include arrhythmias, bleeding at vascular access sites, perforation of cardiac chambers or great vessels by catheters, vascular dissection or hematoma, and embolic phenomena. Arrhythmias are the most frequent complication.[88] Supraventricular tachycardias are the most common and are often related to catheter tip placement, in which case the arrhythmias usually resolve on withdrawal of the catheter. Occasionally, vagal maneuvers, intravenous medication, or cardioversion may be necessary to terminate the arrhythmia. Second- or third-degree heart block may also be seen. Sinus bradycardia may require treatment with atropine. Profound bradycardia may necessitate temporary ventricular pacing if hemodynamic instability results.

Pericardial tamponade can be detected by characteristic hemodynamic alterations, as well as by a widened mediastinum and reduced cardiac motion on fluoroscopy. A definitive diagnosis of tamponade is best made by echocardiography, which is readily available and can be used to guide emergency pericardiocentesis. The pericardiocentesis catheter can cause arrhythmias by mechanical irritation. These arrhythmias can be supraventricular or ventricular, and they may be poorly tolerated in critically ill patients. As with coronary angiography, emergency surgical procedures may be necessary, and hospital systems must allow rapid, safe transport of these patients to the operating suite.

Interventions During Cardiac Catheterization

Balloon atrial septostomy (Rashkind procedure) is performed in infants requiring communication between the pulmonary and systemic circulations for survival (e.g., transposition of the great vessels). A balloon-tipped catheter is placed across the atrial septum. The balloon is inflated to rupture the septum, creating an atrial septal defect and allowing shunting at the atrial level. In the case of transposition of the great vessels, oxygenated blood flowing from the lungs to the left atrium would then mix in the right atrium with venous return blood and flow into the systemic circulation through the right ventricle. Neonates scheduled to undergo this procedure are usually receiving intravenous prostaglandin E_1 to maintain a patent ductus arteriosus. It is critical that this infusion be maintained to keep the ductus patent until the atrial septostomy is complete and is determined to be of adequate size to maintain systemic oxygenation. Anesthesia for the procedure is otherwise as described earlier.

Balloon-tipped catheters have been used to dilate stenotic heart valves and great vessels. The procedure has been performed to dilate congenital pulmonary valvular stenosis,[114] stenotic pulmonary arteries, and aortic coarctation.[115] Balloon valvuloplasty has also been used to ameliorate acquired stenosis of the tricuspid, pulmonary, mitral, and aortic valves.[88] The procedure is generally reserved for patients regarded as very high-risk surgical candidates.[116] During balloon inflation, the circulation is blocked, and severe hypotension may result that because of the tenuous condition of the patient, may not resolve immediately on deflation of the balloon. Inotropic and antiarrhythmic therapy may be necessary, and preload may need to be optimized with intravenous fluid administration. Complications of the procedure are similar to those of cardiac catheterization. In addition, valvular insufficiency may develop.

Older patients usually tolerate this procedure when local anesthetics are infiltrated at the site of catheter entry. Intravenous sedation with fentanyl, midazolam, and propofol attenuates discomfort related to the environment and balloon inflation. When the aortic valve is to be dilated, two intravenous catheters are inserted. Valvuloplasty of other valves requires only a single intravenous catheter. If the patient becomes hemodynamically unstable, the balloon must be deflated immediately. Vagal stimulation can occur with balloon inflation and may require treatment with atropine. Should major complications ensue, prompt surgical intervention may be necessary.

Recent developments have allowed closure of atrial and ventricular septal defects with devices deployed through catheters placed across the defects in the cardiac catheterization laboratory.[97,117] A number of different devices are either in use or being investigated. Teams undertaking such procedures must have plans in place to deal with failure or complications resulting from the procedure.[118] These and similar devices have been used to occlude perivalvular leaks of implanted valve prostheses, and devices to close other abnormal communications, such as ventricular septal defects occurring after myocardial infarction, are under development.[119,120]

Septal ablation for hypertrophic cardiomyopathy may be performed in the cardiac catheterization laboratory. This technique may be performed by septal injection of ethanol or by occlusion of the first septal penetrating artery, a branch of the left anterior descending coronary artery.[121-124] Criteria for selecting patients for transcatheter septal ablation rather than surgical resection are not yet clear. Patients generally tolerate these procedures with sedation/analgesia.

Repair or replacement of defective heart valves in the catheterization laboratory is an exciting recent development. Aortic valve replacement has been performed percutaneously.[125] New techniques to repair valves percutaneously are also in development.[126] Anesthesiologists caring for patients in the cardiac catheterization laboratory must remain abreast of these developments and understand the implications for intraoperative monitoring,

such as invasive lines and transesophageal echocardiography, as well as the anesthetic implications of these developing procedures. Again, timely, preprocedure communication with the cardiologists involved is essential.

Electrophysiologic Studies and Catheter Ablation of Abnormal Conduction Pathways

Electrophysiologic studies involve the placement of special multipolar catheters within cardiac chambers to define the mechanism, origin, and pathways of arrhythmias and to determine the best therapeutic options (see Chapters 34 and 61).[127] Vascular access is usually achieved through the femoral artery and vein, and frequently, additional catheters are placed through the internal jugular vein, with obvious implications for airway management. Programmed electrical stimulation is performed at various locations with the use of standard transvascular catheterization techniques. By using specifically timed electrical impulses, the arrhythmia is reproduced under controlled conditions and monitored through the catheters and the surface ECG leads. Electrical energy delivered through appropriately positioned catheters can then be used to ablate arrhythmogenic foci or accessory pathways. Another intervention that may also be performed in the laboratory is to place the electrodes precisely for subsequent connection to an implantable defibrillator.

Antiarrhythmic drugs are stopped before these studies and are avoided during the procedure because they may prevent detection of the accessory conducting pathways and arrhythmogenic foci. Formerly, these procedures were performed under sedation because the lead technology was exquisitely sensitive to subtle anesthetic drug effects on the conduction pathways. However, improvement in the technology has made this problem less of a concern, and we generally perform the more complex electrophysiology procedures under general anesthesia. It is important to avoid, if possible, the use of drugs that affect the sympathetic nervous system because they affect the ability to map the electrophysiologic pathways. Inotropic support may be required, but this must be discussed with the electrophysiologists, and the procedure may best be performed with temporary ventricular assist device support, as discussed earlier.

Pacemaker and Cardioverter-Defibrillator Implantation

Permanent pacemakers and ICDs are frequently implanted in the cardiac catheterization laboratory (also see Chapter 43). Implantation of both devices involves placement of transvenous leads into the cardiac chambers (usually the right atrium or ventricle or both) with tunneling of the leads to a subcutaneous pocket in which the device is placed. Many of these procedures are performed with sedation/analgesia. General anesthesia is necessary during testing of the ICD. When the ICD is tested, ventricular tachycardia or fibrillation is induced, and the ability of the device to sense the arrhythmia and deliver appropriate cardioversion-defibrillation energy is confirmed. Many patients undergoing ICD placement have poor ventricular function. Return of hemodynamic variables to baseline after cardioversion-defibrillation must be closely monitored. In addition to placement of devices, obsolete, malfunctioning, or infected pacemaker or ICD leads (or both) may need to be removed. Pacemaker or ICD lead extraction is not to be taken lightly.[128] Major complications are rare, but complications such as rupture of the superior vena cava, right atrium, or right ventricle obviously require prompt intervention. Additionally, severe tricuspid regurgitation may result from removal of right ventricular leads adherent to the valvular or subvalvular apparatus, but it generally requires less acute intervention. Leads in place for longer than 1 year may have extensive fibrosis, which may make removal difficult. Placement of additional leads may result in additional fibrosis and eventually lead to vascular occlusion. Therefore, lead extraction before replacement may be beneficial. Clearly, infected leads require extraction. Powered telescoping sheaths, which detach the leads from fibrotic attachments by means of lasers or mechanical means, have improved the ability to remove stubborn leads.

Elective Cardioversion

Cardioversion is used to convert supraventricular and ventricular arrhythmias to sinus rhythm by delivery of synchronized direct-current electric shock. Current evidence indicates that biphasic shock delivery is superior to the damped sinusoidal current formerly used.[129] When these arrhythmias are not causing hemodynamic instability or when the arrhythmia is of long-standing duration and has not responded to drug therapy, cardioversion can be performed on an elective and possibly an outpatient basis. The patient's cardiovascular status and medical therapy are optimized before elective cardioversion. In contrast, emergency cardioversion is often required when the arrhythmia causes hemodynamic instability and when time pressure and the patient's condition may not allow full evaluation or administration of anesthesia.

Elective cardioversion is uncomfortable, and general anesthesia is required. Many medications have been used, including barbiturates, propofol, etomidate, opiates, and benzodiazepines.[130-133] In the case of chronic atrial fibrillation, echocardiography is performed before cardioversion to rule out the presence of left atrial thrombi, which could cause stroke. Standard monitoring is used, and standards for the availability of equipment must be observed. When all is in readiness for cardioversion, the patient is preoxygenated and then given small incremental doses of anesthetic until the eyelid reflex is abolished. Immediately before the countershock, the mask is removed, and it is confirmed that no person is touching the patient or cart. More than one shock may be required to restore sinus rhythm, and it is important to keep the patient anesthetized until the procedure is successful or the attempt is terminated. After cardioversion, the patient is ventilated with 100% oxygen until consciousness is regained and the patient is able to maintain the airway. It should be noted that muscle relaxants are not typically needed for this procedure. If cardioversion is required on an urgent basis, it must be remembered that the patient may not have been fasting before the procedure. To prevent aspiration during anesthesia in this situation, it is appropriate to intubate the trachea with a rapid-sequence induction technique involving the use of cricoid pressure.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) was introduced in the 1930s as a treatment of schizophrenia. Although use of this therapy declined through the 1970s because of negative publicity, acceptance and use of ECT have again increased. Current acceptance of this procedure is in part due to the use of general anesthesia to reduce the physical and psychological trauma associated with ECT. Indications for ECT include major depression, mania, certain forms of schizophrenia, and perhaps Parkinson's syndrome.[134] Pheochromocytoma is a contraindication to ECT. Relative contraindications include increased intracranial pressure, recent cerebrovascular accident, cardiovascular conduction defects, high-risk pregnancy, and aortic and cerebral aneurysms.[135,136] In these conditions, the risk of the patient's psychiatric illness and the side effects of antidepressant medications must be weighed against the risk associated with ECT and anesthesia.

ECT consists of programmed electrical stimulation of the central nervous system to initiate seizure activity. The precise mechanism of the therapeutic effect of ECT remains unknown despite increasing research in this area.[137] After induction of general anesthesia and muscle relaxation to prevent traumatic injury during generalized seizure activity, two stimulus electrodes are applied to the patient's scalp. A series of programmed electrical pulses at precise energy levels are then delivered to induce a generalized seizure. The energy level selected for a given patient is based on an initial titration of stimulus dosage. The seizure is monitored both by observation of the patient and by an electroencephalogram on the ECT machine. Seizure duration is recorded. Treatment efficacy was believed to be related to a minimum seizure duration of 25 seconds and to the total seizure duration over the course of treatment, but this is no longer thought to be the case.[138] However, the efficacy of the treatment does depend on a seizure occurring. Delivery of energy is thus minimized and tailored to the condition of each patient. Treatments continue two to three times per week until either improvement is seen or the treatment is deemed unsuccessful. Successful treatment may be supported by continuation of ECT at weekly to monthly intervals for up to 6 months and by similar maintenance ECT continuing more than 6 months past initiation of treatment.[134]

Physiologic Effects

Direct brain effects of the stimulus and seizure include large increases in cerebral blood flow and intracranial pressure.[139] Seizure activity causes an initial parasympathetic discharge manifested by bradycardia, occasional asystole, premature atrial and ventricular contractions, or a combination of these abnormalities. Hypotension and salivation may be noted. The parasympathetic discharge is followed immediately by sympathetic discharge associated with tachycardia, hypertension, premature ventricular contractions, and rarely, ventricular tachycardia. The tachycardia peaks at 2 minutes after the stimulus and is normally self-limited.[140] ECG changes, including ST-segment depression and T-wave inversion, may also be seen after ECT without any of the myocardial enzyme changes consistent with myocardial infarction. These ECG changes are presumed to be secondary to the sympathetic discharge.[141,142] The arrhythmias associated with ECT, even in patients with preexisting arrhythmias, are self-limited and not in themselves a contraindication to treatment. ECT has been found to be relatively safe even in high-risk cardiac patients, if careful management is provided.[143,144]

Norepinephrine and epinephrine increase immediately after ECT, and epinephrine levels decrease more rapidly thereafter. Glucose homeostasis is variably affected by ECT. Improvement in control of non–insulin-dependent diabetes is generally noted, whereas hyperglycemia may be seen when the diabetes is insulin dependent. A single report noted hyperglycemia in a patient with no previous history of diabetes.[145]

Antidepressant Drug Therapy

Most patients scheduled to undergo ECT are receiving tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), serotonin reuptake inhibitors, lithium carbonate, or a combination of these drugs. Tricyclic antidepressants block the reuptake of norepinephrine, serotonin, and dopamine into presynaptic nerve terminals, thereby increasing central sympathetic tone.[146] Tricyclic antidepressants have antihistaminic, anticholinergic, and sedative properties and also slow cardiac conduction. These side effects are less common with the newer types of antidepressant drugs such as trazodone, bupropion, and fluoxetine.[147] The combination of centrally acting anticholinergics, such as atropine, with tricyclic antidepressants can increase postprocedure delirium.[148]

MAOIs inhibit monoamine oxidase by irreversibly combining with it to form a stable complex, thereby blocking the metabolism of norepinephrine, serotonin, and dopamine. The use of indirectly acting sympathomimetics in patients receiving MAOIs can result in hypertensive crises.[146] An exaggerated response to direct-acting sympathomimetics may also be seen. Hypotension in these patients should be treated with reduced doses of direct-acting sympathomimetic agents. MAOIs can inhibit hepatic microsomal enzymes. They may interact with opioid analgesics and cause excessive depression. Used concomitantly with meperidine, MAOIs may result in severe, possibly fatal excitatory phenomena.[149]

Lithium carbonate prolongs the action of neuromuscular blocking drugs (see Chapter 29).[150] Elevated lithium levels, higher than the therapeutic range, can prolong the action of benzodiazepines and barbiturates. Patients receiving lithium may demonstrate more cognitive side effects after ECT. The American Psychiatric Association recommends discontinuation of lithium therapy before ECT.[151]

Anesthetic Management of Electroconvulsive Therapy

Anesthesia for ECT has been the subject of recent reviews.[140,151,152] Anesthesia and neuromuscular blockade are necessary during ECT to prevent psychological and physical trauma. Rapid recovery is desirable. Careful preoperative evaluation is necessary, with particular attention paid to coexisting neurologic and cardiac disease, osteoporosis and other causes of bone fragility, and medications that the patient may be receiving. The patient may be a poor historian because of the psychiatric condition, and accom-

panying caregivers may need to provide the necessary history and assurance of fasting status. Standard monitors are used. Pretreatment with glycopyrrolate (0.2 mg intravenously), which does not cross the blood-brain barrier, can reduce the occurrence of bradycardia and the amount of oral secretions associated with ECT, as discussed later. After preoxygenation, anesthesia is administered by peripheral intravenous catheter, and neuromuscular blockade is induced. When relaxation is adequate and satisfactory mask ventilation with oxygen is ensured, a bite block is placed and a stimulus is delivered to induce the seizure. If the patient has a hiatal hernia and gastroesophageal reflux, or in the case of ECT for a pregnant patient, rapid-sequence induction and endotracheal intubation with cricoid pressure may be a reasonable approach. Adequate ventilation is ensured during the procedure. The peripheral seizure is monitored by patient observation, as well as by electromyography, and the central seizure is monitored by electroencephalography. It must be remembered that the duration of the central seizure may outlast peripheral clonic manifestations; this is monitored by the electroencephalogram. A blood pressure cuff inflated to isolate a limb before administration of a neuromuscular blocker can assist in monitoring the peripheral seizure. In patients undergoing their initial ECT treatment, more than one stimulus may be necessary because of titration of the stimulus, and additional anesthetic or neuromuscular blocking drug (or both) may need to be administered. After the procedure, ventilation with oxygen by mask is continued until the patient awakens and is breathing adequately. During this time, tachycardia and hypertension, if persistent or of hazardous magnitude, may require treatment. The patient should be monitored in a fully staffed and well-equipped recovery area after the procedure until specific discharge criteria are met, the same discharge criteria for any patient who has undergone general anesthesia. Some patients demonstrate significant oxygen desaturation after ECT, and oxygen should be given by nasal cannula until the patient is fully awake.[153]

Many intravenous anesthetics have been used to induce anesthesia for ECT, including methohexital, thiopental, propofol, and ketamine. Methohexital (0.75 to 1.0 mg/kg) is the most commonly used drug for ECT anesthesia and is considered the "gold standard."[152] Propofol (0.75 mg/kg) was found to reduce seizure duration, which was believed to decrease the efficacy of ECT. However, more recent studies have demonstrated no difference in outcome with propofol versus methohexital.[154-156] Administration of methohexital, as well as propofol, is associated with pain on injection, which may be poorly tolerated by psychiatrically fragile patients. The use of thiopental (1.5 to 2.5 mg/kg) avoids pain on injection, but it is associated with more hypertension and tachycardia than propofol is.[157] Etomidate may prolong seizures and recovery, but prolongation of the seizure may be useful in patients in whom seizures are difficult to elicit or whose seizure duration is deemed too short with other agents.[158] Benzodiazepines have anticonvulsant activity and should be avoided before ECT.[152] Ketamine has been demonstrated to not increase seizure length or produce excessive postprocedure agitation.[159] Given the hemodynamic response expected after ECT, ketamine would seem to be a less desirable agent.[140,152]

Volatile anesthetics have been used for ECT and may be helpful in treating patients in whom placement of an intravenous line is difficult because of patient resistance or poor peripheral veins. Sevoflurane has been studied, and although its use is more time consuming in terms of induction and recovery times, patient outcomes were similar to those of patients who received thiopental.[140,160] Use of sevoflurane obviously requires an anesthesia machine and waste gas scavenging.[152] Various opioids, used as adjuncts to the anesthesia induction regimen, have been studied in patients receiving ECT. The newer, short-acting opioid remifentanil has received the most recent interest. In a study comparing remifentanil, 1 μg/kg, plus methohexital with methohexital alone, no difference was found except for longer seizure duration in the methohexital group.[161] Remifentanil may be a useful adjunct in patients in whom seizures are difficult to elicit or in whom seizure duration is deemed too short.[140] That is, use of remifentanil with a barbiturate may be an alternative to use of etomidate in such patients.

Complete neuromuscular blockade is not necessary for ECT and may not be desirable because monitoring of peripheral seizure duration would be impeded. Partial neuromuscular blockade is necessary, however, to reduce the peripheral manifestations of the seizure and to prevent musculoskeletal trauma to the patient. More complete neuromuscular blockade may be accepted for high-risk patients who may be more likely to suffer fractures if the degree of neuromuscular blockade is overestimated. Succinylcholine has been used most frequently for neuromuscular blockade during ECT because of its short duration of action and low frequency of side effects. An initial dose of 0.5 mg/kg is administered and adjusted for subsequent treatments according to the patient's response. Use of a peripheral nerve stimulator to assess the degree of neuromuscular blockade before the seizure may be useful. Mivacurium has been suggested as an alternative to succinylcholine, but it may not be as effective as succinylcholine in preventing tonic-clonic muscle contractions, which could result in traumatic injury to the patient.[162,163] Mivacurium also necessitates prolonged postprocedure ventilatory support, thus increasing anesthetic requirements and costs.[164] Both succinylcholine and mivacurium are metabolized by plasma cholinesterase, and alternative nondepolarizing muscle relaxants such as atracurium or cisatracurium may be required in patients with pseudocholinesterase deficiency. Relatively prolonged neuromuscular blockade may need to be accepted in such patients to avoid trauma from the seizure. When these nondepolarizing agents are used, the neuromuscular blockade is routinely reversed after the treatment.[140]

Prophylactic medications have been advocated to avoid various side effects of ECT. Transient asystole secondary to parasympathetic discharge during delivery of the stimulus is rare during ECT, but it may be prevented with anticholinergic pretreatment. Glycopyrrolate is preferred over atropine because it produces less tachycardia after ECT.[140] In addition, glycopyrrolate is an effective antisialagogue. Both esmolol and labetalol have been successfully used to control hypertension and tachycardia after ECT.[165] Some evidence has shown that esmolol reduces seizure duration.[166,167] Routine treatment with esmolol or labetalol is not recommended because the hypertension and tachycardia are usually self-limited, as are premature ventricular contractions. Should treatment be necessary, these drugs can be administered immediately after the stimulus.[152] Use of labetalol has not been found to increase orthostatic hypotension during the recovery period.[168]

The anesthetics and neuromuscular blocking drugs administered to each patient should, as in other anesthetic procedures, be accurately recorded. Such recording is especially important with ECT because the treatment is repeated over a period of

several weeks to months and consistent patient conditions must be provided along with a predictable response to the ECT stimulus. Moreover, patients' responses to previous treatment, such as the development of arrhythmias or agitation, and to the additional medications that were required, such as β-antagonists or benzodiazepines, should be noted so that extra precautions can be taken during subsequent treatments. Proper anesthetic care allows safe administration of ECT in patients with multiple coexisting medical conditions, even in very elderly patients.[169]

Therapeutic Radiation

Intraoperative Radiation Therapy

IORT is the delivery of radiation during exposure of a tumor or tumor bed during an operative procedure. In its broadest sense, IORT includes brachytherapy with temporary or permanent implantation of radioactive seeds.[170] Radiation therapy plays a major role in the management of many malignant diseases. The usual method by which radiation is delivered is external beam treatment with high-energy photons. The external beam doses required to achieve local tumor control can exceed the radiation tolerance of some normal organs and other structures of the body.[171] IORT can be effectively used as a supplemental boost to external beam treatments. By delivering the radiation therapy during surgery, it is possible to remove normal structures from the radiation beam or to shield them with lead.[172]

This method of treatment is appealing, particularly for locally advanced malignant lesions when conventional modalities are unlikely to produce local tumor control. Theoretical advantages over conventional external radiotherapy are the ability to increase the tumor dose with less damage to adjacent healthy tissues and more accurate localization of the radiation field. Disadvantages of this technique are that an operation is needed, optimal dose combinations of external beam radiation and IORT are complex to calculate,[170] and complications are not infrequent. Complications include pain, nausea and vomiting, bowel dysfunction, ureteral obstruction, neuropathy, abscesses, and delayed wound healing.[173] Tumors treated with IORT have included locally advanced colorectal cancer, retroperitoneal sarcomas, limb sarcomas, gynecologic malignancies, and pediatric malignancies.[173-177]

Most of the advances in the use of radiation have been achieved by an improved dose distribution and better differentiation of the dose delivered to the tumor relative to normal tissue. Delivering the radiation during the surgical procedure permits direct observation of tumor size and density and the tissues at risk for microscopic spread of tumor. Patient selection for IORT should include no contraindications to surgery and the belief that surgical intervention alone will not result in local tumor control. The tumor should be a localized focus of disease, and no distant metastasis should be apparent.[170] IORT is seen as potentially curative.[178]

Ideally, anesthesia, incision, radiation delivery, and closure occur in a single dedicated IORT room. Alternatively, induction of anesthesia, surgical incision, and tumor isolation can be accomplished in a modified operating room within the radiation oncology area.[179] This alternative allows the linear accelerator room to be used without interruption for treating other patients while the patient who is to undergo IORT is being prepared. After preparation, the anesthetized and surgically draped patient is transported a short distance to the accelerator treatment room. Once radiation treatment is completed, the patient is returned to the modified operating room for closure of the incision. This situation would be subject to the limitations of all procedures requiring anesthesia in non–operating room settings.

Patients typically receive a conventional general anesthetic regimen with endotracheal intubation. Particular attention must be paid to the preoperative evaluation of these cancer patients, who may demonstrate anemia, cachexia, depression, and side effects of chemotherapy and external radiation treatments.[180] Standard monitors are used, as well as additional monitors as dictated by the patient's condition and the surgical procedure planned. Adequate intravenous access for a potentially major operation is necessary. After surgical incision and exploration, the tumor is exposed and isolated. A sterile Lucite cylinder is then inserted to cover the tumor mass, define the radiation beam, and displace normal structures outwardly circumferentially around its perimeter (Fig. 79-2). Radiation therapy may then be focused directly on the isolated tumor.

Throughout the actual radiation treatment period, all personnel must leave the treatment room to avoid high radiation exposure, and the patient, anesthesia equipment, and monitors are observed continuously by closed-circuit television (Fig. 79-3). After treatment, the patient is transported to the recovery room.

External Beam Radiotherapy for Cancer in Children

Optimal treatment of children with cancer often requires combined-modality therapy incorporating chemotherapy, surgery, and radiotherapy (see Chapter 82). Chemotherapy alone is not always sufficient to cure childhood solid tumors; either resection or radiation may be needed for local tumor control.[181] Children with radiosensitive malignant tumors typically require radiation therapy for a number of sessions over a period of several weeks. Although the treatments are painless, young children cannot be depended on to remain absolutely motionless in the strange and frightening surroundings of radiation therapy rooms. Because immobility during treatment is mandatory, sedation/analgesia or general anesthesia is usually necessary.[182]

Anesthetic regimens for external beam radiation in children should provide brief periods of anesthesia at a depth that ensures immobility and minimal time to recovery.[182] Airway management should be appropriate to whatever body position the patient requires for the radiation therapy. Because all personnel must leave the room during actual delivery of the radiation, the anesthetic technique should facilitate remote monitoring for continuous assessment of the patient. During the actual radiation treatment period, the patient and anesthesia equipment are observed continuously by closed-circuit television, and monitors are mirrored to the remote observation site outside the treatment room.

Typically, patients require a series of treatments and hence a series of anesthetic regimens. It is therefore desirable to avoid repeated invasive procedures to the degree feasible and to keep the anesthesia technique as simple as possible. The LMA has

Figure 79-2 Intraoperative radiation therapy room. A sterile Lucite cylinder is used to isolate the tumor mass and displace normal tissues to limit the radiation dose. *(From Mackenzie RA, Southorn PA, Stensrud PE: Anesthesia at remote locations.* In *Miller RD* [*ed*]*: Anesthesiology, 5th ed. Philadelphia, Churchill Livingstone, 2000, p 2261.)*

Figure 79-3 The patient and anesthetic monitors are viewed on closed-circuit television during an intraoperative radiation procedure. *(From Mackenzie RA, Southorn PA, Stensrud PE: Anesthesia at remote locations.* In *Miller RD* [*ed*]*: Anesthesiology, 5th ed. Philadelphia, Churchill Livingstone, 2000, p 2262.)*

proved to be a simple and safe airway device for use in children undergoing general anesthesia for external beam irradiation.[183,184] Intravenous propofol infusion has been used satisfactorily in these children.[182,185,186] If the patient does not have an intracranial mass lesion, intramuscular administration of ketamine has provided satisfactory conditions.[187] However, excessive salivation and postoperative nausea and vomiting make ketamine a less desirable alternative. Given the frequent need for repeated treatments over a period of days or weeks, intravenous access may become difficult. Placement of a peripherally inserted central catheter may provide ongoing intravenous access.[188,189] Repeated access of the central line can be accomplished without undue risk of line-related sepsis, provided that access protocols are scrupulously followed.[182]

Stereotactic Radiosurgery

Stereotactic radiosurgery is the delivery of a large radiation dose to ablate tissue localized stereotactically.[190] Sources of ionizing radiation include photon beams produced by either ^{60}Co gamma ray or linear accelerators and heavy-ion particle beams. The radiation is emitted as multiple beams that can be focused on the desired site. The radiation dose from each beam is small to limit exposure of normal tissue to radiation. However, the radiation dose at the focus of the beams is high to achieve tissue destruction in the desired area.[191] This technique has been used to treat AVMs, dural arteriovenous fistulas, pituitary adenomas, acoustic neuromas, trigeminal neuralgia, and malignant tumors.[192-196]

The procedure consists of the initial placement of a stereotactic head frame, usually under local anesthesia, followed by neuroradiologic imaging, most frequently MRI. Other imaging procedures performed in conjunction with stereotactic radiosurgery have included angiography and CT. After precise stereotactic localization of the target, the radiosurgical procedure commences. Most cooperative patients require only mild sedation/analgesia for the procedure. Because absolute head immobility is necessary, uncooperative adults, those with movement disorders, and pediatric patients may require general anesthesia for any or all components of the procedure. The total duration of the anesthesia may be several hours.[188] Attention to fluid status, maintenance of temperature, and padding of pressure points is particularly important during these potentially long procedures. If general anesthesia is required, intravenous anesthesia with propofol may provide advantages in maintenance during the multiple patient transfers entailed by the procedure.[188] Mechanisms to maintain consistent standard monitoring throughout the procedure and transfers need to be in place. After the procedure, the patient goes to a fully staffed and equipped recovery area and is discharged after meeting standard discharge criteria.

80 Clinical Care in Extreme Environments: At High and Low Pressure and in Space

Key Points

1. Hyperbaric oxygen (HBO) exposure (breathing oxygen at increased ambient pressure, typically 2-3 atmospheres absolute [ATA]) causes an increase in arterial and tissue P_{O_2} and no significant change in arterial pH or P_{CO_2}.
2. During HBO therapy, cardiac output is reduced, systemic vascular resistance is increased, and pulmonary vascular resistance is decreased.
3. Acute illnesses for which HBO is indicated include carbon monoxide (CO) poisoning (based on randomized, controlled studies), gas bubble disease (gas embolism and decompression sickness), and soft tissue necrotizing infections (the latter two based on clinical experience and meta-analysis).
4. The decision to use HBO to treat a patient with arterial gas embolism or decompression sickness should be based on clinical criteria, including the presence of symptoms, abnormal physical examination, or a history of arterial gas embolism within a few hours even in the absence of symptoms. Neither neurophysiologic testing nor radiographic imaging is useful except, rarely, to exclude other pathologic processes.
5. The decision to use HBO to treat a patient with CO poisoning should be based on clinical criteria, including a history of impaired consciousness or other neurologic manifestation, pregnancy, or severe exposure (e.g., peak carboxyhemoglobin [HbCO] > 25%). The HbCO level correlates poorly with the severity of the illness and is generally useful only to make the diagnosis.
6. Oxygen-induced seizures are rare and self-limited. Appropriate management includes discontinuation of inhaled oxygen. Chamber pressure should not be altered during the seizure. Decompression can result in pulmonary barotrauma.
7. The principles of treatment of acute altitude illness include descent and supplemental oxygen. If these options are not available, for acute mountain sickness (AMS) or high-altitude cerebral edema (HACE), dexamethasone and acetazolamide are recommended; for high-altitude pulmonary edema (HAPE), drugs that lower pulmonary artery pressure, such as nifedipine, are recommended.
8. When providing anesthesia for otherwise healthy acclimatized patients at altitude, supplemental oxygen should be used only to maintain arterial oxygen saturation at baseline (not normal levels). Liberal administration of oxygen may reverse acclimatization.
9. As ambient pressure is altered, anesthetic vaporizers deliver a variable concentration but fixed partial pressure. Therefore, there is no need to adjust vaporizer settings when delivering anesthesia in a hyperbaric chamber or at altitude.
10. Unexpected complications have been observed after anesthetics for minor procedures in primates after spaceflight. Physiologic and pharmacologic effects of neuraxial or general anesthesia during or after spaceflight are largely unknown but could include hypotension, resistance to nondepolarizing muscle relaxants, and exaggerated hyperkalemia due to succinylcholine.

Hyperbaric medicine began in the 19th century, when clinical improvement was observed after recompression of divers and compressed air workers with decompression sickness. Hyperbaric air treatment was subsequently used for a variety of diseases, including tuberculosis, heart failure, emphysema, bronchitis, asthma, croup, whooping cough, anemia, anorexia, dyspepsia, leukorrhea, menorrhagia, neuralgic pain, and depression, without any scientific basis. An exception was the use by Fontaine in 1879 of a mobile hyperbaric chamber for anesthesia and surgery.[1] Compressed to 1.25 to 1.33 atmospheres absolute (ATA), a nitrous oxide/oxygen mixture was provided to the patient (Fig. 80-1). Breathing air in Fontaine's chamber would have provided an inspired P_{O_2} equivalent to 26% to 28% O_2 at 1 ATA. This was probably the first use of an elevated P_{O_2} during anesthesia and certainly the first administration of hyperbaric nitrous oxide.

Use of O_2 at high pressure for the treatment of decompression sickness had been suggested[2] and reported for the treatment

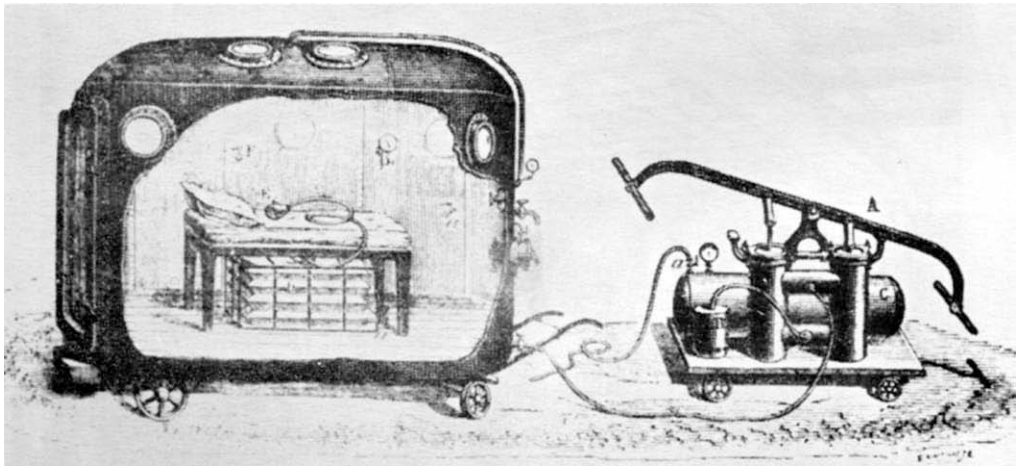

Figure 80-1 Mobile hyperbaric operating room described by Fontaine in 1879.[1] Nitrous oxide storage tanks can be seen under the operating table. Compressed to 1.25 to 1.33 atmospheres absolute (ATA) with air, a nitrous oxide/oxygen mixture was provided to the patient. Breathing air in this chamber would have provided an inspired P_{O_2} equivalent to 26% to 28% O_2 at 1 ATA.

of decompression sickness[3] but remained an isolated medical curiosity until the early 1960s. A few indications, such as support of oxygenation in hyaline membrane disease of the newborn[4] and during open heart surgery[5,6] were not useful. For other indications, such as carbon monoxide (CO) poisoning, arterial gas embolism, and decompression sickness, hyperbaric oxygen (HBO) proved to be effective, as evidenced by substantial clinical experience and randomized controlled studies. Indications are reviewed regularly by the Undersea and Hyperbaric Medical Society (Durham, NC). This medical organization publishes an extensive bibliography with a list of indications for hyperbaric oxygenation that is updated every 2 to 3 years.[7] Laboratory and clinical data support the use of HBO for a select number of acute and chronic illnesses (Table 80-1), and anesthesiologists are often called on to provide care of patients in this unusual environment.

Interest in the physiologic and medical aspects of altitude originated because of mountaineering and high-altitude balloon exploits in the 19th century.[8] An understanding of the physiologic response to altitude hypoxia has had wide application, as increasing numbers of people fly in aircraft, travel from low to high altitude, and live or work at higher elevations (Table 80-2). Significant effort has been devoted to techniques for prophylaxis and treatment of these illnesses in recent years.

The effects of space travel are mostly due to microgravity, radiation, and confinement. Understanding these effects and development of tools to deal with sick or injured astronauts are paramount for the medical support of long-range space missions, such as to Mars.

Table 80-1 Partial List of Conditions for Which Hyperbaric Oxygen Has Been Used

Gas-bubble disease
*Air embolism[7,83]
*Decompression sickness[83,291]
Poisoning
*Carbon monoxide[7,41,48-50,55]
Cyanide[41]
Carbon tetrachloride[292,293]
Hydrogen sulfide[41]
Infections
*Clostridial myonecrosis[7,99-101]
*Other soft tissue necrotizing infections[7,97,98,101]
*Refractory chronic osteomyelitis[7,90,294]
*Intracranial abscess[7,295]
Mucormycosis[296,297]
Acute ischemia
*Crush injury[7,298]
*Compromised skin flaps[7,299]
Central retinal artery occlusion, central retinal vein occlusion[300]
Chronic ischemia
*Radiation necrosis (soft tissue, radiation cystitis, and osteoradionecrosis)[7]
*Ischemic ulcers, including diabetic ulcers[7,11,301,302]
Acute hypoxia
*Exceptional blood loss anemia (when transfusion delayed or unavailable)[7]
Support of oxygenation during therapeutic lung lavage[103,104]
Thermal injury
*Burns[7,303-306]
Envenomation
Brown recluse spider bite[307,308]

*Approved by the Undersea and Hyperbaric Medical Society as an appropriate indication for HBO therapy.[7]

Physiologic Effects of Increased Gas Pressure

Increased Barometric Pressure

Some effects of altered ambient pressure are summarized in Figure 80-2.

Table 80-2 Range of Terrestrial Altitudes

Altitude*		Ambient Pressure		
ft	m	Atmospheres Absolute (ATA)	mm Hg	Comments
		0.32	246†	Lowest pressure to which volunteers have been continuously exposed (hypobaric chamber study: Operation Everest I)[309,310]
29,028	8848	0.35	263†	Mt. Everest, Nepal: highest point on earth
20,320	6194	0.45	345	Mt. McKinley (Denali): highest point in North America
19,521	5950	0.49	372†	Aucanquilcha mine, Chile: highest altitude known to have been continuously inhabited by humans.[311] Miners slept in a village at lower altitude (Quilcha, 5334 m).

4,500	1372	0.86	650	Banff, Alberta, Canada; Katmandu, Nepal
0	0	1.00	760	Sea level

*Altitudes and barometric pressures are shown for Mt. Everest and several locations inhabited at least part time. Barometric pressures have been calculated using an algorithm developed by West[316] except for values with a dagger (†), which were obtained by direct measurement.[310]

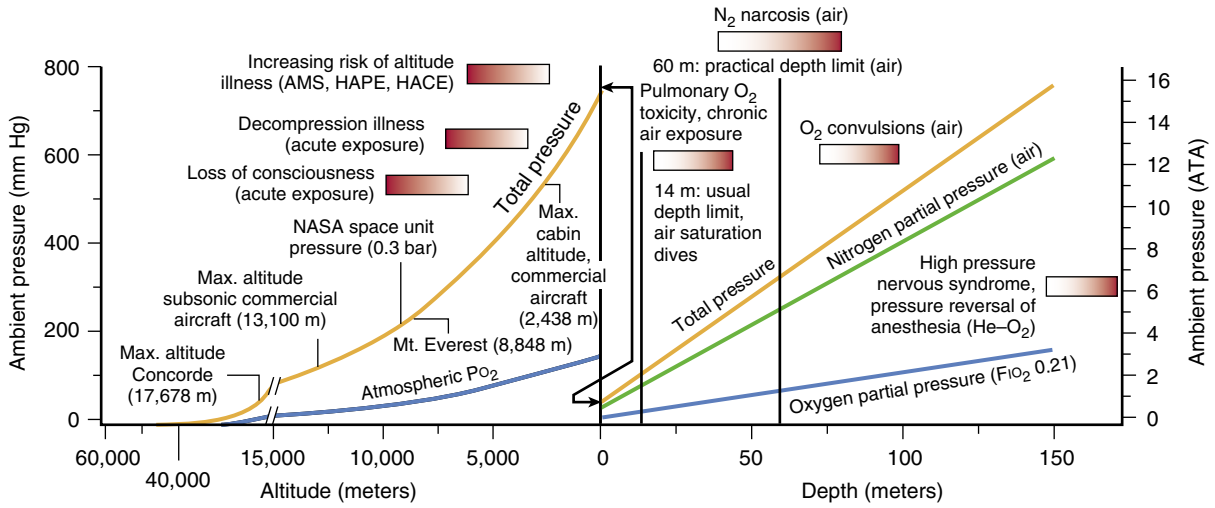

Figure 80-2 Ambient pressure as a function of altitude and water depth. Whereas ambient pressure increases linearly with depth, pressure and altitude are not linearly related. As air is inspired and humidified, there is a small and usually insignificant drop from atmospheric P_{O_2} to inspired P_{O_2}. At altitude, however, this decrease accounts for a greater proportion of the total ambient pressure. The O_2 partial pressure line in the water is shown for a constant F_{IO_2} of 21%. At increasing depth, the inspired P_{O_2} eventually exceeds the pulmonary toxic limit (~14 m in depth) and the central nervous system toxic limit (~70 m in depth). The threshold for high-pressure nervous syndrome and pressure reversal of anesthesia (observed in non-narcotic atmospheres) is 150 to 200 m in depth. The *shaded red bars* represent the depth or altitude ranges over which risk progresses from low (*light shading*) to high (*dark shading*). AMS, acute mountain sickness; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema.

An increase in environmental pressure is accompanied by significant adiabatic heat production, whereas decompression generates cooling. This results in an increase in chamber temperature during compression and in cooling and precipitation of water droplets during decompression. These phenomena may limit the rate of compression in manned chambers in order to maintain temperature within a comfortable range.

Additionally, pockets of trapped gas within the body will contract and expand on compression and decompression. Such pockets include gas in the middle ear, and paranasal sinuses, intestinal gas, pneumothorax, and gas pockets within monitoring and life-support systems. The changes in gas volume will occur according to Boyle's law:

$$PV = \text{constant}$$

such that a doubling of environmental pressure (P) will cause the volume (V) of a gas-filled cavity to decrease by half. This effect also underlies one of the major beneficial effects of hyperbaric treatment of pathologic gas, as in arterial gas embolism or decompression sickness (see later).

A comparison of pressure units used clinically with those in common use in hyperbaric environments is shown in Table 80-3.

Increased Partial Pressure of Oxygen

Breathing O_2 at increased ambient pressure will lead to elevation of alveolar O_2 tension (P_{AO_2}), which can be calculated according to the alveolar gas equation for O_2:

$$P_{AO_2} = F_{IO_2} \cdot (Pb - P_{H_2O}) - P_{ACO_2} \cdot \left(F_{IO_2} + \left[(1 - F_{IO_2})/R\right]\right)$$

where F_{IO_2} is the fractional inspired O_2 concentration; P_{H_2O} is saturated water vapor pressure at body temperature (typically 47 mm Hg); P_{ACO_2} is alveolar P_{CO_2}, assumed to equal arterial P_{CO_2} (Pa_{CO_2}); and R is the respiratory exchange ratio (usually ≈ 0.8 at rest). From calculated values of P_{AO_2}, arterial P_{O_2} (Pa_{O_2}) has been estimated, assuming that the arterial/alveolar P_{O_2} ratio remains constant.[9] Whereas at 1 atmosphere absolute (ATA) the fraction of O_2 in arterial blood that is carried dissolved in the plasma is minimal, it can be seen that at elevated Pa_{O_2} in the range of 1000 to 2000 mm Hg significant quantities of O_2 may exist in dissolved form (Table 80-4).

Increased Pa_{O_2} has at least four pharmacologic effects:

1. Increased blood O_2 content
2. Vasoconstriction
3. Antibacterial action, particularly against anaerobic bacteria
4. Inhibition of endothelial neutrophil adhesion in injured tissue

The increased arterial O_2 content underlies the rationale for administering HBO for the treatment of ischemic conditions, for example, ischemic, nonhealing wounds. The elevation in Pa_{O_2} leads to an increase in tissue P_{O_2}, which can be estimated using transcutaneous P_{O_2} electrodes, even in ischemic tissue.[10,11] The second effect is an explanation for the effectiveness of HBO in the treatment of traumatic edema (e.g., crush injury). The mechanism of HBO-induced vasoconstriction appears to be inactivation of nitric oxide due to increased production of superoxide[12] and possibly decreased release of NO from circulating S-nitrosohemoglobin.[12-14]

These two effects, increased O_2 content and vasoconstriction, lead to hemodynamic changes,[14,15] shown in Table 80-4. There is also a slight increase in mean arterial pressure. Studies of HBO effects on myocardial contractility using denervated hearts[16] or autonomically blocked animals[17] have indicated no intrinsic effect. In intact animals or humans heart rate and cardiac output are decreased and systemic vascular resistance is increased.[14,15,18] In both anesthetized dogs and awake humans pulmonary vascular resistance is decreased.[14,19] At 2 ATA 100% O_2 in conscious dogs has no effect on coronary flow,[18] whereas at 3 ATA both coronary flow and myocardial O_2 consumption are decreased.[17] Cerebral blood flow is decreased by O_2 administration over a range of pressures,[12,18] whereas at 2 ATA, hepatic, renal, and mesenteric flows are unchanged.[18]

HBO also has microcirculatory and cellular effects in various disease states (see later).

Increased Inert Gas Partial Pressure

Elevation of the partial pressure of the inert gas (usually nitrogen) present in a breathing mixture is associated with a narcotic effect, predictable by the Meyer-Overton hypothesis. Based on its solubility in olive oil, N_2 has 0.03 to 0.05 times the narcotic potency of nitrous oxide. At 3 ATA (breathing air) most people experience mild euphoria. At 6 ATA there may be memory loss and poor judgment. At 10 ATA some individuals lapse into unconsciousness. Nitrogen narcosis has been compared with alcoholic intoxication, an increase in ambient pressure of 1.5 ATA resulting in an effect that is said to be similar to drinking one martini. Argon and, to a lesser degree, hydrogen are narcotic, whereas helium has minimal if any narcotic effect. In animals exposed to high partial pressures of nitrogen there is evidence of activation of $GABA_A$ receptors of dopaminergic neurons in the nigrostriatal pathway, leading to a decrease in dopamine release.[20]

Table 80-3 Units of Pressure

Atmospheres Absolute (ATA)	Absolute Pressure (mm Hg)	Gauge Pressure (mm Hg)	Feet of Sea Water (fsw)	Meters of Sea Water (msw)
1	760	0	0	0
2	1520	760	33	10
3	2280	1520	66	20
6	4560	3800	165	50

Elevation of Absolute Pressure

High-Pressure Nervous Syndrome

High pressure induces a constellation of symptoms consisting of tremor, ataxia, nausea, and vomiting, known as the high-pressure nervous syndrome (HPNS).[21] It occurs at an ambient pressure greater than 15 to 20 ATA and was first described during the compression phase of deep dives with a helium-oxygen atmosphere. HPNS is ameliorated by slow compression and addition of a narcotic gas (e.g., nitrogen) to the breathing mix.[22] Its pathogenesis may be related to an increase in striatal dopamine.[23]

Pressure Reversal of Anesthesia

Studies in animals have demonstrated that high pressure has the tendency to reverse general anesthesia. Elevations in ambient pressure in the absence of a narcotic inert breathing gas will tend to decrease the effectiveness of both inhaled and intravenous anesthetics. At 50 ATA a 20% increase in the 50% effective dose (ED_{50}) has been observed in mice for a variety of inhaled anesthetics. At 50 and 100 ATA the effective dose of barbiturates increases by 30% to 60%.[24] The ED_{50} for diazepam in rats is markedly reduced at 90 ATA in a helium/oxygen atmosphere.[25] At 31 ATA, the effective concentration for half maximal effect (EC_{50}) of propofol for loss of righting reflex in tadpoles is increased by 19%, and, at 61 ATA, by 38%.[26] Using the same technique, the EC_{50} for dexmedetomidine at 31 ATA is nearly double the value at 1 ATA and increased 2.5-fold at 61 ATA.[27] At 80 ATA, the MAC of desflurane as assessed by response to a noxious stimulus is increased by 19%.[28] The mechanisms of pressure reversal are not fully understood but may be secondary to physical chemical effects of pressure on membranes[29] or due to alterations in neurotransmitter release.[23] However, within the range of pressures used for hyperbaric oxygen therapy (up to 3-6 ATA) the effects of pressure on sedative or anesthetic drugs are not clinically significant.

Effects of Hyperbaric Exposure on Drug Disposition

A few studies have examined the disposition of drugs and drug effects at increased environmental pressures. Studies in awake dogs at pressures up to 6 ATA and ambient Po_2 up to 2.8 ATA have shown that liver plasma flow decreased when either ambient pressure or Po_2 was raised. There was an apparent increase in plasma volume at 1.3 ATA and a return toward 1 ATA values at higher pressures. In the same studies, plasma volume was inconsistently affected by ambient pressure but reduced by increases in Po_2.[30]

There is no major pharmacokinetic or pharmacodynamic effect of hyperbaria for most drugs up to 6 ATA. Up to 6 ATA pressure and 2.8 ATA Po_2, the pharmacokinetics of meperidine,[31] pentobarbital,[32] theophylline,[33] and salicylate[34] are unaffected.

Use of benzodiazepines, chlorpromazine, and lithium carbonate has been reported for the treatment of agitation, auditory and visual illusions, and paranoia in a previously normal subject participating in an experimental dive to 650 m (66 ATA).[35] The symptoms, poorly controlled with diazepam, 120 mg/day, and temazepam, 60 mg/day, ultimately responded to chlorpromazine, 300 mg/day. Lithium carbonate administered in conventional doses appeared to display normal pharmacokinetics. While the effect of chlorpromazine appeared clinically to be appropriate, the authors were uncertain as to whether the failure of benzodiazepines to elicit a desired therapeutic response was due to the patient's condition or to a pressure-reversal phenomenon.

In summary, clinical experience and the published literature indicate that for a variety of drugs, conventional parenteral drug dosing schedules may be used safely under hyperbaric conditions at the pressures used for clinical treatment of patients with HBO therapy.

Rationale for the Treatment of Selected Specific Syndromes

Carbon Monoxide Poisoning

Hemoglobin (Hb) binds CO with an affinity much higher (by a factor of about 200) than that for O_2. This binding of CO with Hb to form carboxyhemoglobin (HbCO) has two major effects. First, the proportion of Hb that is occupied by CO molecules is unavailable for O_2 transport, resulting in a functional anemia. Second, the avidity with which the remaining Hb binds O_2 is increased (shift to the left of the Hb-O_2 dissociation curve). The result of this is a decreased ability to unload O_2 from blood to tissue at the capillary, and therefore a reduction in tissue Po_2. Previously it was believed that these effects were totally responsible for the toxicity of CO. However, evidence has since been presented to show that the binding of CO to intracellular pigments (e.g., cytochrome aa_3, myoglobin) and oxidative stress may contribute significantly to the toxicity of CO.[36-44] CO exposure also triggers intravascular platelet-neutrophil aggregation and neutrophil activation.[44] These mechanisms result in toxicity to multiple organ systems, including brain and heart.[41,45] Immune-mediated effects have also been described.[46]

Clinical effects include headache, nausea, vomiting, dizziness, myocardial ischemia, loss of consciousness, and, during pregnancy, fetal distress. Persistent or delayed neurologic sequelae can occur, often after a clear window of lucidity.[47-49] Increased risk factors for persistent sequelae include older age (≥36 years) and longer CO exposure.[50]

The diagnosis of CO poisoning is made by a history of exposure (internal combustion engine exhaust, fire, improperly adjusted gas or oil heating, charcoal or gas grills, or exposure to paint stripper containing methylene chloride, which is metabolized by the liver to CO). Confirmation of the diagnosis is made by finding an elevated HbCO level in either arterial or venous blood. HbCO concentration in anticoagulated blood samples is stable for several days. Therefore, if HbCO determination is not available at a referring facility the diagnosis can be confirmed using a blood sample obtained at the time of initial evaluation and transported with the patient. Fetal hemoglobin (HbF) can produce a falsely elevated reading for HbCO on certain four-wavelength laboratory co-oximeters.[51] In the first few weeks of life, blood from normal infants may therefore falsely indicate 7% to 8% HbCO.

Actual HbCO levels measured on arrival in the emergency department correlate poorly with clinical status and should not be used as the sole criterion to determine the need for treatment. Because of the lower intracellular Po_2, elimination of CO from

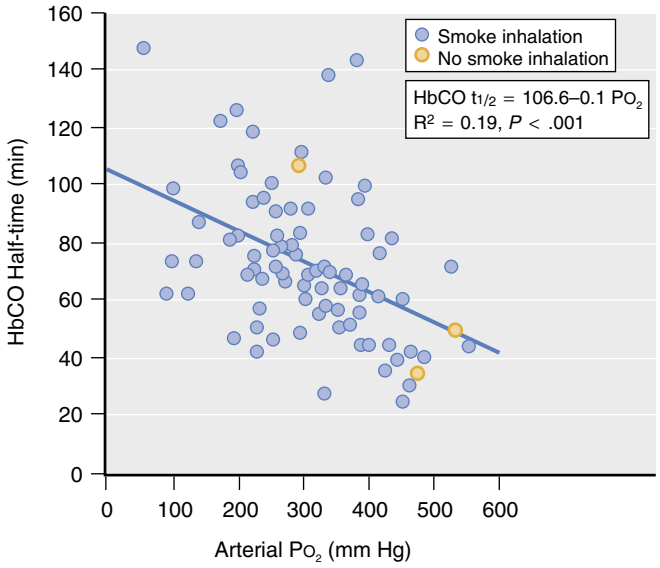

Figure 80-3 Elimination half-time of carboxyhemoglobin in 93 CO-poisoned patients. Although there is scatter in the data, it is apparent that CO dissociates from hemoglobin faster at higher PO_2. *(Redrawn from Weaver LK, Howe S, Hopkins R, Chan KJ: Carboxyhemoglobin half-life in carbon monoxide–poisoned patients treated with 100% oxygen at atmospheric pressure. Chest 117:801-808, 2000.)*

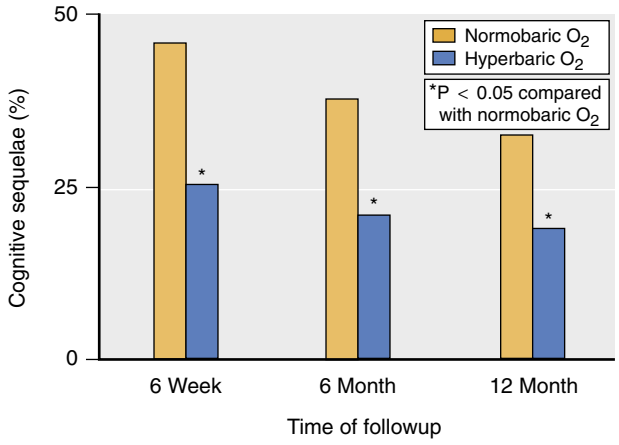

Figure 80-4 Cognitive sequelae in a randomized prospective trial of hyperbaric O_2 in CO poisoning. Cognitive sequelae were defined as any T score for a neuropsychological subtest more than 2 SD below the mean of demographically corrected standardized T scores or if two or more T scores for subtests were more than 1 SD below the mean. If the patient reported difficulties with memory, attention, or concentration, then cognitive sequelae were defined as a T score on any neuropsychological subtest more than 1 SD below the mean of demographically corrected standardized T scores. *(Drawn from data reported by Weaver LK, Hopkins RO, Chan KJ, et al: Hyperbaric oxygen for acute carbon monoxide poisoning. N Engl J Med 347:1057-1067, 2002.)*

intracellular binding sites occurs more slowly. Significant mental obtundation, vomiting, and headache may remain even in the presence of a normal HbCO level.

Brain imaging may reveal a variety of abnormalities in patients with CO poisoning, including hypodensities in the globus pallidus and subcortical white matter, cerebral cortical lesions, cerebral edema, hippocampal lesions, and loss of gray matter/white matter differentiation and white matter hyperintensities.[52-54] Except to exclude other pathologic processes, brain imaging is not useful for determining who should receive HBO, but it may provide prognostic information.[52]

Oxygen is the primary treatment modality for CO poisoning. High Pao_2 hastens the removal of CO from blood, as indicated by a reduced half-life of HbCO. Figure 80-3 shows the HbCO half time in a series of CO-poisoned patients during normobaric O_2 administration; HBO reduces the half-time even further, to around 20 minutes at 2.5 ATA (Table 80-5).[55] Additionally, the increased dissolved O_2 in plasma may support tissue oxygenation pending removal of CO from Hb and other proteins important for O_2 transport. Although the treatment of CO poisoning with HBO remains somewhat controversial, there is mounting evidence that for poisoning in which neurologic symptoms occur, HBO treatment may decrease both early and late morbidity. The results of one randomized prospective trial of hyperbaric versus normobaric oxygen revealed no apparent benefit of HBO[56]; however, in four trials, HBO treatment has resulted in an improved outcome (Fig. 80-4).[48,49,57,58]

Commonly used guidelines for the application of HBO therapy in CO poisoning include the following:

- A history of neurologic impairment (including dizziness, loss of consciousness)
- Evidence of cardiac abnormalities (ischemia, arrhythmias, ventricular failure)
- An HbCO level that has been greater than 25%

Fetuses are particularly susceptible to CO toxicity. Pregnant women who fulfill the criteria just listed or in whom there is fetal distress should be treated with HBO. Case reports,[59-61] published series,[62,63] and a critical review[64] support the concept that inadequately treated CO poisoning is a serious risk to the mother and fetus, and the benefits of HBO outweigh the theoretical risks to the fetus of HBO treatment. Potential adverse effects of currently implemented HBO treatment protocols have not been confirmed in clinical practice.

Gas Embolism and Decompression Sickness

Introduction of gas into the arterial circulation (arterial gas embolism) has traditionally been associated with scuba divers and attributed to pulmonary barotrauma during ascent from a dive while breathing compressed gas. However, it may also occur iatrogenically in several clinical circumstances, such as during cardiopulmonary bypass or as a result of inadvertent injection of air during a diagnostic arteriogram or hemodialysis. Additionally, large amounts of gas may enter the venous system, for example, during neurosurgical procedures with the patient in the sitting position, hemodialysis, major back surgery, total hip replace-

Table 80-5 Carbon Monoxide Elimination Half-times While Breathing Air or 100% Oxygen at 1 ATA and at 2.5 ATA

Breathing Gas	Mean Half-life (min)*	No. Subjects
Air, 1 ATA	214	10
Oxygen, 1 ATA	43	15
Oxygen, 2.5 ATA	19	10

*Mean values from data of Pace N, Strajman E, Walker E: Acceleration of carbon monoxide elimination in man by high pressure oxygen. Science 111:652-654, 1950.

ment, cesarean section, laparoscopy, intrauterine laser surgery, arthroscopy (due to air escaping from faulty air-powered drill), and hydrogen peroxide irrigation or oral ingestion (due to elaboration of gaseous oxygen from tissue and blood catalase). Venous gas embolism can also occur when a central venous catheter is opened to air. Severe venous gas embolism has also occurred during orogenital sex after blowing air intravaginally.[65] Venous gas embolism has been reported in patients with acute respiratory distress syndrome (ARDS) being ventilated with positive end-expiratory pressure.[66] Venous gas embolism in sufficient quantity may overwhelm the ability of the pulmonary vasculature to filter the gas, allowing bubbles to pass into the arterial circulation. Even small amounts of venous gas (e.g., venous gas embolism due to decompression from diving) have recently been implicated in neurologic syndromes in scuba divers because of transatrial passage through a patent foramen ovale.[67,68]

The effects of gas embolism are not solely due to vessel obstruction by bubbles. Bubble-endothelial interaction causes increased capillary permeability and extravasation of fluid[69,70] and impairment of endothelial function.[71] Another effect has been demonstrated in a model of arterial gas embolism in anesthetized rabbits[72,73]: small doses of intracarotid air may pass through the cerebral microcirculation yet produce vasoplegia, delayed reduction of cerebral blood flow, and neurophysiologic impairment. This reduction in blood flow is abolished when there is neutropenia; thus, it has been concluded that leukocytes are required for this effect.[74] This phenomenon of delayed reduction of cerebral blood flow may be responsible for the clinical observation of initial neurologic improvement after arterial gas embolism, followed by delayed deterioration.[75]

A related syndrome that results from pathologic effects of tissue and blood gas bubbles is decompression sickness (DCS) seen in aviators and compressed gas divers. The gas bubbles in these situations occur because of a decrease in ambient pressure at a rate sufficient to induce local inert gas supersaturation, resulting in formation of bubbles in situ from tissue stores. Symptoms of arterial gas embolism classically consist of impaired consciousness, hemiparesis, or seizures but may be of a less severe nature. DCS most commonly presents as any combination of joint pain, paresthesias, motor weakness, bladder or bowel sphincter dysfunction, vertigo, tinnitus, or hearing loss.[76,77]

Treatment principles for both forms of gas bubble disease, arterial gas embolism and DCS, are the same in most instances. First aid includes therapy with oxygen.[78] High P_{O_2} results in increased rate of resolution of gas bubbles because of the resulting higher partial pressure gradient for diffusion of inert gas from the interior of the bubble into the surrounding tissue or blood. Intravascular bubbles cause endothelial leak, extravasation of plasma, and hemoconcentration.[69,79] Fluid resuscitation will replenish intravascular volume, reduce hemoconcentration, and facilitate microcirculatory flow,[80] principles that have been confirmed by both animal[81] and human observations.[69] However, excessive fluid administration can worsen pulmonary gas exchange in cardiorespiratory DCS (pulmonary edema due to venous gas embolism) and aggressive fluid therapy is not indicated for isolated arterial gas embolism.[80]

HBO therapy is the definitive treatment for arterial gas embolism and DCS. The increased pressure will cause a diminution in gas volume and thus further hasten resolution. The usefulness of HBO treatment of diving-related or aerospace-related gas embolism associated with rapid decompression is well documented.[82,83] HBO may effect neurologic improvement even after many hours and sometimes days between the embolic event and treatment,[84-86] although severe abnormalities are less likely to resolve if not treated promptly. Treatment of arterial gas embolism is usually performed at ambient pressures from 2.8 to 6 ATA (see the section "Treatment Schedules").

The decision to administer recompression treatment should be based entirely on clinical evaluation. The only appropriate role for brain or spinal imaging (e.g., computed tomography [CT], magnetic resonance imaging [MRI]) is to exclude other pathologic processes such as hemorrhage, and only if there is a high degree of suspicion that bubbles are not the cause of a patient's symptoms. Some authors have suggested that patients with arterial gas embolism should only be treated with HBO if CT of the brain reveals air[87]; however, brain imaging of patients with arterial gas embolism or DCS reveals abnormalities in only a minority of cases and the abnormalities on either CT or MRI are usually not specific. Intravascular gas is observed in a small fraction of cases,[86] and neither its absence nor presence predicts response to hyperbaric treatment. Neither single-photon emission tomography (SPECT) nor positron emission tomography (PET)[88] has yet been demonstrated to provide clinically useful information in the management of patients with gas bubble disease.

Acute Infections

Anaerobic bacteria are especially sensitive to increased tissue P_{O_2}. High O_2 tensions inhibit clostridial α-toxin production.[89] Other mechanisms include reversal of hypoxia-induced neutrophil function,[90-92] enhanced macrophage interleukin (IL)-10 expression,[93] and anti-inflammatory effects.[94-96] Evidence in favor of the use of HBO in clostridial and nonclostridial infections is provided by clinical series and a meta-analysis.[97-102]

Support of Arterial Oxygenation

HBO is a safe and effective method of supporting arterial oxygenation during therapeutic lung lavage, during which oxygenation has to be maintained by the contralateral (nonlavaged) lung.[103,104] In our experience of over 100 procedures, using this technique to treat arterial oxygenation has been uniformly successful with no resulting complications. A reversible simulation of pulmonary gas exchange during the lavage procedure can be provided by temporarily ventilating the lung to be lavaged with 5% to 6% O_2/balance N_2, which reduces P_{AO_2} in that lung to approximately the level of mixed venous P_{O_2} and confining O_2 exchange to the contralateral lung. Hypoxemia within 5 minutes is predictive of hypoxemia during the actual lavage.

Maintenance of Oxygen Transport in Severe Anemia

The ability of HBO to increase arterial O_2 content in plasma to clinically useful levels may allow support of tissue O_2 delivery even without hemoglobin. HBO can therefore be used for temporary support of severely anemic patients pending availability of definitive therapy in the form of crossmatched blood.

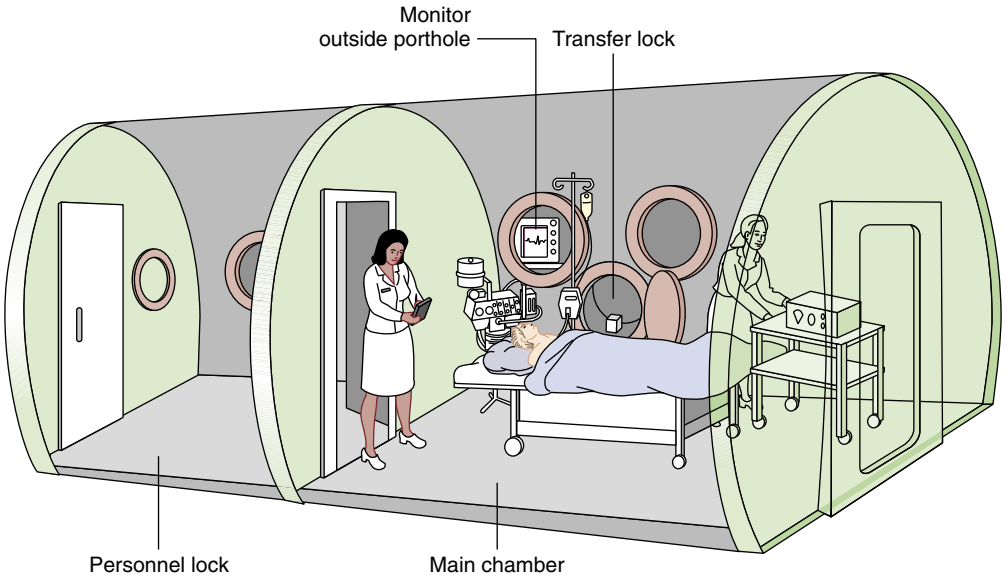

Figure 80-5 Multiplace hyperbaric chamber large enough for one or more patients and tenders. The chamber atmosphere is compressed air. The patient receives 100% O_2 by mask, head tent, or endotracheal tube. Monitors are usually kept outside the chamber because of electrical safety considerations. Monitoring is possible through a porthole. A personnel lock and a transfer lock allow physicians, nurses, or other personnel, in addition to medications, food, and blood samples, to be moved into and out of the chamber without repeated compression and decompression of the patient.

Therapeutic Systems

The traditional method of administering hyperbaric therapy is with a multiplace chamber, which accommodates two or more persons (Fig. 80-5). Size may vary from a small, portable two-person chamber used for transporting patients in the field to one 20 feet or more in diameter, in which up to 12 patients may be comfortably admitted, in addition to tenders. Multiplace chambers are compressed with air while the patient breathes O_2 with a head tent (Fig. 80-6), face mask, or endotracheal tube. Because of immediate access to the patient by accompanying nursing personnel or physicians, monitoring and resuscitative procedures are straightforward. However, multiplace chambers take up a lot of space and are expensive.

Monoplace chambers are large enough to accommodate only 1 patient (Fig. 80-7) or a tender with a small child. The chamber wall in most types is manufactured of Plexiglas, facilitating close visual observation of the patient. The chamber is usually compressed with 100% O_2. The advantage of monoplace chambers is their relatively low cost and ease of installation. Chamber operation can often be implemented by connecting the O_2 inlet to the hospital supply. Operation is relatively simple, but the patient inside is not directly accessible. Monitoring is somewhat more remote, and emergency airway management is not possible. Development of a pneumothorax during treatment, particularly a tension pneumothorax, could be fatal as pleural decompression with a needle or chest tube cannot be performed before decompression; however, this complication is extremely rare. A minor disadvantage of these chambers is that the ambient pressure limit is 3 ATA, and for practical reasons (psychological

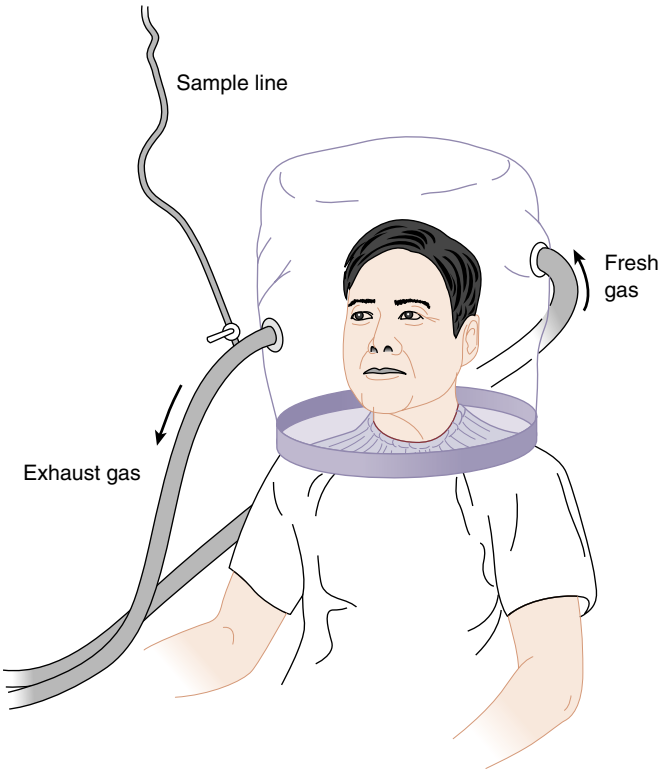

Figure 80-6 Head tent circuit for use in a multiplace chamber. Fresh gas (100% O_2) flows at a constant rate (>30 L/min) through the head tent. Exhaust gas may be either vented outside the chamber or recirculated through a CO_2 scrubber. The sample line attached to the exhaust hose allows monitoring of the patient's breathing gas.

Figure 80-7 Monoplace chamber. This type of chamber has room for one patient or a tender with a small child. The patient is moved into and out of the chamber on a wheeled gurney. The chamber atmosphere is usually 100% O_2. The chamber is constructed of transparent Plexiglas to allow observation. Through-hull penetrators in the door on the left can be seen and allow monitoring, intravenous fluid administration, and control of a ventilator inside the chamber. *(Photograph courtesy of Dr. Lindell Weaver.)*

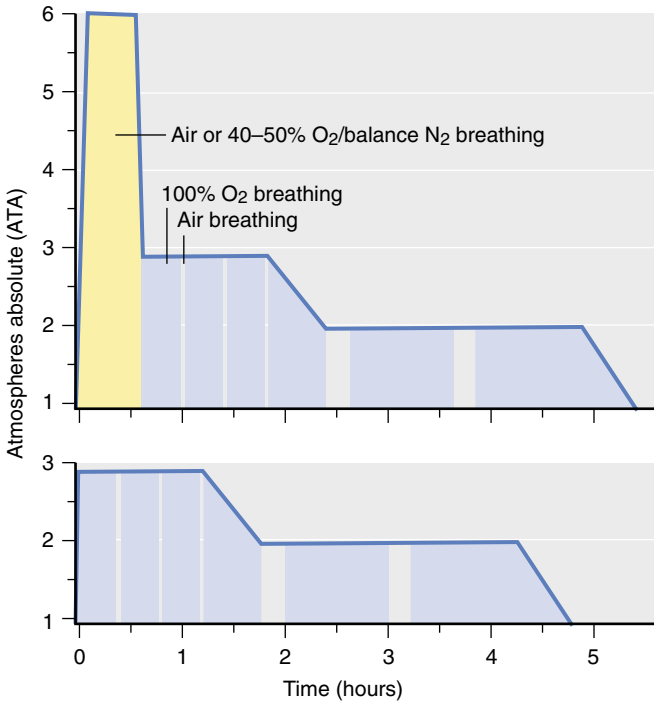

Figure 80-8 U.S. Navy treatment tables 6 (*top*) and 6a (*bottom*). Table 6a is occasionally used for the treatment of arterial gas embolism. During the 30-minute period at 6 ATA, air or 40% to 50% O_2 can be administered. Table 6 was originally designed for the treatment of decompression sickness but is now the most commonly used table for gas embolism as well. The *blue areas* represent 100% O_2 breathing; the *white areas* represent air breathing periods (see Fig. 80-10). *(Further details can be found in the Navy Department: US Navy Diving Manual. Revision 6. Vol 5: Diving Medicine and Recompression Chamber Operations. NAVSEA 0910-LP-106-0957. Washington, DC, Naval Sea Systems Command, 2008.)*

aversion to confinement) treatment times are limited. Moreover, intermittent periods of air breathing, in order to decrease the risk of O_2 toxicity during some types of treatment schedules (see later), requires installation of an additional gas delivery system. Nevertheless, monoplace technology now permits intravenous fluid administration from outside the chamber, invasive intravascular monitoring, mechanical ventilation, and utilization of pleural drainage systems incorporating regulated suction.[105,106]

Hyperbaric Treatment Schedules

Ideally, a patient who has therapeutic indication for hyperbaric O_2 would be exposed for an unlimited time until the condition resolves. Unfortunately, several factors limit the dose and duration of HBO:

- O_2 toxicity
- Decompression obligation for nursing staff (or other tenders) accompanying patient
- Adequacy of monitoring
- Patient isolation and boredom in a confined environment

Treatment schedules have been developed that are compromises between O_2 partial pressure and exposure time on one hand and O_2 toxicity and other practical limiting factors listed on the other. The original schedules (or "tables") were developed by the various navies of the world to treat DCS and gas embolism in divers (Fig. 80-8).

U.S. Navy Table 6 (see Fig. 80-8) prescribes an initial exposure to 2.8 ATA (equivalent to 60 feet of sea water [fsw] or 18 m of sea water [msw]), followed by slow decompression to 1.9 ATA (30 fsw). Periods of O_2 breathing are interspersed with 5- or 15-minute periods of air breathing to decrease O_2 toxicity (see later). This schedule remains the mainstay of treatment for DCS in multiplace chambers throughout the world. Incomplete relief of signs or symptoms can be treated with repeated applications described in Table 6 or a shorter treatment on a daily basis.

Table 80-6 Duke Modifications for Decompression of Tenders

Standard air decompression Within 2 ft of standard Navy depth divisions, use the next greatest depth. Within 2 min of standard Navy time divisions, use the next greatest time. During decompression of the chamber after a compressed air dive, breathe 100% O_2 from an equivalent depth of 50 fsw (2.5 ATA) to the surface or for 15 minutes, whichever is shorter.
Time for decompression: 68-30 fsw (3.06-1.9 ATA): 3 minutes 30-20 fsw (1.9-1.6 ATA): 1 minute 20-10 fsw (1.6-1.3 ATA): 1 minute 10 fsw (or last stop)—"surface" (1.3-1.0 ATA): 5 minutes
When USN Table 6 or 6a is extended, the tender should breathe 100% O_2 for the last 30-90 minutes at 30 fsw (1.9 ATA) according to the number of extensions at 60 fsw (2.8 ATA): 30 minutes (no extensions), 60 minutes (1 extension), 90 minutes (2 extensions). 100% O_2 is breathed by the tender for the entire period of decompression from 30 fsw (1.9 ATA) to "surface" (1 ATA).

fsw, feet of sea water.

"Saturation" treatment consists of an extended exposure to elevated pressure (e.g., 2.8 ATA) for an unspecified period of time (often 1-2 days) until manifestations have stabilized. Periodic O_2 breathing is given according to a recommended schedule as tolerated. Because saturation treatment results in a much larger degree of nitrogen uptake in both the patient and the tender, decompression must occur much more slowly, usually over 24 to 36 hours.[107-109] Although this therapy avoids the theoretical disadvantage of intermittent treatment—failure of resolution of gas bubbles—it is also considerably more labor intensive. Because hyperbaric chambers used for saturation treatments require additional hardware (e.g., CO_2 scrubbing capability) and personnel, their application outside military and commercial diving has been limited.

A schedule used for treatment of patients with clostridial myonecrosis or other life-threatening anaerobic infections is shown in Figure 80-9. This schedule consists of 85 minutes at 3 ATA followed by a 33-minute decompression stop for the tenders at 1.3 ATA. This treatment schedule has been designed to maximize Pao_2 (and hence tissue bactericidal activity due to O_2) without an undue risk of hyperoxic seizures.

Treatment schedules for CO poisoning have varied. However, the proven efficacy of the schedule reported by Weaver (60 minutes at 3 ATA, 60 minutes at 2 ATA in addition to air breaks and compression/decompression time) supports the use of 3 ATA for at least the first treatment.[49]

Administration of HBO to patients with chronic diseases (e.g., radionecrosis) is usually performed using shorter tables at lower ambient pressure, most commonly 1 to 2 hours at 2.0 to 2.5 ATA (see Fig. 80-9) once or twice daily. At this lower ambient pressure the risk of O_2 toxicity is minimal and treatments are well tolerated by most patients.

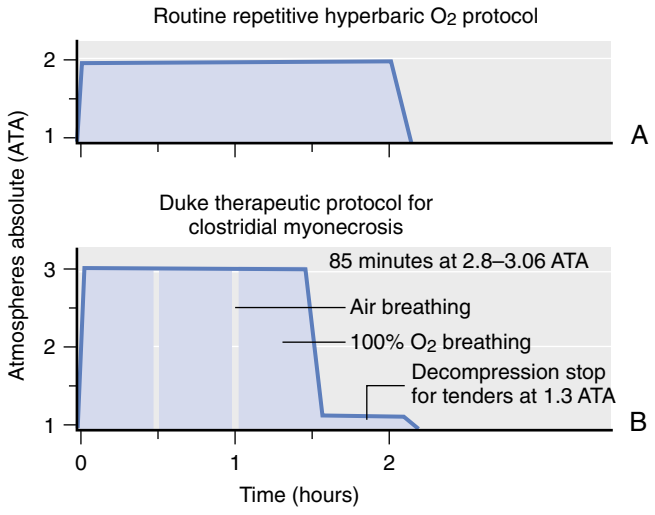

Figure 80-9 Examples of clinical hyperbaric O_2 treatment schedules. **A,** The patient breathes 100% O_2 for 2 hours at an ambient pressure of 2 ATA. Generally, this schedule is used for repetitive treatment of chronic conditions (e.g., osteoradionecrosis). **B,** Therapeutic schedule often used for treatment of clostridial myonecrosis. The patient and the tender spend 85 minutes at 2.8 to 3.06 ATA (3 ATA shown). The patient breathes 100% O_2, except during two 5-minute air breaks to reduce pulmonary and CNS O_2 toxicity. A decompression stop is made at 1.3 ATA, according to the U.S. Navy standard air decompression table. The stop is designed to facilitate safe decompression of the tender, who breathes air at 3 ATA.

Side Effects of HBO Therapy

Oxygen Toxicity

A wide body of evidence supports the notion that O_2 toxicity is caused by excessive production of oxygen free radicals (e.g., superoxide, hydroxyl radicals, and singlet oxygen). At high O_2 partial pressures scavenging mechanisms can be overcome by increased rates of free-radical production.[110] With the use of supplemental O_2 at 1 ATA, the manifestations of O_2 toxicity are almost exclusively confined to the lung; however, during hyperbaric oxygen exposure, other organs can be affected as well.

O_2 toxicity during HBO therapy can affect mainly the lung, the central nervous system (CNS), and the eye. Pulmonary toxicity in the conscious patient is heralded by symptoms of tracheobronchial irritation, namely, cough and burning chest pain. Prolonged exposure may result in a decrease in vital capacity and, if O_2 administration continues, ARDS. In the rare instances in which prolonged HBO is indicated, the rate of development of pulmonary O_2 toxicity can be slowed by intermittent air-breathing periods ("air breaks") (Fig. 80-10).

O_2 toxicity is related to the Po_2 of the inspired gas. At 1 ATA, 100% O_2 is as toxic as 16.7% O_2 at 6 ATA or 2% O_2 at 50 ATA. One method of quantification of O_2 exposure is the unit pulmonary toxic dose (UPTD).[111] In this system the number of UPTD units (U) is calculated by the formula:

$$U = t \cdot \sqrt[m]{0.5/(P-0.5)}$$

where t is the exposure time in minutes; P is the inspired Po_2 in ATA, and m is a slope constant that has an empirical value of 1.2. After 1425 UPTD units of O_2 exposure, there is an average 10% decrease in vital capacity; After 2190 UPTD units, there is an associated decrease of 20%. Complete reversal of vital capacity decrements as large as 40% of control has been observed after extended O_2 exposure at 2 ATA.[111]

Reanalysis of a larger data set than the one used for the UPTD model, which included those data, resulted in a different prediction equation:

$$\%\Delta VC = -0.009 \cdot (P - 0.38) \cdot t$$

where P and t are the same as for the previous equation.[112]

Using previously published data, Arieli and colleagues[113] developed the following equation:

$$\%\Delta VC = 0.0082 \cdot t^2 \left(Po_2/101.3\right)^{4.57}$$

where t is time in hours and Po_2 is measured in kilopascals (kPa).

Although these algorithms may be useful as an approximate guide to safe O_2 exposures in populations, interindividual variability is such that they cannot be relied on to predict accurately the development of pulmonary O_2 toxicity for a specific patient.[114] Furthermore, O_2 toxicity can be modified by humidity,[115] circulating catecholamine and corticosteroid levels, leukocyte accumulation in the lungs (e.g., with pneumonia), and circulating endotoxin. A more useful guide to the development of pulmonary toxicity is the patient's symptoms, which include cough and inspiratory central burning chest pain. These symptoms do not occur during routine repetitive HBO treatment but may become evident during extensive O_2 periods at 2.8 ATA, for example when treating neurologic decompression illness. Asymptomatic persons usually have minimal or no change in vital capac-

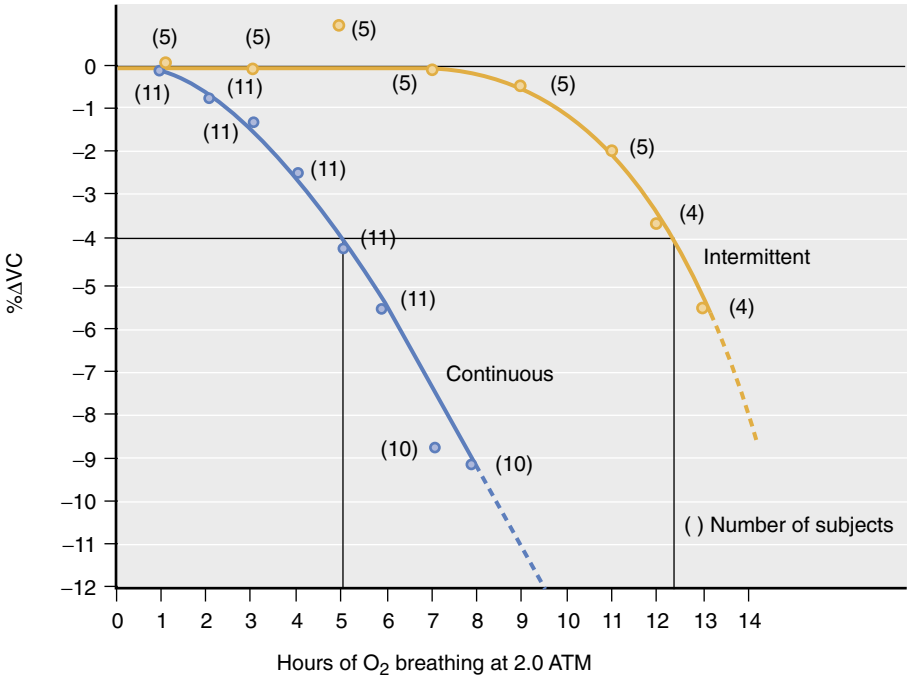

Figure 80-10 Decrease in vital capacity (VC) as a function of time breathing 100% O_2 at 2 ATA in humans. The figure illustrates the value of intermittent O_2 (20 minutes O_2, 5 minutes air) versus continuous administration in the prevention of pulmonary O_2 toxicity. The numbers in parentheses represent the number of subjects tested. *(From Clark JM: Oxygen toxicity.* In *Bennett PB, Elliott DH [eds]: The Physiology and Medicine of Diving. Philadelphia, WB Saunders, 1993, pp 121-169, with permission.)*

ity. Minor changes in forced expiratory volume in 1 second (FEV_1) reported during repetitive HBO treatments[116] are of uncertain clinical importance.

Some antineoplastic agents, such as bleomycin[117] and mitomycin C,[118,119] appear to predispose to fatal pulmonary O_2 toxicity (ARDS and respiratory failure) from what should otherwise have been well-tolerated doses of supplemental O_2. The risk of pulmonary O_2 toxicity due to HBO therapy in patients with previous exposure to such agents is unknown, although we have treated several such individuals with a remote history of bleomycin treatment with repetitive doses of HBO at 2 ATA for 2 hours (initially once daily, then increased to twice daily). Occasional mild pulmonary O_2 toxicity symptoms such as retrosternal chest tightness did occur, but none experienced severe O_2 toxicity. Propensity to pulmonary O_2 toxicity engendered by these drugs appears to diminish a few weeks after their discontinuation.

CNS O_2 toxicity manifests as nausea, vomiting, numbness, twitching, dizziness, olfactory, acoustic, or gustatory sensations, and, in its most severe form, as nonfocal tonic/clonic seizures.[120,121] The probability of seizures increases with increasing P_{O_2} and time of exposure. In a study of 36 divers breathing 100% O_2 at 3.7 ATA, all experienced one or more of these symptoms within 100 minutes or less.[120,121] In clinical practice, convulsions in patients undergoing HBO therapy are rare at ambient P_{O_2} up to 2.5 ATA (typically 0.008% to 0.035% of treatments[122]) and often have another predisposing factor. The probability of a convulsion is also greater when administered for acute indications such as carbon monoxide poisoning.[123] Metabolic factors may reduce the seizure threshold, such as the administration of high-dose penicillin (e.g., for clostridial infection), sepsis, and hypoglycemia.

The treatment of hyperoxic seizures is immediate reduction of the inspired P_{O_2} until the seizure stops. Some physicians then routinely administer an anticonvulsant such as phenobarbital, phenytoin, or a benzodiazepine. It is generally recommended that the chamber should not be decompressed while the patient is actively convulsing because airway closure and failure to exhale during this period may cause pulmonary barotrauma. Hyperoxic seizures otherwise have no sequelae and rarely recur even if HBO is continued. Thus the occurrence of CNS O_2 toxicity should not preclude further HBO. There is no evidence that hyperoxic seizures are more common in patients with preexisting seizure disorders.

An acute effect of HBO on the eye is narrowing of the visual fields,[124] which is generally only observed at a P_{O_2} of 3 ATA or greater and thus rarely during routine HBO treatments. A subacute or chronic ocular effect is a change in the refractive index of the lens, resulting in myopia.[125,126] Such refractive index change occurs during the course of intermittent HBO therapy over several weeks and usually resolves in a similar period of time. However, some patients may be left with residual myopia, particularly if elderly.[127]

Concern has been raised about the risk of retrolental fibroplasia in the unborn child of a woman who may require acute HBO therapy during pregnancy. Although many pregnant women have been treated with single exposures to HBO (e.g., for CO poisoning), we are not aware of any subsequent occurrence of retrolental fibroplasia in the child. Pregnancy is not a contraindication to HBO for appropriate acute indications (e.g., CO poisoning[60,62,64,128,129]), because the risk to the fetus of the underlying condition exceeds that of the treatment.

Table 80-7 Resting Blood Gas and Heart Rate Values in a Group of Normal Volunteers Acutely Exposed to Various Altitudes in a Hypobaric Chamber (mean ± SD)

Altitude (ft)	Barometric Pressure (mm Hg)	Pao_2 (mm Hg)	Sao_2 (%)	$Paco_2$ (mm Hg)	pH	HR (beats/min)
0	750	103 ± 11	99 ± 1	34 ± 5	7.44 ± .04	78 ± 15
5,000	632	78 ± 8	94 ± 4	33 ± 3	7.42 ± .04	92 ± 16

Inert Gas Uptake

Breathing air at high ambient pressure can result in nitrogen narcosis, a dose-dependent decrement in cerebral performance due to the anesthetic properties of nitrogen. This only occurs to any significant extent at ambient pressures exceeding 4 ATA, a treatment pressure that is only utilized for severe arterial gas embolism or DCS. Nitrogen uptake can also result in DCS during or after decompression (see earlier). However, chamber decompression schedules are so conservative that this rarely occurs (most hyperbaric facilities use U.S. Navy compressed air decompression tables[109]). Additional safety for the tender can be provided by requiring the tender to breathe 100% O_2 for a period immediately before and during decompression (Table 80-7). Rare episodes of DCS in hyperbaric tenders are usually of a minor nature, generally consisting of mild joint pain. Nitrogen narcosis and DCS could only occur in tenders in a multiplace hyperbaric chamber; patients breathe 100% O_2 and are therefore not susceptible.

Barotrauma

As the ambient pressure is altered, the pressure within gas-containing spaces in the body must equilibrate with the ambient pressure or undergo a change in volume. Volume change can easily occur in compliant compartments such as the gastrointestinal tract, but if there is obstruction to free flow of gas into and out of containing spaces surrounded by a rigid shell, such as the lung, paranasal sinuses, and middle ear, then tissue disruption and hemorrhage can occur. Indeed, the most common patient side effect of hyperbaric chamber use is the difficulty with middle ear pressure equilibration.[130] In awake patients, equilibration may be accomplished using several techniques, such as performing intermittent Valsalva maneuvers, swallowing while the nose is pinched, thrusting the jaw forward, or simply swallowing intermittently during compression. Patients with prior irradiation of the head and neck and acute respiratory tract infections are at particular risk. Equilibration may be facilitated by application of a topical nasal vasoconstrictor (e.g., oxymetazoline, 0.05% [Afrin]). For patients who cannot equalize despite these measures, or for obtunded or intubated patients, myringotomy or tympanostomy tubes may be required. Theoretically, HBO exposure in a patient with obstructed eustachian tubes could cause labyrinthine window rupture, but to our knowledge this has not been reported during HBO treatment.

Pulmonary barotrauma is most likely during decompression. Areas of regional hypoventilation could lead to pulmonary overpressurization and alveolar rupture, causing pneumothorax, pneumomediastinum, or arterial gas embolism.[131,132] Pulmonary barotrauma during HBO therapy is extremely rare, probably due to slow decompression rates typically used.

Although a pneumothorax would be expected to diminish in size and resorb more quickly after compression, continuing leakage of air from the lung might result in tension pneumothorax during decompression.[131] Pneumothorax detected before treatment is usually treated by insertion of a chest tube and water seal or Heimlich-type valve. Caution must be exercised when using certain commercially available pleural suction regulators, which can exert high negative pleural pressures during chamber compression.[133] Such excessive suction can be relieved by an attendant inside a multiplace chamber by activating the manual pressure relief valve on the chest drainage unit.

Despite these potential adverse effects of HBO therapy, major complications are extremely rare.[130]

Practical Aspects of Hyperbaric Therapy

Patient Monitoring

Despite the changes in the acoustic properties of compressed air, blood pressure measurement may be performed without difficulty with a standard sphygmomanometer and stethoscope (see Chapter 38). Aneroid pressure gauges are preferred to mercury to avoid contamination of the closed environment. Monitoring of the electrocardiogram (ECG) and of intravascular pressures requires that transducer cables be plumbed through the chamber wall to preamplifiers outside the chamber. Standard intensive care monitors can be used to provide simultaneous measurement of arterial and pulmonary artery pressures and intermittent measurement of cardiac output by thermodilution. If pressure bags are used to drive continuous-flow systems, they must be repressurized during compression and vented before or during decompression. Pulmonary artery catheter balloon ports should also be left open to the chamber during compression and decompression.

Defibrillation could generate a fire if there is sparking and combustible materials in the vicinity of the paddles. Sparking and heat generation can be minimized by using a low resistivity conductive gel between the electrodes and the skin[134] or pre-applied

conductive disposable pads.[135] To avoid pressure-related malfunction of the device, the defibrillator can remain outside the chamber and connection to the patient via through-hull high voltage wiring. Despite the fear of causing fire, defibrillation has been carried out in multiplace chambers numerous times without arcing, fire, or explosion.[136,137] Defibrillation cannot be safely performed inside a monoplace chamber compressed with O_2.

Intravenous Fluid Administration

In multiplace chambers the air volume within the drip chamber will shrink during the compression phase of the HBO treatment and expand during decompression (which could force air into the intravenous line). Most intravenous infusion pumps work well inside a hyperbaric chamber at pressure (although there are electrical safety issues [see later]). Glass bottles are best excluded from the chamber because of the possibility of explosive rupture during decompression.

Administration of fluids to patients inside a pressurized monoplace chamber requires an infusion pump capable of handling the pressure differential (up to 3 ATA or 1500 mm Hg pressure gradient across the chamber wall). Check valves can prevent unintended backflow of blood from the patient in the event of disconnection of the pump. Rigid arterial-pressure transducer tubing will help to prevent kinking while the patient is inside the chamber.

Blood Gas Assessment and Ventilator Management

Blood gas measurement on arterial samples obtained from a patient inside a hyperbaric chamber can be erroneous. There are two reasons. At 1 ATA, oxygen tensions that exceed the ambient pressure will be supersaturated and thus O_2 will rapidly diffuse out of the blood, thus lowering its tension. An additional error (extrapolation error) is due to the impossibility of accurate P_{O_2} electrode calibration at P_{O_2} values exceeding around 700 mm Hg. Blood gas tension measurement should therefore ideally be performed inside the hyperbaric chamber using an appropriately calibrated analyzer. If such a capability is not available, rapid analysis at 1 ATA of decompressed samples can produce acceptably accurate values.[138]

Another approach is to estimate the hyperbaric Pa_{O_2} based on measurements obtained at 1 ATA. Using a measured Pa_{O_2} and a calculated alveolar P_{O_2} (P_{AO_2}) the ratio of the two (Pa_{O_2}/P_{AO_2}, or a/A ratio) is a constant.[9,139] On this basis, 1 ATA arterial blood gas values and the following equations can be used to predict Pa_{O_2} at pressure.

The alveolar gas equation is required to calculate P_{AO_2}:

$$P_{AO_2} = F_{IO_2} \cdot (Pb - P_{H_2O}) - P_{ACO_2} \cdot \left(F_{IO_2} + \left[(1 - F_{IO_2})/R\right]\right)$$

where Pb and P_{H_2O} are, respectively, ambient and saturated water vapor pressures, and R is the respiratory exchange ratio. If F_{IO_2} = 0.2, R = 0.8, and body temperature = 37°C, then this equation can be simplified to:

$$P_{AO_2} = (Pb - 47) \cdot 0.2 - 1.2 \cdot P_{CO_2}$$

Having calculated P_{AO_2} and measured Pa_{O_2}, the a/A ratio can then be obtained at 1 ATA. The predicted Pa_{O_2} at increased ambient pressure while breathing 100% O_2 may then be obtained from this next equation:

$$Pa_{O_{2(pred)}} = a/A \cdot \left[(760 \cdot ATA - 47) - Pa_{CO_2}\right]$$

where ATA is the chamber pressure in atmospheres absolute. Although as yet there are no dose-response curves for HBO, a reasonable aim is to achieve Pa_{O_2} greater than or equal to 1000 mm Hg for routine chronic therapy and to as high a level as possible for treatment of acute necrotizing infections (Fig. 80-11).

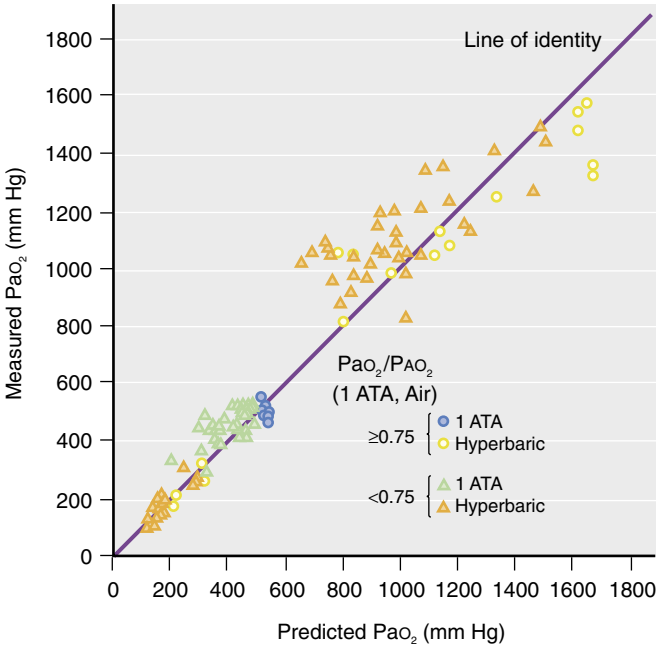

Figure 80-11 Measured versus predicted Pa_{O_2} at increased ambient pressure. Predicted Pa_{O_2} is calculated from room-air arterial blood gases, assuming that the arterial-alveolar P_{O_2} ratio (Pa_{O_2}/P_{AO_2}, or a/A ratio) is a constant. Data are shown both for persons with normal lungs (a/A ratio ≥ 0.75) and for patients with gas exchange abnormalities (a/A ratio < 0.75). It is evident that Pa_{O_2} predicted in this way is close to the actual measured Pa_{O_2}. *(From Moon RE, Camporesi EM, Shelton DL: Prediction of arterial P_{O_2} during hyperbaric treatment.* In *Bove AA, Bachrach AJ, Greenbaum LJ Jr [eds]: Underwater and Hyperbaric Physiology IX. Proceedings of the Ninth International Symposium on Underwater and Hyperbaric Physiology. Bethesda, MD, Undersea and Hyperbaric Medical Society, 1987, p 1127.)*

A better monitor of tissue oxygenation may be mixed venous P_{O_2} ($P\bar{v}_{O_2}$), which, in the absence of left-to-right shunt, may be a reasonably accurate estimate of mean tissue P_{O_2}; thus a low value may indicate inadequate tissue oxygenation despite HBO, owing to insufficiently high cardiac output.[140]

Normal values for pH and P_{CO_2} under resting clinical hyperbaric conditions are the same as they are at 1 ATA.[14,15,141] P_{CO_2} (and hence pH) do not change significantly in blood samples that are decompressed.

Mechanical ventilation in a hyperbaric environment presents a variety of challenges. The ideal requirements for ventilation include small size, no electrical requirement, absence of flammable lubricants, ability to operate on a volume-cycled basis over a wide range of tidal volumes and respiratory rates, minimal modification requirement for installation, and ability to provide positive end-expiratory pressure, as well as to ventilate in inter-

mittent mandatory ventilation and assist/control modes.[142] Additionally, the ideal gas source to actuate the ventilator should minimize the risk of combustion caused by buildup of static electricity.

As ambient pressure increases, gas density is proportionately raised, whereas there is relatively little change in gas viscosity. Therefore, in regions of turbulent flow (i.e., in the large airways) airway resistance increases. Measurements of respiratory conductance (the reciprocal of resistance) during tidal breathing[143] indicate that it varies with gas density according to the following formula:

$$G = G_0\rho(\kappa)$$

where G is lung conductance at gas density ρ; G_0 is the conductance at gas density 1.1 g/L (1 ATA); and κ is a constant that was found to have a mean value of −0.39. At 6 ATA this equation predicts that lung conductance would decrease by 50%, which is equivalent to a doubling of pulmonary resistance. In addition, the higher gas density results in a less efficient distribution of ventilation, manifested by an increase in physiologic dead space.[144] The effects of these two phenomena include higher airway pressures during mechanical ventilation and an increased ventilatory requirement. If ventilator settings are not adjusted to compensate for the higher dead space, a rise in $Paco_2$ will occur.

Several types of ventilators have been used and tested in hyperbaric chambers. Pressure-cycled devices have been used with some success, because their compactness admirably fulfills the requirement for small size. However, continual adjustment of rate and cycling pressure is necessary with changes in ambient pressure. Volume-cycled ventilators seem to work well,[142,145] although at increased pressure some changes in rate may occur.

There are two specific safety considerations. First, in any ventilator delivering enriched O_2, a possible fire hazard can occur owing to O_2 buildup within the ventilator case or leakage of O_2 into the chamber. This can often be offset by minor alterations, for example, for a pneumatic ventilator using air versus oxygen to drive the bellows.[142] The risk of ignition can be substantially mitigated by purging the device with an inert gas such as 100% nitrogen (see later). Air-filled endotracheal tube cuffs will tend to lose volume during compression and reexpand during decompression. Appropriate cuff inflation volume can be maintained either by manual adjustment of the air pressure within the cuff during compression and decompression or filling the cuff with water.

Atmosphere Control

Chamber atmosphere safety includes management of levels of O_2, CO_2, and trace gases. In a multiplace chamber it is essential that the patient breathe as high a concentration of O_2 as possible (usually 98% or greater) while maintaining the chamber O_2 concentration close to 21% to minimize fire hazard. In some hyperbaric units, head-tent O_2 concentration is routinely monitored. In others, the concentration is assumed to be high because of a high rate of O_2 flow through the head tent. Leakage of O_2 from head tents, masks, and ventilators will tend to raise the chamber O_2 concentration. Typically, an upper limit of around 23% is used as a criterion for ventilating the chamber with air or small volumes of 100% nitrogen until the O_2 concentration decreases.

Significant elevations of inspired CO_2 concentration will increase the risk of CNS O_2 toxicity. Therefore, a typical standard for the upper limit for head-tent CO_2 is 1% "surface equivalent" CO_2, equal to a partial pressure of 7.6 mm Hg. Using a nonscrubbing (open circuit) system, head-tent O_2 flow rates of 40 to 60 L/min (measured at chamber pressure) are usually adequate to keep CO_2 levels at such a level. Chamber CO_2 is usually limited to less than 0.5% "surface equivalent" (3.8 mm Hg).

Trace gases that may enter the environment include carbon monoxide and hydrocarbons from improperly functioning compressors or from automobile exhaust that may be near the compressor air intake. Volatile gases such as alcohol vapor from skin disinfectant solutions and mercury vapor from spillage of sphygmomanometer columns may also pollute the atmosphere. Trace gas concentrations that are innocuous at atmospheric pressure can be toxic under hyperbaric conditions because their pharmacologic or toxic effects are related to partial pressure. Mercury in any form should be excluded from hyperbaric chambers, because spillage can cause acute toxicity in chamber occupants.

Considerations of battery use may have implications for chamber atmosphere control as well as fire hazards. All batteries release small quantities of hydrogen, although not usually in amounts that would be hazardous. Lithium/sulfur dioxide batteries carry a theoretical risk of sulfur dioxide discharge. Similarly, there is an objection to the use of mercury cells (now banned in the United States). Alkaline cells are considered safe, although temporary failure has been observed at extremely high ambient pressures (40 to 60 ATA).

Fire Hazards

Although fires in hyperbaric chambers are rare, they are usually lethal. The effects of fire at elevated ambient pressure are so devastating and so fast that fire extinguisher systems may not be effective (see Chapter 77). The very real risk of fire in hyperbaric chambers has been illustrated by recent accidents in which chamber fires were started by a hand warmer, a sparking toy, and other sources of ignition carried into the chamber in the patient's clothing. Minimization of these risks involves the following:

- Control of chamber O_2 concentrations (irrelevant in a monoplace chamber)
- Minimizing the use of combustible materials within the chamber
- Controlling sources of heat and spark
- Chamber fire extinguisher system

The geometric increase in burning rate with increases in O_2 concentrations mandates careful monitoring of chamber O_2, as already noted. At increased ambient pressure, burning occurs more rapidly, even when O_2 concentration is 21%. Cotton garments are recommended because of their reduced risk of static electricity. Elimination of hair grease and humidification of the O_2 within the head tent can reduce the risk of hair ignition. Hydrocarbon lubricants (e.g., for stretcher wheels) can spontaneously ignite on contact with aluminum in the presence of high O_2 tensions and should therefore be replaced with nonflammable fluorocarbon lubricants.

Sources of sparks from electrically powered equipment should be minimized. Cigarette lighters, matches, and other

sources of ignition should be excluded from the chamber. Plugging and unplugging electrical cables during hyperbaric treatments is a source of sparking that can be eliminated by taping all electrical plugs onto female receptacles before compression. In multiplace chambers the flammability of electrically powered devices (e.g., intravenous controllers) can be reduced by purging with 100% nitrogen via ports drilled in the covering, at a rate sufficient to keep O_2 concentration at a level that does not support combustion (typically at a flow rate of two to three times the internal volume per minute). Electrical systems used in monoplace chambers must comply with specific codes, which specify the types of switches, grounding, and insulation that can be used.[105]

Fluorinated anesthetics can be combustible at 1 ATA in high concentrations. However, isoflurane and sevoflurane Dräger vaporizers have been tested up to 3 ATA using 100% O_2, with no evidence of spontaneous combustion at room temperature. Given the experience with halothane under hyperbaric conditions, without any reported fires, and the resistance to combustion in 100% O_2 at 1 ATA, in the absence of a source of ignition it is unlikely that any of the modern fluorinated anesthetics pose a fire safety hazard in the hyperbaric environment.

Evaluation of a Patient for Safety of HBO Treatment

In addition to ensuring that HBO is indicated for the disease process in question, it is important to assess the patient in terms of general effectiveness and safety of HBO. The following issues are pertinent:

- Whether a sufficient elevation in Pao_2 can be obtained
- Whether the patient can equilibrate middle ear pressure
- Optimization of reversible obstructive lung disease and the presence of pulmonary bullae or blebs
- Whether the patient is susceptible to claustrophobia

The calculation of predicted Pao_2 in the hyperbaric chamber was described previously. For example, a patient who has sufficient lung disease or injury such that Pao_2 during treatment would not exceed 1000 mm Hg would probably obtain marginal benefit from HBO unless the reason for HBO is gas bubble disease.

The ability to vent the middle ears may be assessed before treatment by observing directly the tympanic membrane with an otoscope while the patient holds his or her nose or performs a Valsalva maneuver. Movement of the eardrums indicates a patent eustachian tube and the ability to equilibrate middle ear pressure. If otic barotrauma is unlikely to be avoided (e.g., with mental obtundation or the presence of an endotracheal tube) or because of a condition that may render the patient susceptible to inner ear injury (e.g., stapedectomy), myringotomy or tube placement can be performed before HBO treatment. The presence of pulmonary bullae or blebs represents a relative contraindication to HBO because of the possibility of barotrauma, although a large clinical experience suggests that the risk is extremely low.

For patients requiring more than 20 to 30 HBO treatments, periodic checks of visual acuity may be useful to assess hyperbaric myopia.

Because most hyperbaric chamber systems are small and cramped, patients who cannot tolerate enclosed spaces may require anxiolytic therapy to facilitate toleration of the HBO therapy.

Delivery of Anesthesia at Increased Ambient Pressure

A review of the problems of anesthesia under HBO was published as a report to a committee of the American Society of Anesthesiologists.[146] This report explored various issues, including the potential for nitrous oxide to be used as a sole anesthetic.

Anesthesia while breathing spontaneously in a 100% O_2 atmosphere at 3 ATA was reported in the 1950s for radiation therapy.[147] Patients were intubated after administration of pentobarbital, 250 to 750 mg, and meperidine, 100 mg; some patients also received chlorpromazine, 50 mg. Intubation was performed after succinylcholine and topical anesthesia of the airway. Patients breathed spontaneously.

Anesthesia may be required as a procedure incidental to the hyperbaric exposure. Ross and associates[148] discussed the challenges of anesthesia up to 35 ATA in order to provide care for injured divers while in a saturation diving system (e.g., in North Sea oil fields). They suggested using intravenous agents for general anesthesia rather than gaseous anesthetics because of the problems of pollution of the chamber environment with the latter. Regional anesthesia was recommended whenever possible. The authors noted that muscle relaxants should be titrated to effect because some degree of pressure reversal at around 10 ATA has been reported.

Since the 1960s anesthesia has been performed at increased ambient pressure using a variety of agents for carotid endarterectomy,[149] cesarean section,[150] therapeutic lung lavage for patients with alveolar proteinosis,[103,104] emergency surgery in a saturation dive,[151] open heart surgery,[152] and enhancement of the effectiveness of irradiation of carcinoma.[153]

Inhaled Anesthesia

Inhaled anesthesia of any type can pollute the enclosed chamber atmosphere with anesthetic gases, which may exert pharmacologic effects on medical personnel inside the chamber, particularly at high ambient pressures. Russell and colleagues[154] reported nitrous oxide concentrations in chamber air of 2500 ppm; ventilation of the chamber with air at a high rate (3500 L/min of air) was required to reduce the concentration to 25 to 75 ppm.

Nitrous Oxide

The increased ambient pressure in a hyperbaric chamber allows nitrous oxide to be used at partial pressures exceeding its minimum alveolar concentration (MAC).[154-156] Although in both studies induction of anesthesia by nitrous oxide was rapid (<60 seconds) it was accompanied by tachypnea, tachycardia, hypertension, diaphoresis, muscle rigidity, catatonic jerking of the extremities, eye opening, and opisthotonus. After 2 to 4 hours of anesthesia, most subjects emerged rapidly from the anesthetic; however, the majority subsequently experienced nausea and vomiting, which was often severe.

A potential problem associated with nitrous oxide anesthesia at high ambient pressures is the possibility that tissues could

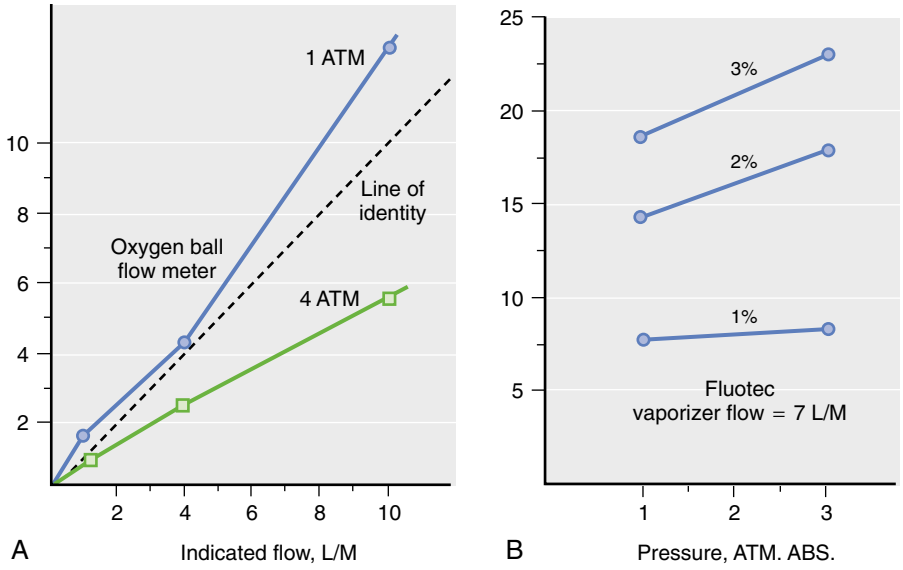

Figure 80-12 Performance of an anesthetic vaporizer system at increased ambient pressure. **A,** Flow characteristics of a rotameter system are shown. At 4 ATA the actual delivered flow is less than 60% of the flow indicated by the rotameter. **B,** Fluotec vaporizer output in partial pressure of halothane as a function of ambient pressure. Only small increases in delivered partial pressure are evident at 3 ATA, at the 2% and 3% settings. *(From Committee on Hyperbaric Oxygenation: Fundamentals of Hyperbaric Medicine [Publication No. 1298]. Washington, DC, National Academy Press, 1966.)*

become supersaturated during decompression, allowing N_2O bubbles to form during decompression. This was not observed by Russell and associates,[154] who used an empirical staged decompression schedule with a decompression stop for 30 minutes at 1.3 ATA while the patients breathed 100% O_2. Bubble formation can occur without decompression if the patient breathes one gas while surrounded by an atmosphere of another gas that is more diffusible. For example, breathing air while in a helium/O_2 environment at 5 to 7 ATA can lead to urticaria and vestibular dysfunction[157] owing to rapid diffusion of helium into tissues, causing local inert gas pressure to exceed ambient pressure (isobaric gas counterdiffusion). This phenomenon can even occur at normal atmospheric pressure if a person breathes nitrous oxide/O_2 while surrounded by helium.[158] Therefore, it is imperative that nitrous oxide never be administered in a helium/oxygen atmosphere.

Another risk of hyperbaric N_2O is the dilutional effect of large volumes of dissolved gas entering the lungs during decompression, causing dilutional hypoxia. This can be prevented by administration of an O_2-enriched breathing mix for several minutes before decompression.

In patients who have recently engaged in scuba diving or have suffered decompression illness, nitrous oxide should be avoided, even at 1 ATA, because its administration may result in tissue or blood bubble growth and recrudescence of pain or neurologic symptoms. Neurologic symptoms were reported after a nitrous oxide anesthetic after apparent spontaneous resolution of decompression illness.[159]

The effect of a volatile anesthetic on a patient is proportional not to the alveolar concentration but to the partial pressure of the anesthetic. For example, the effect of 1% halothane at 1 ATA (with a partial pressure of 7.6 mm Hg) will be equivalent to a 0.5% concentration at 2 ATA (with the same partial pressure). The anesthetic concentration of an anesthetic-specific calibrated vaporizer varies with ambient pressure, but in a manner such that delivered partial pressure remains constant (Fig. 80-12). Because of the effect of increased gas density on this flow ratio, in practice the delivered partial pressure is somewhat dependent on ambient pressure. A slightly increased partial pressure of halothane delivered by a Fluotec vaporizer at 3 ATA has been observed (see Fig. 80-12[146]). Our testing of a sevoflurane vaporizer revealed delivery of a constant partial pressure of anesthetic, up to the maximum tested ambient pressure: 3 ATA.

Rotameter flow meters calibrated at 1 ATA will indicate falsely high values at increased ambient pressure because of the increased gas density. McDowell[160] reported the following relationship for rotameter flow:

$$\text{Flow}_{\text{actual}} = \text{Flow}_{\text{read}} \cdot \sqrt{\rho_1/\rho_P}$$

where $\text{Flow}_{\text{actual}}$ and $\text{Flow}_{\text{read}}$ are the actual and scale reading flows and ρ_1 and ρ_P are the gas densities at 1 ATA and P ATA, respectively. This inaccuracy in rotameter performance up to 4 ATA has been confirmed by others (see Fig. 80-12).[146]

Intravenous Anesthesia

Intravenous anesthetics behave similarly and are unlikely to be affected within the usual clinical range of ambient pressure (see Chapter 26). There is no evident alteration in the pharmacokinetics of either meperidine[31] or pentobarbital[32] at ambient pressures up to 6 ATA. For therapeutic lung lavage we have provided general anesthesia at ambient pressures up to 3 ATA using conventional doses of ketamine and benzodiazepines or propofol and narcotics with nondepolarizing muscle relaxants.

Regional Anesthesia

Regional anesthesia is likely to be both safe and effective in a hyperbaric environment by avoiding the requirement for mechanical ventilation (see Chapters 51 and 52). A bowel resection has been performed at an ambient pressure 6.75 ATA in a helium/O_2 environment using local injection of lidocaine supplemented with

parenteral meperidine.[151] Extreme care should be taken to ensure sterile technique because of the propensity for enhanced bacterial growth in the warm, humidified environment of a hyperbaric chamber, particularly during saturation chamber exposures.

Effects of Altitude

There are approximately 140 million people worldwide living permanently at altitudes greater than 2500 m[161] and possibly an equal number who visit high altitudes each year, many of whom will require medical care. There is therefore clearly a need for anesthesia and critical care practitioners to understand the physiology of this environment.

Unlike the relationship between ambient pressure and water depth, the relationship between pressure and altitude is a nonlinear one (see Fig. 80-2). The physiologic effects of altitude exposure are mainly attributable to reduction in the following three variables: inspired P_{O_2}, ambient pressure, and gas density. Extreme or prolonged altitude exposure may be accompanied by additional factors, which may modulate physiologic responses, such as hypothermia, exertion, dehydration, sunburn, and polycythemia. Pregnant women and individuals with hypoxic conditions such as cerebrovascular disease, congenital heart defects, coronary artery disease, and hypoxic lung disease may carry additional risks that require medical evaluation.[162]

Hypoxia

Physiologic Changes

The major reason for hypoxemia at altitude is the reduction in inspired P_{O_2}, augmented by the failure of erythrocytes in the pulmonary circulation to equilibrate fully with alveolar gas (diffusion nonequilibrium)[163] and increased ventilation/perfusion ($\dot{V}_A/\dot{Q}$) mismatch.[164]

The acute blood gas and heart rate responses to acute hypoxia are shown in Tables 80-4 and 80-7. Heart rate and cardiac output are increased.[165] Systemic vascular resistance is decreased, and pulmonary vascular pressure is increased.[166] There is a corresponding increase in organ blood flow, including cerebral blood flow. Hypoxia also induces hyperpnea (due to increased breathing rate) to a degree that varies considerably among individuals. End-tidal P_{CO_2} measured in one subject breathing air at the summit of Mt. Everest (barometric pressure, 263 mm Hg) was 7.5 mm Hg while P_{AO_2} was 37.6 mm Hg.[167] This hypocapnia has several effects. It results in an increased affinity of Hb for O_2 (leftward shift of the Hb-O_2 dissociation curve), which enhances oxygenation of blood at the lung while simultaneously interfering with transport of O_2 from tissue capillary to mitochondrion. The overall effect on O_2 transport is beneficial.[168]

Hypoxemia may be particularly accentuated during sleep. Figure 80-13 depicts continuous pulse oximetry during transition from sleep to wakefulness at a simulated altitude of 4572 m in a hypobaric chamber, demonstrating periodic breathing and cyclic oscillation of Spo_2. Individuals with moderate obstructive sleep apnea at 1 ATA are at risk of severe central sleep apnea at altitude.[169]

Acute exposure to altitudes in the range of 4000 to 5000 m causes a decrease in arterial P_{O_2} to approximately 40 mm Hg and in arterial HbO_2 saturation to approximately 75%. Acute exposure to mild hypoxia appears to have only minor effects on CNS function. Crow and Kelman[170] found no decrement on free recall and visual scanning when normal subjects were exposed to a simulated altitude of 3658 m (inspired P_{O_2}, 92 mm Hg). Severe hypoxia can cause encephalopathy and loss of consciousness. A measure of this is the effective performance time, defined as the amount of time the individual is able to perform useful flying duties.[171] At 5500 m altitude the effective performance time is 20 to 30 minutes, which is reduced to 2.5 to 3 minutes at 8500 m and 1 to 2 minutes at 9100 m.

Gradual exposure to altitude or chronic exposure results in a series of adaptive changes, allowing individuals to function extremely well and do substantial physical work at altitudes at which newcomers can barely function. For instance, Mt. Everest has been climbed by adapted individuals without the benefit of supplemental O_2, whereas acute exposure to such an altitude would result in rapid loss of consciousness. Subjects exposed to a progressively lower barometric pressure, reaching to simulated

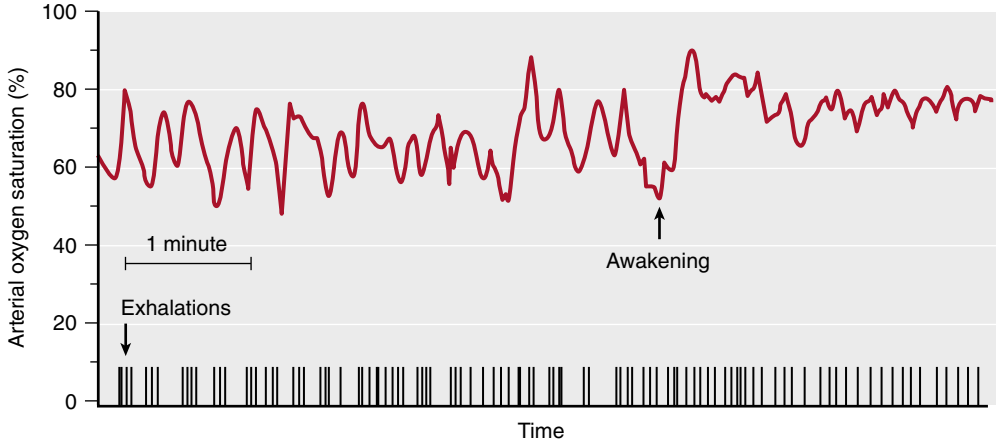

Figure 80-13 Pulse oximetry and breathing pattern (spikes at bottom represent exhalations) are shown in this subject in a hypobaric chamber at a simulated altitude of 4572 m. During sleep, periodic breathing and oscillatory alterations in Spo_2 change after waking up to a more regular breathing pattern and a steady Spo_2.

altitude of 8848 m in a hypobaric chamber over the course of 40 days, were able to work on an exercise ergometer at 120 W while their mean Pao_2 was only 30 mm Hg (arterial HbO_2 saturation, 58%).[172] In the same study, blood Hb concentration increased from 13.5 to 17.0 g/dL (hematocrit from 40.4% to 51.9%). The development of polycythemia may be one of many mechanisms by which tolerance to hypoxia occurs. However, the mechanisms of adaptation are still incompletely understood.

One of the adaptive mechanisms is a gradual reduction in plasma bicarbonate,[172] preceded by a decrease in cerebrospinal fluid (CSF) bicarbonate,[173] tending to offset the initial respiratory alkalosis. After a 40-day simulated "climb" of Mt. Everest in a hypobaric chamber, resting serum bicarbonate had decreased from 22.2 to 9.9 mM whereas pH had increased from 7.43 to 7.56.[172] Other adaptive changes include increases in hematocrit and capillary density, as well as undoubtedly other mechanisms as yet undiscovered.

Despite the adaptive mechanisms, careful neuropsychologic testing of subjects before and after mountaineering expeditions to extreme altitudes of 7000 m or greater has shown evidence of mild persistent performance impairment.[174,175] Such neuropsychologic impairment after prolonged extreme altitude exposure is correlated with a brisk hypoxic ventilatory response,[174] possibly owing to enhanced cerebral vasoconstriction and reduced brain O_2 delivery.

Effect of Maternal Hypoxia on the Fetus

Data on the fetal effects of maternal hypoxia are sparse (see Chapter 69). However, using changes in fetal heart rate (FHR) as an end point, the fetus appears to be relatively resistant to moderate degrees of maternal hypoxia. Administration of 15% O_2 (inspired Po_2 = 108 mm Hg, equivalent to 2500-m altitude) for 4 minutes to five primigravid women at 36 to 38 weeks' gestation resulted in an increase in FHR of only 2 to 3 beats/min.[176] The same investigator observed no change in FHR after administration of mixtures as low as 10% O_2 (inspired Po_2 = 71 mm Hg, equivalent to 5300-m altitude) for 20 minutes in 8 of 28 pregnant women. Administration of 10% O_2 for 10 minutes to pregnant women at 35 to 41 weeks' gestation had no significant effect on FHR, heart rate variability, or Doppler velocimetry in the umbilical and middle cerebral arteries of the fetus.[177] Acute hypoxia of this magnitude appears to exert no detectable effects on the healthy fetus because of augmentation of uterine blood flow; thus, it is unlikely that acute exposure to altitudes up to 2500 to 3000 m would have any adverse fetal effects.

Additional adaptations to chronic altitude exposure specific to pregnant women include an increase in placental capillary volume and a reduction in villous membrane thickness.[178] Infants born at altitude, even as high as 4329 m, have scalp vein O_2 tensions similar to values obtained from infants born at sea level.[179] Consequently, a significant reduction in maternal O_2 delivery can be tolerated without any impact on fetal O_2 consumption.

Infants Born at Altitude

As with adults, SpO_2 decreases with increasing altitude, but also depends on activity (lower during sleep), postnatal age (Fig. 80-14), and race.[180] Perinatal hypoxia appears to predispose to a blunted hypoxic ventilatory drive in adulthood.[181]

At sea level, pulmonary artery pressure decreases to normal levels within 24 hours after birth, whereas at altitude pulmonary artery pressure often remains elevated for several weeks or throughout infancy.[180] In a series of 35 consecutive infants born at term in Leadville, Colorado (altitude, 3179 m), during the first 3 months of life 17% experienced elevated pulmonary artery pressure or respiratory distress requiring supplemental O_2 or mechanical ventilation or both.[180] In infants born at altitude the transition to adult circulation occurs more slowly, with increased frequency of patent foramen ovale and patent ductus arteriosus.[182] Patent foramen ovale was present at 6 months in 7 of 16 infants studied after birth in La Paz, Bolivia (altitude, 3700 to 4000 m).[183] Acute hypoxia after birth (15% O_2 administration) in preterm infants paradoxically produced hypoventilation, periodic breathing, and apnea.[184] Infants with trisomy 21 (Down syndrome) are at

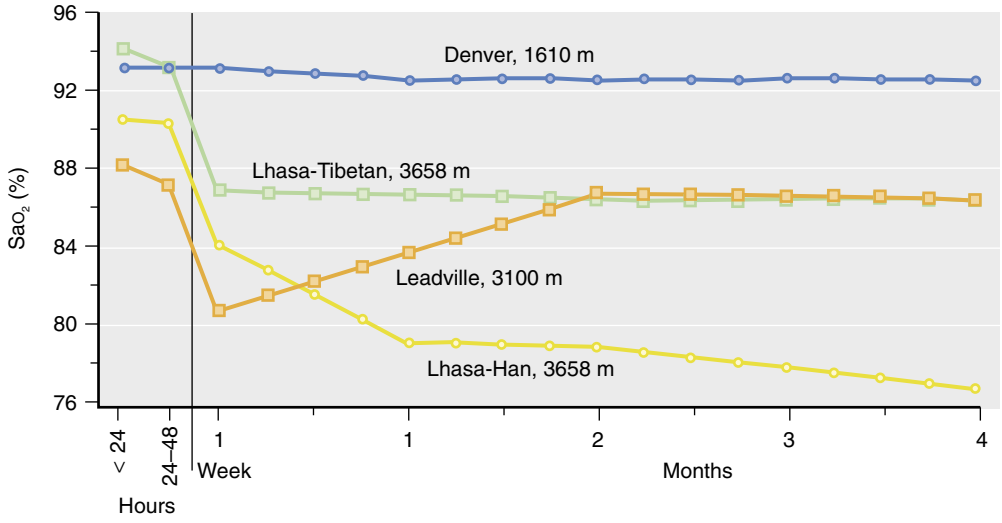

Figure 80-14 Pulse oximetry in infants born at various altitudes. In infants born in Lhasa (altitude of 3658 m), Han Chinese children have progressive arterial desaturation whereas Tibetan infants, following a slight drop shortly after birth, have a stable Spo_2. *(Redrawn from Niermeyer S: Cardiopulmonary transition in the high altitude infant. High Alt Med Biol 4:225, 2003.)*

increased risk of HAPE (see later).[182] Perinatal pulmonary hypertension seems to predispose to exaggerated hypoxic pulmonary vasoconstriction in adulthood.[185]

Effects of Altitude on Children

While Spo_2 is lower at higher elevations, children who reside at altitudes up to 3000 m generally maintain arterial oxygen saturation above 90%.[186] Exaggerated hypoxemia at altitude can suggest previously undiagnosed cardiorespiratory anomalies, such as Pierre-Robin syndrome or tracheomalacia-laryngomalacia.[182]

Altitude Illness

Altitude illness consists of a group of subacute and chronic syndromes, the underlying pathophysiology of which is triggered by continuous exposure to hypoxia. These are described here. Further information can be obtained from detailed reviews.[187,188]

Acute Mountain Sickness

The most common symptoms of AMS are headache, decreased appetite, nausea and vomiting, insomnia, ataxia, and peripheral edema.[189] AMS can occur after several hours of exposure to elevations greater than 2500 to 3000 m, although some people are more susceptible and can experience it at lower altitudes. Approximately 25% of visitors to ski resorts in the American Rockies (altitude, 1920 to 2960 m) develop AMS.[190]

Effective prophylactic measures against AMS in mountaineers include slow ascent (around 300 m/day) or "staging" in which several days are spent at an intermediate altitude of around 2000 m.[189] Pharmacologic prophylactic measures include the administration of acetazolamide,[191] which is believed to work in part by augmenting the ventilatory response to hypoxia due to the ensuing bicarbonate diuresis.[192] However, other purported mechanisms include tissue respiratory acidosis, improved sleep quality due to a reduction in periodic breathing (paradoxically due to its inhibition of the carotid body response to CO_2), and diuresis.[193] An effective dose range is 125 to 250 mg orally twice daily begun the day before ascent.[187]

Although most individuals recover spontaneously after several days at altitude, AMS can be treated effectively with oxygen and descent. A descent of only 500 to 1000 m usually leads to resolution of AMS. Simulated descent using a portable inflatable hyperbaric chamber (Gamow bag or similar) operated by foot pump (Fig. 80-15) is also effective. Depending on the altitude, inflation of such a chamber to only 2 psi (100 mm Hg) produces a decrease in equivalent altitude of 1500 to 2000 m.[187] AMS also responds to dexamethasone in a dosage of 4 mg every 6 hours, although symptoms may occur as soon as it is discontinued.[194,195] *Gingko biloba* has also been used, with mixed results.[196,197] Insomnia associated with AMS responds to treatment with acetazolamide. Sedative/hypnotic agents can depress ventilation and exacerbate hypoxia and should therefore be used cautiously. Both zolpidem (10 mg orally) and zaleplon (10 mg orally) improve sleep quality at altitude, and neither appears to depress ventilation in healthy young subjects.[198,199]

AMS symptoms could conceivably exist due to hypoxemia at sea level. It has been suggested that headache associated with obstructive sleep apnea and opioid-related headache may be due to a form of "AMS"—hypoxemia caused by respiratory depression.

Figure 80-15 Portable altitude chamber at Mt. Everest base camp. The pressure inside the bag can be raised to 2 psig (approximately 100 mm Hg) using a foot pump. This effectively reduces the "altitude" for the occupant of the chamber, thus raising the Po_2. These bags can be used to treat altitude illness when neither oxygen administration nor true descent is feasible. *(Photograph courtesy of Caudwell Xtreme Everest.)*

High-Altitude Pulmonary Edema

High-altitude pulmonary edema (HAPE) is much less common than AMS but more serious. It occurs in a small percentage of unacclimatized, susceptible people within a few days of reaching altitude.[166] A hemodynamic pathophysiology for HAPE is suggested by its tendency to occur when pulmonary vascular flows or pressures are particularly high, for example in the lung contralateral to unilateral absence of the pulmonary artery.[200] Measurements in patients with HAPE have revealed pulmonary hypertension, normal pulmonary artery wedge pressures, but elevated pulmonary capillary pressures (assessed using the single occlusion method).[201] Bronchopulmonary lavage fluid in subjects with HAPE has a high protein content, implicating an increase in permeability or alveolar-capillary disruption.[202-204]

Prophylaxis against HAPE includes slow ascent. People with known predisposing factors such as unilateral absence of the pulmonary artery should avoid high altitudes. For climbers with known HAPE susceptibility, prophylactic measures may include nifedipine (20 mg slow release formulation every 8 hours),[205] tadalafil (10 mg twice daily), or dexamethasone (8 mg twice daily).[206] Inhaled salmeterol also appears to be an effective prophylactic agent.[207] Whether acetazolamide prevents HAPE has not been established by randomized studies, but it is probably at least partly effective based on animal studies and its augmentation of Pao_2 during hypoxia.[208]

Treatment of HAPE consists of descent or supplemental oxygen or both.[187] If either descent is impossible or oxygen is unavailable, pharmacologic reduction in pulmonary artery pressure should be initiated. Nifedipine, 10 mg, sublingually followed by 20 mg of a slow-release preparation administered orally every 6 hours has been successful in HAPE.[209] Pulmonary artery pressure can also be lowered in patients with HAPE using hydralazine, phentolamine, or inhaled nitric oxide.[209-212] Other suggested treatments include agents that could lower pulmonary artery pressure, such as prostaglandins[213] and nitric oxide donors such as sildenafil,[213] or facilitate alveolar fluid clearance, such as β_2-adrenergic agonists,[207] recompression in a Gamow bag,[187] and application of expiratory airway pressure.[214]

High-Altitude Cerebral Edema

High-altitude cerebral edema (HACE) is the rarest but the most lethal form of high-altitude illness. Clinical diagnosis is made when there is ataxia or altered consciousness or both in a patient with AMS or HAPE.[215] Physical findings in patients with HACE may include papilledema, retinal hemorrhages, and, occasionally, cranial nerve palsies.[216] Focal abnormalities in the corpus callosum detected with MRI have been reported.[217] The pathophysiology of HACE is unknown. It has been hypothesized that individuals who develop AMS and HACE have a limited capacity to accommodate the associated increase in brain volume that accompanies the rise in cerebral blood flow during hypoxemia.[187,218]

Treatment of HACE is a medical emergency and ideally should include evacuation or descent and administration of supplemental O_2. Although a reduction in altitude of 500 to 1000 m is usually effective for AMS, treatment of HACE may require descent to a lower altitude. Use of a Gamow bag may also be effective. Recommended adjunctive treatment includes dexamethasone, 8 mg, immediately, then 4 mg every 6 hours. If descent is not possible, acetazolamide, 250 mg twice daily, may also be effective.[187]

Chronic Mountain Sickness (Monge's Syndrome)

Chronic mountain sickness has been defined as a clinical syndrome that occurs to natives or long-life residents above 2500 m. It is characterized by excessive erythrocytosis (females Hb ≥ 19 g/dL; males Hb ≥ 21 g/dL), severe hypoxemia, and, in some cases, moderate or severe pulmonary hypertension, which may evolve to cor pulmonale, leading to congestive heart failure.[219] Other manifestations include headache, dizziness, breathlessness and/or palpitations, sleep disturbance, fatigue, localized cyanosis, burning in the palms of the hands and soles of the feet and dilatation of the veins, muscle and joint pain, loss of appetite, lack of mental concentration, and alterations of memory.[219] The diagnosis requires the exclusion of other conditions that may produce hypoxemia, such as cyanotic heart disease and chronic lung disease. Clinical improvement and increased work capacity often result from phlebotomy, at least transiently, and descent to lower altitudes relieves the symptoms completely. Other suggested modalities for treatment of chronic mountain sickness include angiotensin-converting enzyme inhibitors, the D_2 dopaminergic receptor antagonist domperidone, acetazolamide, and the respiratory stimulants medroxyprogesterone and almitrine.[220] Both nifedipine and sildenafil may be effective to reduce pulmonary artery pressure.[220]

Reduction in Ambient Pressure

Acute ascent to altitude in an aircraft can cause decompression sickness (DCS) due to the reduced barometric pressure and supersaturation of nitrogen. Although symptoms have been reported to occur after rapid ascent in aircraft to only 2437 m[221] DCS usually occurs only in aircraft in which the cabin pressure is higher than 5000 to 6000 m,[222] which typically occurs only in military planes. Exposure to lower altitudes, including the cabin altitude of commercial aircraft (2400 m or less) within 12 to 24 hours after a scuba dive can also precipitate decompression illness.[223] To reduce this risk it is the practice of individuals planning a rapid decompression to low ambient pressure (e.g., military pilots, astronauts) to de-nitrogenate their tissues by pre-breathing 100% O_2 for periods ranging from a few minutes to several hours, depending on the altitude of the planned exposure.

Reduction in Gas Density

Reduction in gas density results in lower breathing resistance. Varene and associates[224] have examined the effect of ambient pressure from 0.5 to 5 ATA on airways resistance in normal subjects. Their data can be summarized by either of the following equations:

$$R_P/R_0 = 0.057 + 0.44 \cdot P_{ATA}$$

or

$$R_P/R_0 = P_{ATA}^{0.59}$$

where P_{ATA} is ambient pressure in ATA, R_P is airways resistance at ambient pressure, and R_0 is airways resistance at 1 ATA. For example, at an ambient pressure of 0.5 ATA (5486 m) airways resistance is reduced by approximately 20%. Under resting conditions, differences in breathing pattern during altitude exposure, compared with a similar degree of hypoxia at sea level, are minor.[225]

Other Environmental Stresses at Altitude

Individuals at altitude are subjected to low temperature, wind, and ultraviolet radiation. The effects of hypoxia may therefore be compounded by hypothermia, dehydration, frostbite, and sunburn. On the basis of a seemingly higher incidence of stroke,[226] thrombophlebitis, and pulmonary thromboembolism[227] at high altitude, it has been suspected that prolonged hypoxic exposure may cause a hypercoagulable state.[228] Indeed, rapid exposure to altitude in a hypobaric chamber has been associated with a decrease in partial thromboplastin time[229] and an increase in prothrombin fragments 1 and 2, thrombin-antithrombin complex, and factor VIIa activity.[230]

Anesthesia at Altitude

General Principles

Because of the reduced ambient P_{O_2} at high altitudes, the risk of perioperative hypoxia is likely to be magnified, particularly in newcomers to altitude. Opiates depress both the tachycardia and hyperpnea that normally occur in response to acute hypoxemia. Slow recovery of consciousness and postanesthetic headache have been reported after anesthesia using thiopental with air or nitrous oxide.[231] When ventilation was assisted or controlled during the anesthetic and when postoperative supplemental O_2 was administered, these complications did not occur, which suggests that intraoperative or postoperative hypoxemia may be a pathophysiologic factor. On the other hand, long-term residents at altitude may be more tolerant of hypoxemia; in such individuals other considerations may be important, including a higher hematocrit, pulmonary hypertension, and lower P_{aCO_2} and bicarbonate concentration.[172] To prevent renal retention of bicarbonate, which will reduce ventilatory drive, patients requiring controlled ventilation

should have their $Paco_2$ maintained at baseline value rather than in the traditionally normal range. Similarly, maintenance of Pao_2 within the sea level normal range will result in loss of adaptation and difficulty in readapting the patient to breathing room air.

Increased oozing of blood from surgical wounds at altitude has been reported[232] and attributed to higher venous pressure, blood volume, vasodilatation, and increased capillary density. Camporesi[233] has reviewed the topic of anesthesia at both high and low ambient pressures.

Anesthesia Equipment

Fluotec Mark II and Drager Vapor halothane vaporizer performance has been compared at sea level, 5000 ft (1524 m) and 10,000 ft (3048 m) altitude.[234] At any given setting the delivered percentage of halothane increased with altitude; however, its partial pressure remained constant. Therefore, when these devices are used at a given vaporizer setting, anesthetic will be delivered at a constant potency regardless of altitude (see Chapter 25).

The effect of altitude on floating-bobbin or floating-ball gas flow meters has also been examined.[234] At 10,000 ft (3048 m) simulated altitude, both nitrous oxide and O_2 flow meters underread the actual flow rate. The percentage error progressively increased up to 4 L/min, at which point both flow meters were approximately 20% in error. A hazard may therefore arise when a low flow of O_2 is mixed with a higher flow of nitrous oxide. Unless an O_2 analyzer is available, the delivered percentage of O_2 may be significantly lower than that calculated on the basis of the flow meter readings.

Venturi-type gas mixing devices tend to deliver higher concentrations of O_2 at altitude than they do at sea level[234]; at 10,000 ft (3048 m) altitude a mask designed to deliver 35% O_2 at sea level actually delivered 41% O_2.

Sedation

Standard sea level doses of sedatives/hypnotics may produce increased respiratory depression at altitude in unacclimatized subjects (see Chapters 78 and 79). A small dose of oral ethanol (50 g, producing an estimated blood alcohol concentration of 65 mg/dL, which was without ventilatory effect at ground level) increased blood Pco_2 by a mean of 1.5 mm Hg after acute ascent to 3000 m.[235] Both diazepam (5 mg orally) and temazepam (10 mg orally)[236] have been shown to have measurable effects on respiration at 3000 m. On the other hand, temazepam, 10 mg orally, improved sleep quality and reduced the number of desaturations during sleep in partially acclimatized mountaineers at 5300 m.[237] The difference in the studies is probably explained by different degrees of acclimatization to altitude. During acute altitude exposure in healthy young subjects neither zolpidem (10 mg orally) nor zaleplon (10 mg orally) adversely affected Spo_2 during sleep.[198,199]

General Anesthesia

The potency of anesthetic gases is proportional to their partial pressure. Therefore, as barometric pressure is reduced, fixed concentrations of inhaled anesthetics will have lower potency. At an altitude of 3300 m a significant reduction in efficacy of 50% nitrous oxide has been observed in reducing pain threshold in normal volunteers (Table 80-8).[238] Successful induction of general anesthesia with halothane in a hypobaric chamber has been reported at a barometric pressure of 375 mm Hg (equivalent altitude = 5490 m).[239] Recovery was rapid and uneventful.

Table 80-8 Effect of 50% Nitrous Oxide on Pain Threshold in Normal Volunteers at Altitude*

Altitude (m)	Barometric Pressure (mm Hg)	Increase in Pain Threshold (%)	Side Effects
0	760	71.5	3 subjects, nausea; 2 subjects, semi-comatose
1460	636	40.0	None
3300	517	19.0	None

*Pain threshold was measured in 20 subjects at each altitude by applying pressure to the anterior aspects of the tibia using a spring balance. Simulated altitude exposures were in a hypobaric chamber. At increasing altitudes a fixed concentration of N_2O is progressively less effective.
Data from James MFM, Manson EDM, Dennett JE: Nitrous oxide analgesia and altitude. Anaesthesia 37:285-288, 1982.

Because supplemental O_2 may not be available in some mountain locations it may be imperative to choose an anesthetic technique that is least likely to suppress ventilation. Ketamine anesthesia with spontaneous ventilation has been reported in 23 patients requiring general anesthesia at an altitude of 1830 m.[240] Two patients developed significant, although brief, desaturation, which resolved quickly. The authors concluded that this form of anesthesia is a practical method in a rural hospital setting at altitude without access to supplemental O_2.

Ketamine (total dose, 1-6 mg/kg) after intravenous premedication with atropine, 0.02 mg/kg, and midazolam, 0.05 mg/kg, was reported in a consecutive series of 11 patients (ASA Physical Status 1-2) requiring general anesthesia for short procedures at Kunde Hospital (Fig. 80-16) in Nepal (3840 m).[241] Nine patients required reduction of dislocations or fractures, one (9 years old) required suturing of a facial laceration, and one required drainage of an abscess. The induction dose of ketamine was 1 mg/kg administered intravenously over 1 to 2 minutes, followed by additional incremental doses, titrating to effect. Baseline Spo_2 on room air was 86% to 91%. Oxygen was administered in 3 of 11 cases via an O_2 concentrator if Spo_2 fell below 80% for 1 minute and was not correctable by forward jaw thrust or vocal and tactile stimulation. Both low-altitude residents required supplemental O_2 for 20 minutes during recovery, whereas only one of nine high-altitude residents required O_2. Use of ketamine has been reported at even higher altitude (4243 m) for control of postpartum hemorrhage in a 22-year-old woman.[242] Deep general anesthesia was obtained with only 25 mg of intravenous ketamine (approximately 0.5 mg/kg), which induced 5 minutes of apnea, requiring airway manipulation and supplemental oxygen. The total dose of ketamine required for the 20- to 25-minute procedure was 50 mg. The authors attributed the exaggerated response to a low dose of ketamine to a combination of hypoxemia and hemodynamic instability.

High-altitude natives anesthetized at 3500 meters above sea level (mean preoperative Spo_2 88.5%) appear to require significantly larger amounts of propofol when administered with fentanyl compared with lowlanders at 300 m.[243] Compared with the low-altitude residents, the highlanders had a lower resting heart rate, and heart rate responses to surgical stress were significantly attenuated.

Figure 80-16 Kunde Hospital, Nepal (altitude 3840 m), the site of the published series of general anesthetics described in the text.[241] The photo depicts Dr. David Murdoch assisted by Kami Temba Sherpa. *(Photo courtesy of Dr. Lynley Cook.)*

Regional Anesthesia

Spinal anesthesia has been reported to result in unacceptably high incidence of dural puncture headache,[231] possibly owing to chronically increased CSF pressure, dehydration, and altered sensitivity of the altitude resident's CNS to intracranial pressure changes.[231] Headaches were not reported in 20 young native mountain dwellers in whom CSF samples were obtained with 25-gauge needles.[231]

Perioperative Supplemental Oxygen

At high altitude, P_{AO_2} is normally increased by hyperventilation induced by the hypoxic ventilatory drive. Administration of anesthetics or narcotic analgesics, both of which blunt the hypoxic ventilatory drive, may therefore precipitate hypoxia. The resulting hypoxic symptoms of irritability, confusion, and restlessness may be misinterpreted as due to pain, and misguided administration of additional narcotics would only compound the problem. Analgesic-induced respiratory depression has been reported as a likely cause of death in a Sherpa who had débridement of frostbitten fingers at 4300-m altitude.[239] Therefore, if opiate analgesics are administered, supplemental O_2 may be required.

Monitoring

Oxygen analyzers, both electrochemical and paramagnetic, measure P_{O_2} rather than O_2 percentage. Thus, if the display is in "percent," the actual percentage will be falsely low unless the analyzer is calibrated at altitude. Nevertheless, it is the P_{O_2} that is physiologically important. CO_2 analyzers similarly measure partial pressure. Since end-tidal P_{CO_2} at altitude is within the normal range (or somewhat low), readings will be unaffected by altitude.

Air evacuation in an unpressurized or partially pressurized aircraft will engender expansion of the gas volume in enclosed spaces such as tracheal tube cuffs and pulmonary artery catheter balloons.

Commercial Air Travel

Clinical Effects of Aircraft Flight

During commercial aircraft flight the pressure within the cabin is mandated to be no less than the barometric pressure at 8000 ft altitude (typical cabin altitude 1500-2438 m). During flight the ambient air P_{O_2} would fall from 159 mm Hg at sea level to as low as 118 mm Hg. The ensuing mild hypoxemia (Sa_{O_2} usually above 90%) is generally well tolerated by normal individuals, although altitude-related symptoms such as discomfort and fatigue can occur.[244] Changes in ambient pressure can induce otic and sinus barotrauma and pain due to expansion of intestinal gas. Motion sickness is now rare. More serious manifestations that have been attributed to immobility and possible hypoxemia include phlebothrombosis.[245,246] Airborne spread of communicable diseases has also been reported.[246] Medical guidelines for air travel have been discussed in review articles.[246,247]

Prediction of Oxygenation during Commercial Flight

Patients with impaired gas exchange due to chronic obstructive pulmonary disease or restrictive disease during flight may experience significant hypoxemia[248,249] and symptoms of dyspnea, edema, wheezing, cyanosis, and chest pain.[250]

To predict the effect of altitude on arterial oxygenation the patient can be exposed to simulated altitude in a hypobaric

chamber with assessment of Spo_2 and/or arterial blood gases. Alternative measures include administering a hypoxic gas premixed to produce the same inspired Po_2 as air at the target altitude (typically 15% O_2)[251] or supplying a Venturi mask designed to deliver 35% to 40% O_2 with 100% nitrogen.[252,253] Prediction algorithms based on sea level blood gas values have also been used with success.[254] Predicted Pao_2 at altitude ($Pao_{2alt(predicted)}$) can be predicted from the ground level blood gases (Pao_{2GL}, $Paco_{2GL}$), ground level calculated alveolar Po_2 (PAo_{2GL}) and altitude alveolar Po_2 (P_Ao_{2alt}) using the following equation:

$$Pao_{2alt(predicted)} = PAO_{2alt} \cdot \left(Pao_{2GL}/PAO_{2GL}\right)$$

Systematic testing of a number of other prediction equations has been reported.[253,255]

It has been recommended that patients with baseline hypoxemia due to lung or heart disease be considered for in-flight O_2 administration.[256] Procedural details have been reviewed by Stoller.[254]

In-Flight Emergencies

From 1 to 75 in-flight medical events per million passengers have been reported by commercial airlines.[257] The most common are due to syncope, gastrointestinal complaints, minor trauma, or cardiac, pulmonary, or neurologic issues. Emergency care of severely ill passengers is facilitated by medical kits that are carried aboard all U.S. commercial aircraft requiring a flight attendant. In addition, automatic external defibrillators (AEDs) are aboard all U.S. commercial planes with a payload exceeding 7500 pounds. In-flight deaths are extremely uncommon (0.01-0.8 deaths per million passengers). In a study of 1 year's (1999-2000) experience of a U.S.-based airline it was estimated that an onboard physician was available in approximately half of all flights.[257] A system of ground-based physicians is available for consultation and to assist with decisions regarding flight diversion.

Medical Care in Space

Physiologic and Medical Issues During Space Flight

For a few minutes during launch of a space vehicle there is an increase in gravitational force as the space craft accelerates to orbital speed (typically 3 *G* for the NASA shuttle, 4 *G* for the Russian Soyuz). During the period in space the major physiologic stress on astronauts is the absence of gravitational stress (microgravity). This results in an increase in left ventricular end-diastolic volume, paradoxically accompanied by a decrease in central venous pressure.[258] The central redistribution of blood causes facial edema and initiates a diuresis, and thence plasma volume depletion (up to 20% or more), which persists until after landing.[259] Shortly after attaining orbit most astronauts experience self-limited dizziness, drowsiness, nausea, and vomiting.[260] During reentry, astronauts are reexposed to increased G force, typically 1.5 *G* for the shuttle and 3 to 4 *G* for the Soyuz craft. After landing, astronauts typically experience some degree of orthostatic intolerance[261] and often a recurrence of nausea and vomiting.[260] Postural hypotension has been attributed to hypovolemia, enhanced eNOS expression, and downregulation of α-adrenergic receptors.[262] Reduced ventricular mass has been observed after several days in orbit,[263] which may be due to cardiac atrophy[264] or dehydration.[265] Skeletal muscle atrophy can occur even after short missions.[266]

Cabin pressure in the Shuttle and International Space Station is 760 mm Hg. However, during extravehicular activity (EVA) space suit pressure is 4.3 psi (222 mm Hg). During EVA astronauts prevent hypoxia by breathing 100% O_2; however, the reduced pressure engenders the potential risk of DCS.[267] If the suit becomes disrupted during EVA, the astronaut's ambient pressure would quickly drop to zero, causing hypoxia and generalized bubble formation, referred to as *ebullism* (body fluids boiling due to ambient pressure lower than saturated water vapor pressure).

Gravitational unloading causes loss of calcium from bones, which during long space flights could produce significant osteoporosis. This problem, along with the resulting hypercalciuria and increased probability of nephrolithiasis, constitutes major obstacle to human interplanetary travel.

Emergency care during space includes numerous challenges.[267-272] Hypovolemia due to hemorrhage may not be adequately treatable due to limited quantities of supplies, and hypotension could be exacerbated by preexisting volume loss and increased G forces during reentry. Air-fluid interfaces in intravenous fluids generate bubbles (Fig. 80-17). Thus, intravenous fluid bags must be degassed before flight or bubbles must be removed by in-line filtration. The physiologic effects of general or regional anesthesia in microgravity are unknown. Conventional anesthesia vaporizers require gravity to confine the liquid to the bottom of the reservoir; thus, a different design would be required for use in space. Additional practical limitations include the need to prevent pollution of the enclosed environment by volatile anesthetics or exhaust oxygen (fire hazard).

Tracheal intubation may be difficult because of facial edema. The laryngeal mask airway (LMA), cuffed oropharyngeal airway, and intubating LMA have all been successfully demonstrated in microgravity simulated using a neutral buoyancy tank.[273] Studies using secured mannequins during short periods of microgravity in an aircraft have demonstrated successful intubation using laryngoscopy and standard tracheal tube (Fig. 80-18), Combitude (Nellcor, Pleasanton, CA), and an intubating LMA.[274,275] However, tracheal intubation in microgravity by a

Figure 80-17 Air in the bag of intravenous fluid in microgravity with an infusion pump. The lack of a gravitational field makes it difficult to remove gas. *(Courtesy of NASA.)*

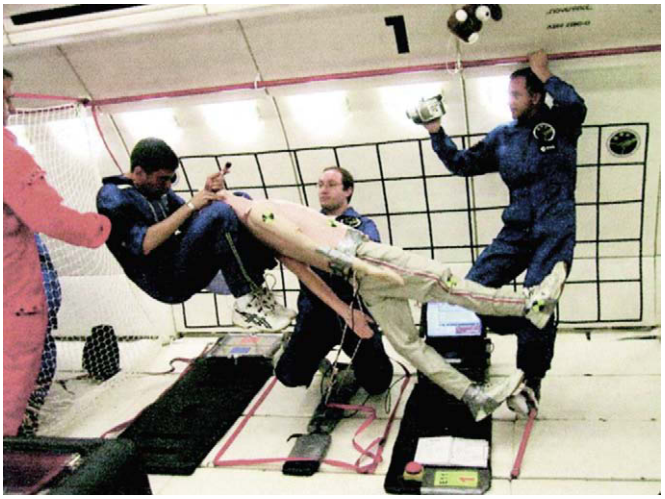

Figure 80-18 Tracheal intubation of a free-floating mannequin in microgravity. The intubator stabilizes the head by holding it between his knees. *(From Groemer GE, Brimacombe J, Haas T, et al: The feasibility of laryngoscope-guided tracheal intubation in microgravity during parabolic flight: A comparison of two techniques. Anesth Analg 101:1533-1535, 2005, with permission.)*

nonphysician using conventional laryngoscopy is frequently unsuccessful.[274] All intubation techniques require that both the patient and the intubator be secured.[274] Gastroesophageal reflux is more common in microgravity; thus, aspiration during general anesthesia may be more likely.

On-board diagnostic tools are being developed, such as remotely guided ultrasound examination (Fig. 80-19).

Remote robotic surgery has been considered as a substitute for an on-board surgeon. Indeed, a robotic laparoscopic cholecystectomy was successfully performed on a patient in Strasbourg, France, by surgeons operating from New York City. The total delay time between movement initiated by the surgeon and detection on the monitor was approximately 155 msec.[276] The limit of the acceptable time delay is believed to be around 330 msec. Whether training or technology will allow this to be increased to permit surgery during interplanetary flights (with a much longer delay time) is unknown.

Physiologic and Medical Issues after Return to Earth

Medical challenges may extend into the period after landing. After 14 days in space, in order to obtain biopsies, two rhesus monkeys were administered general anesthesia (ketamine, 10 mg/kg IM, then 1% to 1.5% isoflurane for 3½ to 4 hours) within 24 hours after landing by a competent veterinary anesthesiologist. One animal aspirated during emergence and could not be resuscitated. Three hours after recovery, the other inexplicably developed lethargy and facial edema.[277] From this experience it can be inferred that well-accepted standard-of-care techniques may not be safe when anesthetizing astronauts shortly after space flight.

Several specific challenges have been elucidated. Details can be found in two excellent reviews.[278,279] Some issues most pertinent to anesthetic risk are as follows.

Hypovolemia and Adrenergic Hyporesponsiveness

Following flight a large percentage of astronauts experience orthostatic intolerance. This is in part due to hypovolemia but also due to a dysfunctional adrenergic response.[280] In astronauts with post-flight orthostatic intolerance the pressor response to phenylephrine is not different from pre-flight; however, it is attenuated compared with astronauts who are tolerant of acute orthostasis.[281] Cardiovascular deconditioning, ventricular atrophy, and changes in arterial stiffness may also play a role.[264,265,282,283] The immediate post-flight hemodynamic response to general or neuraxial anesthesia could include unexpected hypotension but to date is unknown.

Electrolyte Disorders

Reductions in both serum potassium and magnesium have been reported after some space missions,[284,285] possibly owing to decreased dietary intake. Hypokalemia has been blamed for cardiac arrhythmias observed during Apollo 15.[286]

Hyperkalemic Response to Succinylcholine

Skeletal muscle atrophy due to immobilization and disuse causes proliferation of acetylcholine receptors, increased sensitivity to succinylcholine (see Chapter 29), and decreased cholinesterase activity.[287] Based on data from patients with neuromuscular disease and immobilized limbs, there may be a resistance to nondepolarizing neuromuscular blocking drugs.[288] Use of succinylcholine in immobilized intensive care patients has been associated with exaggerated hyperkalemia and cardiac arrest.[289,290] It has been suggested that skeletal muscle atrophy in astronauts may put them at a similar risk.[279]

Summary

Increasingly widespread use of HBO to treat critically ill patients has created a demand for individuals skilled in using this technology. Planning and design of monitoring capabilities will enable optimal control of hemodynamics and oxygenation. Careful

attention to detail will maximize patient safety in this environment. Optimized treatment schedules will evolve from further studies of mechanism of action. Advances in prevention and treatment of O_2 toxicity may allow more prolonged therapy than can currently be safely administered, and hence a more aggressive approach to ischemic and infectious syndromes.

The reduction in ambient pressure and ensuing hypoxia associated with acute altitude exposure result in well-described physiologic changes that are often associated with clinical symptoms. Methods for prophylaxis and treatment have been described. Safe anesthesia at altitude requires some modification of sea level techniques, not only because of the hypoxia and reduced ambient pressure but also because suboptimal equipment may be available under mountain conditions.

Anesthesia in space poses unique challenges that may extend even beyond return to earth.

81 Regional Anesthesia in Children

Over the past 30 years, regional anesthesia has progressively become a major technique of pain management in surgical and nonsurgical pediatric patients. It was made easier and safer by the development of needles and catheters specifically designed for pediatric patients. Over the years, many pediatric studies involving large series of patients from the neonatal period to the end of adolescence have evaluated virtually all techniques of nerve blockade, thus allowing precise delimitation of their indications, contraindications, and adverse effects. With the use of nerve stimulators, peripheral blocks can now be safely achieved in anesthetized patients provided that no muscle relaxants had been previously administered.

Ultrasound imaging techniques represent the second revolution of regional anesthesia (see Chapter 53). The advantage of ultrasonography over neurostimulation is to make visible the spread of the local anesthetic, thus allowing both adjustment of needle positioning in case of inappropriate spread and dose reduction when complete circumferential spread of the local anesthetics is clearly obtained.

Relevant Differences between Children and Adults

Anatomic Differences

Change in Body Size Due to Growth Process

The most obvious difference between children and adults pertains to body size: "Normal" full-term neonates weigh 3 to 3.5 kg with a height of 50 cm, and within 10 to 15 years they will multiply their weight by more than 12 (>1200%) and their height by more than 3 (>300%). During the early stages of development the spinal cord occupies the spinal canal entirely, but later on the growth of vertebrae exceeds that of the cord,[1] and the last spinal nerves, the cord, and its envelopes are "attracted" within the spinal canal. At birth the dura mater ends at the level of the third or fourth sacral vertebra and the cord (conus medullaris) at the L3 or L4 level. It is only at the end of the first year of life that adult level is attained, namely, L1 for the conus medullaris and S2 for the dural sac.

Anatomic relationships and landmarks are constantly changing throughout infancy and childhood, which interferes with regional procedures and requires quite a good knowledge of developmental anatomy and the assistance of accurate techniques for localization of anatomic spaces and nerve trunks.

Congenital malformations, genetic disorders, and consequences of fetal/neonatal asphyxia (cerebral palsy) are frequent and specific to the pediatric period. They result in abnormal development and deformities of bone/joint and neurologic structures that tend to worsen during childhood.

The main pediatric anatomic and physiologic factors that can influence indications for or performance of regional block procedures are listed in Table 81-1.

Delayed Ossification of Bones and Fusion of Sacral Vertebrae

Bones of neonates, including vertebrae, are mostly cartilaginous. They can be easily traversed by sharp needles because cartilage offers little resistance to penetration, and ossification nuclei can be severely damaged, thus compromising further bone/joint development. Consequently, bone contact should be avoided as often as possible during block procedures, especially in infants. This cartilaginous structure also allows easy penetration of x-rays and ultrasound (Fig. 81-1).

Delayed Myelinization of Nerve Fibers

Myelinization begins during the fetal period in cervical neuromeres and extends cephalad and caudad,[2,3] but the process is not finalized before the 12th year of life. Myelinization is especially poor in infants; this lack of fully developed nerve fibers is the main reason why they are unable to walk. A major pharmacologic consequence of this condition is that local anesthetics can penetrate and block nerve fibers more easily: Diluted solutions of local anesthetics provide the same quality of nerve blockade as with at least twofold more concentrated solutions in adults. Onset time is shortened but, on the other hand, duration of blockade is reduced because trapping of local anesthetics within myelin with subsequent progressive release is reduced and because local circulation and therefore vascular absorption are greater in infants.

Development of Flexures of the Spine

At birth, there is a single spinal flexure and the orientation of epidural needles is the same whatever the intervertebral space. Flexures, however, are not fixed and they can be easily counteracted by forced flexion almost throughout childhood due to

Table 81-1 Main Anatomic and Physiologic Factors in the Pediatric Period That Can Influence the Selection or Performance of a Regional Block Procedure

Pediatric Factors (Infants Mainly)	Resulting Danger	Implications for Regional Anesthesia
Lower termination of spinal cord	Increased risk of direct trauma to the spinal cord	Avoid epidural approaches above L3 whenever possible.
Lower projection of dural sac	Increased risk of inadvertent penetration of the dura mater	Check for cerebrospinal fluid reflux, including during caudal approaches. Favor low approaches to the epidural space.
Delayed myelinization of nerve fibers	Easier intraneural penetration of local anesthetics	Onset time is shortened, and diluted local anesthetic is as effective as more concentrated anesthetic in adults.
Cartilaginous structure of bones and vertebrae	Reduced resistance to penetration by sharp needles Danger of direct trauma and bacterial contamination of ossification nuclei compromising further bone/joint growth	Avoid use of thin and sharp needles; use short and short beveled ones instead. Do not apply excessive force on needle: if resistance is felt, stop trying to insert the needle farther.
Lack of fusion of sacral vertebrae	Persistence of sacral intervertebral spaces	Intervertebral sacral epidural approaches can be performed throughout childhood.
Delayed development of curvatures of the spine	Cervical lordosis (3-6 months) Lumbar lordosis (8-9 months)	Same orientation of epidural needles is appropriate whatever the spinal level before 6 months of age; then adapt needle orientation to spinal flexures.
Changing axis of coccyx and absence of growth of sacral hiatus	Sacral hiatus comparatively smaller with increasing age	Identification of sacral hiatus becomes more difficult above 6-8 years (increased failure rate of caudal anesthesia).
Delayed ossification and growth of iliac crests	Tuffier's line, which joins anterior superior iliac spinous processes, crosses the spine at L5 or lower in infants.	This line passes over L5-S1 interspace instead of L4-L5 interspace.
Increased fluidity of epidural fat	Increased diffusion of local anesthetic up to 6-7 years of age	Excellent blockade after caudal anesthesia can be achieved up to 6-7 years of age.
Loose attachment of sheaths and aponeuroses to underlying structures	Increased spread along nerve paths with danger of penetrating remote anatomic spaces and blocking distant nerves	Larger volume of local anesthetic is required for epidural blocks due to leakage along spinal nerve roots. Smaller volume of local anesthetic is necessary to produce excellent peripheral blocks.
Enzymatic immaturity	Slower metabolism of local anesthetics (usually compensated by other enzyme pathways)	Increased mean body residency time and half-life, with accumulation (especially after repeat injection and continuous infusions of local anesthetic), are characteristic.
Increased extracellular fluids	Increased distribution volume and mean body residency time of local anesthetic (and most medications)	Decreased Cmax after single injection but accumulation with repeat/continuous injections
Low plasma protein content (HSA and AAG)	Competition at nonspecific HSA binding sites Limited capacity of specific binding of local anesthetic by AAG, resulting in increased plasma concentration of the free fraction	Increased unbound free fraction of all local anesthetic: greater danger of systemic toxicity
Increased cardiac output and heart rate	Increased regional blood flow resulting in increased systemic absorption of local anesthetic	Increased systemic absorption of local anesthetic (decreased Tmax and shorter duration of blockade) Increased efficacy of epinephrine: vasoconstriction reduces absorption (thus toxicity) and prolongs duration of blockade.
Sympathetic immaturity, diminished autonomic adaptability of the heart, smaller vascular bed in lower extremities	Hemodynamic stability during neuraxial blocks	Fluid preloading and use of vasoactive agents are unnecessary.
Delayed acquisition of body scheme and conceptualization, anxiety	Inability of patients to locate precise body areas Concept of paresthesia not understandable Difficult cooperation	Nerve/space identification requires application of location techniques independent of patient's cooperation. Heavy sedation or general anesthesia is required in most patients (especially when a "dangerous" technique is planned to avoid detrimental consequences of panic attacks at a critical phase of the block procedure).

AAG, α_1-acid glycoprotein; Cmax, peak plasma concentration; HSA, human serum albumin; Tmax, time to reach Cmax.

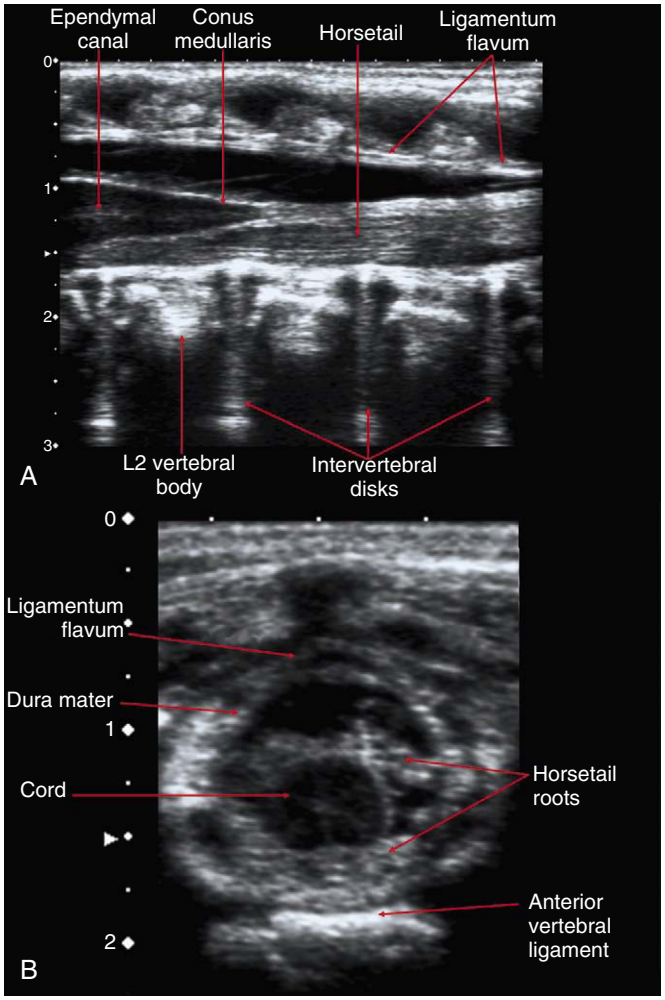

Figure 81-1 Ultrasound imaging of the caudal part of the spine in a 3-week-old infant. **A,** Long-axis view. **B,** Short-axis view (transverse echotomography).

persistent spinal flexibility, which is a major advantage in the pediatric period (in addition to the absence of osteophytes).

Loose Attachment of Fascias and Fluidity of Epidural Fat

Fascias and perineurovascular sheaths are loosely attached to underlying structures (e.g., nerves, muscles, tendons, vessels). This allows extended spread of local anesthetics, resulting in high-quality nerve blockade whatever the technique but also, occasionally, undesirable spread to distant nerves or anatomic spaces.

The epidural fat is very fluid in infants and young children (up to 6-7 years of age). This fluidity combined with the loose attachment of the sheaths surrounding the spinal roots favors consistent leakage of the local anesthetics injected within the epidural space; therefore, comparatively large volumes of epidural local anesthetics (up to 1.25 mL/kg) are required to reach desired levels of anesthesia.

Perception of Pain

Somatic pain is a subjective sensory experience resulting from the intermixing of three main components[4,5]: motivational-directive, sensory-discriminatory, and cognitive-evaluative. The motivational-directive component is conveyed by unmyelinated C fibers ("slow" pain or "true" pain). It leads to protective reflexes such as autonomic reactions, muscle contraction, and rigidity. C fibers are fully functional from early fetal life onward.

Connections between C fibers and dorsal horn neurons are not mature before the second week of postnatal life. However, nociceptive stimulations transmitted to the dorsal horn by C fibers elicit long-lasting responses,[6,7] probably owing to extensive depolarization of surrounding neurons in response to the production of large amounts of substance P. As the number of dorsal horn receptors to substance P decreases during the first 2 weeks of life, this exaggerated response of neonates to nociceptive stimulation progressively disappears. The inhibitory control pathways, which are immature at birth, develop concomitantly.

Painful procedures during the neonatal period modify subsequent pain responses in infancy and childhood,[8] depending on the developmental stage of the infant (full-term versus preterm) and his or her cumulative experience with pain. To later noxious procedures, full-term neonates react with heightened behavioral responsiveness whereas preterm neonates react with a damped response. When analgesic agents (local anesthetics or opioids) are administered before painful procedures, infants demonstrate less evidence of procedural pain and a reduction in the magnitude of long-term changes in pain behaviors.[8]

A major difficulty is assessment, and, at times, even identification of pain in children pertains to the inability of young patients to communicate with their caregiver and precisely express their distress and discomfort. During the past 2 decades, pediatric pain has received considerable attention, and reliable age-related pain scales have been developed to evaluate both the severity of pain and the efficacy of its treatment.

Pharmacology of Local Anesthetics and Additives

Two main factors influence pharmacologic properties of medications in children: (1) immaturity of some enzyme pathways and their replacement by other biochemical pathways and (2) progressive increase in body surface area concomitantly with the growth process. Drug prescriptions made according to body surface area are the same as (or in simple ratio with) adult dosing.[9] However, body surface area is not easily obtained and, in practice, doses are calculated according to body weight and require constant adaptation as the child grows up; dosage errors are not infrequent.

Local Anesthetics

Chemical properties and mechanisms of action of local anesthetics are detailed elsewhere in this textbook (see Chapter 30); they are basically the same during the pediatric period and only pharmacokinetic properties may notably differ, especially in neonates and infants.[10]

Local Fixation

Schematically, local fixation is reduced and spread is increased in infants as compared with adults, especially within the epidural space, because the epidural fat is more fluid and less densely packed. The main consequences are (1) shorter onset time of

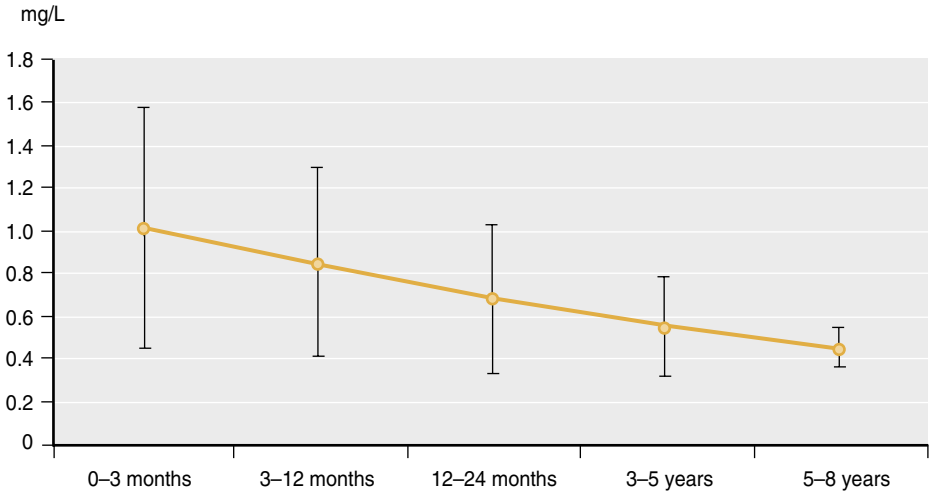

Figure 81-2 Cmax values of ropivacaine after caudal injection of 2 mg/kg in different age groups.

action; (2) more extended longitudinal and circumferential spread of local anesthetics; and (3) shorter duration of action because of reduced secondary release from local binding sites.

Regional Spread toward the Target

The target of local anesthetic action is voltage-dependent Na^+ channels located within nerve fibers. Penetration of biologic membranes can only be achieved by nonionized molecules, and the speed of the process depends on the number and thickness (increasing with age) of sheaths.

Systemic Absorption and Distribution

Plasma Protein Binding. Nonionized local anesthetics cross almost freely the capillary wall close to the injection site. Because cardiac output and local blood flow are two to three times greater in infants than in adults, systemic local anesthetic absorption is increased accordingly and vasoactive agents such as epinephrine are very effective in slowing down systemic uptake.

Once they have penetrated within the vascular bed, local anesthetics undergo plasma protein binding mainly to human serum albumin (HSA) and α_1-acid glycoprotein (AAG), or orosomucoid. HSA has a low affinity for local anesthetics, and many pharmacologic agents can compete at available binding sites. Furthermore, plasma levels of HSA are low during the first months of life, especially in premature and fasted infants; thus, the protection offered by HSA against systemic toxicity of local anesthetics is low and decreases postoperatively. The affinity of AAG for local anesthetics is 5,000 to 10,000 times greater than that of HSA, which makes AAG very effective to protect the patient from systemic toxicity (which depends on the nonbound free form of local anesthetics). However, again, plasma concentration of AAG is very low at birth (0.2-0.3 g/L) and does not reach adult levels (0.7-1.0 g/L) before 1 year of age.[11-13]

Because plasma concentration of the two proteins able to bind local anesthetics are low at birth, the free fraction of all local anesthetics is increased in infants; therefore, the maximum doses of all aminoamides must be significantly reduced in this age group even though the plasma concentration of AAG increases postoperatively except in case of liver insufficiency.[13]

Red Cell Storage. Once in the bloodstream, local anesthetics distribute to red blood cells, which retain 20% to 30% of the total dose, depending on the anesthetic agent and the hematocrit. Red cell storage usually has a minor impact on the pharmacokinetics of local anesthetics except:

- In neonates: high hematocrit values (which may exceed 70%) and enlargement of erythrocytes (physiologic macrocytosis) result in consistent "entrapment" of local anesthetics, thus lowering Cmax values after a single injection but increasing secondary release, thus increasing the half-life of all local anesthetics.
- In infants: physiologic anemia reduces red cell storage and its protective effect against systemic toxicity of local anesthetics (after a single-shot injection only) when the plasma protein binding sites are saturated, that is, close to toxic blood concentrations.

Absorption from the Epidural Space. Absorption has been rather well evaluated in the epidural space. In children and infants, the same kinetics of absorption is reported, but the younger the patient, the less accentuated is the biphasic shape of the plasma concentration curve. The peak plasma concentration and the slope of the decreasing concentration curve are increased,[14,15] whereas the time (Tmax) to reach peak plasma concentration (Cmax) remains basically unchanged; for example, the Tmax of bupivacaine is around 30 minutes whatever the patient's age.

Ropivacaine is a remarkable exception. After caudal or lumbar epidural injection, Tmax is prolonged up to 2 hours in infants and Cmax, too, is increased (Fig. 81-2).[16] This unusual pharmacokinetic profile is difficult to understand; some hypotheses have been tentatively considered, such as enzyme immaturity, slower systemic uptake, and decrease in distribution volume.[17,18] Intrinsic vasoconstrictive properties of ropivacaine may also play a role in the same way as addition of epinephrine. Anyway, such an increase in both Cmax and Tmax values cannot be ignored because many surgeries in infants are brief and the young patient may have left not only the operating room but also the postanesthesia care unit (PACU) less than 2 hours after the caudal/epidural was performed, that is, before peak plasma concentration were reached.

Levobupivacaine displays a similar pharmacokinetic profile. After caudal injection of 2 mg/kg of levobupivacaine in infants younger than 2 years of age, the Cmax range is 0.41 to 2.42 µg/mL

(0.91 ± 0.40 µg/mL), which is higher than the Cmax reported after caudal injection of the same dose of racemic bupivacaine.[19] Tmax values also are delayed (50 min versus 30 min) in infants younger than 3 months of age[20] owing to reduced plasma clearance.

When repeat injections are considered, the epidural dose must be reduced to keep Cmax values in the same range as that resulting from the first injection. For the second injection, either:

- Reduce the dose to a third of the initial dose and do not inject it less than 30 minutes (lidocaine, mepivacaine, prilocaine) or 45 minutes (bupivacaine, levobupivacaine, ropivacaine) after the first injection; or
- Inject half of the initial dose but 60 minutes (lidocaine, mepivacaine, prilocaine) or 90 minutes (bupivacaine, levobupivacaine, ropivacaine) after the first injection.

If more reinjections are necessary, dosing should be further reduced to half of the second dose (i.e., one sixth of the initial dose) while respecting the same delay as for the second injection.

Continuous infusions aim to produce a steady-state concentration at the 24th hour postoperatively. This goal is easily achieved in adolescents with infusion rates around 0.3 mg/kg/hr of bupivacaine and levobupivacaine or 0.4 mg/kg/hr of ropivacaine. In infants, infusion rates must be reduced[21-23]; they should not exceed 0.2 mg/kg/hr with bupivacaine (or equipotent doses of other local anesthetics) in infants younger than 4 months and 0.25 mg/kg/hr later on.

Infants younger than 4 months (occasionally up to 9 months) may develop systemic toxicity even at these "safe" infusion rates with racemic bupivacaine because no steady-state plasma concentration is reached, even at the 48th hour. In this age group, levobupivacaine[24] or ropivacaine[25] instead of racemic bupivacaine is preferred because stable plateau concentrations are obtained from the 24th hour onward.

Absorption from Other Injection Sites. Absorption of local anesthetics deposited along mucous membranes is increased in infants. Mucosal topical anesthesia has long been considered contraindicated in this age group. However, the technique can be safely used with certain precautions: selection of specific transmucosal patches[26] or sprays with diluted lidocaine[27,28] and recognition that topical lidocaine exaggerates laryngomalacia.[29]

After cutaneous application of EMLA cream, peak plasma concentrations occur 4 hours later and remain low[30]: less than 200 ng/mL for lidocaine and less than 131 ng/mL for prilocaine, even in infants younger than 6 months of age.

Absorption of local anesthetics from compartment blocks (e.g., fascia iliaca, umbilical, ilioinguinal, pudendal blocks) follows the same biphasic curve as for the epidural space.[31-35] Because of the extended surface of absorption, injection of highly concentrated solutions of local anesthetics often leads to high, occasionally potentially toxic peak plasma concentrations, especially with 0.5% ropivacaine[35] whereas use of more diluted solutions results in rather low plasma concentrations.

Absorption from peripheral conduction blocks also follows a similar biphasic curve with different Cmax and Tmax values depending on the local anesthetic, the addition of epinephrine, and the site of injection: The more distal the injection, the slower the absorption process (as in adults).

Pulmonary Extraction. After they have reached the venous bloodstream and undergone plasma protein linkage and erythrocyte storage, aminoamides reach the right cardiac cavities and then the pulmonary circulation from which they are extracted by the lung; their plasma concentration in pulmonary veins and then in systemic arterial circulation (especially coronary and cerebral arteries) is consistently decreased. Thus, pulmonary extraction represents a temporary protection against systemic toxicity. However, certain medical conditions suppress this protective effect. Some medications such as propranolol decrease pulmonary extraction in a clinically relevant way. Also, children with right-to-left shunts undergo considerable increase in arterial plasma concentration of local anesthetics due to pulmonary bypass: even with small doses of local anesthetics they can develop systemic toxicity.[36]

Distribution Volume. After intravenous (IV) injection, distribution volume at the steady state (Vd_{ss}) is 1 to 2 L/kg for all aminoamides (Table 81-2). After administration at other sites,

Table 81-2 Age-Related Differences in Pharmacokinetic Parameters of Aminoamides

Local Anesthetic	Protein Binding (%)	Vd_{ss} (L/kg)	Clearance (mL/kg/min)	Elimination Half-Life (hr)
Lidocaine				
Neonate	25	1.4-4.9	5-19	2.9-3.3
Adult	55-65	0.2-1.0	11-15	1.0-2.2
Mepivacaine				
Neonate	36	1.2-2.8	1.6-3	5.3-11.3
Adult	75-80	0.6-1.5	10-13	1.7-6.9
Bupivacaine				
Neonate	50-70	3.9 (± 2.01)	7.1 (± 3.2)	6.0-22.0
Adult	95	0.8-1.6	7-9	1.2-2.9
Levobupivacaine				
Infant	50-70	2.7	13.8	4
Adult	95	0.7-1.4	28-39	1.27 ± 0.37
Ropivacaine				
Infant	94	2.4	6.5	3.9
Adult	94	1.1 ± 0.25	4-6	1.15 ± 0.41

Table 81-3 Variation of Body Fluid Distribution by Age Group

Distribution of Body Fluids	Preterm Neonates	Full-Term Neonates	Infants	Children	Adults
Total body fluids	80-85%	70-75%	65%	55-60%	50-55%
Intracellular	20-25%	30-35%	35%	35-40%	40-45%
Extracellular	55-60%	45%	30%	20-25%	20%

calculated distribution is increased, often considerably, owing to the "flip-flop" effect, especially for long-lasting local anesthetics. In infants and neonates, owing to higher extracellular fluid content (Table 81-3), the distribution volume of all LA is greater than in adults, the consequences of which are (1) significant decrease in peak plasma concentration of all local anesthetics, thus decreasing the danger of systemic toxicity after a single dose, and (2) accumulation with reinjections, which increases drug plasma concentration and elimination half-life while concomitantly decreasing clearance.

Hepatic Extraction and Clearance of Aminoamides. Short-acting local anesthetics undergo high hepatic extraction (0.65-0.75 ratio for lidocaine), which depends mainly on hepatic blood flow and not much on their plasma concentration. Only limited pediatric data are available for levobupivacaine. After a single injection, the clearance of levobupivacaine increases during the first months of life, but during continuous infusion (even with 0.0625% levobupivacaine), it tends to decrease almost to the same extent as for racemic bupivacaine, and plasma concentrations do not reach a plateau.[20]

Placental Transfer. In pregnant women, placental extraction may consistently affect tissue distribution of local anesthetics. Protein binding influences placental transfer: the concentration ratio between umbilical venous blood and maternal arterial blood is around 0.73 for lidocaine, 0.85 for prilocaine, but only 0.32 for bupivacaine.[37] Chirality may play a role, too, at least for bupivacaine, because placental transfer of dextrobupivacaine exceeds that of levobupivacaine but only with solutions containing epinephrine.[38]

Most aminoesters undergo such a rapid plasma hydrolysis that placental transfer is not an issue. Tetracaine and cocaine, the hydrolysis of which is slow, are only used for topical applications or (tetracaine only) spinal anesthesia: systemic uptake is slow and plasma concentrations remain extremely low and, thus, are not issues again for placental transfer.

Metabolism

Aminoesters are rapidly hydrolyzed by plasma cholinesterases. This enzymatic activity is low at birth (but no adverse clinical consequences are to be feared) and gradually reaches adult levels by 1 year of age.[39] Chloroprocaine is eliminated at the fastest rate (4.7 mol/mL/hr), procaine at a slower rate (1.1 mol/mL/hr), but cocaine only at 0.3 mol/mL/hr. Procaine and chloroprocaine are also metabolized, in part, by hepatic cholinesterases.

Aminoamides are metabolized within the liver, where they are subjected to two types of enzymatic reactions: phase I reactions first, during which oxidation of the amide link is achieved within hepatic microsomes by the cytochrome P450 enzyme superfamily; then phase II reactions, during which glucuronic acid or aminoacids residues are appended to phase I metabolites, producing atoxic and hydrosoluble compounds, which are thus easily eliminated from the body.

Cytochrome P450 enzymatic activities are reduced during the first months of life. Bupivacaine is mainly metabolized by CYP_{3A4} in adults, but this enzyme is defective in infants. However, fetal CYP3A7 remains very active in infants, thus allowing metabolism of bupivacaine almost as effective as with CYP3A4. Ropivacaine and levobupivacaine[20] are metabolized by CYP1A2, which is not fully functional before the third year, and, to a minor extent, by CYP3A4. This enzyme immaturity is clinically relevant but with limited consequences (lower clearance, delayed Tmax and, for ropivacaine only, increased Cmax but within clinically acceptable levels): it does not preclude administering these local anesthetics in neonates and infants.

Phase II reactions, especially glucuroconjugation, are immature at birth and remain so until the third year of life. However, other conjugation pathways such as sulfoconjugation are active and quite effective during the first months of life.

Elimination Half-Life

Elimination half-life ($t_{1/2}\beta$) depends on both distribution and metabolism. It can be calculated using the formula below (Cp is the plasma clearance and Vd_{ss} the distribution volume at the steady state):

$$t_{1/2}\beta = (0.693 \times Vd_{ss})/Cp$$

Basically $t_{1/2}\beta$ is the same in children older than 1 year and in adults, mainly because the increase in Vd_{ss} is compensated by concomitant increase in Cp (related in part to higher hepatic blood flow in children, whose liver accounts for 4% of body weight, versus 2% only in adults). Before the age of 1 year, Cp is low and elimination half-life of all local anesthetics is prolonged (see Table 81-2), thus favoring accumulation with repeat injections. Nevertheless, no consistent differences in pharmacokinetic parameters between infants and adults were measured by Bricker and colleagues.[40]

Systemic Toxicity

Clinical signs of neurologic toxicity have been reported with plasma concentration ranging from 7 to 10 µg/mL for lidocaine or mepivacaine and 1.5 to 2 µg/mL (intraoperatively) to 2 to 2.5 µg/mL (postoperatively) with bupivacaine. However, plasma concentrations of bupivacaine higher than 4 µg/mL have been reported without any evidence of clinical toxicity. From studies in adult volunteers, the following thresholds of toxicity of the unbound form of local anesthetics have been defined:

- 0.3 µg/mL for unbound bupivacaine
- 0.6 µg/mL for unbound levobupivacaine or ropivacaine

Because plasma protein binding is lower in infants, hazards of systemic toxicity might be increased, the more so as cardiac toxicity is usually concomitant with, not preceded by, central nervous system toxicity.

Opioids

Elimination half-life of neuraxial opioids is considerably increased in neonates and infants.[41] After epidural injection, morphine reaches its peak concentration in plasma within 10 minutes, but

Table 81-4 Commonly Used Additives and Recommended Doses in Pediatric Regional Anesthesia

Additive	Recommended Doses	Maximum Doses
Morphine		
Epidural	30 µg/kg	50 µg/kg
Intrathecal	10 µg/kg	20 µg/kg
Fentanyl (epidural)	1-1.5 µg/kg	2.5 µg/kg
Sufentanil (epidural)	0.25-0.5 µg/kg	0.75 µg/kg
Clonidine (epidural or along peripheral nerves)	1-1.5 µg/kg	2 µg/kg
Ketamine* (epidural or occasionally along peripheral nerves)	0.5 mg/kg	1 mg/kg

*Preservative free-ketamine (preferably preservative-free *S*-ketamine).

this concentration is very low and unable to provide clinically relevant analgesia.[42,43] Elimination half-life from CSF is similar to that from plasma, but CSF concentrations are very high after epidural injection; therefore, it takes 12 to 24 hours before their decrease below minimal effective concentrations (near 10 ng/mL). Consequently, vital parameters of children given neuraxial opioids must be monitored for 24 hours and are not eligible for outpatient surgery. Usual doses of neuraxial narcotics are listed in Table 81-4.

Short-acting lipid-soluble opioids (fentanyl, sufentanil) can be used but, as in adults, they do not significantly prolong postoperative pain relief unless repeat injections are given or a continuous infusion is established. Their analgesic effect is mainly a systemic effect, and the patient may experience acute respiratory depression (sudden apnea); this condition is very different from the progressive and delayed respiratory depression, preceded by generalized pruritus, sedation, and bradypnea, reported after excessive doses of epidural/intrathecal morphine.

Other Additives

Epinephrine (5 mg/L or 1/200,000 concentration) is frequently co-administered with local anesthetics to decrease plasma peak concentration[31] and prolongs the duration of blockade, especially in children younger than 4 years of age.[44,45] Another benefit expected from epinephrine is early detection of accidental IV injection (test dose) because young children are very sensitive to arrhythmogenic properties of epinephrine. Neuraxial epinephrine has long been suspected to elicit spinal ischemia: Even though this fear proved to be unfounded,[46] many anesthesiologists recommend using lower concentrations of epinephrine (2.5 mg/L or 1/400,000) in local anesthetic solutions administered to neonates and infants; at such concentrations, the absorption rate of caudal bupivacaine is decreased by 25%.[45]

Clonidine, like epinephrine, is an α_2-adrenergic agonist that offers several benefits in children when added to local anesthetics either neuraxially[47-49] or peripherally (see Table 81-4)[50]: It increases (by a factor of 2 approximately) the duration of nerve blockade without eliciting hemodynamic disorders, decreases plasma peak concentration of the local anesthetics, and produces a slight sedation for 1 to 3 hours postoperatively (which does not preclude hospital discharge). Addition of clonidine often makes unnecessary the placement of a catheter to prolong postoperative pain relief, thus reducing morbidity and costs. However, its clearance in neonates is approximately one third that in adults owing to immature elimination pathways[51] and several instances of respiratory depression in neonates and small infants have been reported[52,53]; this additive should be avoided during the first 6 month of life.

Ketamine, especially *S*-ketamine, is an interesting adjuvant owing to its blocking effects on *N*-methyl-D-aspartate (NMDA) receptors and interaction with Na^+ channels in a local anesthetic–like fashion (it shares a binding site with local anesthetics). Coadministered at a dose of 0.25 to 0.5 mg/kg, ketamine prolongs the duration of analgesia for many hours[48,54] with no significant adverse effects.

Many other agents have been occasionally used as adjuvants to local anesthetics.[55] Even though some of them proved to have analgesic properties (corticosteroids, buprenorphine, neostigmine, tramadol, midazolam, and biodegradable bupivacaine/polyester microspheres), they all produce significant adverse effects that preclude their use in most patients. Furthermore, their administration to pediatric patients raises ethical questions, and they have no approval for pediatric use.

Physiologic Factors

Surgery generates a neuroendocrine stress response in neonates, infants, and children[5,56] resulting in undesirable alterations of the metabolic state and immune function.[57,58] Epidural anesthesia diminishes or even suppresses this stress response.[59-61]

Central blocks do not affect left ventricular function and are virtually free of measurable hemodynamic effects, at least up to the age of 8 years.[62-64] Epidural anesthesia does not result in systemic or pulmonary hemodynamic changes as measured by mean blood pressure, end-diastolic diameter of the left ventricle, ejection fraction of the left ventricle, and mean velocity circumferential fiber shortening.[65] However, pulmonary Doppler flow velocity is decreased during epidural anesthesia, probably owing to an increase in the pulmonary arterial resistance. Preloading with saline is not recommended in children and, even in adolescents, fluid therapy or injection of vasoactive agents is rarely required.

Psychological Factors

Children are frightened by new environmental conditions in the operating room and most of them cannot cope with their anxiety.[66,67] They feel abandoned by their parents and exposed to strangers who are threatening them with needles. Furthermore, children younger than 10 years of age have not acquired their complete body image and cannot clearly make a distinction between adjacent parts of their body such as forearm and arm. Young patients cannot understand the concepts of paresthesia and differential blockade ("touch" is not "pain"). Thus, localization of nerve trunks as well as anatomic spaces requires using physical methods independent of the patient's cooperation (loss of resistance seeking, neurostimulation, ultrasound techniques) (see Chapter 82).

Infants and most children cannot cope with their anxiety and fear of needles; therefore, sedation or light general anesthesia is mandatory before block procedure to avoid panic attacks and dangerous movements at the wrong point in the procedure.

Regional anesthesia has a significant psychologic impact. A pain-free postoperative course improves the morale of the patient, the family, and the nurses. Surgeons are happy to examine quiet, alert, and manageable patients. Occasionally, negative psychological effects can be observed: Persistent motor (even sensory) blocks postoperatively may be frightening to some children (3-5 years old especially) and their parents even though precise explanations had been given preoperatively as to the expected course of events during the postoperative period. This postoperative anxiety can be reduced by offering friendly environmental conditions, empathy, and additional explanations on local anesthetic pharmacology. In any case, it should be kept in mind that a motor block must be avoided when not absolutely required for surgery.

Indications, Contraindications, and Complications

Indications

Indications for regional anesthesia in children are not exactly the same as in adults, not only because surgical pathologic processes are quite different but also because regional block procedures are used as techniques of analgesia in anesthetized children rather than in conscious or lightly sedated patients.

Anesthetic Indications

Mature children and adolescents are occasionally willing to undergo their surgery under regional anesthesia while remaining conscious. If adequate analgesia can be provided by a regional block, there is no reason to refuse such management, especially for short-duration surgery.

Occasionally, such a management approach can be considered in children at risk of severe complications during general anesthesia from certain problems[68]:

- Testicular torsion or incarcerated hernia at immediate risk of rupture in nonfasted children
- Inguinal hernia repair in former preterm infants younger then 60 weeks of postconceptual age who are at risk of developing severe postoperative apneas
- Severe acute or chronic respiratory insufficiency
- Emergency conditions in children with severe metabolic or endocrine disorders
- Neuromuscular disorders, myasthenia gravis, or some types of porphyria
- Some types of polymalformative syndromes and skeletal deformities

Cervical instability (making tracheal intubation at risk of tetraplegia) is constant in Chiari syndrome and common in achondroplasia and Down syndrome. Patients with facial deformities, microstomia, and mandible abnormalities can be difficult to intubate, thus making general anesthesia a dangerous technique. Also, infants with epidermolysis bullosa are extremely difficult to manage under general anesthesia; occasionally, regional block procedures may represent an alternative with lower morbidity.[69,70]

Trauma patients with extremity lesions may greatly benefit from peripheral nerve block for alleviating pain without impeding monitoring of head trauma or hemodynamic disorders and allowing wound dressing as well as temporary stabilization of fractures, provided that appropriate precautions are taken to avoid hiding development of compartment syndromes (see later).

Intraoperative/Postoperative Analgesia and Procedural Pain

Analgesia is currently the main indication for regional blocks in children because they offer the best benefit/risk ratio for many outpatient and inpatient surgeries: orthopedic (including scoliosis surgery), thoracic, urologic, and upper and lower abdominal surgeries.[71-74] Cardiac surgery is a more controversial indication,[75,76] and many anesthesiologists are reluctant to perform neuraxial blocks in children scheduled to receive anticoagulants.

Procedural pain can easily be anticipated and thus prevented mostly by topical anesthesia or infiltration techniques.[77-79] A comparative evaluation of most regional techniques is provided in Table 81-5.

Management of Nonsurgical Pain

Relief of pain associated with some medical conditions such as herpes zoster, AIDS, mucosal/cutaneous lesions, and cancer can be achieved using regional block techniques.[80-82] Children with sickle cell disease may greatly benefit from epidural analgesia during vaso-occlusive crisis or thoracic syndromes with intractable pain by other means, provided that pain is localized to limited areas and concomitant fever is not due to bacteremia.[83,84]

Chronic Pain Relief and Palliative Care

Chronic pain is less unusual in children than commonly believed, and regional techniques such as epidural anesthesia, stellar ganglion blockade, or continuous peripheral nerve blocks may help treat this condition, especially in case of phantom limb pain and complex regional pain syndrome (CRPS).[85] Erythromelalgia, a rare but extremely painful condition, can be successfully relieved by continuous epidural analgesia.[86] Cancer pain resulting either from primary tumor or from metastases can also be controlled by regional techniques when other medications fail or produce too many adverse effects. Virtually all techniques of regional anesthesia have been reported in this ultimate management of pain in children, from epidural analgesia to intrathecal infusions to celiac or brachial plexus block.[87-89]

Nonanalgesic Indications

For certain medical conditions, analgesia is not the only benefit expected from regional blockade. Sympathetic blockade is essential to protect/improve blood supply to an upper or lower extremity in a context of severe trauma. Also, continuous epidural blockade proved to be effective in treating vascular insufficiency resulting from Kawasaki disease,[90] accidental intra-arterial injec-

Table 81-5 Evaluation of the Suitability and Benefits of Most Techniques of Regional Anesthesia in Children

Technique	Ease of Performance*	Benefit/Risk Ratio	Suitability for Catheter Placement
Neuraxial Block			
Spinal anesthesia	+ to +++	+++	No
Caudal anesthesia	+++	++++	Occasionally
Sacral epidural anesthesia	+++	+++	Yes
Lumbar epidural anesthesia	+++	+++	Yes

tion of an anesthetic drug,[91] penile block with a local anesthetic containing epinephrine,[92] and severe frostbite.[93] Acute vascular insufficiency of the upper limb has also been successfully treated by axillary and stellate ganglion blocks.[94,95]

Contraindications and Limitations

Absolute Contraindications to Neuraxial Blocks

Seven medical conditions contraindicate neuraxial blocks in children: (1) severe coagulation disorders, which may be either constitutional (hemophilia), acquired (disseminated intravascular coagulation), or therapeutic; (2) severe infection such as septicemia or meningitis; (3) hydrocephaly and intracranial tumoral process; (4) true allergy to local anesthetics, a very rare condition even with aminoesters; (5) certain chemotherapies (such as with cisplatin) prone to induce subclinical neurologic lesions that can be acutely aggravated by a block procedure; (6) uncorrected hypovolemia; and (7) cutaneous or subcutaneous lesions, whatever their nature (infection, angioma, dystrophic or tumoral, tattoo) at the contemplated site of puncture. Parental refusal is a nonmedical absolute contraindication.

Depending on the clinical condition of the patient and the possibility to cure (at least temporarily) the impeding disorder, a regional block occasionally may be contemplated in spite of the existence of a medical contraindication. After correction of hypovolemia, injection of factor VIII to a hemophilic child, or effective antibiotic treatment of a septicemic patient,[96-98] a central block may be performed, provided that the expected benefits consistently outweigh the risks by comparison with other techniques of analgesia. Also, some authors consider it acceptable to perform a caudal block in children with shunt devices under protection of antibioprophylaxis.[99]

Absolute Contraindications to Peripheral Nerve Block Procedures

True allergy to local anesthetics is the only absolute medical contraindication to peripheral nerve blocks. Coagulation disorders are less hazardous than during neuraxial blocks, but it is prudent to avoid techniques with a danger of arterial trauma, especially in an area where compression is difficult or impossible (supraclavicular brachial plexus block, psoas compartment block). Septicemia does not necessarily contraindicate peripheral nerve blockade if expected benefits are significant. Hypovolemia should

preferably be corrected but does not preclude peripheral blocks because hemodynamic consequences are minimal.

Patients at Risk of Compartment Syndrome

Because pain is one of the cardinal symptoms of a compartment syndrome, any pain treatment, including regional anesthesia, is often claimed to be contraindicated because it can suppress this presenting symptom, thus delaying the rescuing surgery. Such a refusal of pain management is not acceptable both medically and ethically.[100] Fractures are very frequent in the pediatric population whereas compartment syndromes are very rare; whether or not a compartment syndrome is in progress, intense pain is a constant feature. Adequate pain management including continuous epidural analgesia[101] does not preclude early diagnosis, and this fact was confirmed by the national pediatric epidural audit in Great Britain.[102]

Excruciating pain is not a "presenting" symptom but a late—possibly too late—symptom of compartment syndrome. Patients at risk should be monitored adequately, which is not done most of the time even in university hospitals, and precautions must be taken: avoidance of closed plaster casts and elbow immobilization with an angle greater than 90 degrees,[103] closed reduction of supracondylar fractures of the humerus, repeat clinical evaluation of the distal perfusion and tissue oxygenation of the limb, and noninvasive monitoring of the intracompartmental pressure, even though this monitoring is not 100% reliable. If the risk is considered high (e.g., displaced humeral fractures, intramedullary nail fixation of tibia or radius, obtunded patients), intracompartmental pressure close to the fracture site should be invasively monitored: the procedure is easy and almost inexpensive, requiring only a venous cannula, an IV line, and a pressure gauge (as for central venous pressure measurement).[104,105]

Hemoglobinopathies

Children with sickle cell disease are prone to develop massive hemolysis in case of desaturation and undergo repeat episodes of extreme pain due to extended microthromboses when local blood flow slows down (e.g., hemoconcentration, shock, surgical tourniquet).[106,107] If there is a danger of hypoxemia (respiratory disease) or hemodynamic disorders (surgery known to produce significant blood loss, tourniquet placement), regional (especially neuraxial) blocks would better be avoided.[108]

Bone and Joint Deformities

Minor or localized malformations of the spine (hemivertebra, spina bifida occulta, Scheuermann's disease) do not preclude neuraxial blocks whereas extended malformations of vertebrae, spinal fusion, myelomeningoceles, open spina bifida, and major spondylolisthesis are contraindications. Tethered cord syndrome is not unusual and often misdiagnosed; neuraxial blockade may increase the overall morbidity of patient management because it facilitates excessive bending or extension of the spine that can occasionally damage the spinal cord forever. The diagnosis must be suspected if there is a clump of hairs or a dystrophic lesion of the skin at the lower extremity of the spinous process line or in case of minor neurologic disorders involving pelvic nerves (minimal sphincter disorders, perineal dysesthesia). Even though some authors consider that this condition is not a contraindication,[109] it is preferable to select another technique of analgesia than epidural blockade.

Many pediatric syndromes, cerebral palsy, and kyphoscoliosis are associated with bone and joint deformities that represent more of a technical difficulty than a contraindication to performing a regional block.

Preexisting Neurologic Disorders or Diseases

Controlled epilepsy is not a contraindication to regional anesthesia, including neuraxial blockade. Preexisting central nervous system disorders and degenerative axonal diseases have long been considered to be contraindications, at least relative, even though no data support the hypothesis that a regional block could worsen their course.[110] A recent pediatric study involving 139 patients showed that preexisting neurologic disorders were not associated with bad neurologic outcome (the reverse was observed) after central block procedures.[111]

Complications

Complications of regional anesthesia are basically the same as in adults. They can be classified as local, regional, and general (or systemic).

Local Complications

There are four main types of local complications:

1. Inappropriate needle insertion damaging the nerve and surrounding anatomic structures
2. Tissue coring and introduction of epithelial cells into tissues where they do not belong and where they can develop as compressive tumors (especially in the spinal canal)[112]
3. Injection of neurotoxic solutions (syringe mismatch, epinephrine close to a terminal artery)
4. Leakage around the puncture site, especially when a catheter has been introduced, which may cause partial block failure and favor bacterial contamination (very rare)

These local complications are easily avoidable by using adequate devices and applying standard precautions (appropriate dressing and bacterial precautions). Leakage around the catheter can be reduced by tunneling the catheter and applying a slightly compressive dressing.

Systemic Complications

Systemic complications usually result from accidental IV injection of local anesthetics or, less frequently, excessive dosing.[10,113] They can be life-threatening and should be managed in the same way as in adults. The major difference between adults and children is that cardiovascular complications are not preceded by neurologic signs but are concomitant with cerebral toxicity.[114]

Epidemiology

Available pediatric information is limited.[113,115] In the first report of the ASA closed malpractice claims, there were 238 pediatric cases (10% of claims) but only 7 involved children given a regional block procedure[116]; however, at that time regional anesthesia was not commonly used in American children, thus making this apparently low rate of complications meaningless. In 1996, the 1-year prospective study of the French-Language Society of Pediatric Anesthesiologists (ADARPEF) evaluated 85,412 pediatric anesthetic procedures, including 24,409 involving regional anesthesia.[117] There were 23 complications (no sequelae, no death, and no legal consequences), all following neuraxial blocks. In

2000, the Australian Incident Monitoring Study[118] included 2000 claims involving 160 pediatric cases with a regional block procedure (83 epidurals, 42 spinals, 14 brachial plexus, 4 Bier blocks, 3 ophthalmic blocks, and 14 local infiltrations); the largest single cause of complications was circulatory problems, and there were 24 drug errors (including 10 "wrong drugs" and 14 "inappropriate use"). In 2007, the British national pediatric epidural audit[102] reported 96 incidents in 10,633 epidural blocks performed:

- 56 (0.53%) were associated with the insertion or maintenance of epidural anesthesia and most were of low severity; only 1 child had residual effects from a cauda equina syndrome (following a programming error of the infusion pump).
- 40 (0.38%), mainly pressure sores (33), were believed to be associated with the epidural infusion technique.

There was a significantly higher rate of incidents in the neonatal age group, mainly because of drug errors (13) and local anesthetic toxicity (1); these incidents were not related to catheter insertion. There were 28 infection-related incidents, of which 85% were relatively minor skin infection; caudal catheters did not result in increased incidence of infections. Six children, all older than age 8 years, suffered from mild postdural puncture headache. Four patients developed a compartment syndrome, but the condition was not masked by the epidural infusion.

In conclusion, regional block procedures, mainly neuraxial blocks, are associated with the occurrence of adverse incidents (around 0.5%) that are mostly minor but occasionally severe. The majority of these complications results from insufficient precautions at the time of the block procedure (drug errors) and postoperatively (pressure sores). Also, of major importance is the fact that compartment syndrome is not hidden by a regional procedure provided that adequate monitoring is guaranteed.

Selection of Materials, Techniques, and Agents

Selection of a Suitable Block Procedure

Sound selection of block procedures is based on anatomic considerations first: sensory blockade must cover all areas from which noxious stimuli can originate (e.g., operative field, sites for skin or bone graft tissue, placement of tourniquet or drains). Then, the potential morbidity of the technique, either from the medical condition of the patient, the requested positioning, or the "intrinsic" morbidity of technique itself, must be evaluated. The anticipated duration of postoperative pain is the third most important factor to take into account because the regional technique should provide adequate analgesia until minor analgesics are sufficient. The anesthesiologist will select one of the following approaches:

- A single-shot technique with either a short-acting or a long-acting local anesthetic
- A single-shot technique with local anesthetic and adjuvants
- A catheter technique with repeat/continuous injections of local anesthetic

Equipment and Techniques Used to Identify Anatomic Spaces and Nerve Trunks

Quality of blockade depends on needle or catheter positioning in close proximity to the nerve.

These location techniques require some adaptations in infants. Cerebrospinal fluid (CSF) hydrostatic pressure is low, necessitating slow progression of the spinal needle so as not to miss CSF reflux. Ligaments are more hydrated and less densely packed, thus making the loss of resistance technique with saline less dependable than that with air (or preferably CO_2) in infants and young children. Nerve structures are more superficial, and infants' skin can be slenderized to such an extent that nerve stimulation with low current can elicit twitches even if the tip of the needle is still outside the epidermal layer. This property can be used to locate the relevant nerve ("surface mapping" or "percutaneous guidance"[119-121] and identify the cutaneous site at which twitches can be elicited with the lowest current, that is, closest to the nerve; this point will be the site of puncture. Application of ultrasound techniques in pediatric patients also requires some adaptations. For obvious reasons, small probes should be available ("jockey stick"). Because of poor mineralization of bones, especially vertebrae, ultrasound techniques allow excellent visualization of the spinal cord of neonates and small infants (see Fig. 81-1), which allows guiding the progression of an epidural needle and that of a catheter. At the same time, nerve structure is less echoic than in older patients, thus requiring both use of a good ultrasound machine and excellent knowledge of anatomy to correctly identify the relevant nerve (Fig. 81-3).

Other localization techniques are occasionally used, mostly for educational purposes. Penetration into the epidural space can be detected using an acoustic device. Electrostimulation can be used to locate the position of the needle tip or catheter within the epidural and subarachnoid space.[122-124] "Whoosh test" (injection of air into the epidural space via the sacral hiatus) and paresthesia seeking are techniques of the past that should no longer be used.

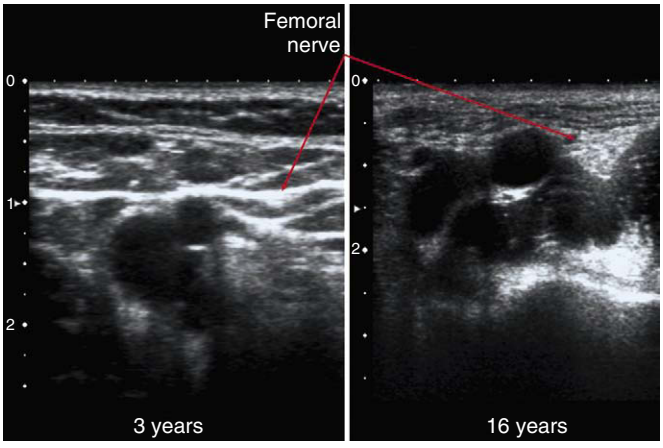

Figure 81-3 Ultrasound imaging of the inguinal area to locate the femoral nerve at different ages. The femoral nerve is clearly visible in the 16-year-old adolescent but difficult to identify in the 3-year-old child. Note the highly contrasted images of aponeuroses in the younger patient.

Selection of the Anesthetic Solution

The prerequisites for selecting a local anesthetic are not exactly the same in children as in adults because regional techniques are mostly used for analgesic purposes rather than anesthesia. The factors to be considered are (1) site and severity of surgery, (2) expected duration of intense postoperative pain, and (3) hospital stay versus early discharge. Usual doses are listed in Table 81-6.

Lidocaine and mepivacaine are preferred for outpatient surgery. For continuous infusion, levobupivacaine and ropivacaine are preferred to racemic bupivacaine owing to their safer pharmacokinetic profile. In infants younger than 3 months old, epidural infusion of ropivacaine should not be maintained for more than 36 hours.[125]

Addition of clonidine or ketamine helps improve the quality and duration of blockade without precluding early hospital discharge. In many cases, these drugs make it unnecessary to insert a catheter and establish a continuous infusion to provide adequate postoperative pain relief.

For many years, continuous epidural anesthesia was the only suitable technique for treating protracted pain. In recent years, peripheral nerve catheter techniques have proved to be effective,[72] with less morbidity and limitations than continuous epidural blockade, even allowing hospital discharge[85] and management at home in selected pediatric patients. For these techniques, continuous infusion (2 to 5 mL/hr) or on-demand injections (2 to 5 mL) of low-concentration levobupivacaine or ropivacaine (0.1 to 0.2%) represent the best and safest choice.

Selection of Block Needles and Catheters

Epidural anesthesia (sacral, lumbar, or thoracic) is performed using Tuohy needles ranging in size from 22 to 17 gauge and in length from 50 to 90 cm; shorter Tuohy needles (25 cm) would be more appropriate in neonates and infants but are not easily available. Caudal anesthesia has been performed in the past with almost all types of needles. This is no longer acceptable, and only short beveled needles (Crawford needles) with a guide sealing their lumen or IV cannulas with an introducer needle should be used.

Spinal anesthesia in premature infants can be performed using either a neonatal lumbar puncture needle (22 gauge) or, preferably, a thinner spinal needle (shorter than 50 mm). The distal end of the needle does not have the same importance as in adults because the incidence of postdural puncture headache remains (very) low in children and is not influenced by the design of the tip of the needle.[126,127] What matters the most is the distance separating the tip of the needle from its distal orifice: this distance must be as short as possible to avoid extradural leakage if the needle has not been introduced far enough through the dura mater. Pencil-point needles have no advantage in infants and young children; they do not improve the results and are even suspected to decrease the success rate by favoring subdural spread of the local anesthetic.

A summary of recommended needles for most regional block procedures in pediatric patients is provided in Table 81-7.

Safety Precautions and Discharge Criteria

Acceptable Environments for Performing a Regional Block

Regional techniques are techniques of anesthesia; therefore, they must be performed only in places where all the monitoring, anesthetic, and resuscitation equipments (including anesthetic and emergency drugs) are available. Additionally, the anesthesiologist must be assisted by staff members able to provide adequate patient monitoring and trained to help in emergency situations. The operating theater represents the best location to guarantee safe performance of any type of regional anesthesia.

Sedation and General Anesthesia

Regional procedures are performed in conscious adult patients, with or without sedation, but usually not under general anesthesia. In some pediatric patients, the same management can be offered and is sometimes requested by the child.[128] However, most children require being unconscious during the block procedure. If general anesthesia is not medically contraindicated, it is widely accepted that regional blocks be performed with the patient under light general anesthesia.[74,93,129]

Table 81-6 Usual and Maximum Recommended Doses of Local Anesthetic for Conduction Nerve Blocks (Excluding Bier Blocks and Spinal Anesthesia)

Local Anesthetics	Usual Concentrations	Maximum Dose of Plain Solutions (mg/kg)	Maximum Doses with Epinephrine (mg/kg)
Aminoesters			
Procaine	1-2	7	10
Chloroprocaine	2-3	7	10
Aminoamides			
Lidocaine	0.25-2	5 (or 400 mg)	10 (or 700 mg)
Mepivacaine	0.25-2	5-7 (or 400 mg)	Not available
Bupivacaine	0.125-0.5	2 (or 150 mg)	3 (or 200 mg)
Levobupivacaine	0.125-0.5	3 (or 200 mg)	4 (or 250 mg)
Ropivacaine	0.1-10	3 (or 300 mg)	Not available (and not recommended)

Table 81-7 Recommended Devices for Most Regional Block Procedures in Children

Block Procedure	Recommended Device	Alternate Device
Intradermal wheals and metacarpal blocks	Intradermal needles (25 gauge)	None
Subcutaneous infiltrations and field blocks	Standard intramuscular needles (21-23 gauge)	Intradermal needles (25 gauge)
Compartment blocks (thoracic paravertebral, rectus sheath, ilioinguinal-iliohypogastric, pudendal, penile)	Short (25-50 mm) and short beveled (45-55 degrees) needles	Epidural needles (intercostal block) Neonatal spinal needle
Peripheral mixed nerve blocks and plexus blocks	Insulated 21-23 gauge short beveled needles of appropriate length connected to a nerve stimulator (0.5-1 mA) Specific catheter (for continuous techniques)	Sheathed pencil-point needles Unsheathed needles only when ultrasound guidance is used Epidural catheter (for continuous techniques)
Spinal anesthesia	Spinal needle (24-25 gauge; 30, 50 or 100 mm long, Quincke bevel, stylet)	Neonatal lumbar puncture needle (22 gauge, 30-50 mm long) Whitacre spinal needle
Caudal anesthesia	Short (25-30 mm) and short beveled (45-degree) needle with stylet	IV cannula (22-18 gauge), especially for epidural catheter insertion Pediatric epidural (occasionally spinal) needle
Epidural anesthesia	Tuohy needle (22, 20, and 19/18 gauge); LOR syringe and medium epidural catheter	Crawford, Whitacre, or Sprotte epidural needles appropriately sized; LOR syringe and medium epidural catheter

LOR, loss of resistance.

Patient Monitoring and Safety Precautions During the Block Procedure

Monitoring and Anesthesia Chart

Even when general anesthesia is not used, regional techniques must be performed by an experienced anesthesiologist in an operating room environment with the usual monitoring recommended for pediatric general anesthesia, that is, electrocardiographic (ECG) tracings, blood pressure, temperature, respiratory rate, and oxygen saturation measurements. An IV line must be established before any injection of local anesthetic,[130] and vital parameters as well as the techniques and doses of local anesthetics have to be reported on a detailed anesthesia chart.

Technique of Injection

Techniques in adults and children are similar. Of prime importance is to evaluate the effects on ECG tracings of a test dose containing epinephrine (0.1 mL/kg up to 3 mL containing 0.5-1 µg/kg of epinephrine) for 30 to 60 seconds: Any elevation of ST segment or increase in T-wave amplitude,[131-135] followed by an increase in blood pressure[136] but only occasionally by tachycardia, suggests inadvertent IV injection and necessitates cessation of the procedure; when epinephrine is contraindicated, isoproterenol (0.05 to 0.1 µg/kg) should be used instead.[137]

Assessment of the Block

After every block procedure, the quality and extension of analgesia must be evaluated before surgical incision. However, this evaluation is difficult, even in conscious children. Gentle skin pinching is the most dependable technique of sensory testing, especially in lightly anesthetized children. Postoperatively, this evaluation should be comparative (blocked versus nonblocked areas) and requires that the child has gained the confidence of the caregiver, cannot see what he or she is doing, and is not influenced either by the caregiver or the family. Electrical stimulation using a nerve stimulator at different threshold intensities proved to be suitable in healthy volunteers but available data on children are limited. Skin temperature is not suitable, and whether pupillary reflex dilation of 0.2 mm is sensitive to the loss of analgesia it is not clinically useful.[138]

Prevention of Irrelevant Medicolegal Claims

Whenever something wrong happens to a patient after a regional procedure has been performed, the first condition incriminated is the block procedure even though on closer analysis it is rarely the cause of the alleged consequence or damage. To minimize irrelevant medicolegal claims, the recommendations listed in Table 81-8 should be followed whenever possible.

Postoperative Monitoring in the Recovery Room

After combined regional and general anesthesia, all children must be transferred to a PACU where the stability of their respiratory and hemodynamic status is checked as following any general anesthesia. In addition to this standard postanesthetic care, they require repeat evaluations of the anesthetized area. In case of motor blockade, which should be avoided as often as possible, it is important to verify that its distribution corresponds to the area supplied to the blocked nerve. Motor blockade is a stressful condition: The children (and their parents) should be comforted, and the information that it is just a time-limited condition should be repeated. Patient positioning must be carefully and regularly checked to avoid pressure points. Anesthetized areas must also be protected from patients' inadequate behavior, imprudence, or attempts to remove dressings. The possibility that a compartment syndrome is evolving must be always kept in mind, and both the

Table 81-8 Basic Safety Recommendations for Any Type of Regional or Local Anesthesia Aiming to Avoid Irrelevant Medicolegal Claims

1. Evaluate carefully the physical status of the patient and ask for complementary laboratory, radiographic, or any other examination whenever useful.
2. Select the least hazardous technique for a given block.
3. Provide detailed explanations concerning the scheduled anesthetic management, including beneficial as well as potentially detrimental effects, even in emergency situations.
4. Discuss the possibility of block failure and explain what replacement procedure(s) will then be used.
5. Obtain written consent for anesthesia care.
6. Manage the patient in the same way and with the same monitoring procedures as recommended for the same surgical procedure under general anesthesia.
7. Fill in an anesthesia chart detailing the monitoring procedures, vital parameters, techniques and doses used, and adverse effects if any.
8. Treat all complications and provide full details with precise timing.
9. Transfer all pediatric patients to a PACU requesting appropriate monitoring of vital function and repeat evaluations of the extension and quality of blockade; data are to be reported on a detailed postanesthetic chart, and discharge should be allowed only when objective signs of recovery are obtained.
10. Keep hospitalized at least overnight all patients given epidural or intrathecal morphine in units where their respiratory function will be regularly/continuously monitored (hourly for the first 6 hours, then every 2 hours).

hemodynamic status of the relevant limb and the quality of analgesia must be repeatedly evaluated.

Urinary retention can be of concern after neuraxial blocks. In many institutions, however, voiding is not requested before discharging the child. In infants and disabled children it may be prudent to keep them in the PACU until they have urinated or to check their bladder content with an ultrasound probe, especially after hypospadias repair, because the incidence of urinary retention is greater than usual in this surgery.[139]

Adults operated on under regional blockade often bypass the recovery room. In children, even if no sedative has been given, it is not wise to do so: Adequate monitoring and skilled assistance improve recovery from immediate postoperative incidents.[140] After short procedures especially, sudden cessation of external stimulation may unmask some compensated adverse effects (hemodynamic and respiratory especially) that will not be harmful if detected early. Also, as detailed earlier, ropivacaine and, to a lesser extent, levobupivacaine, have both a longer Tmax (up to 2 hr) and Cmax in infants; therefore, after short-duration surgeries, these patients may leave the operating room before local anesthetic plasma peak concentration has been reached. It is safer to keep them monitored in a PACU up to 2 hours after the block procedure.

Discharge Criteria After Single-Shot Procedures

Discharge from the PACU depends on the same criteria as following general anesthesia (pediatric adaptation of Aldrete score or specific scoring method in use in the relevant institution); in the absence of motor blockade, children may usually be discharged within 30 minutes. In other cases, discharge depends on the behavior of the child. Partial restoration of motor function is mandatory, even in quiet children with caring families. Boisterous children should not leave before motor functions have been fully restored; additionally, protective dressings (including casts) may be useful to prevent harm to the operated limb.

Persistence of sensory blockade is not a contraindication to early discharge unless the familial environment is really inadequate. Pain medication should be systematically prescribed and administered on a regular basis to prevent the return of intense pain at home, when the sensory block is no longer effective.[141]

Most additives do not preclude early discharge except for epidural/intrathecal opioids, especially morphine, which necessitate that the child stay hospitalized overnight.

Management and Follow-up of Continuous Techniques

Children with repeat, on-demand, or continuous epidural infusion should remain hospitalized to be adequately monitored. Occasionally, a few selected patients can be allowed to return home with an epidural catheter, mostly in a context of chronic pain or cancer pain in terminally ill children.

Adult patient with continuous techniques of peripheral nerve blockade can be returned home provided surgical care does not require hospital stay. These continuous techniques are rather new in pediatrics[73] and not yet widely used. In one institution, children suffering from complex regional pain syndrome were treated at home with peripheral nerve catheters.[85] Such management will probably gain wider acceptance in the near future but, currently, it should be considered under evaluation.

Neuraxial Blocks

Caudal Anesthesia

Caudal anesthesia is the oldest and still most commonly used technique of epidural blockade in children. It is performed via the sacral hiatus, through the sacrococcygeal membrane. Caudal anesthesia considerably decreases stress hormone response to surgery[142-144]; therefore, fasted infants are prone to develop hypoglycemia if intraoperative fluids do not contain any glucose.

Anatomy of the Sacral Hiatus

The sacral hiatus is a V-shaped aperture resulting from the lack of dorsal fusion of the fifth and often fourth sacral vertebral arches. It is limited laterally by two palpable bony structures, the sacral cornua, and it is covered by the sacrococcygeal membrane (sacral continuation of the ligamenta flava). The distance separating the summit of the sacral hiatus and the dural sac ending is 30 ± 10.4 mm (range: 13.6 to 54.7 mm) in children aged 10 months to 18 years.[145] Mean distance from skin to anterior sacral wall is 21 mm (extremes: 10 to 39 mm) between 2 months and 7 years of age.[146] The distance from skin to the epidural space is hardly influenced by the age and weight of the patient (Fig. 81-4): 25-mm-long needles are long enough to reach the sacral epidural space

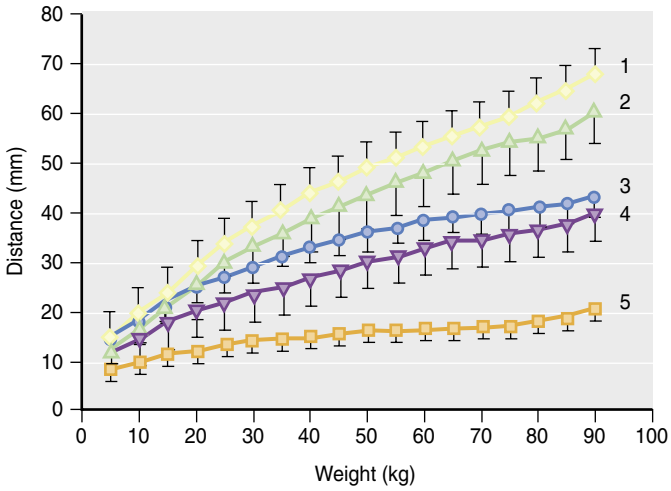

Figure 81-4 Distance from the skin to the epidural and subarachnoid spaces at different intervertebral levels and through the sacral hiatus. 1, Spinal anesthesia; 2, lumbar epidural approach (midline); 3, thoracic epidural approach (midline); 4, sacral epidural approach; 5, caudal approach.

and short enough to prevent inadvertent dural puncture in most patients.

With growth, the axis of sacrum changes: the sacral hiatus becomes more difficult to identify and may even close.[147] Concomitantly, the epidural fat becomes more densely packed, thus reducing the spread of local anesthetics. These changes make caudal anesthesia less suitable and more difficult to perform in children older than 6 to 7 years of age.

Indications and Contraindications

Caudal anesthesia is recommended for most surgical procedures of the lower part of the body (mainly below the umbilicus), including inguinal hernia repair, urinary and digestive tract surgery, and orthopedic procedures on the pelvic girdle and lower extremities.[148,149] It is usually performed in lightly anesthetized patients but can be used as the sole anesthetic regimen in fully awake ex-premature infants younger than 50 to 60 weeks of postconceptual age after local anesthesia of the skin covering the sacral hiatus, either as a single-shot technique[150,151] or after placement of an epidural catheter allowing repeat/continuous injection of local anesthetics.[152,153]

Specific contraindications include major malformations of the sacrum (myelomeningocele, open spina bifida), meningitis, and intracranial hypertension.

Technique

The technique is performed with the patient in the semiprone or, especially in nonanesthetized premature infants, in the prone position either with a rolled towel slipped under the pelvis or with the legs flexed in the "frog" position. The two sacral cornua limiting the V-shaped sacral hiatus are located by palpation along the spinal process line at the level of the sacrococcygeal joint (Fig. 81-5). The hiatus along with the two posterior superior iliac crests is claimed to form an equilateral triangle but, in clinical practice, this assumption does not help in locating the hiatus when palpation is not informative.

Caudal anesthesia is basically a single-shot technique. Occasionally, placement of an epidural catheter for repeat/continuous infusion is contemplated. The "normal" length of catheter to be introduced into the epidural space is 2 to 3 cm, as for any epidural block. Because the epidural fat is very fluid in infants, a longer distance can be inserted to reach lumbar or even thoracic levels: this technique should be considered with caution, by experts only, and the final position of the tip of the catheter must be controlled because it is misplaced in 28% of cases.[154] This is usually achieved by obtaining a contrast-enhanced radiograph, but other techniques are available:

- Neurostimulation at rather high intensities (however, safety of this technique is not established)[122,155]
- Recording ECG tracings from the metallic wire of the catheter and comparing them with those obtained from an electrode placed on the spinous process line, at the level where the tip of the catheter should be placed. The position is correct when the two tracings are identical.[156] This technique is very elegant and noninvasive, but the "second" ECG tracing is not easily readable in some patients (especially when they are conscious and moving).
- Ultrasound guidance,[157] which is the most promising noninvasive technique but still under evaluation

Catheter tunneling has been recommended to decrease the risk of bacterial contamination.[158] The dosage prescription scheme of Armitage that was published many years ago still remains the most dependable[159]:

- With 0.5 mL/kg, all sacral dermatomes are blocked.
- With 1.0 mL/kg, all sacral and lumbar dermatomes are blocked.
- With 1.25 mL/kg, the upper limit of anesthesia is at least midthoracic.

However, when 1.25 mL/kg is injected there is a danger of excessive rostral spread (above T4)[160]; it is therefore preferable not to administer more than 1.0 mL/kg of local anesthetic.

When a catheter has been inserted, repeat injections must be reduced, as detailed earlier (see "Pharmacokinetics") to avoid systemic toxicity. The second injection should be made no earlier

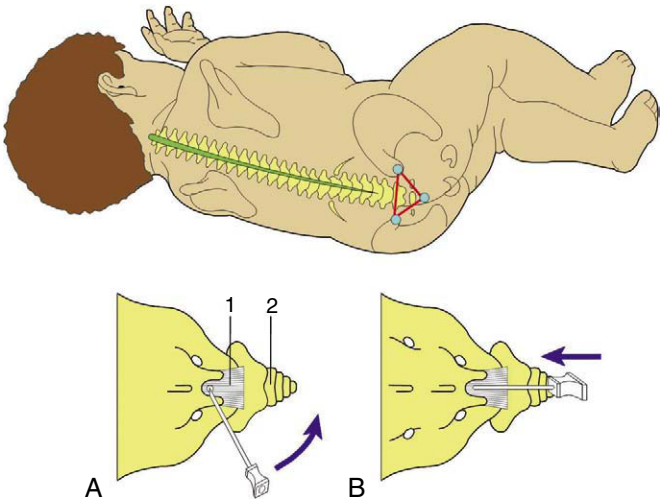

Figure 81-5 Caudal block procedure. **A,** Insertion of the needle at right angles to the skin. 1, Coccyx; 2, Sacrococcygeal membrane. **B,** Cephalic redirection of the needle after piercing the sacrococcygeal membrane.

than 60 minutes (for a short-duration local anesthetic) or 90 minutes (for a long-duration local anesthetic) after the first one and should consist of half of the initial dose. Further injections should be reduced to half of the second dose (i.e., one sixth of the initial dose) while respecting the same delays.

Specific Complications

Complications of caudal anesthesia are infrequent and usually minor[102,117] when adequate devices are used. Delayed postoperative voiding was an issue years ago when preoperative fasting was excessively prolonged, but this should not be an issue anymore and true urinary retention is (very) rare. Block failure is not unusual (3% to 5%), especially in children older than 7 years of age, but even in younger patients the failure rate can be rather high.[136]

Intervertebral Epidural Anesthesia

Anatomy and Physiology of the Epidural Space

The epidural space surrounds the spinal cord and the meninges from the foramen magnum to the sacral hiatus. Limited posteriorly by the vertebral laminae and the ligamenta flava, it communicates quite freely with both the paravertebral spaces and the root sleeves. In the "dural cuff" region, near the spinal ganglia, it is intimately connected with the subarachnoid space owing to protrusion of arachnoid granulations, which are easily traversed by local anesthetics. It contains blood vessels and lymphatics and is filled with loose fat in infants and in children up to 6 to 8 years of age.

The line joining the two iliac crests (Tuffier's line) crosses the spinous process line at the L5-S1 level up to 1 year of age instead of at L4-L5 as in older children and adults.[161] Bending the spine (as for performing an epidural block) does change the level at which Tuffier's line crosses the spine in 58.3% of patients.

Epidural injections result in considerable pressure changes. After placement of a 20-gauge epidural catheter in 20 infants, Vas and coworkers measured the following changes[162]:

- Pressure on penetrating the epidural space: 1 ± 10 mm Hg (extremes: −17 to +16 mm Hg)
- Peak pressure during injection of a local anesthetic at 1 mL/min: 27.8 ± 18.6 mm Hg with residual pressure of 12 ± 5.5 mm Hg 1 minute after completion of injection
- Peak pressure during injection of a local anesthetic at 0.5 mL/min: 15.2 ± 9.5 mm Hg with residual pressure of 14.8 ± 5.4 mm Hg 1 minute after completion of injection

As previously mentioned, young children tolerate epidural anesthesia well without any significant blood pressure change or bradycardia.[62,64]

Indications and Contraindications

Epidural anesthesia is recommended for all major abdominal, retroperitoneal, pelvic, and thoracic[163,164] surgeries, including pectus excavatum repair[165] and scoliosis surgery,[166] preferably with a two-catheter technique.[167] The technique is also used for cardiac surgery in a few institutions,[76,168] but this indication is controversial and most authors consider it contraindicated due to anticoagulation.

The intervertebral level at which the epidural space should be approached is a matter of debate and depends both on the patient's age and on the experience of the anesthesiologist. When a single-shot technique is planned for a surgery below the umbilicus, a caudal approach is most often selected in infants and young children and a lumbar approach is used in older patients. When catheter placement is contemplated it is preferable to select a lumbar approach in all patients to decrease the risk of bacterial contamination from anal proximity even though this is rare.[102]

When sensory blockade of high thoracic dermatomes is required, the most reliable approach is a thoracic epidural block, which requires expertise because the spinal cord could be damaged. When the anesthesiologist is not used to performing thoracic epidural blocks in infants, some authors recommend a caudal approach with cephalic insertion of a catheter over a long distance to reach thoracic levels.[169] This technique, however, requires experience, too, and luck: The catheter is misplaced in almost 30% of cases even in experienced hands,[154,170] serious complications are possible (e.g., spinal cord/vessel trauma during insertion, bacterial contamination, breakage or buckling around a nerve root on removal attempts).[171-173]

Specific contraindications to epidural anesthesia include severe malformations of the spine and the spinal cord (not spina bifida occulta), intraspinal lesions or tumors, and, for most authors, tethered cord syndrome. In most instances, epidural anesthesia should be avoided in children with a history of hydrocephalus, elevated intracranial pressure, unstable epilepsy, or reduced intracranial compliance, but these disorders are not absolute contraindications, depending on the context.[174] Also, previous surgery on the spine usually makes epidural (and spinal) anesthesia technically difficult or impossible, but they are not contraindications unless there are underlying lesions of the spinal cord.

Techniques

Lumbar Epidural Anesthesia

The lumbar epidural space is usually approached in anesthetized patients via a midline route below the L2-L3 interspace, which represents the lower limit of the conus medullaris. A paramedian approach can be used instead in cases of spinous process anomaly or spine deformity. The child is positioned in the semiprone position with the side to be operated lowermost and the spine bent to enlarge the interspinous spaces (Fig. 81-6). The sitting position can be used in conscious patients.

Medium selection for the loss of resistance (LOR) technique has elicited considerable debates in the past. In infants, the most dependable is gas (air or, preferably, CO_2), whereas in children older than 8 to 10 years saline is as reliable as it is in adults.

The distance from the skin to the epidural space is correlated with patient's age and size (see Fig. 81-4), but 1 mm/kg is a useful approximation between 6 months and 10 years of age. Use of an ultrasound probe allows precise measurement of the distance from skin to ligamenta flava (see Fig. 81-1).

When the tip of the needle has penetrated the epidural space, the LOR technique syringe is disconnected: no reflux of biologic fluid (blood or CSF) should appear at the hub. The next step consists of injecting the local anesthetic at a slow speed, either through the epidural needle or through a catheter. Progressive displacement of the dura mater can be visualized by placing an ultrasound probe in line with the spinous process line during injection in infants younger than 2 years of age.[175] When a catheter is inserted, it should not be introduced more than 3 cm in

Table 81-9 Usual Doses and Infusion Regimens for Epidural Anesthesia in Pediatric Patients

Agent	Initial Dose	Continuous Infusion (Max. Doses)	Repeat Injections
Bupivacaine, levobupivacaine	*Solution*: 0.25% with 5 µg/mL (1/200,000) epinephrine *Dose:* <20 kg: 0.75 mL/kg 20-40 kg: 8-10 mL (or 0.1 mL/year/number of metameres) >40 kg: same as for adults	*<4 mo:* 0.2 mg/kg/hr (0.15 mL/kg/hr of a 0.125% solution or 0.3 mL/kg/hr of a 0.0625% solution) *4-18 mo:* 0.25 mg/kg/hr (0.2 mL/kg/hr of a 0.125% solution or 0.4 mL/kg/hr of a 0.0625% solution) *>18 mo:* 0.3-0.375 mg/kg/hr (0.3 mL/kg/hr of a 0.125% solution or 0.6 mL/kg/hr of a 0.0625% solution	0.1 to 0.3 mL/kg every 6-12 hr of a 0.25% or 0.125% solution (according to pain scores)
Ropivacaine	*Solution:* 0.2% *Dose:* same regimen in mL/kg as for bupivacaine (see above)	Same age-related infusion rates in mg/kg/hr as for bupivacaine (usual concentration of ropivacaine: 0.1%, 0.15%, or 0.2%) Do not infuse for more than 36 hr in infants < 3 mo	0.1 to 0.3 mL/kg every 6-12 hr of a 0.15% or 0.2% solution (according to pain scores)
Adjuvants	Avoid in infants < 6 mo Fentanyl (1-2 µg/kg) or sufentanil (0.1-0.6 µg/kg) or clonidine (1-2 µg/kg)	*Select only one additive:* Fentanyl: 1-2 µg/mL Sufentanil: 0.25-0.5 µg/mL Morphine: 10 µg/mL Hydromorphone: 1-3 µg/mL Clonidine 0.3 at 1 µg/mL of solution	Morphine (without preservatives): 25-30 µg/kg every 8 hr

order to avoid buckling, knotting, and lateralization of blockade or erratic migration. Tunneling the catheter reduces the incidence of accidental removal and bacterial contamination.[176] Catheters inserted over a long distance have to be controlled in the same way as for caudal catheters.

The volume of anesthetic solution depends on the upper level of analgesia required for completion of the surgery; around 0.1 mL per year of age is necessary to block 1 neuromere.[177] Usual volumes of injectate range from 0.5 to 1 mL/kg (up to 20 mL), and the upper limit of sensory blockade ranges between T9 and T6 in more than 80% of patients.

Single-shot epidural blocks are appropriate for many pediatric surgeries, especially when adjuvants such as clonidine (1-2 µg/kg), preservative-free ketamine (0.25-0.5 mg/kg), and, in appropriate indications, morphine (30 µg/kg) are co-administered. Major operations resulting in long-lasting postoperative pain require placement of an epidural catheter and postoperative infusion of local anesthetics (Table 81-9).

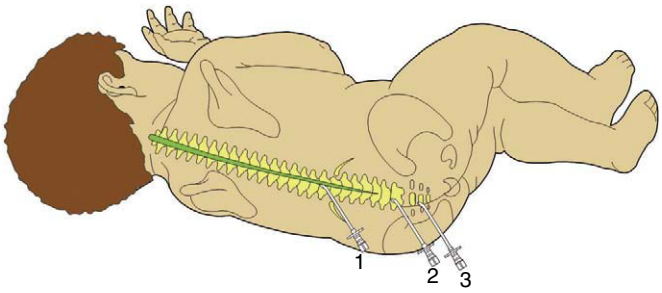

Figure 81-6 Epidural block procedures. 1, Thoracic approach (midline route); 2, lumbar approach (midline route); 3, sacral intervertebral approach.

In mature children understanding the concept of patient-controlled analgesia and willing to use it, patient-controlled epidural analgesia (PCEA) can be an interesting option. A prospective study involving 128 children older than 5 years of age reported a 90.1% success rate; PCEA was stopped in 6.1% of children because of adverse effects and only in 3.8% because of inadequate analgesia.[178] The local anesthetic was either 0.0625% or 0.125% bupivacaine with fentanyl (2 to 10 µg/mL); background infusion rate was less than or equal to 0.2 mL/kg/hr, and 1- to 3-mL bolus doses were permitted every 15 to 30 minutes with a 0.4-mg/kg/hr maximum dose of bupivacaine.

Another prospective study involving 58 children (age range: 7-12 years) undergoing lower extremity orthopedic surgery compared continuous epidural infusion of 0.2% ropivacaine (0.2 mL/kg/hr) with PCEA with background infusion of 1.6 mL/hr and 2-mL bolus doses (lock-out interval: 10 min) of the same solution. Pain scores were excellent and identical in both groups, but children from the PCEA group required half the doses of ropivacaine on a hourly basis as compared with the continuous infusion group.[179]

Sacral Epidural Anesthesia

Because sacral interspaces remain nonfused until early adulthood, the sacral epidural space of children can be approached from posteriorly via the S2-S3 interspace, which is identified by palpation 0.5 to 1 cm below the line joining the two posterior superior iliac spinous processes,[180] but any other sacral interspace can be used.[181] The procedure is the same as for a lumbar approach. Because sacral spinous processes are atrophic, the Tuohy needle can be oriented cephalad or, preferably, caudad to contact the dura mater with the convex part of the needle tip, thus reducing the danger of accidental dural penetration. Attention must be paid to the closer skin proximity of the epidural space as com-

pared with lumbar approaches (see Fig. 81-4). If mandatory, an epidural catheter can be inserted (using the same technique as for lumbar epidural catheter placement) to provide long-lasting postoperative pain relief.

Sacral epidural anesthesia is an alternative to caudal anesthesia, either in infants when skin lesions contraindicate a caudal approach or in children older than 6 to 7 years of age, in whom caudal anesthesia becomes more difficult and less reliable. The same volumes and doses of local anesthetic as for a caudal anesthesia are administered. Ultrasound imaging can be used to precisely evaluate the distance from skin to epidural space and, in infants mainly, visualize both the progression of the needle and catheter and the spread of the local anesthetic.

Thoracic Epidural Anesthesia

Thoracic epidural blocks are indicated for major operations requiring long-lasting pain relief, thus requiring placement of an epidural catheter to allow repeat injections or continuous infusion of local anesthetic. These are not commonly used techniques in children because indications are limited to thoracic and upper abdominal surgery and there is fear of spinal cord damage. In children younger than 1 year of age, the procedure is similar to that for a lumbar approach, with a needle insertion perpendicular to the spinous process line, because the spine displays a single flexure, especially when bent. As the patient grows and the flexure develops, the technique becomes progressively similar to thoracic approaches in adults, requiring cephalic orientation of the Tuohy needle up to a 45-degree angle to the skin. A paramedian approach can be used instead, but it is rarely required in children.

In infants, ultrasonography makes visible the dura mater, the progression of the Tuohy needle, and, in many cases, the progression and final position of the tip of the epidural catheter.[182]

Cervical Epidural Anesthesia

There are no surgical indications for cervical epidural blockade in children. Very rarely, the technique can be contemplated for chronic pain patients or to prevent phantom limb pain before an amputation of the upper arm at the scapular level (osteosarcoma of humerus), which is done almost exclusively in adolescents. The block procedure is the same as in adults.

Specific Adverse Effects and Complications

Specific complications are the same as those reported in adults but with a lower incidence and severity.[102,117]

Spinal Anesthesia

Anatomy and Physiology

The spinal cord and dural sac of infants younger than 1 year of age end at a lower level than in older patients (see "Caudal Anesthesia," earlier). Also, the volume of CSF varies considerably according to patient's age, from more than 10 mL/kg in neonates, to 4 mL/kg in infants weighing less than 15 kg, to 3 mL/kg in children, to 1.5 to 2.0 mL/kg in adolescents and adults. The spinal/cerebral distribution of CSF also varies with age: Half the CSF volume is located within the spinal subarachnoid space versus only 25% in adults. This has considerable pharmacokinetic consequences and explains why larger doses of local anesthetics are required for spinal anesthesia in infants and young children.

CSF hydrostatic pressure is lower in infants in the dorsal recumbent position[183] and further decreased during general anesthesia. In performing a spinal block, the progression of the needle must be slow to detect CSF reflux before the needle had been advanced farther.

Children older than 5 years of age behave like adults after spinal anesthesia, whereas younger patients remain hemodynamically stable, without significant hypotension or bradycardia,[184] even in case of cardiac malformations.[185] However, a decrease in mean arterial pressure during the first 10 minutes after injection of 0.8 mg/kg of 0.5% bupivacaine was reported in infants aged 1.5 to 5 months.[186] This decrease was time limited, well tolerated, and rapidly corrected by IV fluids. Similar results with concomitant decrease in cerebral blood flow were reported in former preterm infants of 41 weeks of postconceptual age.[187]

Indications and Contraindications

Spinal anesthesia has limited indications in pediatric patients. One of these is inguinal hernia repair in former preterm infants younger than 60 weeks of postconceptual age[188,189] who are prone to develop postoperative apnea after general anesthesia or even light sedation.[190] However, even after pure spinal anesthesia, apneas may occur postoperatively (as they may preoperatively) and it is prudent to keep at-risk infants hospitalized. Other indications are scarce, mainly for elective lower abdominal or lower extremity surgery[191-193] and, occasionally, for cardiac surgery or cardiac catheterization,[194,195] but these indications are controversial.

Technique

The technique of spinal anesthesia is that of lumbar puncture. It can be performed with the patient in the lateral decubitus position or sitting.

Currently, hyperbaric tetracaine and bupivacaine are the most commonly used local anesthetics.[196] Isobaric bupivacaine can be used instead.[191] Ropivacaine[197] and levobupivacaine[198] may become the standard of the future but are not currently approved for spinal administration in pediatric patients. Usual doses are given in Table 81-10 for infants and in Table 81-11 for children.

Adverse Effects and Complications

Spinal anesthesia is technically difficult in neonates and infants; the overall failure rate ranges from 10% to 25%.[190,199] Short dura-

Table 81-10 Usual Doses of Local Anesthetics for Spinal Anesthesia in Neonates and Former Preterm Neonates Younger than 60 Weeks of Preconceptual Age (up to a Weight of 5 kg)

Local Anesthetic	Dose (mg/kg)	Volume (mL/kg)	Duration (min)
Tetracaine 1%	0.4-1.0	0.04-0.1	60-75
Tetracaine 1% with epinephrine	0.4-1.0	0.04-0.1	90-120
Bupivacaine 0.5% isobaric or hyperbaric	0.5-1.0	0.1-0.2	65-75
Levobupivacaine 0.5%	1.0	0.2	75-88
Ropivacaine 0.5%	1.08	0.22	51-68

Table 81-11 Usual Doses of Local Anesthetics for Spinal Anesthesia in Children and Adolescents

Local Anesthetic	Usual Dose(s)
0.5% Isobaric or hyperbaric bupivacaine	5 to 15 kg: 0.4 mg/kg (0.08 mL/kg) >15 kg: 0.3 mg/kg (0.06 mL/kg)
0.5% Isobaric or hyperbaric tetracaine	5 to 15 kg: 0.4 mg/kg (0.08 mL/kg) >15 kg: 0.3 mg/kg (0.06 mL/kg)
0.5% Isobaric levobupivacaine	5 to 15 kg: 0.4 mg/kg (0.08 mL/kg) 15-40 kg: 0.3 mg/kg (0.06 mL/kg) >40 kg: 0.25 mg/kg (0.05 mL/kg)
0.5% Isobaric ropivacaine	0.5 mg/kg (max 20 mg)

tion of blockade and lack of residual analgesia are important limitations: Alternative (awake caudal anesthesia) or complementary techniques (ilioinguinal/iliohypogastric block) are often contemplated. Postdural puncture headache is rare in children younger than 8 years of age but not exceptional, and its incidence may be increased with use of pencil-point spinal needles.[200] All complications reported after lumbar epidural blockade can occur after spinal anesthesia.

Upper Extremity Conduction Blocks

Anatomic Considerations

Nerve supply to the upper extremity depends mainly on the brachial plexus formed by the union of the ventral rami of the fifth cervical to the first thoracic spinal nerves within the interscalene space. As in adults, brachial plexus nerve fibers redistribute first to three trunks (within the interscalene space), then to three divisions at the level of the clavicle under which they lie, then to three cords surrounding the axillary artery before splitting into terminal nerves in the axilla. Because of this complicated redistribution of nerve fibers, distribution of anesthesia varies considerably depending on the level at which the local anesthetic is injected.

The most important anatomic difference between infants and adults pertains to the upper part of the lung and apical pleura that penetrates the neck, above the plane formed by the clavicle and first rib (superior thoracic aperture). Subclavian vessels and the lower division of the plexus are impacted in the apical pleura, thus making any peri-subclavian approach at major risk of pleural penetration. The concept of peri-neurovascular sheath has been challenged in spite of strong embryological and anatomical evidences, but it received additional confirmation in a recent radiological study, and even the volume of the "axillary tunnel" could be precisely measured (5.1 to 9.5 mL in adults).[201]

Ultrasound imaging allows precise localization of the parietal pleura and subclavian/axillary vessels, thus improving the safety of supraclavicular as well as infraclavicular approaches, provided the tip of the block needle can be continuously seen during the procedure.

Indications and Contraindications

Indications for brachial plexus blocks include emergency as well as elective surgery of the upper extremity in conscious or anesthetized children.[202-205] These blocks are particularly useful for outpatient surgery and elicit a high degree of patient satisfaction. Axillary blocks are considered first, especially when the lesions involve the forearm and the hand, because they are virtually free of complications. Infraclavicular paracoracoid approaches are being increasingly used with the development of ultrasound guidance: The technique is easy and provides complete blockade of the upper extremity; catheter placement is easier and more comfortable than at axillary levels; catheter immobilization and protection against accidental removal are also easier.

Supraclavicular blocks are recommended when the lesion (or a tourniquet) is located on the proximal part of the arm, including the elbow. Peri-subclavian approaches should not be used in infants owing to the proximity of the apical pleura, even with the help of ultrasound imaging. Finally, the safest techniques are the parascalene and the modified interscalene approach (the tip of the block needle is placed virtually at the same place in the interscalene space with both techniques).

Distal nerve blocks are used either as complementary blocks when distribution of anesthesia is incomplete after a more proximal block or for distal lesions (surgery involving one finger only).

Brachial Plexus Blocks below the Clavicle

Axillary Blocks

Axillary block is the most common approach to the brachial plexus in pediatric patients, aiming to contact the cords and terminal nerves of the plexus in the axilla. The child is placed in the supine position[202] with the ipsilateral arm both supinated and abducted by 90 degrees. Depending on the technique used to identify the position of the nerves, muscle twitches (with neurostimulation) are elicited in the forearm and hand or the needle tip is visualized along the axillary artery, close to one of the three main cords (preferably the posterior one) and, often, close to the coracoid process of the scapula.

A most useful variant of this technique is the transcoracobrachialis approach.[202] The block needle is introduced posteriorly at the crossing of the coracobrachialis muscle with the lower border of the pectoralis major muscle (Fig. 81-7). The needle is advanced posteriorly toward the medial border of the humerus through the upper and lateral part of the coracobrachialis muscle (within which runs the musculocutaneous muscle).

With neurostimulation, the musculocutaneous nerve is usually the first nerve encountered (it will be preferably blocked on removal of the needle); the needle is moved deeper until it crosses the perineurovascular sheath[201] and elicits twitches in the muscles of the hand and forearm. At this level the cords have split into terminal nerves and the median nerve is usually contacted first: the local anesthetic is then injected and the needle is removed while a small volume (0.1 mL/kg up to 5 mL) is injected close to the musculocutaneous nerve. There is no need to try to locate each nerve and perform multiple injections.[206]

With ultrasound guidance, a high-frequency probe is placed perpendicular to the major axis of the arm ("short axis"

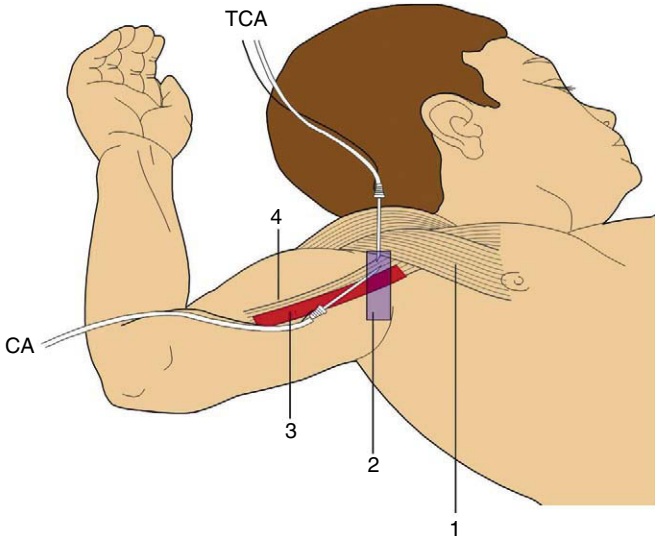

Figure 81-7 Axillary approaches to the brachial plexus. CA, classic approach; TCA, transcoracobrachialis approach; 1, pectoralis major muscle; 2, axillary artery; 3, coracobrachialis muscle.

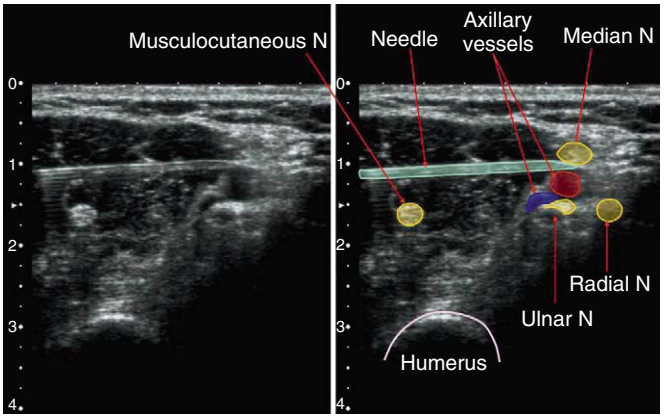

Figure 81-8 Ultrasound-guided axillary block (transcoracobrachialis approach).

[SA]). The needle can be visualized throughout the procedure as it progresses in the plane of the ultrasound beam (SAX-IP, "short axis—in plane") (Fig. 81-8); its tip can be precisely placed close to each of the three main nerves and, on removal of the needle, close to the musculocutaneous nerve. A catheter can be inserted in the axillary neurovascular sheath for continuous infusion, but its immobilization at this level is difficult and, usually, another approach is preferred when continuous infusion is contemplated.

Local anesthetics are selected according to the mandatory duration and intensity of sensory blockade (see earlier). The volume of injectate is critical and depends on the technique used to locate the nerves. With neurostimulation, no information is obtained regarding the circumferential spread around nerve trunks; thus, recommended volumes of injection are based on the probability to obtain complete blockade. These volumes are listed in Table 81-12 for single-shot techniques and in Table 81-13 for continuous infusions. With ultrasound-guided techniques, the circumferential spread of local anesthetics can be clearly seen and once a complete "donut" surrounding the relevant nerve trunk is obtained there is no need to inject additional volumes of local anesthetic.

Axillary blocks are very safe. Accidental arterial puncture is the most undesirable incident/accident, which may occasionally result in transient vascular insufficiency or a compressive hematoma.

Intraneural injection is the most feared complication. It is usually thought to be the main cause of permanent nerve damage and mostly undetected in the patient under general anesthesia. In a prospective study on 26 volunteers (that surprisingly got approval from an ethical committee), Biegeleisen deliberately attempted to penetrate axiallary nerve trunks under echoguidance. A total of 72 deliberate intraneural injections were made and the patients were evaluated after the injection and 6 months later. No motor or sensory deficits were observed. Whether the design of this study is debatable, the results are interesting in showing that intraneural injection might not be as detrimental as commonly believed and might even be innocuous provided no intrafascicular injection (which elicits strong resistance to injection and excruciating pain) is made. However, such intraneural injections should be avoided as often as possible, especially when US imaging is suggestive (tip of the needle within the nerve path and increase in nerve diameter when a fraction of the LA is being injected).

Thoracic Infraclavicular Blocks

Infraclavicular blocks have gained considerable interest in recent years, especially with the development of ultrasound guidance. They consist of approaching the divisions (close to the clavicle) or the cords (close to or below the coracoid process) of the brachial plexus. There are basically two main approaches: (1) midclavicular and (2) paracoracoid; both are performed with the patient in the dorsal recumbent position.[207] A catheter can be rather easily inserted and safely secured, which is not the case in the axilla. The same local anesthetics as for any peripheral conduction block can be used. Usual volumes of local anesthetics are listed in Table 81-12 for single-shot procedures and in Table 81-13 for infusion regimens.

Table 81-12 Recommended Volumes of Local Anesthetic for Single-Shot Upper Limb Blocks with Neurostimulation by Patient Weight*

	Patient Weight			
Conduction Block	**≤10 kg**	**11-30 kg**	**31-60 kg**	**>60 kg**
Brachial plexus above clavicle	1 mL/kg	10 mL + 0.5 mL/kg above 10 kg	20 mL + 0.25 mL/kg above 30 kg	30 mL
Brachial plexus below clavicle	0.5 mL/kg	5 mL + 0.25 mL/kg above 10 kg	10 mL + 0.15 mL/kg above 30 kg	15 mL
Any nerve trunk at elbow	0.2 mL/kg	0.15 mL/kg	0.15 mL	10 mL
Any nerve trunk at wrist	0.05 mL/kg	0.05 mL/kg	0.05 mL/kg	3-5 mL

*Volumes can usually be reduced with ultrasound imaging.

Table 81-13 Usual Local Anesthetic Infusion Rates with or without Bolus Doses of Either Ropivacaine 0.2%, Bupivacaine 0.125%, or Levobupivacaine 0.15% to 0.2% for Continuous Peripheral Nerve Blocks

Techniques	Plexus and Proximal Conduction Nerve Blocks*	Axillary and Popliteal Blocks
Infusion rate	0.2 mL/kg/hr up to 10 mL/hr	0.1 mL/kg/hr up to 5 mL/hr
Bolus doses	0.2 mL/kg up to 5 mL	0.1 mL/kg/hr up to 3 mL/hr
Maximum bolus doses per hour	3	3

*Including supraclavicular and coracoid approaches to the brachial plexus, femoral nerve block, fascia iliaca compartment block, and proximal approaches to the sciatic nerve.
From author's data.

Midclavicular Approaches

Two midclavicular approaches, vertical and anterolateral, have been described. The vertical midclavicular approach is performed by inserting a block needle at right angle to the skin, immediately below the midpoint of the lower border of the clavicle, until twitches are elicited in the upper extremity. Even though use of this technique was reported in pediatric patients without apparent complication,[208,209] the path followed by the needle threatens the apical pleura and lung, thus contraindicating this approach in children.

The anterolateral midclavicular approach can be safely used in children lying supine with the ipsilateral arm alongside the thorax. The landmarks are the coracoid process of the scapula, the lower border of the clavicle, and the deltopectoral groove (Fig. 81-9). The block needle is introduced 1 cm below the midpoint of the lower border of the clavicle at a 30- to 45-degree angle dorsally and a 30-degree angle laterally, aligned with the deltopectoral groove, in direction to the axilla. The objective is to enter the neurovascular sheath 1.0 to 1.5 cm medially to the coracoid process of the scapula until twitches are elicited in the arm, forearm, or hand. A catheter can be inserted along the nerve trunks and securely immobilized. Ultrasound guidance helps in locating the axillary vessels and parietal pleura; the tip of the needle should preferably be placed posteriorly to the artery to obtain good circumferential spread of the local anesthetic.

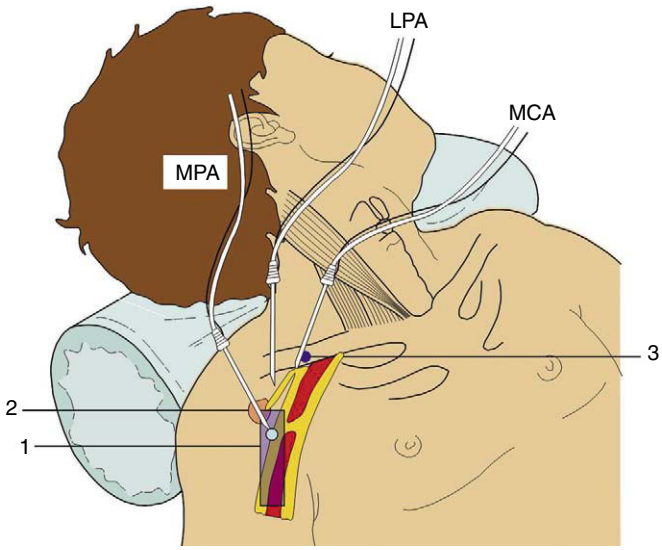

Figure 81-9 Infraclavicular approaches to the brachial plexus. MPA, median paracoracoid approach; LPA, lateral paracoracoid approach; MCA, midclavicular approach; 1, ultrasound probe; 2, coracoid process of the scapula; 3, midpoint of the clavicle.

Paracoracoid Approaches

Paracoracoid approaches are currently the most popular techniques of infraclavicular blockade in children. The medial approach is the reference technique with neurostimulation and the one with the lowest morbidity. The puncture site is located at the caudal extremity of the deltopectoral groove, 1 to 2 cm (according to patient's age) both caudally and medially to the coracoid (see Fig. 81-9). Abducting the upper arm at 90 degrees instead of placing it alongside the thorax brings the plexus closer to skin and favors circumferential spread of local anesthetic.[210] The needle is inserted perpendicularly to the skin until twitches are elicited in muscles of the upper extremity.

The lateral paracoracoid approach elicits considerable interest when ultrasound guidance is available (see Fig. 81-9). The technique can be performed with the arm extended alongside the thorax or abducted by 110 degrees and the elbow flexed by 90 degrees[207] to take away the neurovascular sheath from the parietal pleura and loosen it to favor circumferential spread of the local anesthetic. The puncture site is located 1 to 2 cm below the lower border of the clavicle on the parallel to the sternum drawn from the medial border of the coracoid process.[211] Needle repositioning might be necessary until complete circumferential spread is obtained; then the injection is stopped. Performing this technique under neurostimulation only is technically feasible but unsafe if concomitant ultrasound imaging is not available due to the danger of pleural penetration.

Cervical Brachial Plexus Blocks

Parascalene Approach

The parascalene approach[212] aims to penetrate the interscalene space at a distance from the apical pleura and great vessels of the neck. The child is lying supine with the ipsilateral arm extended alongside the thorax and a roll slipped under the neck to stretch and make more superficial the primary trunks of the brachial plexus. The landmarks are the midpoint of the upper border of the clavicle and the transverse process of C6 located by palpation in the interscalene groove, just posterior to the sternocleidomastoid muscle, at the level of the cricoid cartilage. The puncture site is identified at the junction of the upper two thirds, with the lower third of the line joining the skin projection of the C6 process and the midpoint of the clavicle (Fig. 81-10).

A catheter can be introduced in the interscalene space and safely immobilized at this level; the usual infusion regimens of local anesthetics are presented in Table 81-13.

The success rate for this approach is very high, with a good safety record. Occasionally, blockade of the lower cord (ulnar nerve and/or medial branch of the median nerve) can be incomplete when neurostimulation only is used. The morbidity of this technique is virtually nil.[213]

Posterior Approach

This technique was originally described in (conscious) adult patients in the sitting position. Even though no pediatric publication is available yet, it can be performed in anesthetized children

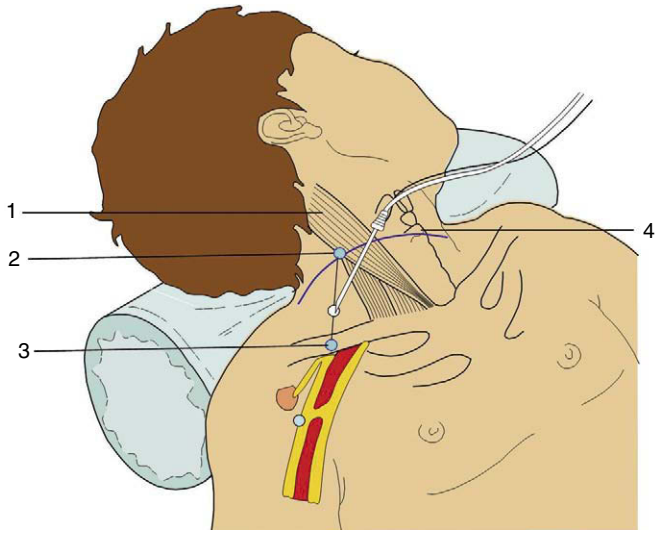

Figure 81-10 Parascalene approach to the brachial plexus. 1, Sternocleidomastoid muscle; 2, skin projection of Chassaignac's tubercle; 3, midpoint of the clavicle; 4, cricoid cartilage.

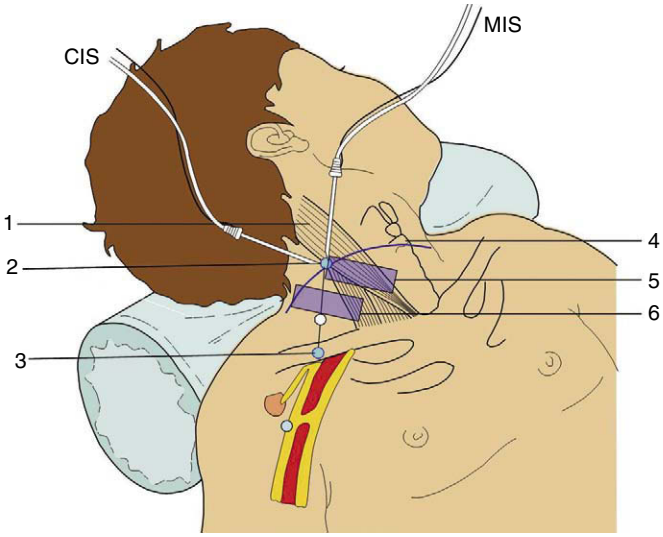

Figure 81-11 Interscalene approach to the brachial plexus. CIS, Classic interscalene approach (after Winnie); MIS, modified interscalene approach (after Borgeat); 1, sternocleidomastoid muscle; 2, skin projection of Chassaignac's tubercle; 3, midpoint of the clavicle; 4, cricoid cartilage; 5, probe positioning (classic approach); 6, probe positioning (Borgeat approach).

placed in the semiprone position with the head in neutral position to keep the anterior aspect of the neck freely accessible to palpation.

Interscalene Approach

This approach aims to enter the interscalene space at its upper extremity, close to the transverse process of C6. The child is placed in the dorsal recumbent position with the arms extended alongside the thorax and head slightly turned to the contralateral side. The landmarks are the cricoid cartilage, the anterior ramus of the C6 transverse process (Chassaignac's tubercle), and the interscalene groove. The puncture site is located at the skin projection of Chassaignac's tubercle in the interscalene groove, just posterior to the lateral border of the sternocleidomastoid muscle. The needle is inserted at an 80-degree angle (not perpendicularly) to the skin, that is, dorsally and slightly caudal in direction to the C6 transverse process until muscle twitches are elicited in the upper limb (Fig. 81-11). This technique is not very popular in children because of its adverse effects: ipsilateral phrenic nerve blockade, danger of vascular damage (vertebral artery and vein), and accidental cervical epidural/intrathecal penetration.

Ultrasound imaging improves the safety of this approach by showing the great vessels of the neck, aponeuroses of scalene muscles, and C5-C7 brachial plexus roots.[214,215] Borgeat and coworkers[216] described a modified technique in adults that can be used in children. The block needle is inserted at the same puncture site, but the needle is oriented laterally, pointing toward the midpoint of the clavicle until one of the primary trunks (instead of roots) of the brachial plexus is located and twitches are elicited in the upper arm. A catheter can be inserted if mandatory. The usual selection of local anesthetics and volumes of injectate is given in Tables 81-12 and 81-13.

Peri-subclavian Artery Approaches

The brachial plexus trunks gather at the lower part of the interscalene space where they surround the subclavian artery. They can be approached by several insertion routes that all begin with penetration of the interscalene space slightly above the first rib. All these techniques are very effective on virtually all branches of the brachial plexus, but they are dangerous in children, especially infants, as the apical pleura overpasses the clavicle in the neck. Ultrasound imaging allows precise identification of the pleura, subclavian vessels, and nerve trunks, thus making the technique less hazardous than with neurostimulation only. However, there are equally effective and safer alternatives to this approach; therefore, it should still be considered to be contraindicated even with ultrasound guidance.

Distal Conduction Blocks

In pediatrics, approaching the radial, median, or ulnar nerve at the elbow or wrist is still not very usual. These approaches are rather difficult with neurostimulation only, and their failure rate is relatively high when blind subcutaneous injections are made: Indications have long been limited to complementation of partially failed brachial blocks. Ultrasound imaging is currently widening the field of indications for these techniques because these superficial nerves are easy to identify and approach with ultrasound guidance, the more so as very small amounts of local anesthetic (1-3 mL usually, even less in infants) are sufficient to produce complete nerve blockade.

Metacarpal/Transthecal Blocks

These two techniques can be contemplated to treat or prevent finger pain whatever its cause without the limitations of digital ring blocks, which are almost never used in children, at least by anesthesiologists.

Transthecal Blocks

Transthecal blocks[217] consist of injecting a local anesthetic within the small space between the synovial sheath of each digital flexor

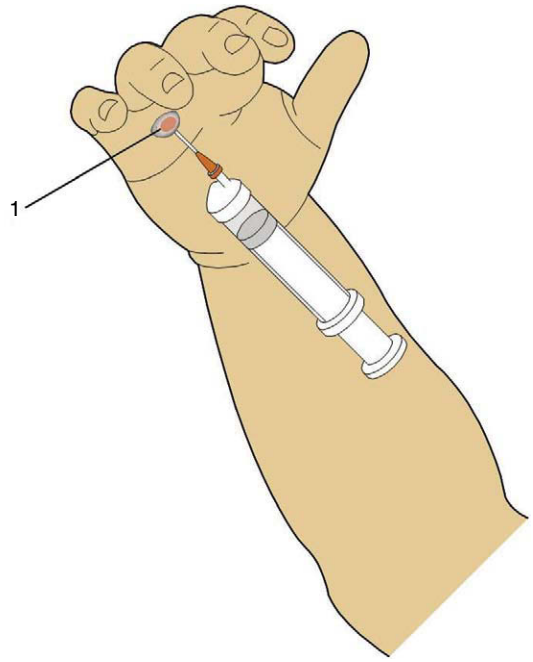

Figure 81-12 Metacarpal (or transthecal) nerve block. 1, Head of the metacarpal bone located by palpation.

tendon and the fibrous sheath that surrounds it and is attached proximally to the head of the metacarpal bone of the three median fingers (this sheath is more extended at the levels of the thumb and forefinger). Even though the procedure is moderately painful, it is reasonably well accepted by conscious children. The landmark is the head of the relevant metacarpal bone located by palpation of the palm while the hand is supinated. Then a 25- to 27-gauge intradermal needle is inserted perpendicularly to the palm, right in the center of the skin projection of this metacarpal head (Fig. 81-12), until bone contact is made. The needle is then slightly withdrawn (to avoid subperiosteal injection) and the local anesthetic (1% or 2% lidocaine without epinephrine) is injected until resistance is felt, which occurs after injection of a volume of

- 0.5 to 1.0 mL: index, middle, and fourth fingers
- 3 to 5 mL: little finger
- 5 to 10 mL: thumb

The last two phalanges and the ventral aspect only of the proximal phalanx are deeply anesthetized.

Metacarpal Blocks

The procedure consists of inserting at right angles to the skin a 25-gauge needle both lateral and then medial to the relevant head of the metacarpal bone, usually with the patient's hand in the prone position.[218] The anesthesiologist places his or her finger at the same level on the palmar aspect to feel tissue deformity produced by the tip of the needle on the palm. The needle is then immobilized, and 1 mL of local anesthetic without epinephrine is injected while the needle is slightly withdrawn. With this procedure, the two ipsilateral digital nerves are blocked. The procedure is then repeated on the other side of the finger. This two-injection procedure provides quick and excellent analgesia. Its morbidity is virtually nil, but, unfortunately, it is as painful as the classic four-injection technique for digital nerve blocks.

Lower Extremity Conduction Blocks

Lumbar Plexus Nerve Blocks

Anatomic Considerations

The lumbar plexus is formed by the union of L1 to L5 spinal nerves. It lies within the substance of the psoas muscle, in a fascial plane termed the *psoas compartment*, where it can be approached via a posterior route through the quadratus lumborum. It contributes four nerves to the lower extremity: the femoral, lateral cutaneous, obturator, and genitofemoral nerves. At their emergence from the psoas muscle, these nerves run a variable part of their course just below the fascia iliaca, which is the common fascia covering psoas and iliacus muscles. A sufficient volume of local anesthetic injected at the inner surface of this fascia will spread along it and reach these nerves, thus producing a fascia iliaca compartment block.

The main anatomic difference between children and adults pertains to the smaller size of nerve trunks and extensive spread of local anesthetic along fascial planes and perineural sheaths. Even though these nerves, especially the femoral nerve, are large, they are not very echoic (the younger the patient, the less echoic they are) (see Fig. 81-3), whereas aponeuroses (and blood vessels) are. Consequently, excellent knowledge of anatomy, especially relationships between muscle fascias and nerves, is required to avoid misidentification.

Indications, Contraindications, and Complications

Indications

Femoral nerve and fascia iliaca compartment blocks are commonly practiced both in emergency conditions (femoral shaft fractures) and for elective surgery of the thigh.[219,220] Conscious and slightly sedated children tolerate muscle biopsy quite well when the procedure is performed under femoral and lateral cutaneous nerve block.[221] Catheter placement allows long-lasting pain relief after surgery of the femur[222,223]; because bacterial contamination (but not infection) is reported in 57% of cases at 48 hours, such catheters should not be kept in place any longer, and aseptic techniques of catheter insertion and dressing are of critical importance.

Contraindications

There are no specific contraindications to femoral nerve blocks.

Complications

Psoas compartment blocks may result in direct trauma of retroperitoneal (right kidney mainly) and intraperitoneal content due to wrong needle insertion (too cephalic for the kidney, too medial for abdominal vessels). Also, accidental spread to neuraxial spaces, especially subarachnoid, may result in severe complications, including fatalities, if adequate monitoring and management of the patient are not achieved.

Nerve impalement is possible as in any nerve block procedure[224] and can result (rarely in fact) in permanent damage. Falls at home are mainly a problem in adults[225,226] but also can occur and be detrimental to children; strong recommendations to keep children in bed should be made.

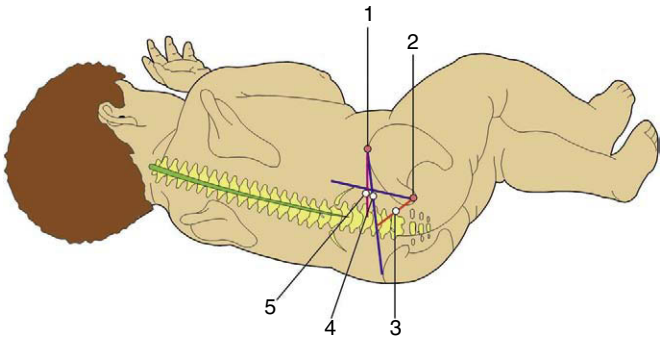

Figure 81-13 Direct lumbar plexus block. 1, Anterior superior iliac spine; 2, posterior superior iliac spine; 3, Chayen's puncture site (slightly modified); 4, Winnie's puncture site (slightly modified); 5, Shuepfer's puncture site.

Direct Lumbar Plexus Block (Psoas Compartment Block)

Psoas compartment block is performed with the child in the lateral decubitus position lying on the nonblocked side. The landmarks are the iliac crests, the ipsilateral posterior superior iliac spine, and the L5 spinous process. Three puncture sites can be used (Fig. 81-13)[227]:

- The midpoint of the line joining the posterior iliac spine to the L5 spinous process (modified Chayen's approach)[228]
- A point located on the intercristal line (Tuffier's line), 1 to 2 cm medial to its crossing by a perpendicular line[229] drawn from the posterior iliac spine (modified Winnie's approach)
- The point located at the union of the lateral third with medial two thirds of the line extending from the L4 spinous process to the ipsilateral anterior superior iliac spine

Whatever the puncture site used, the block needle is inserted perpendicularly to the skin until twitches are elicited in the ipsilateral quadriceps muscle. Medial orientation as well as excessive penetration of the needle must be avoided to prevent trauma of abdominal and retroperitoneal content (especially right kidney).

Femoral Nerve and Fascia Iliaca Compartment Blocks

Femoral Nerve Block

Femoral nerve blocks are performed while the child lies supine, preferably with the ipsilateral limb slightly abducted. The landmarks are the inguinal ligament and the femoral artery. The puncture site is located 0.5 to 1.0 cm both below the inguinal ligament (not the inguinal crease) and lateral to the femoral artery (Fig. 81-14). The block needle is inserted posteriorly, either perpendicular to the anterior aspect of the thigh or, especially when a catheter has to be inserted, at a 45-degree angle cephalad, pointing to the umbilicus, until twitches are elicited in the quadriceps muscle when neurostimulation is used (Fig. 81-15).

Ultrasound imaging makes the technique even easier.[230] The probe is placed slightly above and parallel to the inguinal ligament.

Usual doses of local anesthetic are displayed in Table 81-14. A catheter can be inserted and its position should preferably be controlled either by nerve stimulation (stimulating catheter) or

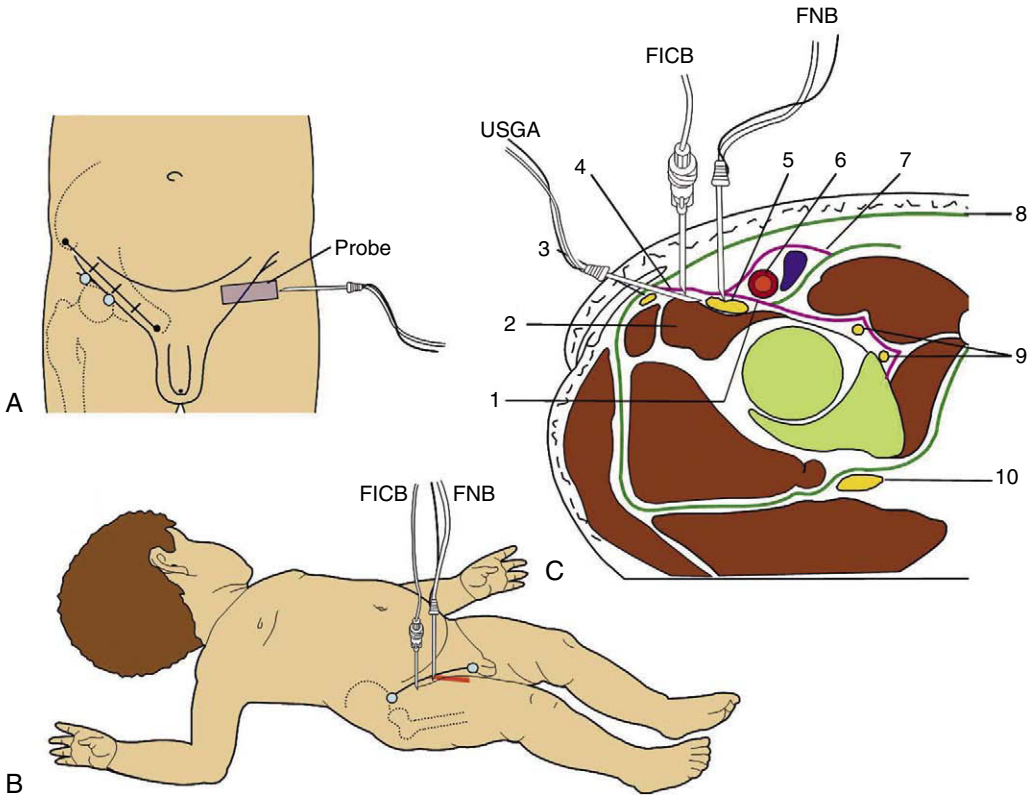

Figure 81-14 Femoral nerve and fascia iliaca compartment blocks. **A,** Landmarks and probe positioning. **B,** Patient's position. **C,** Transverse section of the thigh. Figure 81-15 Femoral nerve block: ultrasound-guided tomography of the inguinal region (probe parallel to the inguinal ligament).

by ultrasonography. Usual regimens of repeat injections/continuous infusions are displayed in Table 81-13.

Fascia Iliaca Compartment Block

The technique consists of injecting a local anesthetic below the fascia iliaca.[231] The injectate will spread at the inner surface of the fascia and, depending on its volume, bathe the nerves emerging from the lumbar plexus that supply the lower extremity. The technique is performed with the child lying supine (see Fig. 81-14).

Placement of the catheter is improved by ultrasound guidance.

With this technique, the femoral and lateral cutaneous nerves are almost constantly blocked; the local anesthetic usually reaches the upper division branch of the obturator nerve, which is the branch giving a twig to the hip joint. The anesthetized area also includes areas supplied by upper branches of the lumbar plexus in more than 70% of procedures, such as the genitofemoral nerve. Usual doses of local anesthetic are displayed in Table 81-14. Local anesthetics with epinephrine produce significantly lower plasma concentrations and should be preferred whenever possible. Addition of clonidine (1-2 µg/kg) significantly prolongs the duration of analgesia.[50] Placement of a catheter is easy and allows long-lasting pain relief (see Table 81-13).

Other Lumbar Plexus Nerve Blocks

Saphenous Nerve Block

Saphenous nerve blocks are used to complement sciatic blocks with small amounts of local anesthetic. Because the saphenous nerve is a purely sensory nerve, it is not identifiable by neurostimulation. Many block procedures have been published, all resulting in high failure rate (30% or higher). Ultrasound imaging, currently underevaluated in this indication, is a promising technique.

The classic approach is performed at knee level with the patient supine. The anterior edge of the medial head of the gastrocnemius muscle and the tibial tuberosity are identified by palpation. A line is drawn at a 45-degree angle with the intercondylar line, from the tibial tuberosity to the anterior edge of the gastrocnemius muscle. The technique consists of subcutaneously injecting local anesthetic along this line. This very simple technique is virtually free of complications, but its failure rate is rather high.

The saphenous/vastus medialis nerve block takes advantage of the proximity of the vastus medialis and saphenous nerves within the adductor canal in the upper part of the thigh. Being a mixed nerve, the vastus medialis nerve can easily be located by neurostimulation and injecting a local anesthetic results in concomitant blockade of the two nerves. The landmarks are the femoral artery, the inguinal ligament, and the upper border of the sartorius muscle (Fig. 81-16). A short, short-beveled insulated needle is inserted perpendicularly to the skin, 0.5 cm lateral to the femoral artery just above the upper border of the sartorius until twitches are elicited in the vastus medialis muscle. Injecting 0.1 to 0.2 mL/kg of a local anesthetic is sufficient to block the two nerves and obtain complete analgesia of the medial aspect of the leg and foot.

The transsartorial approach aims to infiltrate the fat pad located between the inner aspect of the sartorius muscle and great adductor tendon. The puncture site is situated at the level of the upper border of the patella, on the medial aspect of the sartorius muscle located by palpation. The block needle is inserted medially and slightly posteriorly with a 45-degree angle caudally, in the direction of the medial femoral condyle until a loss of resistance

Table 81-14 Recommended Volumes of Local Anesthetic for Single-Shot Lower Limb Blocks with Neurostimulation*

Conduction Block	≤10 kg	11-30 kg	31-60 kg	>60 kg
Lumbar plexus (psoas compartment)	1 mL/kg	10 mL + 0.5 mL/kg above 10 kg	20 mL	20 mL
Femoral	0.5 mL/kg	5 mL + 0.35 mL/kg above 10 kg	12 mL + 0.3 mL/kg above 30 kg	25 mL
Fascia iliaca	1 mL/kg	10 mL + 0.5 mL/kg above 10 kg	20 mL + 0.25 mL/kg above 30 kg	30 mL
Proximal sciatic	1 mL/kg	10 mL + 0.5 mL/kg above 10 kg	20 mL + 0.3 mL/kg above 30 kg	30 mL
Sciatic in popliteal fossa	0.3 mL/kg	3 mL + 0.2 mL/kg above 10 kg	6 mL + 0.15 mL/kg	12.5 mL

*Volumes can usually be reduced with ultrasound imaging.

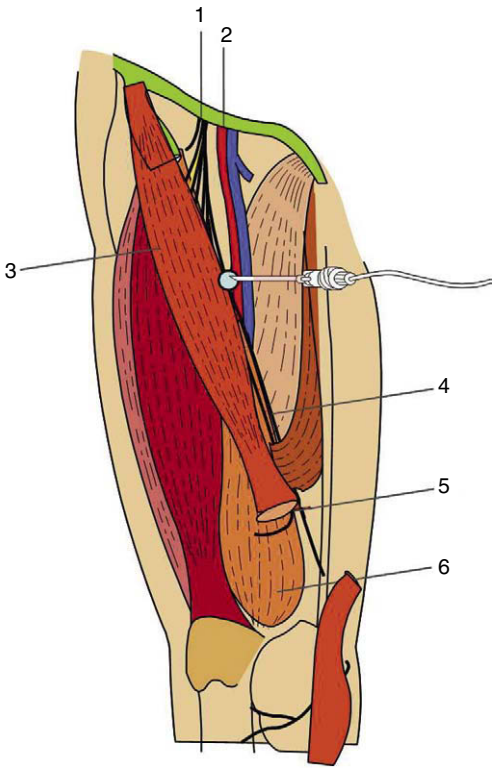

Figure 81-16 Saphenous/vastus medialis nerve block. 1, Femoral nerve; 2, femoral artery; 3, sartorius muscle; 4, saphenous nerve; 5, motor nerve supplying the sartorius muscle; 6, vastus medialis muscle.

is felt as the subsartorial fat pad (through which runs the saphenous nerve) is penetrated. The paravenous approach, originally described as a "blind" infiltration technique on both sides of the saphenous vein in the upper part of the medial aspect of the leg, is considerably improved by ultrasound imaging because the saphenous vein is very easy to locate. Inserting the needle along the major axis of the probe (SAX-IP) allows clear visualization of needle progression toward the vein and circumferential spread of the local anesthetic.

Lateral Cutaneous Nerve Block

A specific lateral cutaneous nerve block is rarely used in children; its main indication is as a technique complementary to a femoral block. Ultrasound guidance can be used.

Obturator Nerve Block

This procedure is performed with the child supine and the thigh slightly abducted and externally rotated (if possible). The landmarks are the groove between the tendon of the long adductor muscle and medial border of the pectineus muscle. The puncture site lies in this groove at the level of the greater trochanter of the femur.

With neurostimulation, the needle is inserted following a strict anterior posterior path until twitches are elicited in the long and short adductors muscles (stimulation of the anterior division branch of the obturator nerve). The needle is further advanced dorsally over 1 to 2 cm until twitches are elicited in the great adductor (posterior branch). Half of the local anesthetic solution (of a total of 0.1 mL/kg up to a maximum of 5 mL per nerve) is injected; the needle is then removed until stimulation of the anterior branch is obtained again and the second half the anesthetic is injected.

The same technique can be performed with ultrasound imaging. The probe is placed below the pubic tubercle, with its major axis parallel to the inguinal ligament. The aponeuroses of the sartorius and long and short adductors are easily identified. The anterior branch can be easily found between the long and short adductors while the posterior branch lies between the short and great adductors (Fig. 81-17).

Sciatic Nerve Blocks

Anatomic Considerations

The sacral plexus supplies the posterior aspect of the limb; it lies on the anterior aspect of the piriformis muscle, behind the posterior wall of the pelvic cavity, and cannot be directly approached by a block needle. It contributes two nerves to the lower extremity, the posterior femoral cutaneous nerve and the sciatic nerve. The sciatic nerve is the largest mixed nerve of the body. It is formed by two distinct nerves, the common peroneal nerve and the tibial nerve, enclosed in the same perineural sheath.

Indications and Contraindications

Sciatic nerve blocks are recommended for operations on the foot and the leg (a complementary saphenous nerve block is often required because this nerve provides cutaneous innervation of the medial aspect of the leg). Depending on the surgery, the sciatic nerve will be approached in the popliteal fossa or more proximally. Sciatic blocks have no specific contraindications. As with other extremity nerve blocks, patients at risk for compartment syndrome require close monitoring and use of diluted solution to avoid motor blockade (see earlier).

Proximal Sciatic Nerve Blocks

Numerous techniques have been described, for which the associated morbidity can differ significantly. When successful, they provide the same distribution of anesthesia. When contemplating a proximal sciatic block, the anesthesiologist must consider the following points: (1) morbidity of the technique; (2) positioning

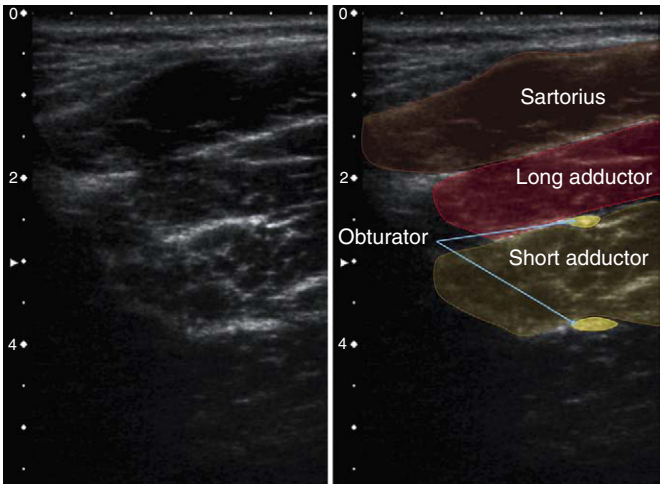

Figure 81-17 Obturator nerve block: ultrasound imaging of the anterior and medial aspect of the thigh.

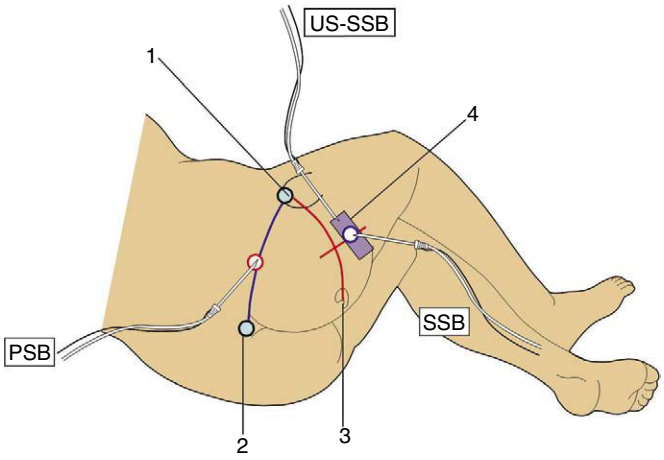

Figure 81-18 Proximal sciatic nerve block: posterior and subgluteal approaches. PSB, Posterior sciatic block; SSB, subgluteal sciatic block; US-SSB, ultrasound-guided sciatic subgluteal block; 1, greater trochanter of the femur; 2, coccyx; 3, ischiatic tuberosity; 4, probe.

of the patient; (3) technique used to locate the nerve; (4) necessity for catheter placement; and (5) experience of the anesthesiologist with this particular technique. Usual doses of local anesthetic are listed in Table 81-14, and usual regimens of repeat injections/continuous infusions after catheter placement are listed in Table 81-13.

Posterior Approach

This is the most classic approach. The child is placed in the semiprone position, resting on the nonoperated side. The site of puncture is located at mid-distance from the greater trochanter of the femur and the caudal extremity of the coccyx (Fig. 81-18). The block needle is inserted perpendicularly to the skin, that is, both medially and ventrally, pointing to the ischial tuberosity, until twitches are elicited in the leg or the foot or both. Ultrasound guidance is not easy at this level because of the distance from the skin at which the sciatic nerve runs.

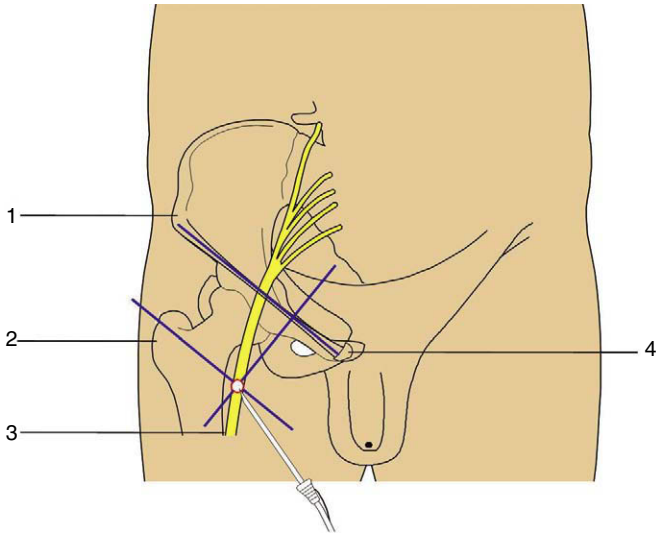

Figure 81-19 Proximal sciatic nerve block: anterior approach. 1, Anterior superior iliac spine; 2, greater trochanter of the femur; 3, sciatic nerve; 4, pubic tubercle.

Anterior Approach via the Femoral Triangle

This approach was developed to allow sciatic blockade in a patient who must remain in the dorsal position.[232] The landmarks are the inguinal ligament and the greater trochanter of the femur. The location of the site of puncture is rather complicated, requiring that two lines be drawn. The site of puncture is located at the crossing of the two lines (Fig. 81-19). This technique is the most difficult and hazardous approach to the sciatic nerve; it threatens the division branches of the femoral nerve, femoral vein, and femoral arteries. It should be the last option when a proximal sciatic block is contemplated.

Subgluteal Approach

The child is placed in the semiprone position with the operated side uppermost, the lower thigh and leg flexed by 90 degrees, and the upper thigh and leg extended. The landmarks are the ischiatic tuberosity and the greater trochanter of femur. At midpoint of the line joining the two landmarks, a perpendicular line is drawn and the puncture site is located on this line 2 to 4 cm caudally (see Fig. 81-18). The needle is inserted at right angles to the skin towards the femur until twitches are elicited in the foot. Echo guidance can be used instead of (or in conjunction with) neurostimulation.[233]

Lateral Approach

A lateral approach to the sciatic nerve has been described for use in patients lying supine[234] with the relevant leg slightly rotated medially. The needle is inserted horizontally toward the lower border of the femur (Fig. 81-20). If bone contact is made, the needle is withdrawn and reinserted slightly more posteriorly until twitches are elicited in the leg and the foot. The distance at which the sciatic nerve is found can be correlated with patient age (Fig. 81-21).[234]

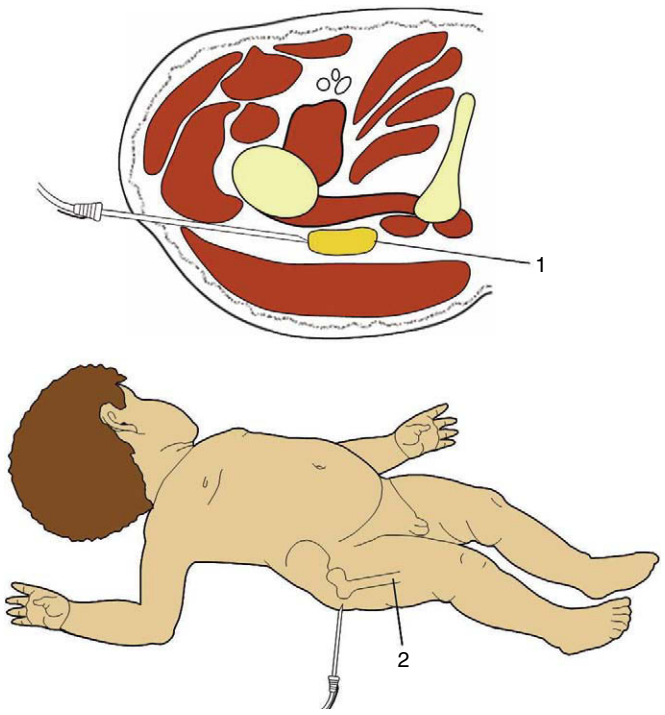

Figure 81-20 Proximal sciatic nerve block: lateral approach. 1, Sciatic nerve; 2, femur.

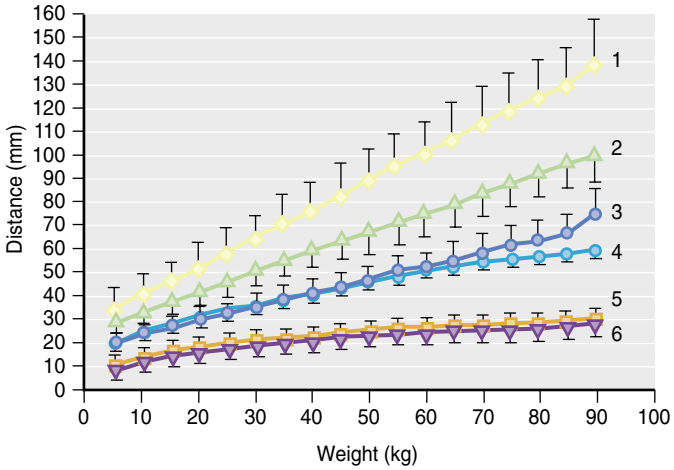

Figure 81-21 Distance from skin to plexus/nerve following the most commonly used techniques of peripheral nerve blocks. 1, Proximal anterior and lateral approach to sciatic nerve; 2, lumbar approach to lumbar plexus; 3, proximal posterior approach to sciatic nerve; 4, thoracic paravertebral; 5, axillary, femoral nerve, and fascia iliaca compartment blocks; 6, parascalene approach to brachial plexus.

Popliteal Sciatic Nerve Block

This approach is the easiest approach to the sciatic nerve. The child is placed in the prone or, preferably, the semiprone position (Sims position), resting on the nonoperated side (Fig. 81-22).[235]

Ultrasound guidance is easy at this level. Usual doses of local anesthetic are listed in Table 81-14, and usual regimens of repeat injections/continuous infusions after catheter placement are listed in Table 81-13.

Metatarsal and Transthecal Blocks

The metatarsal (or midtarsal) block is an easy technique for providing good pain relief for surgical procedures on the toes. The child is placed supine, and the head of the relevant metatarsal is palpated on the sole. The technique consists of inserting a standard intramuscular needle dorsally on the dorsum of the foot in close contact with the medial border of the base of the metatarsal until the tip of the needle is felt and seen as it pushes the skin of the sole. A volume of 1 to 3 mL of 0.25% to 0.5% plain bupivacaine or 0.2% to 0.5% ropivacaine is then injected while the needle is slowly withdrawn. The same procedure is repeated along the lateral border of the same metatarsal to provide full anesthesia of the relevant toe.

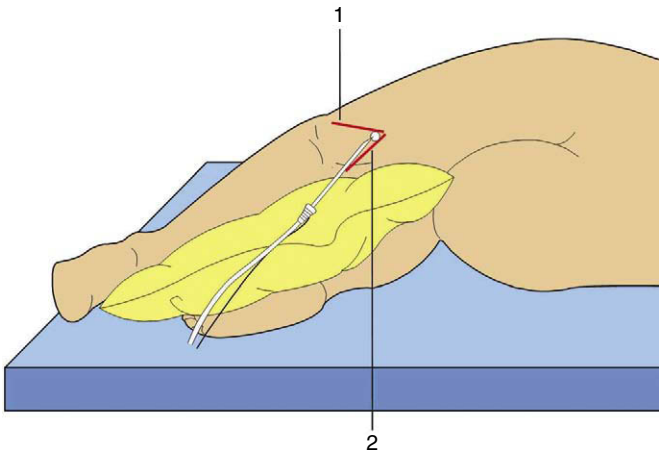

Figure 81-22 Popliteal sciatic nerve block. 1, Tendon of the biceps femoris. 2, Tendons of the semimembranosus and semitendinosus muscles.

The transthecal technique as described for finger procedures can be transposed to the sole of the foot by palpating the head of the relevant metatarsal bone and injecting a small volume of local anesthetic in the fibrous sheath surrounding the tendinous sheath of flexor tendons. However, except for the greater toe, the landmarks are more difficult to identify and, due to the thickness of the sole, the infiltration is technically more difficult and less precise.

Blocks of Nerves Supplying the Trunk

Intercostal Nerve Block

Intercostal nerves run along the lower border of each rib, within the intercostal space, a triangular space, with (1) a medial border formed by the posterior intercostal and innermost intercostal muscles, endothoracic fascia, and parietal pleura; (2) a lateral border formed by the internal and external intercostal muscles and intercostal membrane (thickening of the inner fascia of external intercostal muscles); and (3) a base formed by the lower rib. Intercostal nerve block is obtained by injecting a local anesthetic within the intercostal space and, provided several adjacent intercostal spaces are infiltrated, adequate intraoperative and postoperative pain relief is obtained for thoracotomy,[236] liver transplantation, pleural drainage, and management of rib fractures.

This block must be avoided in the presence of impaired blood or gas exchange, and it requires that all patients be kept under intensive medical observation because of the danger of clinically delayed pneumothorax: it is not suitable for outpatient surgery.

The safest approach to the intercostal space is along the midaxillary line with the child lying semiprone using a short 22- or 20-gauge Tuohy needle (intradermal needles are not appropriate) (Fig. 81-23).

A catheter can be introduced in the intercostal space located at the center of the area to be anesthetized to allow reinjections; the catheter can also be inserted intraoperatively under direct vision by the surgeon.[237,238] However, the safety of continuous techniques is questionable due to high systemic uptake of local anesthetic.[239] Spread of large-volume anesthetic solution can reach distant intercostal spaces (even contralateral ones), probably via the paravertebral space, thus providing adequate duration of pain relief with a single injection in a number of patients. Spread to the epidural space can also occur. Thus, the patient should be admitted to the intensive care unit for careful monitoring of respiratory function and for delayed pneumothorax.

Thoracic Paravertebral Space Block

This technique aims to penetrate the thoracic paravertebral space to provide unilateral thoracic anesthesia involving several der-

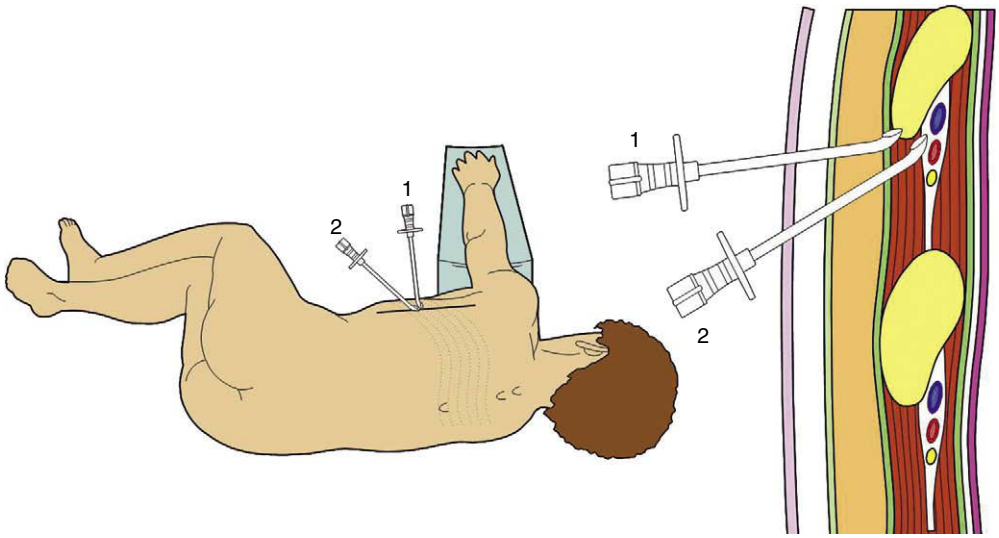

Figure 81-23 Intercostal nerve block. 1, Insertion of the needle at an 80-degree angle to the skin; 2, caudal and dorsal redirection of the needle.

matomes. The technique is the same as for adult patients (see Chapter 52) (Fig. 81-24).

Rectus Sheath/Paraumbilical Block

The technique consists of injecting a local anesthetic within the substance of the rectus abdominis muscle along the course of the terminal branch of the 10th intercostal nerve that supplies sensory innervation to the periumbilical area (Fig. 81-25).[240] It is indicated for any surgery involving the umbilical region (umbilical hernia repair especially) and can be modified to block other thoracoabdominal intercostal nerves for repair of hernias of the linea alba.

Ultrasound imaging is very demonstrative.[241] Both aponeuroses of the rectus muscle and the parietal peritoneum are very echoic. The probe is placed horizontally over the umbilicus, and the block needle is inserted medially in long-axis orientation. The superficial fascia is bent and then crossed by the tip of the needle that should be forwarded until it contacts the deep fascia (in order to favor the longitudinal spread of the anesthetic): the anesthetic is then injected and can be visualized in the form of an expanding biconvex black shadow (Fig. 81-26).

Some authors recommend injecting half the dose at the upper border and half at the lower border of the umbilical ring and to inject a small amount (1 mL) subcutaneously while the needle is withdrawn.[240] The technique is then repeated on the other side. The success rate is high and morbidity extremely low unless attempts are made to inject the drug between peritoneum and deep rectus fascia.

Block of the Ilioinguinal, Iliohypogastric, and External Spermatic Nerves

The inguinal area is supplied by three nerves: the ilioinguinal, iliohypogastric, and genitofemoral. In 50% of patients, sensory innervation of the inguinal canal depends exclusively on the genital branch of the genitofemoral nerve (also termed the external spermatic nerve in males). In recent years, several publications focusing only on the ilioinguinal and iliohypogastric nerves have appeared in the literature, especially with the development of

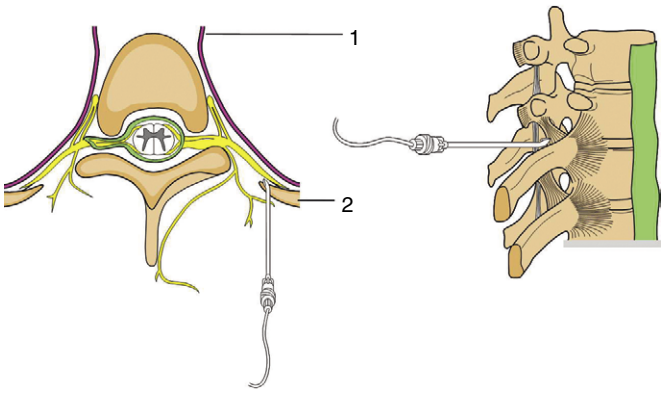

Figure 81-24 Block of the thoracic paravertebral space. 1, Parietal pleura; 2, rib.

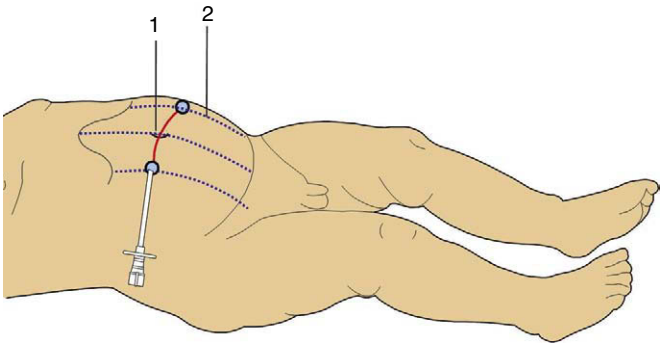

Figure 81-25 Umbilical/rectus sheath block. 1, Umbilicus; 2, lateral border of the left rectus muscle.

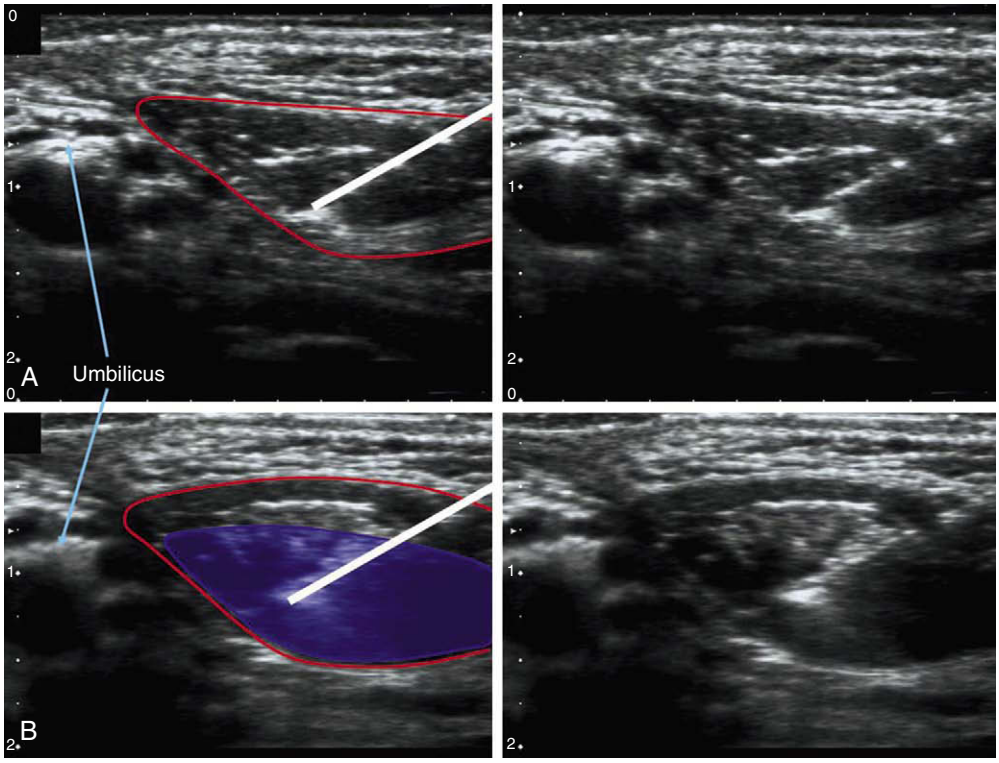

Figure 81-26 Ultrasound-guided insertion of umbilical/rectus sheath. **A,** Insertion of the needle close to the posterior fascia of the rectus muscle. **B,** Injection of the local anesthetic creating a biconvex black cloud. *Red line,* fascia of the rectus sheath muscle; *blue area,* spread of the anesthetic; *diagonal white line,* shadow of the needle.

ultrasound imaging.[242,243] Not surprisingly, the quality of analgesia produced is often unsatisfactory because a major contributor to sensory innervation remains unchanged.

A single injection technique can safely and reliably block the three relevant nerves at once because these nerves are located in the same fascial plane close to the subcutaneous inguinal ring formed by the aponeurosis of the external oblique muscle. The landmarks are the umbilicus, ipsilateral anterior superior iliac spine (ASIS), and midpoint of the inguinal ligament. The ASIS-umbilicus line is divided into four equal parts; the puncture site is located at the union of the lateral fourth with the medial three fourths (Fig. 81-27). The success rate of this technique is very high and its morbidity very low. Several complications have been reported with techniques attempting to locate the ilioinguinal nerve close to the ASIS. At this level, parietal abdominal muscles are slenderized and fibrous. Perceiving distinct losses of resistance, even with ultrasound imaging, is difficult and can be misinterpreted; a consequence may be abdominal penetration and damage to intestinal loops.[244-246] Also, the transverse fascia is continuous with the iliacus fascia; thus, spread of the anesthetic agent at the inner surface of the fascia iliaca can occur and produce a femoral block.[247-249] These adverse effects/complications are not seen with the technique described in this section.

Pudendal Nerve Block

The pudendal nerve provides sensory and motor innervation to the pelvic cavity and its content including external genital organs. Complete blockade of this nerve provides complete analgesia for all operations in this area (surgery of penis, genitourinary surgery below the bladder, anorectal surgery) and can be easily obtained by injecting a local anesthetic in the ischioanal (ischiorectal fossa) space. The patients are placed either in the dorsal decubitus position with the knees flexed and their soles conjoined as for bladder

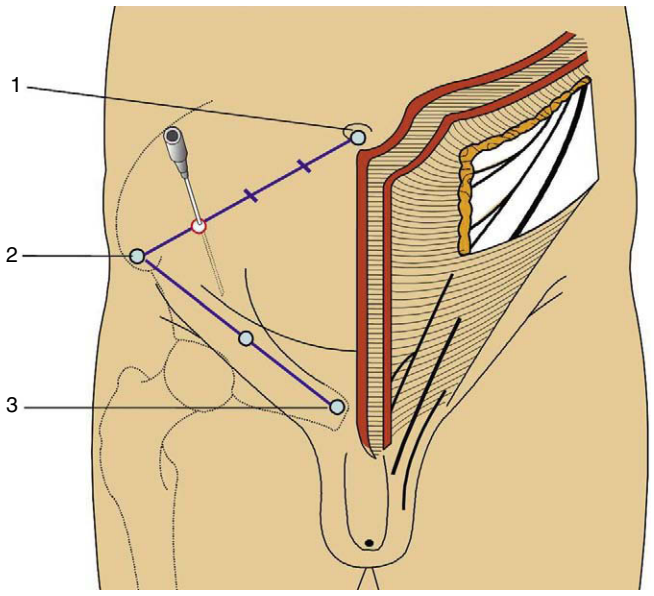

Figure 81-27 Iliohypogastric and ilioinguinal nerve blocks. 1, Umbilicus; 2, anterior iliac crest; 3, pubic spine.

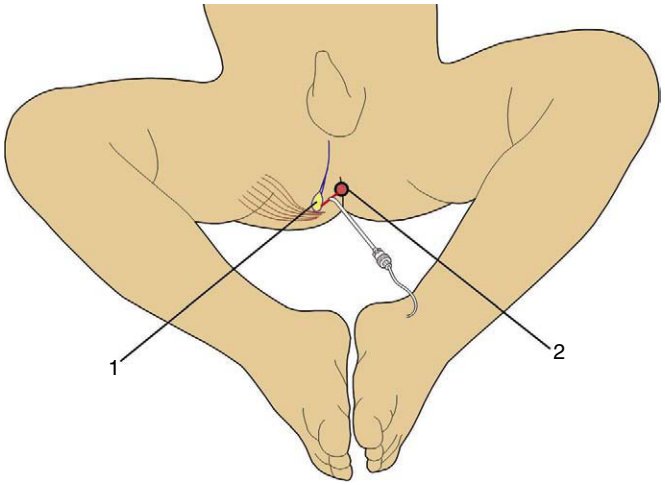

Figure 81-28 Perineal/pudendal nerve block. 1, Ischial tuberosity; 2, anus.

catheterization in girls (infants and young children) or in the lithotomy position (adolescents). The landmarks are the two ischial tuberosities and anus (Fig. 81-28). The distribution of anesthesia depends on the volume of injectate. With 0.1 mL/kg (up to 5 mL), anesthesia is usually limited to the perineal nerve that supplies the posterior part of the scrotum (this is enough to complement an ilioinguinal/iliohypogastric/genitofemoral nerve block when a scrotal incision is required). With 0.3 to 0.4 mL/kg on each side (up to 15 mL), all division branches of the pudendal nerve are blocked, thus providing complete analgesia of the perineum, including blockade of the dorsal nerve of the penis.

Because the pudendal nerve is a mixed nerve, a nerve stimulator can be used to locate it more precisely if this is deemed useful.[250] Ultrasound guidance has been used in adults, but identification of the pudendal nerve was possible in only one half of the procedures. Because this nerve is accompanied by a terminal artery (pudendal artery), only plain solution of local anesthetics must be injected.

Penile Block

Nerve supply to the penis depends mainly on the dorsal nerve of the penis, which is a terminal branch of the pudendal nerve. There is also a contribution of (1) the ilioinguinal nerve and genital branch of the genitofemoral nerve supplying the proximal part of the penis and (2) the perineal nerve, another terminal branch of the pudendal nerve, supplying the midline of the dorsal aspect and sometimes involving the frenulum (Fig. 81-29).

Crossing of Scarpa's fascia can also be verified by ultrasound imaging.[251]

This block procedure is easy and its learning curve is particularly short.[252] The morbidity is extremely low (almost nil when a local anesthetic without epinephrine only is used), whereas complications have been reported after attempts to block the nerves by infiltration of a local anesthetic below Buck's fascia at the dorsal part of the penis.[253,254]

A subcutaneous ring of local anesthetic at the base of the penis can provide satisfactory analgesia but requires relatively large amounts of drug (2 mg/kg bupivacaine) and fails to provide adequate analgesia in 20% of patients.[255] Topical anesthesia has been recommended for urethral meatotomy and even neonatal circumcision,[256] but the quality of analgesia is less than that obtained from "true" penile blocks.[255,257,258]

Other Blocks of Nerves of the Trunk

Interpleural (or intrapleural) blocks that consist of injecting a local anesthetic within the pleural cavity without creating a pneumothorax elicited some enthusiasm 15 years ago but they did not find an established place in pediatric anesthesia and fell into disuse. Other blocks of nerves of the trunk, including paravertebral ganglion, genitofemoral, paracervical (uterosacral), and transsacral nerve blocks are not used in pediatric patients.

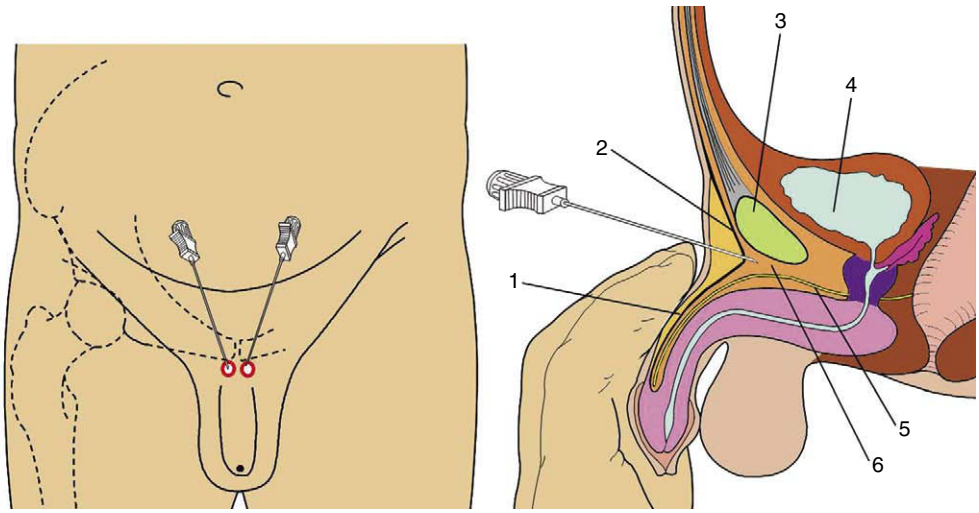

Figure 81-29 Penile block via the subpubic space. 1, Buck's fascia; 2, Scarpa's fascia; 3, pubic bone; 4, bladder; 5, dorsal nerve of penis; 6, subpubic space.

Block of Nerves Supplying the Head and Neck

Cervical Plexus Blocks

Cervical plexus blocks have few but specific indications in pediatric surgery: cervical lymph node biopsy, excision of thyroid nodules,[259,260] and surgery of vocal cords.[261] Only the superficial branches are blocked by a subcutaneous infiltration along the lateral border of the sternocleidomastoid muscle.

Laryngeal Nerve Block

Laryngeal nerve blocks can be used for short-duration laryngoscopic examinations in conscious patients or to facilitate awake intubation when difficult intubation is suspected. It also can be used to prevent or treat laryngospasm.[262] Several techniques have been described but the easiest consists of subcutaneous injection of a local anesthetic just lateral to the dorsal ending of the hyoid horns (on each side) (Fig. 81-30). An intradermal needle is inserted close to the hyoid horn ending until contact is made with cartilage. The needle is then slightly withdrawn and 0.1 to 0.2 mL/kg (up to a maximum of 8 mL) of 1% lidocaine is injected subcutaneously. Excellent laryngeal block is usually obtained.

Cervicothoracic (Stellate) Ganglion Block

Stellate ganglion block is a rather dangerous procedure with very few but very specific indications in children: (1) ventricular tachyarrhythmia due to congenital long QT syndrome[263,264] (a left stellate block is recommended) and (2) severe ipsilateral circulatory disorders of the upper extremity. Patients with certain acute pain syndromes such as herpes zoster ophthalmicus[265] or rare chronic pain syndromes such as sympathetically maintained pain syndrome[266,267] may benefit from the technique.

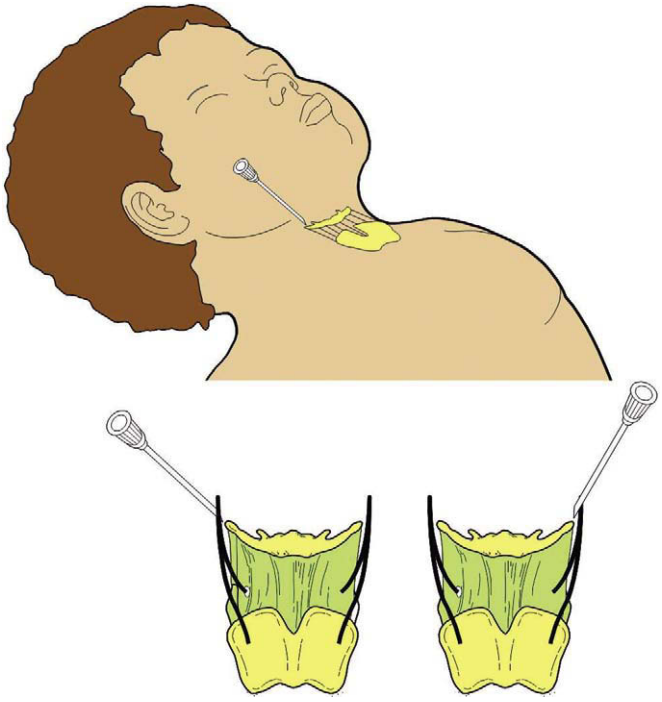

Figure 81-30 Laryngeal nerve block.

Blocks of Nerves Supplying Facial Sensory Innervation

Facial sensory supply is mainly provided by the fifth cranial (trigeminal) nerve. In pediatric patients, only three terminal branches of this nerve are commonly blocked by anesthesiologists, for either emergency (skin lacerations) or elective surgery procedures (cleft lip/palate repair, excision of skin lesions). Ultrasound guidance has not been reported yet, but the technique may be helpful in some patients. These block procedures have a low failure rate and are very safe, provided that no attempt is made to penetrate the foramen from which the relevant nerve emerges (danger of nerve trauma). Two complications can be observed very rarely: hematoma at the site of puncture and intravascular injection (but the volume of injectate is very small, so systemic toxicity is very unlikely).

Block of the Supraorbital and Supratrochlear Nerves

The supraorbital and supratrochlear nerves are terminal branches of the frontal nerve (V_1) that supply the upper eyelid, forehead, and scalp. Indications for blocking these nerves include frontal craniotomy, skin lesion removal of the eyebrow and medial part of the forehead, and placement of frontal ventroperitoneal shunts or an Ommaya reservoir.[268,269] The procedure consists of a subcutaneous infiltration below the eyebrow. The landmarks are the eyebrow and supraorbital foramen, which is located by palpation of the upper orbital rim, at its intersection with the vertical line passing over the ipsilateral centered pupil. The site of puncture is located at midpoint of the orbital rim (Fig. 81-31). An intradermal needle (25, 27, or 30 gauge) is inserted medially toward the supraorbital foramen where 1.0 to 1.5 mL of local anesthetic (1% lidocaine or 0.25% bupivacaine, with or without epinephrine) is injected. The needle is then removed, and strong pressure is exerted on the skin covering the supraorbital foramen to favor the spread of the drug and prevent the development of hematoma.

Block of the Infraorbital Nerve

The infraorbital nerve is a terminal branch of the maxillary nerve (V_2). It emerges from the infraorbital foramen and divides into four terminal subcutaneous branches (internal and external nasal nerves, inferior palpebral nerve, and superior labial nerve) that supply the nose, lower eyelid, and upper lip.

Infraorbital nerve blocks are indicated for surgery of cleft lip,[270,271] laceration of upper lip,[272] endoscopic surgery of sinus, surgery of nasal septum, and transsphenoidal hypophysectomy. The procedure is contraindicated in case of facial trauma with facture and displacement of the orbital floor, which prevents localization of the infraorbital foramen and increases the hazards of (additional) nerve damage.

The percutaneous technique consists of inserting an intradermal needle at the crossing of the vertical line passing over the ipsilateral centered pupil with the perpendicular line passing just

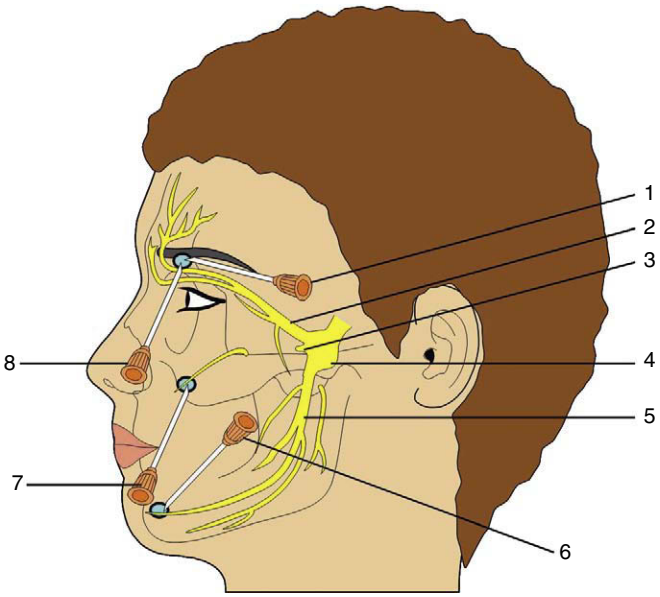

Figure 81-31 Block of nerve supplying the face: supraorbital, infraorbital, and mental nerve blocks. 1, Block of the supratrochlear nerve; 2, ophthalmic nerve; 3, maxillary nerve; 4, trigeminal ganglion (also gasserian ganglion or semilunar ganglion); 5, mandibular nerve; 6, block of the mental nerve; 7, block of the infraorbital nerve; 8, block of the supraorbital nerve.

below the nostrils.[270] The needle is directed cephalad toward the lower border of the infraorbital foramen (avoiding penetration into the foramen) until bone contact is made (see Fig. 81-31). The anesthetic is then injected following usual safety rules. The skin covering the infraorbital foramen is then gently massaged to promote homogeneous diffusion of the drug.

Both approaches provide excellent analgesia of the lower eyelid, jaw, palate, and ipsilateral nostril. They should be performed on both sides to provide excellent intraoperative and postoperative analgesia for cleft lip repair.

Block of the Mental Nerve

The mental nerve is the terminal branch of the mandibular nerve (V_3) that supplies the lower lip and chin. Main indications for mental nerve blocks are with surgery involving lower incisor and canine teeth; bilateral blocks allow pain-free procedures on the lower lip. The landmark is the mental foramen located by palpation on the line passing over the ipsilateral centered pupil. Again, two approaches can be used.

In the intrabuccal approach, after turning the lower lip outward, the lower incisor and first premolar are located. The intradermal needle is inserted into the gingival sulcus toward the mental foramen over which the anesthesiologist maintains his or her index finger. When the tip of the needle is close to the foramen, 1 to 2 mL of the anesthetic is slowly injected after a negative aspiration test. The skin covering the mental foramen is then gently massaged to favor homogeneous diffusion of the drug.

In the percutaneous approach the intradermal needle is inserted slightly below the skin projection of the mental foramen and directed toward its lower border (see Fig. 81-31). The drug is then injected as just described, and the infiltrated area is gently massaged.

Other Blocks

Several other conduction blocks of nerves supplying the head are commonly used in adults but only occasionally in children for extended laceration of the scalp (scalp blocks), ophthalmic surgery, operations involving the facial bones, or dental procedures. These blocks are not performed by anesthesiologists and are not described here.

Other Procedures

Intravenous Regional Anesthesia

Intravenous regional anesthesia (Bier block) has never been very popular in pediatric anesthesia. Currently, the technique is outdated, even though it is still used in some institutions mainly for fracture repairs (often in emergency departments).[273-275] The technique is the same as in adults. The limb is exsanguinated either by an Esmarch bandage or by simple gravitation. A tourniquet is placed around the proximal part of the arm and inflated at two to three times the systolic pressure before the Esmarch bandage is removed and 1 mL/kg of 0.5% lidocaine (not exceeding 3 mg/kg) is injected. Prilocaine can be used instead in adolescents. Children tolerate the pain produced by the inflated tourniquet very poorly, and this technique was responsible for several deaths in the past.

Local Infiltrations and Topical Anesthesia

Surface Anesthesia

Topical anesthesia has gained an established place for 15 years owing to the availability of new ointments containing mixtures of local anesthetics, such as EMLA cream, TAC cream, or lidocaine-epinephrine-tetracaine gel. When applied on the skin and maintained in place with a sterile dressing for 1 hour at least, these creams can provide complete analgesia of the skin and subcutaneous structures. The duration of application may vary among the different cream formulations. They allow pain-free performance of venous cannulation and most techniques requiring needle puncture, such as lumbar taps and repair of skin lacerations are made possible.[276-278] Recently, new devices and techniques have been developed to shorten the time necessary to obtain effective analgesia: iontophoresis,[279,280] heat-activated systems, high-pressure needle-free delivery systems,[281,282] and two techniques still under development, skin electroporation by application of high-frequency currents and sonophoresis by use of ultrasound waves.

Surface anesthesia of the larynx by local anesthetic sprays has long been contraindicated in children, but the efficacy and safety of the technique are now established,[28] provided that low doses of 5% lidocaine are administered (i.e., 8 mg in infants <10 kg and 16 mg in infants >10 kg). Topical anesthesia can be produced by instilling eye lotions containing a local anesthetic (oxybuprocaine) or using auricular lotion/ointment or viscous solutions on buccal mucosa and gums. Care must be taken to avoid administering excessive dosage and to prevent inadvertent swallowing of concentrated solutions of local anesthetics, especially in infants.

Intradermal Wheals

Intradermal wheals are routinely used in adult patients to anesthetize the skin covering deeper structures to be approached. The technique is used less often in children, except for anesthetizing the puncture site of a regional block procedure in nonanesthetized children. It consists of inserting a 25-, 27- or 30-gauge interdermal needle almost tangentially to the skin, with the bevel facing downward, without penetrating the subcutaneous layers. A small amount (<0.5 mL) of local anesthetic (0.5% to 1% lidocaine or prilocaine, with or without epinephrine) is then injected. The skin covering the wheal looks like an orange peel and almost immediate anesthesia of the relevant area is obtained. The only drawback of this technique is that the injection is moderately painful.

Local Infiltrations and Field Blocks

Infiltrations of local anesthetics (lidocaine, prilocaine, bupivacaine, or levobupivacaine with or without epinephrine or plain ropivacaine) in a fan-shaped manner in the subcutaneous fat and muscles surrounding the operative site (or the edges of a wound) provide adequate analgesia for surgery of soft tissues and wound stitching. Precautions must be taken to avoid bacterial contamination and overdosage, especially in case of extensive wounds or reinjections. In the latter instance, an important consideration is that plasma concentration of lidocaine after subcutaneous administration is linearly related to the dose per kilogram of body weight.[283]

Other Injections

Tracheal instillation of local anesthetics is regularly used in adults for awake tracheal intubation and prevention of laryngospasm but is not commonly practiced in children because of dangers of systemic toxicity and potential damage to the vocal cords.

The increasing use of laparoscopic surgery has generated new types of abdominal pain. Intraperitoneal injection of local anesthetics led to contradictory results in adult studies. The technique has not been evaluated in children, both in terms of safety and efficacy, and caution is recommended in considering its potential use.

Intra-articular injection of local anesthetics provides consistent analgesia of joint capsules. The technique can be used for diagnostic or therapeutic procedures (injection of painful joints), but it is almost never performed by anesthesiologists and its efficacy is inconstant.

Conclusion

The importance of regional anesthesia has considerably increased during the past 3 decades. Block procedures represent a major therapeutic option for preventing and treating pain both intraoperatively and postoperatively, especially for outpatient surgery (single-shot procedures) and for long-lasting postoperative pain relief (with catheter techniques). Over the years, there was a shift from neuraxial toward peripheral nerve blockade to reduce the incidence of adverse effects and allow early discharge from the hospital. Peripheral catheter techniques are becoming routine practice, and selected patients can be managed at home. The expansion of regional anesthesia was favored by the development of devices specifically designed for pediatric use and techniques, allowing precise localization of nerve trunks and not requiring the cooperation of the patient. Nerve stimulation is currently the gold standard for locating nerves and plexuses, but ultrasound guidance is an emerging technique that is currently challenging the primary role of neurostimulation. The growing number of publications based on regional anesthesia procedures, in children as well as in adults, is good testimony of the efficacy and safety of regional techniques if they are adequately performed. Provided that they are taught in detail to residents in anesthesia, these techniques will probably continue their expansion as the reference techniques for management of procedural, trauma, and surgical pain.

82 Pediatric Anesthesia

Key Points

1. During the first few weeks of life, neonates are vulnerable to the so-called flip-flop circulation, that is, going from an adult-type to a fetal-type circulation. Factors such as hypoxia, hypercapnia, acidosis, infection, hypothermia, and prematurity increase the potential for sudden increases in pulmonary artery pressure and subsequent shunting of blood past the lungs through a patent foramen ovale or the ductus arteriosus, which may reopen, particularly during the first 10 days of life.
2. The reduced cellular mass of the neonatal heart devoted to contractility results in less compliant ventricles. This leads to sensitivity to volume loading, poor tolerance of afterload (i.e., the development of biventricular failure), and rate-dependent cardiac output. In addition, the reduced cardiac calcium stores produces increased susceptibility to myocardial depression by potent anesthetic agents. This also makes neonates dependent on exogenous calcium (blood ionized calcium) values and vulnerable to the negative inotropic effects of ionized hypocalcemia, particularly that caused by infusion of citrated blood products such as fresh frozen plasma.
3. The neonatal airway differs from the adult airway in five ways: the tongue is larger, the larynx is located higher in the neck, the glottis is shaped differently and angled over the laryngeal inlet, the vocal cords are angled, and the narrowest portion is the subglottic region at the level of the cricoid cartilage. Accordingly, straight blades are more useful than curved blades in neonates, and uncuffed endotracheal tubes are commonly used.
4. Glomerular filtration and tubular function are immature but develop rapidly in the newborn period; adult levels are achieved at approximately the age of 2 years. The frequency with which medications excreted by the kidneys (e.g., antibiotics) can be administered during the first month of life changes rapidly. Particular attention is required in this period to avoid drug-induced toxicity (e.g., ototoxicity) caused by excessive plasma drug levels.
5. Hepatic metabolic capacity is immature at birth. Some cytochrome P450 enzymes (phase I reactions) are fully developed, whereas others are approximately 50% of adult values. Phase II reactions, that is, reactions that make a drug more water soluble, are usually impaired in neonates. Some of these reactions do not achieve maturity until the age 1 year. This hepatic immaturity can have important clinical implications regarding a neonate's ability to excrete some medications, such as benzodiazepines.
6. Cardiac dysfunction from anesthetic overdose is a particular danger for neonates and infants because of a combination of factors, including immaturity of the myocardium, decreased calcium stores of the neonatal myocardium, and the "systems issue" of the vaporizers for halothane and sevoflurane having different maximum minimum alveolar concentration (MAC) delivery capability; that is, nearly 6 MAC multiples of halothane may be delivered to a newborn, whereas only 2½ MAC multiples can be delivered with sevoflurane. Thus, anesthetic agent–induced cardiac arrest is a function of vaporizer design and vulnerability of the neonatal myocardium to anesthetic-induced cardiac depression, especially on changing from spontaneous to controlled respirations.
7. Remifentanil is a unique potent opioid in neonates. Unlike virtually every other medication used in newborns, its half-life is shorter rather than longer as in older children. This, then, makes the ability to rapidly induce or stop an intense opioid effect even easier to achieve in neonates than in older children. Careful attention to opioid-induced bradycardia and chest wall rigidity is obviously very important.
8. Former preterm infants younger than 60 weeks' postconceptual age are potentially at risk for postoperative apnea, and those who are anemic are at particular risk (i.e., hemoglobin <10 gm/dL). Both gestational age and postconceptual age at the time of surgery are independent risk factors. The use of regional anesthesia in these children may reduce but does not

eliminate the incidence of postanesthesia apnea. Postoperative apnea has been associated with all of the inhaled agents, including desflurane and sevoflurane.

9. Preoperative laboratory testing is minimal for most pediatric patients. The only groups of children who require routine hemoglobin measurement are infants younger than 6 months to assess the severity of the physiologic hemoglobin nadir (especially former preterm infants with a potential risk for apnea) and older children expected to experience significant blood loss. Preoperative chest radiographs are not generally indicated. Children who have undergone chemotherapy with anthracyclines, children with congenital heart disease, and neonates at risk for associated cardiac anomalies may require a preoperative echocardiogram. Children undergoing chemotherapy should usually have a complete recent hematology profile, including platelet counts. Children taking antiseizure medications will generally benefit from preoperative assessment to ensure therapeutic levels.
10. Temperature regulation is a particular issue for neonates and infants. Because of the large body surface–to–weight ratio, they are especially vulnerable to intraoperative hypothermia. Efforts to maintain a warm operating room, use of warming devices such as hot air mattresses, warm surgical skin preparation solutions, and transport in an appropriate transport device, as well as keeping the patient covered during transport, all help prevent dangerous hypothermia.

Provision of safe anesthesia for pediatric patients depends on a clear understanding of the physiologic, pharmacologic, and psychological differences between children and adults. Special consideration must be given to preterm infants, as well as to those with congenital malformations. This chapter describes how the unique characteristics of children influence the safe conduct of anesthetic procedures.

Developmental Considerations

Organogenesis takes place within 8 weeks of conception; organ function develops during the second trimester; and the infant gains weight, primarily muscle and fat, during the third trimester. Any physiologic or pharmacologic injury or stress during the first trimester may cause abnormal organogenesis; during the second trimester, abnormal functional development of organs; and during the third trimester, smaller organs or reduced muscle and fat mass. Injuries and stress take the form of congenital viral infections, exposure to drugs (therapeutic or recreational), nutritional insufficiency (caloric or vascular), or other maternal illness. A genetic predisposition to developmental malformations can also produce adverse effects. Such interruptions in normal growth and development may cause a variety of physiologic abnormalities ranging from simple preterm birth to a constellation of congenital malformations.

A preterm infant is one born before 37 weeks gestation; a postmature infant is one born after 42 weeks gestation. Any infant born at less than 2500 g is considered a low-birth-weight infant. Plotting weight against gestational age allows classification into three general categories: small for gestational age, appropriate for gestational age, or large for gestational age (Fig. 82-1). Infants who are small or large for gestational age often have developmental problems or difficulties associated with maternal disease (Table 82-1). Careful physical and neurologic examination at birth allows a fairly accurate estimate of gestational age. The anesthesiologist should be aware of this type of evaluation so that potential problems can be anticipated. Obtaining a perinatal history of problems during pregnancy (e.g., maternal drug abuse, maternal infection, eclampsia, diabetes) or during and after delivery (e.g., fetal distress, meconium aspiration, prematurity, postdelivery intubation) is also valuable for assessing possible anesthetic implications that may require specific considerations during and after anesthetic management. In the weeks after birth, measures of weight, height, and head circumference are plotted on standard developmental curves; deviations from normal (i.e., crossing developmental lines) usually indicate a severe physiologic insult. The anesthesiologist should examine the growth chart to evaluate how the child is developing.

The Cardiovascular System

The cardiovascular system undergoes dramatic physiologic and maturational changes during the first year of life. In utero, most

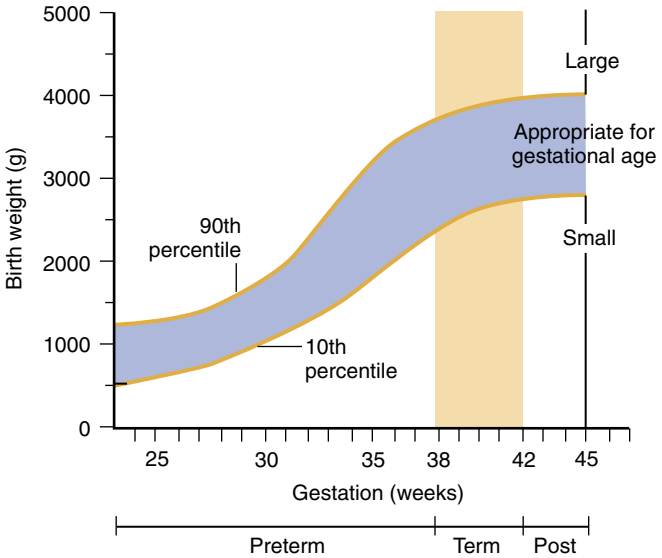

Figure 82-1 Plotting birth weight against gestational age for neonates determines whether infants are small, appropriate, or large for gestational age. Babies who are either small or large for gestational age are particularly likely to have a variety of problems such as metabolic, developmental, infectious, or structural abnormalities, as well as drug addiction and withdrawal. *(Modified from Battaglia FC: Intrauterine growth retardation. Am J Obstet Gynecol 106:1103-1114, 1970, with permission.)*

Table 82-1 Common Neonatal Problems Associated with Weight and Gestational Age

Gestational Age	Body Size	Neonatal Problems Occurring with Increased Frequency
Preterm	Small	Respiratory distress syndrome Apnea Hypoglycemia Hypomagnesemia Hypocalcemia Fetal alcohol syndrome Viral infection Thrombocytopenia Congenital anomalies Maternal drug addiction Neonatal asphyxia Aspiration pneumonia
Term	Small	Congenital anomalies Viral infection Thrombocytopenia Maternal drug addiction Neonatal asphyxia Hypoglycemia Fetal alcohol syndrome
Postmature	Small	Congenital anomalies Viral infection Thrombocytopenia Maternal drug addiction Neonatal asphyxia Aspiration pneumonia Hypoglycemia Fetal alcohol syndrome
Any gestational age	Large	Birth trauma Hyperbilirubinemia Hypoglycemia: infant of diabetic mother Transposition of great arteries

From Coté CJ, Lerman J, Todres ID (eds): A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, Saunders, 2008.

of the cardiac output is directed from the placenta across the foramen ovale into the ascending aorta (oxygenated blood), whereas superior vena cava blood (deoxygenated) is directed to both the pulmonary artery and the ductus arteriosus. This pattern of circulation results in minimal intrauterine pulmonary blood flow. At birth, a number of events change hemodynamic interactions such that the fetal circulation becomes an adult-type circulation. Specifically, the placenta is removed from the circulation; portal blood pressure falls, which causes the ductus venosus to close; and blood becomes oxygenated through the lungs. Exposure of the ductus arteriosus to oxygenated blood induces ductal closure. As a result of the combined effects of lung expansion, exposure of blood to oxygen, and loss of low resistance through placental blood flow, pulmonary vascular resistance decreases while peripheral vascular resistance rises rapidly. The fall in pulmonary vascular resistance occurs on the first day of life and continues to decrease gradually during the next several years as the architecture of the pulmonary vessels changes. An increase in pressure on the left side of the heart (caused by the rise in peripheral vascular resistance) induces mechanical closure of the foramen ovale. Thus, all three connections between the right and left side of the circulation close. Although closure of the ductus arteriosus probably occurs primarily in response to a rise in arterial oxygen concentration, successful completion requires arterial muscular tissue. The fact that such tissue is less prevalent in preterm infants may account, in part, for the high incidence of patent ductus arteriosus in preterm infants. True mechanical closure by fibrosis does not occur until 2 to 3 weeks of age.

During this critical period, the infant readily reverts from the adult circulation to a fetal type of circulation; this state is called transitional circulation. Many factors (hypoxia, hypercapnia, anesthesia-induced changes in peripheral or pulmonary vascular tone) can affect this precarious balance and result in a sudden return to the fetal circulation. When such a "flip-flop" occurs, pulmonary artery pressure increases to systemic levels, blood is shunted past the lungs via the patent foramen ovale, and the ductus arteriosus may reopen and allow blood to shunt at the ductal level. A rapid downhill spiral may occur and lead to severe hypoxemia, which explains why hypoxemic events in infants are often prolonged despite adequate pulmonary ventilation with 100% oxygen.

Risk factors increasing the likelihood of prolonged transitional circulation include prematurity, infection, acidosis, pulmonary disease resulting in hypercapnia or hypoxemia (aspiration of meconium), acidosis, hypothermia, and congenital heart disease. Care must be directed to keeping the infant warm, maintaining normal arterial oxygen and carbon dioxide tension, and minimizing anesthetic-induced myocardial depression.

The myocardial structure of the heart, particularly the volume of cellular mass devoted to contractility, is significantly less developed in neonates than in adults. These differences, as well as developmental changes in contractile proteins, produce a leftward displacement of the cardiac function curve and less compliant ventricles. This developmental immaturity of myocardial structures accounts for the tendency toward biventricular failure, sensitivity to volume loading, poor tolerance of increased afterload, and heart rate–dependent cardiac output.[1,2] Another issue is that cardiac calcium stores are reduced because of immaturity of the sarcoplasmic reticulum; consequently, neonates have a greater dependence on exogenous (ionized) calcium and probably increased susceptibility to myocardial depression by potent inhaled agents that have calcium channel blocking activity.

The Pulmonary System

The pulmonary system is not capable of sustaining life until both the pulmonary airways and the vascular system have matured sufficiently to allow exchange of oxygen from "air" to the bloodstream across the pulmonary alveolar/vascular bed. Independent life is not generally possible until a gestational age of 24 to 26 weeks. Alveoli increase in number and size until the child is approximately 8 years old. Further growth is manifested as an increase in size of the alveoli and airways. At term, complete development of surface-active proteins helps maintain patency of the airways. If a child is born prematurely and these proteins are insufficient, respiratory failure (respiratory distress syndrome) may follow.

Several anatomic differences make respiration less efficient in infants. The small diameter of the airways increases resistance to airflow; resistance is inversely proportional to the radius raised

to the fourth power for laminar flow and to the fifth power for turbulent flow. The airway of infants is highly compliant and poorly supported by surrounding structures. The chest wall is also highly compliant, so the ribs provide little support for the lungs; that is, negative intrathoracic pressure is poorly maintained. Thus, each breath is accompanied by functional airway closure. Dead space ventilation is proportionally similar to that in adults; however, oxygen consumption is two to three times higher. In preterm infants, the work of breathing is approximately three times that in adults, and this work can be increased significantly by cold stress (increased metabolic demand for oxygen) or any degree of airway obstruction. Another important factor is the composition of the diaphragmatic and intercostal muscles. These muscles do not achieve the adult configuration of type I muscle fibers until the child is approximately 2 years old (Fig. 82-2).[3] Because type I muscle fibers provide the ability to perform repeated exercise, any factor that increases the work of breathing contributes to early fatigue of the respiratory muscles of infants. These differences partially explain the infant's high respiratory rate, the rapidity with which hemoglobin desaturation occurs, and their propensity for fatigue and apnea.

Differences in airway anatomy make the potential for technical airway difficulties greater in infants than in teenagers or adults. The airway of infants differs in five ways[4]: (1) the relatively large size of the infant's tongue in relation to the oropharynx increases the likelihood of airway obstruction and technical difficulties during laryngoscopy; (2) the larynx is located higher (more cephalic) in the neck, thus making straight blades more useful than curved blades; (3) the epiglottis is shaped differently, being short, stubby, omega shaped, and angled over the laryngeal inlet; control with the laryngoscope blade is therefore more difficult; (4) the vocal cords are angled, so a "blindly" passed endotracheal tube may easily lodge in the anterior commissure rather than slide into the trachea; and (5) the infant larynx is funnel shaped, the narrowest portion occurring at the cricoid cartilage (Fig. 82-3). Classic teaching has been that the adult larynx is cylindrical and the infant larynx is funnel shaped. However, recent autopsy data have demonstrated that the narrowest portion in approximately 70% of adults is also in the subglottic region at the level of the cricoid cartilage, but the opening is so large that commonly used endotracheal tubes are nearly always easy to advance past the glottic opening.[5] In infants or young children, an endotracheal tube that easily passes the vocal cords may be tight in the subglottic region because of the relatively greater proportional narrowing at the level of the cricoid cartilage. It is for this reason that uncuffed endotracheal tubes have generally been preferred for children younger than 6 years. However, the development of better endotracheal tube design and several prospective studies have combined to allow more common use of cuffed endotracheal tubes, even in infants.[6] It is vital to be certain that there is a leak around the cuff (with or without inflation) because injury to the tracheal mucosa is still possible. The recently introduced Microcuff tube may further improve the safety of cuffed endotracheal tubes; the new material is very soft, the shape of the cuff is more uniform (allowing a more uniform distribution of lateral sealing pressure), and the cuff itself is located more distally and thus perhaps beyond the cricoid cartilage (Fig. 82-4).[7] Unfortunately, at this time their cost is prohibitive (three to four times more expensive than current standard endotracheal tubes) for routine use. It is likely that for the present, the more expensive endotracheal tubes will be reserved for children with anticipated prolonged intubation and the lower-cost endotracheal tubes used for short-term intraoperative intubation.

Infants have often been described as obligate nasal breathers; however, approximately 8% of preterm neonates (31 to 32 weeks postconceptual age [PCA]) and 40% of term infants can

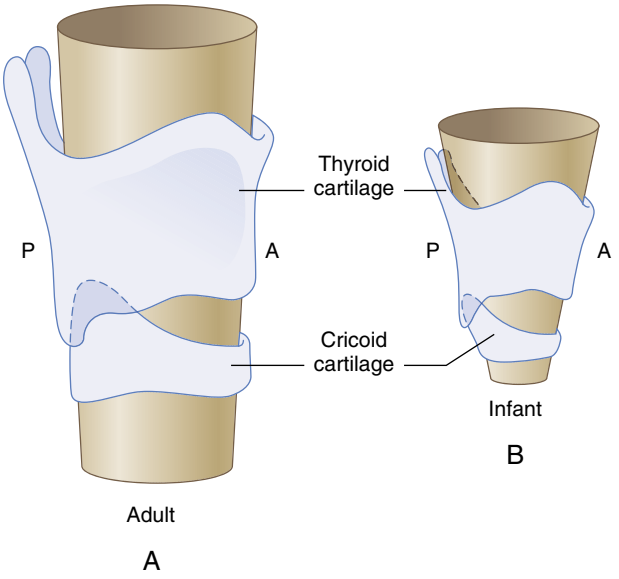

Figure 82-3 The narrowest part of the adult larynx and the pediatric larynx is at the level of the cricoid cartilage. Traditionally, the adult larynx was thought to be cylindrically shaped, but autopsy data suggest that the narrowing in adults (**A**) is not as pronounced as it is in infants (**B**). The narrowest part of the infant larynx occurs at the level of the cricoid cartilage; the normal adult configuration of the larynx is not achieved until the teenage years. This anatomic difference is one of the reasons why uncuffed endotracheal tubes have been traditionally preferred for children younger than 6 years. A, anterior; P, posterior. *(From Coté CJ, Lerman J, Todres ID [eds]: A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, WB Saunders, 2008.)*

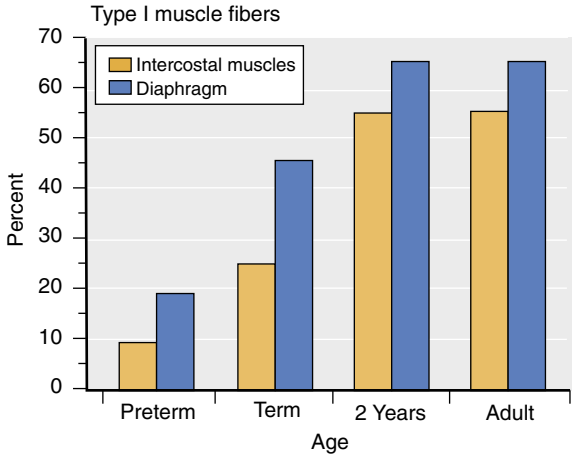

Figure 82-2 The composition of the diaphragm and intercostal muscles changes markedly during the first 2 years of life. The number of type I muscle fibers is inversely related to age and may account in part for the ease of inducing respiratory fatigue as the work of breathing increases. *(Data from Keens TG, Bryan AC, Levison H, Ianuzzo CD: Developmental pattern of muscle fiber types in human ventilatory muscles. J Appl Physiol 44:909-913, 1978.)*

Figure 82-4 The Microcuff endotracheal tube ((Microcuff; PET; I-MPEDC, Microcuff GmbH, Weinheim, Germany, Kimberly-Clark USA) (*right*) has a soft polyurethane cuff that inflates symmetrically and is located more distally than standard endotracheal tubes (*left*). This configuration results in more even pressure applied to the mucosa of the trachea and perhaps less potential for edema formation in the subglottic region because the cuff is located below the cricoid cartilage.

but not yet induced (stimulated) by the agents that they metabolize. As the infant grows, the ability to metabolize medications increases rapidly for two reasons: (1) hepatic blood flow increases and more drug is delivered to the liver, and (2) the enzyme systems develop and are induced.[8] The cytochrome P450 system is responsible for phase I drug metabolism of lipophilic compounds. This system reaches approximately 50% of adult values at birth, thus suggesting an overall reduced capacity for drug metabolism (e.g., caffeine). However, this generalization does not hold true for all lipophilic medications, and the ability of neonates to metabolize some drugs is dependent on specific individual drug cytochromes. CYP3A is generally present at adult values at birth,[9] whereas other cytochromes are absent or reduced.[10] Phase II reactions involve conjugation, which makes the drug more water soluble to facilitate renal excretion.[11] These reactions are often impaired in neonates and result in jaundice (decreased bilirubin breakdown) and long drug half-lives (e.g., morphine and benzodiazepines). Some of these reactions do not achieve adult activity until after 1 year of age.

A preterm infant's liver has minimal glycogen stores and is unable to handle large protein loads. This difference accounts for the neonate's tendency toward hypoglycemia and acidemia and for the failure to gain weight when the diet contains too much protein. Additionally, plasma levels of albumin and other proteins necessary for binding of drugs are lower in full-term newborns (and are even lower in preterm infants) than in older infants (Fig. 82-6). This condition has clinical implications regarding neonatal coagulopathy (e.g., the need for vitamin K at birth), as well as for drug binding and pharmacodynamics, in that the lower the albumin value, the less protein binding of some drugs with resultant greater levels of unbound drug (unbound drug is the portion available to cross biologic membranes). In addition, binding of

convert to oral breathing if the nasal airway is obstructed. Almost all infants can easily convert to oral breathing by 5 months of age. Most infants can convert to oral breathing if the obstruction lasts longer than 15 seconds.

The Kidneys

Renal function is markedly diminished in neonates and further diminished in preterm infants because of low perfusion pressure and immature glomerular and tubular function (Fig. 82-5). Nearly complete maturation of glomerular filtration and tubular function occurs by approximately 20 weeks after birth, although it is somewhat delayed in preterm infants. Complete maturation of renal function takes place by about 2 years of age. Thus, the ability to handle free water and solute loads may be impaired in neonates, and the half-life of medications excreted by means of glomerular filtration will be prolonged (e.g., antibiotics, hence the longer intervals between doses in neonates).

The Liver

At term, the functional maturity of the liver is somewhat incomplete. Most enzyme systems for drug metabolism are developed

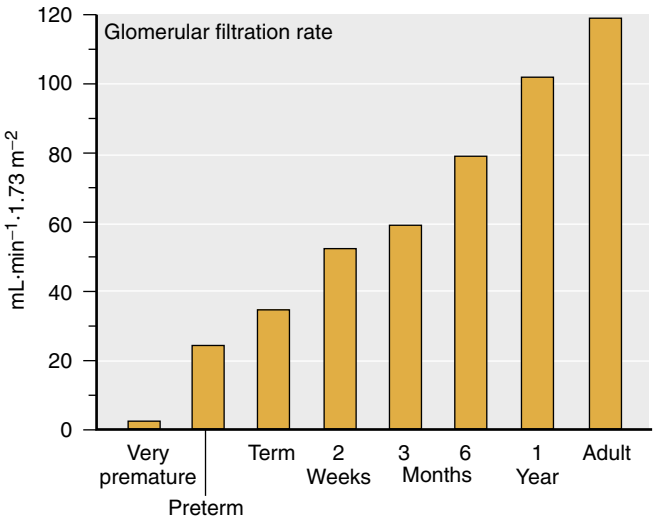

Figure 82-5 Glomerular filtration is markedly impaired at birth but develops rapidly during the first year of life. The ability of the kidney to handle large amounts of solutes and water is also limited during the first several months of life. These developmental changes have significant implications for drug excretion and fluid therapy, particularly during the first 4 weeks of life. Maturation of renal function may be delayed in sick neonates. *(Data from McCrory WW: Developmental Nephrology. Cambridge, MA, Harvard University Press, 1972.)*

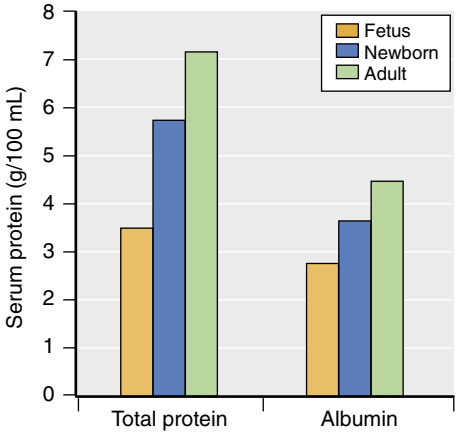

Figure 82-6 Changes in total serum protein and albumin values with maturation. Note that total protein and albumin are less in preterm than in term infants and less in term infants than in adults. The result may be altered pharmacokinetics and pharmacodynamics for drugs with a high degree of protein binding because less drug is protein bound and more is available for clinical effect. *(Abstracted from Ehrnebo M, Agurell S, Jalling B, et al: Age differences in drug binding by plasma proteins: Studies on human fetuses, neonates and adults. Eur J Clin Pharmacol 3:189-193, 1971. From Coté CJ, Lerman J, Todres ID [eds]: A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, WB Saunders, 2008.)*

some drugs to albumin may be altered in the presence of hyperbilirubinemia in the neonatal period.

The Gastrointestinal System

At birth, gastric pH is alkalotic; by the second day of life, pH is in the normal physiologic range for older children. The ability to coordinate swallowing with respiration does not fully mature until infants are 4 to 5 months of age, thus resulting in a high incidence of gastroesophageal reflux in newborns. This problem is particularly common in preterm infants. In general, if a developmental problem occurs within the gastrointestinal system, symptoms will occur within 24 to 36 hours of life; upper intestinal abnormalities are manifested as vomiting and regurgitation, whereas lower intestinal abnormalities produce abdominal distention and failure to pass meconium.

Thermoregulation

Infants are especially vulnerable to hypothermia (see also Chapter 48) because of the large ratio of body surface area to weight, the thinness of the skin, and a limited ability to cope with cold stress. Cold stress will result in increased oxygen consumption and can cause metabolic acidosis. A preterm infant is more susceptible because of even thinner skin and limited fat stores. The infant may compensate by means of shivering and nonshivering (cellular) thermogenesis. The minimal ability to shiver during the first 3 months of life makes cellular thermogenesis (metabolism of brown fat) the principal method of heat production. It is very important to address all aspects of possible heat loss during anesthesia, as well as during transport to and from the operating room. Placing the baby on a warming mattress and warming the operating room (80°F or warmer) reduce heat lost by conduction. Keeping the infant in an incubator, covered with blankets, minimizes heat lost through convection. The head should also be covered. Heat lost from radiation is decreased with the use of a double-shelled Isolette during transport. Heat lost through evaporation is lessened by humidification of inspired gases, the use of plastic wrap to decrease water loss through the skin, and warming of skin disinfectant solutions. Hot air blankets are the most effective means of warming children. Anesthetic agents can alter many thermoregulatory mechanisms, particularly nonshivering thermogenesis in neonates.

Pharmacology and Pharmacodynamics

Developmental Pharmacology

The response of infants and children (and particularly neonates) to medications is modified by many factors: body composition, protein binding, body temperature, distribution of cardiac output, functional maturity of the heart, maturation of the blood-brain barrier, the relative size (as well as functional maturity) of the liver and kidneys, and the presence or absence of congenital malformations.[8]

The body compartments (fat, muscle, water) change with age (Fig. 82-7). Total body water content is significantly higher in preterm than in term infants and in term infants than in 2-year-olds. Fat and muscle content increases with age. These alterations in body composition have several clinical implications for neonates: (1) A drug that is water soluble has a larger volume of distribution and usually requires a larger initial dose (mg/kg) to achieve the desired blood level (e.g., most antibiotics, succinyl-

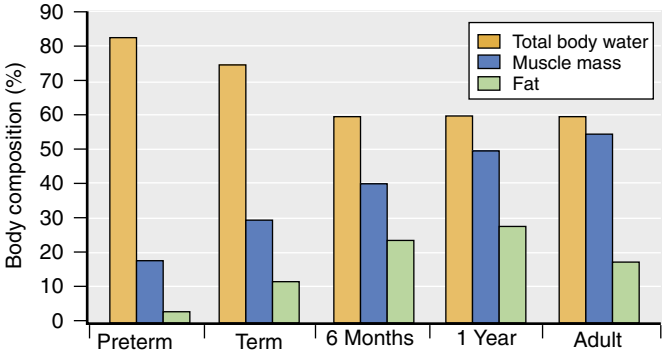

Figure 82-7 Body composition changes rapidly in preterm and term infants during the first 12 months of life. Their high water content provides a large volume of distribution for water-soluble medications, whereas their low fat and muscle content provides a small reservoir for drugs that depend on redistribution into these tissues for termination of drug effect. Thus, body composition may significantly affect pharmacokinetics and pharmacodynamics. *(Data from Friis-Hansen B: Body composition during growth. In vivo measurements and biochemical data correlated to differential anatomical growth. Pediatrics 47:169-181, 1971. From Coté CJ, Lerman J, Todres ID [eds]: A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, WB Saunders, 2008.)*

choline); (2) because there is less fat, a drug that depends on redistribution into fat for termination of its action will have a longer clinical effect (e.g., thiopental); and (3) a drug that redistributes into muscle may have a longer clinical effect (e.g., fentanyl, for which, however, saturation of muscle tissue has not been demonstrated).

In addition to these very basic concepts, other important factors play a role in the neonate's response to medications: (1) delayed excretion secondary to the larger volume of distribution, (2) immature hepatic and renal function, and (3) altered drug excretion caused by lower protein binding. Further perturbations in drug pharmacodynamics and pharmacokinetics occur with extreme prematurity and with factors such as sepsis, congestive heart failure, increased intra-abdominal pressure, controlled ventilation, and poor nutritional state.[8] All of these factors lead to clinically important neonatal patient-to-patient variability in pharmacokinetics and pharmacodynamics.

Older children tend to have mature renal and hepatic function, with normal adult values for protein, fat, and muscle content. A greater proportion of cardiac output is diverted to the liver and kidneys—which also weigh more in relation to body mass—in older children than in infants. These factors usually mean that the half-life of most medications in children older than 2 years is shorter than in adults or equivalent. As the child approaches adulthood, the half-life of many drugs lengthens. In general, most medications will have a prolonged elimination half-life in preterm and term infants, a shortened half-life in children older than 2 years up to the early teen years, and a lengthening of half-life in those approaching adulthood.

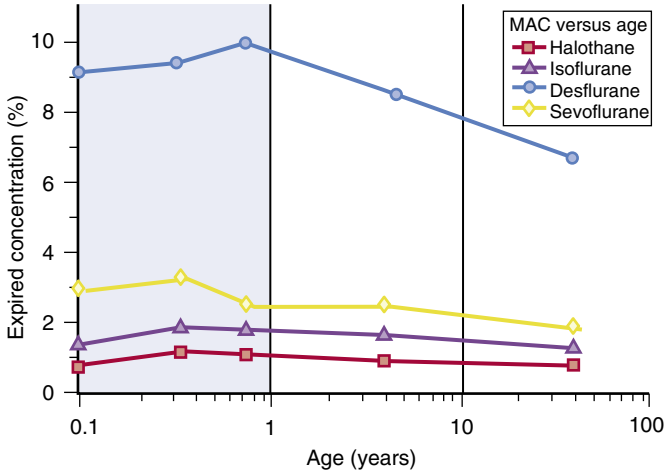

Figure 82-8 The minimum alveolar concentrations (MACs) of four commonly used inhaled anesthetics are plotted versus age. Note that MAC is highest in infants 3 to 6 months of age. The reasons for this are not clear. *(Extracted from data from references 12-19.)*

Inhaled Anesthetics

The expired minimum alveolar concentration (MAC) of an inhaled anesthetic required in pediatric patients changes with age (Fig. 82-8) (also see Chapters 20 and 21). Controlled studies show that the anesthetic requirement is lower for preterm than for term neonates and lower for term neonates than for 3-month-olds. Infants have a higher MAC than that noted in older children or adults, but the reasons have not been adequately explained. This fact, combined with the need for deeper planes of anesthesia to achieve satisfactory conditions for endotracheal intubation, places the infant in a precarious position because there is a small safety margin between anesthetic overdose (from a cardiovascular standpoint) and inadequate depth of anesthesia (for endotracheal intubation). Avoidance of controlled respirations until an intravenous line is inserted, rapid reduction in the delivery of inspired anesthetic drug, especially with the initiation of controlled respirations after the administration of a muscle relaxant, and in some cases, substitution of opioids for an inhaled agent are practices that improve safety.

Uptake of potent anesthetics is more rapid in children because of an increased respiratory rate and cardiac index and a greater proportional distribution of cardiac output to vessel-rich organs. This rapid rise in blood anesthetic levels combined with functional immaturity of cardiac development probably explains in part why it is so easy to deliver an inhaled anesthetic overdose to infants and toddlers. Age-related differences in blood-gas partition coefficients may also facilitate a more rapid rise in alveolar concentration in infants. Other factors include the state of hydration (e.g., excessive fasting would make a small infant relatively dehydrated) and the type of anesthesia circuit used. For example, a Mapleson D has a smaller volume than a circle system, so less volume is needed to achieve equilibration when the concentration of anesthetic agent exiting the vaporizer increases. With a Mapleson D circuit, the fresh gas flow is introduced into the system at the airway and enters directly into the child's lungs. Perhaps the most important factor influencing the potential for anesthetic overdose in neonates is the number of MAC multiples that can be delivered by the vaporizer (e.g., a halothane vaporizer can deliver up to 5.75 MAC multiples versus 2.42 MAC multiples for a sevoflurane vaporizer [Table 82-2]).

Sevoflurane

Sevoflurane has a gas partition coefficient similar to that of nitrous oxide (also see Chapters 20 and 21). Broad clinical experience has shown that it is less pungent than isoflurane and desflurane; some authors believe it to be superior or equivalent to halothane for gaseous induction. As with all potent volatile anesthetics, the MAC is highest in younger patients: 3.3% for neonates, 3.2% for infants 1 to 6 months old, and 2.5% for children older than 6 months.[12,13] When data from multiple studies are pooled, it is clear that sevoflurane and halothane are approximately equivalent in terms of airway complications during induction of anesthesia (laryngospasm, bronchospasm, breath-holding) but that the rate of induction is more rapid with sevoflurane. There is a lower incidence of coughing during induction with sevoflurane (~6% versus ~10%) and a 33% higher incidence of excitement during emergence (~21% versus ~15%) (Table 82-3). Both sevoflurane and halothane produce dose-related respiratory depression; however, halothane produces a decrease in tidal volume and an increase in respiratory rate, whereas sevoflurane decreases both the respiratory rate and tidal volume. I have often seen the need to assist respirations during the early induction stage in sevoflurane-anesthetized children. Unless the inspired concentration is markedly reduced (usually to ~3%), such assistance then increases the potential for anesthetic overdose while attempts are made to establish intravenous access.[20]

Table 82-2 MAC Multiples for a Neonate Allowed by Current Vaporizers

Agent	Maximum Vaporizer Output (%)	MAC (%)	Maximum Possible MAC Multiples
Halothane	5	0.87	5.75
Isoflurane	5	1.20	4.2
Sevoflurane	8	3.3	2.42
Desflurane	18	9.16	1.96

MAC, minimum alveolar concentration.

Sevoflurane and halothane also have a different cardiovascular profiles. Children older than 3 years usually experience an increase in heart rate and no change in systolic blood pressure with sevoflurane, whereas with halothane, the heart rate does not change but systolic blood pressure decreases. It should be noted that the children most vulnerable to anesthetic overdose are the age groups shown to have the least increase in heart rate and the greatest decrease in systolic blood pressure (34% ± 16% and 26% ± 20%, respectively, for neonates and infants <6 months of age) during carefully conducted MAC studies.[13] These changes in systolic blood pressure are comparable to those produced by equi-MAC concentrations of halothane.[14] As described in the Pediatric Perioperative Cardiac Arrest (POCA) registry, there is an association between the use of controlled ventilation and cardiac arrest; generally, arrest occurs before the establishment of intravenous access.[20] It is important to respect the fact that even sevoflurane can cause catastrophic effects on the infant's cardiovascular system. One should not be lulled into thinking that because sevoflurane causes less myocardial depression than halothane does, it is much safer than halothane. Therefore, use of a muscle relaxant to facilitate endotracheal intubation and avoidance of high inspired concentrations of sevoflurane would seem to be the safest approach in this age group.

The safety of all potent anesthetics relates to how the drugs are used, the experience of the person administering anesthesia, and other less obvious factors. I generally induce anesthesia with sevoflurane, and if the infant becomes apneic, then I rapidly reduce the inspired concentration of sevoflurane while gently assisting respirations. After intravenous access is established, a decision must be made regarding continued management with just a facemask, with a supraglottic airway device (e.g., laryngeal mask airway [LMA], laryngeal tube, Cobra), or with an endotracheal tube. If I am going to place a supraglottic device, I usually administer propofol (1.5 to 2 mg/kg) and then insert the device 30 to 45 seconds later. Most children will become apneic and require assisted ventilation for several minutes. If I am going to place an endotracheal tube, two techniques seem reasonably safe: (1) If an endotracheal tube is required and the case is relatively brief or a nerve stimulator is to be used, I return to 8% sevoflurane and hyperventilate the child for a brief time (usually 1 to 2 minutes) to abolish spontaneous respirations and rapidly deepen the plane of anesthesia, administer approximately 1 mg/kg propofol, shut the vaporizer off (so that the 8% sevoflurane is not accidentally continued), and then insert the endotracheal tube; (2) if there is no need for a nerve stimulator or if muscle relaxation is necessary, I simply maintain the sevoflurane at approximately 3.5% to 4% (lower for a neonate), administer an appropriate muscle relaxant (based on the desired side effects or avoidance of undesired side effects and the duration of the procedure), and then insert the endotracheal tube. At this point I will further reduce the inspired concentration of sevoflurane or change to an appropriate concentration of halothane or isoflurane for maintenance to reduce cost. Because multiple studies have found no difference in time to discharge (street readiness), there seems to be little logic in using sevoflurane for the entire procedure except for very brief anesthesia.

Several other issues related to sevoflurane are worthy of mention. The most important is the risk of exothermic reactions with dry desiccant,[21-24] which has resulted in fires and explosions (sevoflurane and Baralyme). A number of cases have occurred in pediatric institutions (see also Chapter 100) (Fig. 82-9).[25-27] These incidents seem to most often be associated with high flow of oxygen through the circuit for extended periods and then the use of high inspired sevoflurane concentrations (e.g., the first procedure on a Monday morning). Another issue is the production of toxic metabolites as a result of interaction with the carbon dioxide absorbent.[28,29] Compound A appears to be nephrotoxic in animal models; however, conflicting data have been presented regarding the clinical importance of this observation. Studies of low-flow (2 L/min) and prolonged anesthesia have not demonstrated significant alteration in the usual markers of renal function. It appears that sevoflurane is a safe anesthetic even for prolonged surgical procedures. Fresh gas flows less than 1 L/min are not recommended. Use of new but more expensive carbon dioxide

Table 82-3 Summary Statistics for 17 Studies That Compared the Characteristics of Sevoflurane and Halothane

	Sevoflurane			Halothane			
Problem	Yes	No	Percent	Yes	No	Percent	Chi Square
Laryngospasm	22	773	2.8	22	601	3.5	.503
Breath-holding	33	635	4.9	34	439	7.2	.143
Coughing	42	662	6.0	52	454	10.3	.008
Excitement during induction	92	556	14.2	58	423	12.0	.338
Bronchospasm	2	604	0.33	2	436	0.46	.856
Excitement during emergence	169	645	20.8	102	573	15.1	.006

Figure 82-9 Sevoflurane-Baralyme interaction produced this fire in an anesthesia machine. *(From Coté CJ, Lerman J, Todres ID [eds]: A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, Saunders, 2008. Reproduced with permission from Mr. A. Rich.)*

absorbents that do not contain a strong base seems to eliminate most of these issues.

The other concern is the apparent higher incidence of emergence agitation with sevoflurane than with halothane (see Table 82-3). Unfortunately, there is much confusion regarding the definitions and descriptions of agitation/delirium, thus making it difficult to compare studies. This response during emergence from sevoflurane anesthesia is not related to pain, appears to be inversely related to age, and is especially frequent in children 5 years or younger. Some investigators have reported a lower incidence with midazolam premedication and administration of clonidine (orally or epidurally), ketorolac, fentanyl, or dexmedetomidine. It is of interest that when one combines the data from many studies, the true difference in emergence agitation is quite small (~21% with sevoflurane and ~15% with halothane). It is my impression that the major reason that this is perceived to be such a problem is that the children often arrive in the postanesthesia care unit (PACU) in this agitated state. With halothane, children generally arrive in the PACU still partially anesthetized, the nurses are able to chart their initial vital signs, and then the children become agitated, but at this point it is less worrisome for the nurses so it is perceived as less of a problem. In either case, this condition does respond to low doses of fentanyl or propofol and is generally short-lived (~5 to 10 minutes). Another issue of interest is reports of seizure-like activity during induction with sevoflurane. At least one careful electroencephalographic (EEG) study has not documented seizure activity, thus suggesting that these abnormal movements are not central in origin.[30]

One personal observation is that airway reflexes are inadequately suppressed for performance of bronchoscopy during spontaneous respirations; supplementation with any combination of intravenous propofol, low-dose remifentanil, or a muscle relaxant is usually required with sevoflurane. Halothane appears to still be a superior inhaled agent for this procedure because higher MAC multiples may be used to maintain the concentration of inhaled drug, even in the face of large losses when the facemask is removed to allow insertion of the bronchoscope. The longer elimination half-life and maintenance of spontaneous respirations with halothane also contribute to its advantage for procedures in which the facemask will be applied intermittently, such as bronchoscopy or suture removal from a cleft lip repair.

Halothane

The use of halothane in the United States has fallen dramatically; however, it is still used widely in other parts of the world (also see Chapters 21 and 24). Halothane does not have a noxious smell and is still commonly used for the gaseous induction of anesthesia in places where budgetary concerns limit the availability of sevoflurane. There is nearly always a statistically significant, but clinically unimportant difference in the rapidity of awakening when comparing halothane with either desflurane or sevoflurane (usually 3 to 5 minutes). I often induce anesthesia with sevoflurane and then use halothane or isoflurane for maintenance to reduce cost. Most important, airway-related problems during induction occur less frequently with halothane and sevoflurane than with enflurane, isoflurane, or desflurane. Halothane and sevoflurane are the anesthetics of choice for the gaseous induction of anesthesia in children.

A 1987 report describing seven cases (one fatal) of "halothane hepatitis" concluded that children should not undergo repeated exposure to halothane (also see Chapter 24).[31] This report must be placed in proper perspective. To date, millions of children have been anesthetized with halothane. Perhaps a dozen instances of halothane hepatitis—and one or two deaths—have been reported in children. This is a remarkable safety record for any medication. Because "halothane hepatitis" appears to be primarily an adult issue, it may make sense to use other anesthetics or techniques in teenage patients. Halothane will probably remain the most commonly used potent anesthetic in undeveloped countries because of cost. It should be noted that hepatic dysfunction has been reported in children after all potent anesthetic agents, including sevoflurane and desflurane.

Another concern with halothane is sensitization of the myocardium to arrhythmias because of exogenous and endogenous catecholamines. Most arrhythmias associated with halothane anesthesia in children are caused by either hypercapnia or an inadequate level of anesthesia.[32] Up to 10 μg/kg of epinephrine may be used with minimal risk of cardiac arrhythmias in pediatric patients. In fact, I like the arrhythmogenic effects of halothane because the development of an arrhythmia suggests that the child is inadequately anesthetized or hypercapnic. In addition, the heart rate is generally stable or slightly decreased. If tachycardia develops in a halothane-anesthetized child, inadequate anesthesia or hypovolemia is usually the cause. This is distinctly different from isoflurane, desflurane, and sevoflurane, all of which can directly cause tachycardia.

Halothane is a potent myocardial depressant that can have profound effects on neonates and children with congenital heart disease. Such depression is responsible for the occasional inability to give critically ill children sufficient concentrations of halothane to provide "anesthesia" without inducing severe hypotension. In this circumstance, the liberal use of short-acting narcotics with light concentrations of halothane generally provides the desired response. The POCA study reported a greater number of anesthetic-induced cardiac arrests with halothane; the use of controlled ventilation (probably without reducing the inspired concentration of the anesthetic agent) was a common observation.[14] It is of interest that both halothane and sevoflurane have been shown to depress cardiac function but that sevoflurane is considered to be less of a myocardial depressant.[33,34] However, at both 1 and 1.5 MAC in children, there was no significant difference is mean arterial blood pressure[33]; in infants, there was no difference at 1 MAC but there was a difference at 1.5 MAC. It should be further noted that the simple administration of atropine would abolish these differences.

Isoflurane

Isoflurane is claimed to have some advantages over halothane: less myocardial depression, preservation of the heart rate, and a

greater reduction in the cerebral metabolic rate for oxygen (also see Chapters 21, 22, and 24). These properties may be beneficial in selected children. The major disadvantage of isoflurane is its noxious smell, which is unacceptable to many pediatric patients, and a greater incidence of airway-related events (laryngospasm, coughing). Hypertension is also observed occasionally, especially in teenagers, when the inspired concentration is rapidly increased or there is a sudden change from sevoflurane to isoflurane. The probable mechanism is similar to that of desflurane: stimulation of pulmonary irritant receptors causing increased sympathetic activity and stimulation of the renin-angiotensin system. In these children I have also occasionally observed a diffuse rash primarily on the torso. All signs and symptoms regress with a reduction in the inspired concentration of isoflurane.

Desflurane

Desflurane has a gas partition coefficient similar to that of nitrous oxide (also see Chapter 21). Unfortunately, it has been found to cause an unacceptable incidence of laryngospasm (~50%) during the gaseous induction of anesthesia in children.[35] Gaseous induction of anesthesia with halothane or sevoflurane and then changing to desflurane for maintenance and wake-up may be reasonable. This changeover, unlike a similar change to halothane or isoflurane, may be clinically important in that the gas partition coefficient clearly favors rapid excretion. However, it would appear to be more important to change to desflurane for longer procedures, where there is the potential for accumulation of potent agent within fat, than for brief cases, in which such accumulation is less likely. The more rapid awakening may also be advantageous for neurosurgical and spinal fusion procedures, for which early assessment of mental and neurologic status is important. One study of pediatric adenoidectomy patients demonstrated more rapid wake-up with desflurane than with sevoflurane or halothane, but this agent was also associated with the highest rate of emergence agitation.[36] Nasal fentanyl (2 μg/kg) reduces the incidence of emergence agitation, but my impression is that it also increases the incidence of postoperative vomiting.[37]

The MAC for desflurane is dependent on age: 9.2% for neonates, 9.4% for infants 1 to 6 months of age, 9.9% for infants 6 to 12 months of age, 8.7% for 1- to 3-year-olds, and 8% for 5- to 12-year-olds.[15] Interestingly, nitrous oxide does not appear to contribute to the MAC of desflurane to the same degree as it does with other potent inhaled agents.[38] There is virtually no hepatic metabolism of this agent, which clearly sets it apart from the other currently available potent anesthetics. Concern for the potential for carbon monoxide poisoning with desflurane as a result of dry carbon dioxide absorbent (also possible with isoflurane) can be prevented by rehydration before use. New carbon dioxide absorbents that do not contain a strong base may offer improved safety.

Drugs Used to Induce Anesthesia

Propofol

Propofol is highly lipophilic and promptly distributes into and out of vessel-rich organs; its rapid redistribution, hepatic glucuronidation, and high renal clearance account for the short duration of its effect (also see Chapter 26). As with barbiturates, the induction dose is higher in younger children (2.9 mg/kg for infants younger than 2 years) than in older children (2.2 mg/kg for children 6 to 12 years of age). This may be related in part to a larger central volume and greater clearance in younger children.[39] The major drawback of propofol is pain on intravenous administration, particularly through small veins. As little as 0.2 mg/kg of lidocaine (mixed with the propofol) is effective in reducing but not eliminating this discomfort. I will often place a tourniquet on the child and administer 1.0 mg/kg of lidocaine 15 to 20 seconds before administering the propofol. I then administer the propofol with the intravenous line running, and once most of it has entered the vein, I let the tourniquet down. This "mini–Bier block" technique seems to be quite effective in reducing pain. Another method for minimizing pain is to use a small-gauge catheter (22 to 24 gauge) and administer the drug through a large antecubital vein. Propofol is particularly useful for the brief and repeated sedation needed for radiotherapy in children with central venous lines. A constant infusion is useful for sedating children undergoing radiologic procedures and as a means of maintaining anesthesia during transport from one location to another, for example, from radiology to the operating room. A modest reduction in systolic blood pressure often accompanies bolus administration. Propofol has been associated with a reduced rate of postoperative vomiting. Because propofol contains egg and soy products, it should be used with caution in children with egg or soy allergies.[40,41]

The major concern with propofol is the potential for propofol infusion syndrome (lactic acidosis, rhabdomyolysis, cardiac and renal failure), which is generally associated with high-dose infusions for an extended period (usually days in an intensive care unit [ICU] environment).[42] Although no such cases have been reported in healthy children during routine anesthesia care, there is one case report in a child with a genetic defect in lipid metabolism who had received approximately 150 μg/kg/min (~9 mg/kg/hr) for 6.5 hours during scoliosis repair. This case report suggests caution in the use of propofol in children with known defects in lipid metabolism; this may include some forms of mitochondrial disease. It should be noted that propofol has been used safely in many children with mitochondrial disease and that this caution applies only to those with defects in lipid metabolism.[43]

Methohexital

Methohexital is generally administered intravenously at a concentration of 1% and a dose of approximately 1 to 2 mg/kg (also see Chapter 26). Problems associated with intravenous administration include burning, hiccups, apnea, and extrapyramidal-like movements. Methohexital has a shorter elimination half-life than thiopental does. It is also useful for providing sedation during radiologic procedures by rectal administration (10% solution). Usually, 25 to 30 mg/kg produces light sleep within 8 to 10 minutes that lasts for 20 to 40 minutes. Obstructive or central apnea may occur occasionally. Therefore, a means of ventilating the child must be available, and appropriate monitoring with pulse oximetry is important. Because it can cause seizures, methohexital is contraindicated in children with temporal lobe epilepsy. Children receiving seizure medications generally require larger doses.

Thiopental

Intravenous bolus administration of 2.5% thiopental (5 to 6 mg/kg) is sufficient to induce anesthesia in most healthy, unpremedicated pediatric patients (also see Chapter 26). Termination of effect occurs through redistribution of the drug in muscle and fat;

thiopental should be used in reduced doses (2 to 4 mg/kg) in children who have low fat stores, such as neonates or malnourished infants. Limiting the total dose to 10 mg/kg or less in older children minimizes the possibility of prolongation of anesthesia caused by residual barbiturate sedation. Thiopental (30 mg/kg in a 10% solution) may also be administered rectally if methohexital is contraindicated.

Ketamine

Ketamine causes central dissociation of the cerebral cortex while providing analgesia and amnesia (also see Chapter 26). In addition to the intravenous and intramuscular routes, ketamine may be administered rectally (10 mg/kg), orally (6 to 10 mg/kg), or intranasally (3 to 6 mg/kg). The combination of oral ketamine (4 to 6 mg/kg), oral midazolam (0.5 mg/kg), and oral atropine (0.02 mg/kg) provides a well-sedated child. Intravenous administration of doses as low as 0.25 to 0.5 mg/kg may be used to provide sedation/analgesia for painful procedures, whereas doses of 1 to 2 mg/kg produce sedation sufficient for a smooth transition to general anesthesia. Higher doses (up to 10 mg/kg intramuscularly) provide sufficient analgesia for the insertion of invasive monitoring devices before induction of anesthesia (cardiac surgery) or in children with limited venous access. Ketamine is useful for induction of anesthesia in hypovolemic children. Patient-to-patient variability in response to this drug is relatively large, however. A major side effect, increased production of secretions, usually requires the administration of an antisialagogue. Other undesirable side effects include vomiting and postoperative "dreaming" or hallucinations; the incidence of dreaming may be reduced by the concomitant administration of a benzodiazepine. Although spontaneous respirations and a patent airway are usually maintained, apnea and laryngospasm may occur.

Contraindications to the use of ketamine in children include the presence of an active upper respiratory tract infection (URI), increased intracranial pressure, open-globe injury, and a psychiatric or seizure disorder. Ketamine does not preserve the gag reflex and thus should not be used as the sole anesthetic for children with a full stomach or a hiatal hernia. Ketamine has also been used as an adjunct for epidural analgesia.[44] However, *because the preservative in usual ketamine preparations is neurotoxic, one must administer only preservative-free ketamine in the epidural space*.

Etomidate

Etomidate is a steroid-based hypnotic induction agent (also see Chapter 26). As with propofol, there is a high incidence of pain on intravenous administration. Concerns regarding anaphylactoid reactions and suppression of adrenal function resulted in most anesthesiologists avoiding this induction agent. Etomidate is very useful in children with head injury and those with unstable cardiovascular status, such as children with a cardiomyopathy, because of the virtual absence of adverse effects on the cardiovascular system.[45,46] This drug has gained increasing popularity for airway management in the emergency department setting.[47-49] Common doses are 0.2 to 0.3 mg/kg given before the administration of low-dose opioid and a muscle relaxant. Etomidate is often used to facilitate endotracheal intubation in critically ill children. Because a very high proportion of critically ill children, particularly those resistant to vasopressors, suffer from relative adrenal insufficiency, steroid supplementation may be indicated in such children in whom etomidate is deemed necessary for their safe airway management.[50,51]

Sedatives and Anxiolytics

Diazepam

Oral absorption of diazepam is more rapid in children than in adults, with 0.1 to 0.3 mg/kg orally usually providing excellent peak sedation within 1 hour (also see Chapter 26). Intravenous administration is painful and not well tolerated; diazepam may also be administered rectally. Because the liver is the main site of degradation, this medication should be given with caution to any child with hepatic disease. Diazepam has an extremely long half-life in neonates (80 hours) and may not be indicated until the infant is 6 months of age or until hepatic metabolic pathways have matured.

Midazolam

Midazolam is water soluble and therefore not generally painful on intravenous administration (also see Chapter 26). It should be noted that because of its water solubility, *it takes three times as long to reach a peak EEG effect as the more fat-soluble diazepam*. The clinical importance of this is that one should wait at least 3 minutes between intravenous doses to avoid "stacking" of effect.[52] The shorter elimination half-life (~2 hours) of midazolam than diazepam (~18 hours) offers an advantage for use as a premedicant in children. Midazolam is the only benzodiazepine approved by the Food and Drug Administration for use in neonates; in this population the half-life is much longer (6 to 12 hours).[53,54] In addition, severe hypotension has been reported in neonates after bolus administration, and the potential for this problem is apparently increased in neonates also receiving fentanyl. Midazolam is absorbed rapidly after intramuscular (0.1 to 0.15 mg/kg, maximum of 7.5 mg), oral (0.25 to 1.0 mg/kg, maximum of 20 mg), rectal (0.75 to 1.0 mg/kg, maximum of 20 mg), nasal (0.2 mg/kg), or sublingual (0.2 mg/kg) administration.[55] Nasal administration is uncomfortable for most children. Midazolam must always be used with caution when administered with narcotics because of the potential for respiratory depression. One important interaction is that erythromycin, calcium channel blockers, protease inhibitors, and even grapefruit juice produce a clinically important delay in midazolam metabolism because of inhibition of cytochrome P450.[56] In this circumstance either midazolam should be avoided or the dose reduced by 50%.[56] One further concern is that with nasal administration there is the theoretical possibility of central nervous system (CNS) toxicity as a result of drug entering the CNS along neural connections (olfactory nerves).[57] Because neurotoxicity has never been examined and most children cry with nasal administration, I believe that this route should generally be avoided.

Dexmedetomidine

Dexmedetomidine is a selective α_2-adrenergic agonist with anxiolytic, sedative, and analgesic properties (also see Chapter 26). The role of this new agent for the care of children awaits further investigation to clarify its exact advantages and disadvantages. At the time of this writing the drug is currently undergoing phase II and early phase III investigations; there are very limited well-controlled pediatric studies. A pharmacokinetic trial involving 36 children 2 to 12 years of age revealed a terminal elimination half-life of approximately 110 minutes with both heart rate (≤15%) and systolic blood pressure (≤25%) decreasing over time as the dose was increased; these observations are similar to those in

adults.[58] Infusions of 2, 4, or 6 µg/kg/hour (0.33 to 1.0 µg/kg) were administered over a 10-minute period, and there was no significant effect on the respiratory rate or oxygen saturation during the 1-hour period of observation before induction of anesthesia. Only one child initially demonstrated an increase in blood pressure, but it was unclear whether it was drug related. Transient sedation was noted in all children, and the authors recommend slow intravenous infusion to minimize any possible adverse hemodynamic events that might occur with bolus administration. Use of dexmedetomidine as the sole sedating agent or combined with other sedatives has been described in children undergoing cardiac catheterization and a variety of radiologic procedures.[59-64] Dexmedetomidine has also been used to facilitate fiberoptic intubation,[65] to sedate a child undergoing awake craniotomy,[66] to reduce the incidence of emergence agitation,[67,68] and to facilitate withdrawal from opioids.[69] In addition, this medication has been used to provide prolonged sedation in critically ill children.[70] Thus, the indications in children would seem to be the same as in adults.

Opioids

Morphine

Morphine is the oldest commonly used long-acting narcotic (also see Chapter 27). Its use in neonates (those younger than 10 days) remains controversial inasmuch as early studies in newborn infants suggested that morphine produces greater respiratory depression than meperidine does. Higher brain levels of morphine were found in neonatal than in adult rats, thus implying that permeability of the blood-brain barrier may account in part for the apparent sensitivity of the human neonate to morphine.[71] This rationale led to the common belief that infants are sensitive to the effect of narcotics. More recent studies have found age-dependent pharmacokinetics. Newborns have lower clearance of morphine, and therefore a lower dose will result in higher plasma values because of a longer elimination half-life.[72] Term infants older than 10 days may clear morphine more rapidly and at a similar rate as adults.

The issue of respiratory sensitivity and the age at which it decreases in humans have yet to be resolved; animal studies suggest that there appears to be a difference between morphine and fentanyl that may not relate to transport of drug into the brain.[73] Some of these effects may therefore be due to changes in pharmacodynamics rather than simply maturation of the blood-brain barrier. Morphine should be administered with caution to neonates and preterm infants who are not in a monitored setting. Infants older than 6 months probably have a normal adult response to morphine.

Meperidine

Meperidine received great attention when it was found on a milligram-per-kilogram basis to cause less respiratory depression in newborns than morphine does (also see Chapter 27).[74] This difference may be related in part to the fact that meperidine is much more lipophilic than morphine. Unlike morphine, the fraction of drug that enters the brain of neonates is similar to that entering the brain of older children. As with all drugs administered to neonates, there is large patient-to-patient variability in metabolism and response. Meperidine is not appropriate for long-term administration because of accumulation of the toxic metabolite normeperidine; this drug has been removed from the formulary of many children's hospitals.

Fentanyl

Fentanyl is the most commonly used narcotic in infants and children (also see Chapter 27). Its major advantages relate to its rapid onset and brief duration of action. This narcotic is more lipophilic than meperidine; the potential effects of the blood-brain barrier are of no importance with fentanyl. Termination of the effect of low doses of fentanyl results primarily from redistribution, whereas termination of the effect of high doses depends on elimination. High doses of fentanyl achieve the properties of long-acting narcotics.

Fentanyl induces a very stable cardiovascular response while providing an anesthetic state. The dosage required to produce anesthesia varies considerably, depending on the child's age, the surgical procedure, the health of the child, and the use of anesthetic adjuvants.[75] Neonates undergoing abdominal surgery have a longer fentanyl half-life than do those undergoing other procedures; hepatic blood flow—and factors that greatly increase or decrease hepatic blood flow, such as positive end-expiratory pressure (PEEP) or the use of vasopressors—may alter the pharmacokinetics. Impaired hepatic function may also play a role in the altered kinetics with increased intra-abdominal pressure.[76] Therefore, the pharmacokinetic and pharmacodynamic profile is very different and more variable for neonates than for older children. A dose of 12.5 µg/kg produces anesthesia in full-term neonates undergoing abdominal surgery, whereas higher doses (30 to 100 µg/kg) are used for cardiac surgery. These doses are safe in children whose ventilation will be controlled postoperatively; much lower doses (2 to 10 µg/kg) should be used with other anesthetics if ventilation is not to be controlled postoperatively. Because the cardiac output of neonates is determined by the heart rate, fentanyl-induced bradycardia may require administration of a vagolytic drug, such as atropine or pancuronium.

Alfentanil

Alfentanil is eliminated more rapidly than fentanyl; its pharmacokinetics is independent of dose (also see Chapter 27). This may provide a margin of safety because the greater the administered dose, the greater the elimination. Clearance of alfentanil may be increased in children in comparison to adults. As with any narcotic, there is important patient-to-patient variability in pharmacokinetics and pharmacodynamics in neonates and in children with impaired hepatic blood flow.

Sufentanil

Sufentanil has been used primarily for cardiac anesthesia; age-dependent kinetics is also evident, particularly in the first month of life (also see Chapter 27). Children are able to clear sufentanil more rapidly than adults do. This drug must be administered with caution because severe bradycardia and asystole have been reported when a vagolytic drug was not administered simultaneously.[77] Sufentanil has may be administered nasally as a premedicant or analgesic (2 µg/kg); however, desaturation may follow.

Remifentanil

Remifentanil is the most recent addition to the opioids available for the care of children (also see Chapter 27).[78] The main advantage of this opioid is its very brief half-life. Studies in adults have

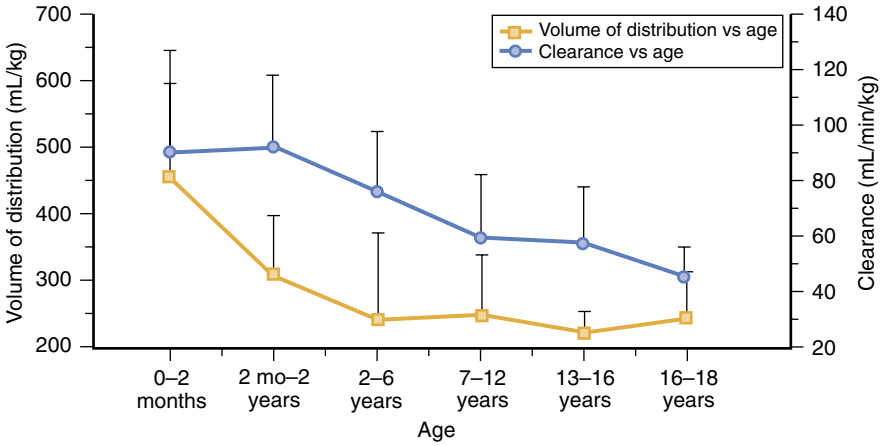

Figure 82-10 Remifentanil is the newest potent opioid available for the care of neonates. Note that unlike with virtually all other medications, its half-life is shorter in neonates than in older children, probably because of elimination of remifentanil by nonspecific plasma and tissue esterases, as well as the larger volume of distribution in neonates. The importance of this observation is that developmental immaturity of liver and renal function does not affect the pharmacokinetics of remifentanil. Because this was a single-bolus administration study, it is not clear whether similar pharmacokinetics would follow a long continuous infusion. *(Data abstracted from Ross AK, Davis PJ, Dear Gd GL, et al: Pharmacokinetics of remifentanil in anesthetized pediatric patients undergoing elective surgery or diagnostic procedures. Anesth Analg 93:1393-1401, 2001.)*

found that even after prolonged infusions, the time to a 50% reduction in effect-site concentration (effect on respiration) is approximately 4 minutes. One study examining its pharmacokinetics in children found that there are age-related differences in the volume of distribution and clearance but not half-life (Fig. 82-10).[79] Contrary to the pharmacokinetics of most drugs, neonates are able to clear the drug more rapidly than older children! This difference may in part relate to the larger volume of distribution with equivalent half-life. Of further interest is the very small patient-to-patient variability in pharmacokinetic parameters when compared with similar studies examining other opioids, particularly in infants and neonates. Because remifentanil is broken down by nonspecific plasma and tissue cholinesterases, the importance of maturation of renal and hepatic function is minimal. This also helps explain the minimal differences in remifentanil's half-life between infants and adults. This drug has great utility in infants with hepatic or renal failure. The particularly favorable pharmacokinetics in neonates allows provision of a deep opioid-induced plane of anesthesia while avoiding cardiovascular depression and the need for postoperative ventilation. One multicenter study of infants undergoing pyloromyotomy found no difference in intraoperative hemodynamic parameters, time to extubation, PACU discharge times, need for pain medications, or adverse events when compared with halothane anesthesia.[80,81] In older children, remifentanil is very helpful in the anesthetic management of those in whom neurologic status must be rapidly assessed. This drug is also very useful for cardiac surgery in children as a means of providing adequate opioid analgesia, cardiovascular stability, and early extubation.

Several studies have examined bolus doses of remifentanil as an alternative to succinylcholine.[82,83] One study found that 1.25 µg/kg of remifentanil combined with 4 mg/kg of propofol allowed all children (2 to 16 years) to be intubated successfully, but there was more coughing and the duration of apnea was longer in the remifentanil group than in those who had received an equivalent dose of propofol combined with succinylcholine (1 mg/kg); in none of the children in the remifentanil group did chest wall rigidity develop.[82] Another study of infants 2 to 12 months old and children 1 to 6 years of age determined the 98% effective dose (ED_{98}) for successful intubation to be similar in both age groups (~2.9 µg/kg).[83] The second half of that study compared remifentanil, 3 µg/kg, combined with propofol, 4 mg/kg, in 2- to 12-month-old infants with succinylcholine and found similar intubating conditions; the duration of apnea was similar in both groups. It is my opinion that at this point data are insufficient to support the routine substitution of remifentanil for succinylcholine and that further study that truly mimics rapid-sequence intubation is needed. Because bolus doses of remifentanil are associated with hypotension and bradycardia, a vagolytic is indicated.

In neonates and toddlers, use of a more dilute concentration and bypassing the dead space of the injection port with a needle (or priming the dead space) are necessary so that the onset of drug effect is not delayed.[84,85] In older children, a standard solution of 50 µg/mL may be used. In general, a starting bolus dose of 0.1 to 0.25 µg/kg is followed by an infusion at 0.25 µg/kg/min. Increases or decreases in the infusion rate of 0.05 to 0.1 µg/kg/min are useful starting points for managing altered anesthetic requirements. Two studies have compared the somatic and autonomic responses to skin incision during continuous remifentanil infusion in adults and children.[86,87] The infusion rates to block somatic and autonomic responses in 50% of children were significantly higher (approximately twofold greater) than in adults. The reason for such a disparity in drug requirement between adults and children is not clear. However, this is certainly a clinically important observation because it suggests the possible need to (1) start at higher initial infusion rates, (2) rapidly increase infusion rates after initial assessment of responses, (3) supplement the anesthetic with nitrous oxide or a potent agent, or (4) add another analgesic. I have used a fix combination of 100 µg of remifentanil combined with 18 mL of propofol (final concentration, 5 µg/mL of remifentanil) run at a starting infusion rate equivalent to 150 µg/kg/min of propofol to provide excellent conditions for upper and lower endoscopic procedures. One study has demonstrated adequate stability of this mix for 6 hours.[88]

For practical purposes and for safety, it is vital that the drug be administered by continuous infusion and that it be carried into the vein by a second continuous infusion because variations in drug delivery related to differences in intravenous fluid delivery can have profound effects on the rate of opioid administration.[84,85] For neonates and small children, I generally use a continuous infusion pump for the maintenance intravenous fluid and "piggyback" the remifentanil infusion as close to the intravenous catheter as possible. In complex cases I will use a separate intravenous line for all other anesthetic management issues. A further very important concern is the need to provide analgesia once the use of remifentanil is discontinued. I usually accomplish this with morphine (0.05 to 0.2 mg/kg, depending on the severity of pain expected) or with a regional nerve block administered well before discontinuation of the remifentanil. I have also used remifentanil as a means of producing profound analgesia while taking advantage of its vagotonic effects to reduce blood pressure in children undergoing spinal instrumentation. This strategy avoids interference of evoked motor or sensory potentials because a low-dose inhaled agent or a propofol infusion may be used for anxiolysis and amnesia.

Muscle Relaxants

Depolarizing Muscle Relaxants

Succinylcholine

Succinylcholine is highly water soluble and rapidly redistributes into the extracellular fluid volume (also see Chapter 29). For this reason the dose required for intravenous administration in infants (2.0 mg/kg) is approximately twice that for older children (1.0 mg/kg). Succinylcholine is the only short-acting relaxant that is effective when given intramuscularly; reliable muscle relaxation occurs within 3 to 4 minutes after 5 mg/kg in infants and 4 mg/kg in children older than 6 months. The skeletal muscle relaxation produced by intramuscular administration may last up to 20 minutes; more rapid onset is not achieved by splitting the dose into two injections or by changing the concentration. In an emergency situation, succinylcholine may be administered intralingually (via a submental approach), which will further speed the onset of relaxation because the drug is more rapidly absorbed from the tongue than from peripheral skeletal muscle.

Cardiac arrhythmias frequently follow intravenous administration, especially during halothane anesthesia. Prior intravenous administration of atropine (but not intramuscular administration of atropine as a premedication) reduces the incidence of arrhythmias. Cardiac sinus arrest may follow the first dose of succinylcholine but is more common after repeated bolus administration; such arrest may occur in children of any age. Although the incidence of bradycardia is low in older children, I have observed one 13-year-old child in whom asystole developed for approximately 30 to 45 seconds after a single dose of succinylcholine administered with thiopental but not atropine; the asystole occurred before intubation and with 100% oxygen saturation and responded immediately to the administration of atropine and several chest compressions to circulate the atropine. Therefore, atropine should probably be given intravenously just before the first dose of succinylcholine in all children, including teenagers, unless there is a contraindication to tachycardia.

Succinylcholine has received much attention because of the severity of its possible complications. The potential for rhabdomyolysis and hyperkalemia (particularly in boys younger than 8 years, who may have unrecognized muscular dystrophy), as well as the risk for masseter spasm and malignant hyperthermia, suggests that succinylcholine should not be used routinely in children.[89,90] Increased jaw muscle tone after succinylcholine has been observed (masseter spasm), and this may be a normal variant. However, masseter tetany ("jaws of steel"), which prevents any mouth opening, may represent an extreme variation in increased masseter muscle tone and may be the reaction associated with malignant hyperthermia. I have observed this effect two times; in neither child did malignant hyperthermia develop, but one did have creatine kinase values greater than 20,000 IU the next morning.

With the foregoing cautions in mind, one should not yet completely abandon succinylcholine because it is the only commercially available ultrashort-acting muscle relaxant that provides a dependable, rapid onset of action. Intravenous use of this drug should be limited to children who have a full stomach or to treat laryngospasm; intramuscular or submental (intralingual) administration is indicated for children with difficult intravenous access when control of the airway is deemed essential.

There is hope on the horizon for a safer alternative for rapid-sequence intubation and for treatment of laryngospasm (i.e., high-dose rocuronium, 1.2 mg/kg).[91] If the new reversal agent sugammadex is demonstrated to be safe and effective in children (see further on) and its preliminary ability to antagonize profound neuromuscular blockade is confirmed in children, the vast majority of life-threatening adverse effects associated with succinylcholine will disappear (provided that the cost of sugammadex does not outweigh the potential benefits of avoiding succinylcholine).

Nondepolarizing Muscle Relaxants

A comparison of infants with older children or adults regarding their response to nondepolarizing muscle relaxants shows that infants are generally more sensitive to these drugs and that their response varies to a greater degree (also see Chapter 29). Although the initial dose per kilogram needed for neuromuscular blockade is often similar for children of all ages, the greater volume of distribution and reduced renal or hepatic function of neonates result in a slower rate of excretion and hence a prolongation of effect. Neuromuscular blockade occurs at a lower blood concentration.

The choice of nondepolarizing muscle relaxant depends on the side effects and the duration of muscle relaxation desired. If tachycardia is desired (e.g., with fentanyl anesthesia), pancuronium would be an appropriate choice. Vecuronium, atracurium, rocuronium, and cisatracurium are useful for shorter procedures in infants and children; they may also be administered as a constant infusion. The method of excretion of atracurium and cisatracurium (Hofmann elimination and ester hydrolysis) makes these relaxants particularly useful in newborns and children with liver or renal disease. Vecuronium is valuable because no histamine is released; however, its duration of action is prolonged in newborns, which makes it similar to pancuronium.

Rocuronium has a clinical profile similar to that of vecuronium, cisatracurium, and atracurium but offers the advantage that it can be administered intramuscularly. One study observed that acceptable conditions for intubation are produced by rocuronium within 3 to 4 minutes after 1 mg/kg intramuscularly in infants and

1.8 mg/kg intramuscularly in children older than 1 year; these effects were more dependable with deltoid than with quadriceps muscle injection.[92] This onset time is similar to that produced with intramuscular succinylcholine; however, the duration of action is approximately 1 hour, which could be a distinct disadvantage for a brief procedure. The onset of neuromuscular blockade with intravenous rocuronium (1.2 mg/kg) is also nearly the same as and intubation conditions are identical to those produced with intravenous succinylcholine (1.5 mg/kg).[91] I have used this intravenous rocuronium dose with thiopental (5 to 6 mg/kg) for rapid-sequence induction after preoxygenation in children in whom succinylcholine might present an added risk. Even better intubating conditions are achieved with the administration of lidocaine (1 mg/kg) and propofol (3.0 mg/kg) instead of thiopental just before rocuronium. Most children can be intubated at 45 seconds. The disadvantage is that the duration of action is 60 to 90 minutes, thus limiting its usefulness to either long procedures or accepting the fact that prolonged neuromuscular blockade is more desirable than the potential risk from but the shorter duration of succinylcholine. Conversely, at low doses of rocuronium (0.3 mg/kg), satisfactory conditions for intubation occur at about 3 minutes when combined with an inhaled drug, but successful reversal can usually be achieved within 15 to 20 minutes.

Table 82-4 provides commonly recommended guidelines for dosages. Because of the extreme variability in response, the doses of long-acting muscle relaxants used for infants should be titrated carefully, starting with one third to one half of the usual dose administered to older children. I recommend antagonism of neuromuscular blockade in all neonates and small infants, even if they have recovered clinically, because any increase in the work of breathing may cause fatigue and respiratory failure. Useful signs of reversal are the ability to lift the legs and arms and recovery of the train-of-four response to peripheral nerve stimulation.

Sugammadex

Sugammadex is a cyclodextrin whose endoskeleton forms a water-soluble complex with the exoskeleton of rocuronium; it was specifically designed to antagonize the effects of rocuronium (also see Chapter 29).[93-95] The purported advantage of this reversal agent is that antagonism occurs as a result of covalent bonding, and because sugammadex is made of sugars, the potential for adverse side effects would appear to be minimal.[94,96,97] This agent will also reverse the other steroidal relaxants vecuronium and pancuronium to a lesser extent. The mechanism of reversal is lowering of the plasma concentration and thus reversing the concentration gradient and pulling the rocuronium off the myoneural junction.[94,98,99] Data suggest more rapid antagonism than with neostigmine/atropine.[100] The importance of this new approach to antagonism of neuromuscular blockade is the ability to avoid all the side effects of neostigmine and anticholinergic medications, as well as the ability to antagonize profound neuromuscular blockade. This very exciting development could virtually eliminate the need for succinylcholine in pediatric practice, except perhaps for intramuscular use in children without intravenous access. Even in this circumstance, intramuscular rocuronium would be antagonized by sugammadex, provided that adequate doses are administered. Certainly, the adult data are very promising, and if it has a minimal adverse event profile, sugammadex may completely change our approach to anesthesia in children.

Anesthetic Considerations

Preoperative Preparation

The preoperative visit and preparation of the child for surgery are more important than the choice of premedication.[101] During this time the anesthesiologist evaluates the medical condition of the child, the needs of the planned surgical procedure, and the psychological makeup of the child and family. The anesthesiologist also formulates the approach to induction of anesthesia, explains the possibilities regarding induction, and helps soothe family concerns. Because the anxiety felt by the parents may be transferred to the child, any practice that reduces anxiety in the parents may also reduce anxiety in the child. Therefore, the anesthesiolo-

Table 82-4 Commonly Used Muscle Relaxants and Reversal Agents in Pediatrics

Drug	Average Intubation Dose (mg/kg)	Category	Approximate Duration
Muscle Relaxants*			
Pancuronium	0.1	Long acting	~45-60 min
Cisatracurium	0.1	Intermediate acting	~30 min
Vecuronium	0.1	Intermediate acting	~30 min
Rocuronium		Dose related:	
	0.3	Short acting	~15-20 min
	0.6	Intermediate acting	~30-45 min
	1.2	Long acting	~45-75 min
Reversal Agents†			
Edrophonium	0.3-1.0 mg/kg + atropine, 0.02 mg/kg		
Neostigmine	0.02-0.06 mg/kg + atropine, 0.02 mg/kg		

*The response of preterm and term neonates (who may be more sensitive to the drugs) to muscle relaxants varies greatly from patient to patient. Therefore, all doses should be titrated to response. The recommended intubation doses may be reduced 30% to 50% in the presence of a potent inhaled agent.
†The dose of reversal agent given to antagonize nondepolarizing neuromuscular blockade should be determined by the degree of residual neuromuscular blockade (i.e., the dose should be titrated to clinical effect).

gist should explain in great detail what the child and family can expect and what will be done to ensure the utmost safety. The more information that the parents and child have, the more easily they will deal with the stress of surgery and hospitalization. Presurgical programs such as videotapes, literature, and hospital tours also help.

After chart review, physical examination, and furnishing of information regarding the approximate time and length of surgery, the anesthesiologist should describe to the child what anesthesia is and what will be done to ensure good care. The purpose of all monitoring devices should be explained to both the child and family. Children need to understand that none of these devices will hurt and that they can watch during their application. If an intravenous line will be started, the child needs to be told that "numbing" medicine will be used. Any special monitoring devices, such as an arterial line, a central venous line, a nasogastric tube, or urine catheter, should also be described to the parents, with assurances that these devices will be inserted after induction of anesthesia. Part of this informed consent is also a description of our role in the operating room. It is vital to explain to the family that your anesthetic "prescription" will be tailored to meet their child's medical as well as surgical needs. I like to use the phrase "anesthetic prescription" because we are physicians, just as a surgeon or pediatrician, and it is important for families to clearly understand this.

Children think in very concrete terms, so care must be taken to avoid misunderstandings. It is important to explain to children that the "sleep" caused by anesthetic drugs differs from normal sleep They should know that the anesthesia medicines keep them from awakening during surgery and from remembering the operation. It should also be explained that the anesthesia medicines will be removed at the end of surgery and that they will then wake up and return to their parents. This kind of explanation does not require a significant amount of time and goes a long way toward reassuring the child and family about the quality of care provided.

The issue of pain must not be avoided. Children need to be reassured that everything possible will be done to minimize pain on awakening. Therefore, it should be stressed that pain medications will be administered and that local infiltration nerve blocks, continuous epidural or caudal infusions, child-controlled epidural analgesia, or patient/parent/nurse-controlled analgesia will be used (see also Chapter 87). The PACU or ICU must also be described so that there are no surprises.

The Fearful Child

There are some children who from either past experience or general lack of understanding are terrified to come to the operating room. When I see a child break into tears, if the child is old enough to talk with, I stop whatever is happening at the moment, sit on the bed next to the child, and ask what exactly is concerning them. Sometimes there is no response. In this situation I ask such children if they are afraid to go to sleep, afraid of feeling their operation, or afraid of pain afterward. Generally they are able to verbalize their concern, but even with no response at this point I reiterate that "*the sleep from anesthesia is different from sleep at home. At home if mom or dad shakes you, you would wake up. In the operating room no matter what we do you will not feel it, you will not remember it, and then at the end I will take the medicine away, you will breathe it all back out again, and then you will wake up and return to your family.*"

This explanation usually ends the tears. Sometimes the tears flow because they want a parent present for induction, even some of the older children. This is an easy request to grant, and it will also usually end the tears. If on the other hand there is a specific event in the past causing concern, it is important to investigate to see whether something was misunderstood or something can be carried out differently to avoid the issue. For some children with previous anesthetic experience, simply allowing them to hold the anesthesia mask themselves provides them with sufficient control of the situation to stop the tears. I once had a 7-year-old who wrote a will: "*leave my doll to, … leave my blanket to …*". When I asked her what this was all about, she responded that she was "*going to sleep today and that sometimes when people go to sleep they do not wake up.*" Because she had suffered a burn injury and needed many procedures, I explained to her that yes people can go to sleep and not wake up, but that this was usually an older person with a problem with the heart or the brain and that I had not seen this in someone her age having this operation. I asked her if she would feel better if she held the mask herself, and she in fact held the mask for a smooth anesthetic induction. In recovery she later thanked me as "*the first doctor that ever explained anything to me!*" This brief anecdote emphasizes the importance of talking directly to children regardless of their age. Finally, other children cannot be consoled and it is not possible to find the source of their concern. It is these children who will benefit from heavy premedication, such as the combined oral midazolam, ketamine, and atropine described earlier.

Fasting

A number of studies have found no difference in gastric residual volume or pH in children allowed to ingest unlimited clear liquids (water, apple juice) up until 2 to 3 hours before anesthetic induction versus standard fasting. This practice provides a more humane approach for both children and their parents without increasing the risk for pulmonary aspiration of gastric contents. Infants and young children have a higher metabolic rate and a larger body surface area–to-weight ratio than adults and become dehydrated more easily than adults. The major advantage of the liberalized fasting guidelines may be a reduced incidence of hypovolemia at the time of anesthetic induction. My approach is to restrict milk and solids after midnight but allow unlimited clear fluids up to 3 hours before induction; if there is a change in the operative schedule, I still feel comfortable with 2 hours of fasting (Table 82-5). Infants who are breast-fed may have their last breast milk 4 hours before induction of anesthesia. I consider breast milk to be equivalent to formula because the fat content varies with maternal diet and delayed gastric emptying may result. The American Society of Anesthesiologists (ASA) guideline also allows a "light meal" of toast and clear liquids up to 6 hours before induction of anesthesia, but I have found that parents frequently confuse this to mean any type of meal, including eggs and bacon![102]

Table 82-5 Fasting Guidelines for Pediatric Patients

	Fasting Time (hr)*	
Age	**Milk and Solids**	**Clear Liquids**
<6 months	4	2
6-36 months	6	3
>36 months	8	3

*Note that the American Society of Anesthesiologists guideline allows a "light breakfast" (tea and plain toast) 6 hours before anesthesia; however, it is difficult to determine what a "light breakfast" is for a child.

Premedication

The many published reports on premedication have produced approximately the same results: Almost all sedatives are effective. The important issue is effectiveness for individual anesthesiologists at their own institutions. The need for premedication must be individualized according to the underlying medical conditions, the length of surgery, the desired induction of anesthesia, and the psychological makeup of the child and family. Premedication is not normally necessary for the usual 6-month-old infant but is warranted for a 10- to 12-month-old who is afraid to be separated from parents. Oral midazolam is the most commonly administered premedication in the United States. An oral dose of 0.25 to 0.33 mg/kg (maximum, 20 mg) generally results in a very compliant child who will separate from parents without crying.[51] A review of previous anesthetic records is particularly helpful in ascertaining how the child has responded in the past.

Premedications may be administered orally, intramuscularly, intravenously, rectally, sublingually, or nasally. Although most of these routes are effective and reliable, each has drawbacks. Oral or sublingual premedication does not hurt but may have a slow onset or be spit out; drug taste and child cooperation are the main determinants of success. Intramuscular medications hurt and may result in a sterile abscess. Intravenous medications may be painful during injection or at the start of infusion. Rectal medications sometimes make the child feel uncomfortable, cause defecation, and occasionally burn. Nasal medications can be irritating, although absorption is rapid. Midrange doses of *intramuscular* ketamine (2 to 4 mg/kg) combined with atropine (0.02 mg/kg) and midazolam (0.05 mg/kg), or *oral* ketamine (4 to 6 mg/kg) combined with atropine (0.02 mg/kg) and midazolam (0.5 mg/kg, maximum of 20 mg), will result in a deeply sedated child.[103] This combination is generally reserved for children who refuse oral premedication or those in whom lighter premedication regimens have failed in the past. Higher doses of intramuscular ketamine (up to 10 mg/kg) combined with atropine and midazolam may be administered to children with anticipated difficult venous access or in whom an intravenous line is necessary for induction (e.g., infants with congenital heart disease) to provide better conditions for insertion of an intravenous line.

Anticholinergic drugs are not routinely administered intramuscularly to children because they are painful on administration and do not significantly reduce laryngeal reflexes during induction of anesthesia. On the other hand, atropine (0.02 mg/kg) administered orally or intramuscularly less than 45 minutes before induction does reduce the incidence of hypotension during induction with potent inhaled anesthetics, but only in infants younger than 6 months.[104]

The Child with an Upper Respiratory Tract Infection

A child with a URI is a major concern for the anesthesiologist because the anesthetic implications can be quite important. Unfortunately, data regarding URIs and the anesthetic implications are difficult to place in perspective because complications are not particularly common and the definition of what a URI consists of has varied from study to study. The decision whether to proceed with surgery and anesthesia is dependent on a number of factors. The URI may represent a prodrome of a much more serious illness, or it may simply be the usual viral infection so common in children, particularly in the wintertime. It is likely that a child with a URI has an irritable airway and is at increased risk for laryngospasm, bronchospasm, postintubation croup, atelectasis, pneumonia, and episodes of desaturation. Several studies have found an increased incidence of airway-related problems in children who are passively exposed to tobacco smoke.[105-107] These complications can be reduced by avoiding endotracheal intubation or using a supraglottic device such as an LMA. However, the incidence of adverse airway-related events is not reduced by the administration of anticholinergics or bronchodilators.[108,109] Because bronchial hyperreactivity may last for up to 6 weeks after a URI, cancellation will make a difference only if surgery is delayed for this amount of time or longer.[110,111] It is also known that there is virtually the same incidence of airway-associated complications in children who are recovering from a URI as for those in the acute phases of a URI.[105,111,112] The approach that I take with these children is rather commonsense. If the child is acutely ill and obviously getting worse, the case is canceled. If the child has rhonchi and a productive cough, the case is canceled. If the child is stable and afebrile and has had the URI for several days, I usually proceed. My main concern is with a child who is going to have a very long procedure or will be admitted to the hospital postoperatively, which may in turn result in exposure of other hospitalized children who may be immunocompromised. When faced with this dilemma for a child who will be going home postoperatively, I inform the family and the surgeon of the increased risks, and they generally end up making the decision to proceed. It is my feeling that we have the tools to successfully manage the reasonably common complications. We have oxygen to treat hypoxemia, we have albuterol and inhaled anesthetics to treat bronchospasm, we have muscle relaxants to treat laryngospasm, and we can usually find a way to avoid intubation for simple procedures. Cancellation of a procedure at the last minute is unfair to the family and upsets the operating room schedule. On the other hand, one should not place the child at risk merely for economic or social concerns. The best way of avoiding last-minute cancellations is a phone call by nursing staff the day before to inquire about the child's health. If the child has a URI, the anesthesiologist can call the family and take a history to determine how best to proceed. In this way wasted trips to the hospital are avoided and the father or mother, or both, do not take a day off work unnecessarily. Physicians are really left to their own best clinical judgment for an individual child on a particular day undergoing a specific procedure. If the decision is made to

proceed, it is helpful to write a note in the chart documenting the discussion.

Induction of Anesthesia

The method of inducing anesthesia is determined by a number of factors: the medical condition of the child, the surgical procedure, the level of anxiety of the child, the child's ability to cooperate and communicate (because of age, developmental delay, or language barrier), the presence or absence of a full stomach, and other factors.

Infants

Mask induction without premedication is generally used in infants younger than 10 to 12 months because this age group readily separates from their parents. Induction by mask is accomplished most easily by holding the end of the anesthesia circuit in a cupped hand over the infant's face or by holding the mask just off the surface of the face; the other hand can adjust the concentration of anesthetic. Allowing neonates and small infants to suck on a rubber nipple or on a gloved finger generally prevents crying during induction. As the infant loses consciousness, the anesthesia mask is adjusted to improve delivery and decrease operating room pollution. This phase is the most dangerous time because it is very easy to misjudge the depth of anesthesia and depress the heart. Once anesthesia has been induced, it is critical to rapidly reduce the inspired concentration of halothane (down to 1.0% to 1.5%) or sevoflurane (down to 2% to 4%) and to keep it at this level or less until an intravenous line is in place. After the intravenous line is inserted, one may either deepen the plane of anesthesia or add a muscle relaxant. It is dangerous to proceed directly to a deep plane of anesthesia without having an intravenous line in place; without this precaution, resuscitation would be difficult.

The second most dangerous point occurs immediately after endotracheal intubation. If the vaporizer has not been closed before laryngoscopy, it is easy to forget that a relatively high inspired concentration is being delivered and, during checking for breath sounds, to perhaps give an overdose of inhaled anesthetic. Therefore, the prudent clinician will discontinue all anesthetics until laryngoscopy and endotracheal intubation have been completed. With a Mapleson D circuit, a high concentration of anesthetic can be delivered more easily because the anesthetic enters directly at the airway. In contrast, changes made at the vaporizer of a circle system take a longer time to achieve equilibration with the circuit; therefore, the inspired concentration of anesthetic rises (or decreases) more gradually unless high fresh gas flow is being used. Particular caution should be used when changing from sevoflurane to halothane or isoflurane because the myocardial depressant effects of these drugs are additive.

Older Pediatric Patients

Successful, psychologically atraumatic induction of anesthesia by mask in an older pediatric patient requires that the child understand and cooperate. Premedication is particularly helpful in the 1- to 4-year-old age group. Several different techniques may be used. One method is to play a game. For example, a smaller child may be asked to "*blow up the balloon*." A slightly older child (4 years and older) may be receptive to hypnotic suggestions during induction. A young child may be susceptible to a suggestion that the anesthesia mask is an "*airplane pilot's mask*" and that the smell of halothane or sevoflurane is "*oxygen*" or "*aviation fuel*." Stating that the "*faster and higher the plane goes, the stronger the aviation fuel smell*" is one means of distracting the child. During this type of induction, the operating room must be free of distractions, and the anesthesiologist must be able to communicate with the child. The use of constant conversation and incremental increases in the inspired concentration of anesthetic every third or fourth breath usually produce a smooth transition to general anesthesia. Often the child will breath-hold. If so, the anesthesiologist should not attempt to assist respiration because this action often elicits coughing or laryngospasm. The anesthesiologist must be certain that airway obstruction and laryngospasm can be differentiated from breath-holding. Observing the chest wall and abdomen helps identify airway obstruction, which creates a rocking-type movement of the chest and abdomen (when the diaphragm descends, the abdomen appears to expand but the chest does not). As soon as the child loses consciousness, the inspired concentration of anesthetic can be reduced and an intravenous line inserted. Should partial laryngospasm or upper airway obstruction occur, closing the pop-off valve to create approximately 10 to 15 cm H_2O of positive pressure, while allowing the child to breathe spontaneously, often facilitates gas exchange. If this procedure is not effective, administration of rapid positive-pressure breaths, while avoiding inflation of the stomach, often disrupts the laryngospasm. Obviously, administration of a muscle relaxant will also break the laryngospasm; succinylcholine remains the agent of choice in an emergency situation.

A third method of induction involves the use of flavored masks. A variety of flavored scents (Loran Oils, Inc., Lansing, MI) are available to reduce the noxious smell of anesthetics; the child can select a favorite scent.

A fourth method, the single-breath technique, requires a very cooperative child who can follow instructions. Using an unattached anesthesia mask, the anesthesiologist should demonstrate the procedure to the child, who then rehearses the following steps: (1) take a big breath in and hold at full inspiration; (2) exhale completely, hold at full expiration, and place the mask on the child's face at exactly the end of expiration; (3) take another full inspiration held as long as possible; (4) and then resume normal breathing. Before induction, the anesthesia circuit is filled with either 5% halothane or 8% sevoflurane in 60% nitrous oxide. The circuit bag must be emptied and filled several times so that the entire circuit is filled with 5% halothane or 8% sevoflurane. Steps 1 to 4 are then repeated with the mask attached to the Y-piece of the anesthesia circuit. When placing the facemask, care should be taken to not direct the gas toward the eyes because this can frighten the child. If the child fully cooperates, this generally produces loss of the eyelid reflex in less than 1 minute. Occasionally, a child does not take a full breath or becomes frightened, or application of the facemask was not complete. If the child is partially anesthetized, induction takes slightly longer, but the child does not usually remember the induction. If the child panics before inhalation of anesthetic, induction should not be forced, and an alternative plan should be undertaken.

Parents in the Operating Room

It is very common for parents to request to be present during induction of anesthesia. I welcome their participation in this

process (usually limited to one parent) because on some occasions, the security of having a parent present and avoiding separation allows us to omit premedication. *Parental presence should not be substituted for premedication if the child needs premedication.* In other situations, parental presence reduces anxiety sufficiently so that light premedication is adequate. Decisions regarding parental presence must, however, take into consideration the developmental level of the child and the reason for their presence. It serves no purpose to have a parent present during induction of anesthesia in a newborn or a 6-month-old who is completely trusting of strangers. Likewise, it is unlikely to benefit a child who has been heavily premedicated. Certainly, parents must not be present for rapid induction in the presence of a full stomach. Parents are present for the benefit of their child, and if the child does not benefit or if it makes the physicians uncomfortable, a parent should not be present. The safety and care of the child are top priority. I sometimes even explain that their participation in this process is a privilege but not a right. Each physician and each institution must determine what works and what does not work for them. If I make a decision to allow a parent to be present, it is vital to explain to them what they might see so that there are no surprises. I explain that "*when anyone goes to sleep their eyes roll upward*." This is a normal response, and they might see their child do this a few times. I assure them that they should expect this and not to worry that something is wrong. I next warn them that as children fall asleep "*they often make noises from their throat*" (e.g., snoring) and that this is also normal and that they might hear noises from their child's throat as their child falls asleep (I do not explain that this might be airway obstruction or developing laryngospasm). Third, I point out that the "*brain often gets excited before it goes to sleep*"; thus, after their child breathes the anesthesia medicine for 15 to 30 seconds, it is common for the child to suddenly become restless and move the arms and legs. This response is expected, and shortly afterward their child will be completely anesthetized. I further explain that despite appearing to be awake, they do not remember this at all. Thus, the eye rolling, possible airway obstruction, and excitement are all explained and the parent is not frightened should any of these events occur. I also make sure that the parent is sitting in a chair and explain that as soon as we ask them to leave, they must do so because at that point we must completely focus on the care of their child.

For smaller children I like to anesthetize them on the parent's lap. I have the child facing straight forward with the parent's arms wrapped around the child and helping to hold the arms near the child's side to reduce the potential for them to reach up and grab the mask. I explain to the parent that they are going to be able to hug their child as they go to sleep. I also explain that the child will become limp and could fall unless they hold on tight. I further state that as their child looses consciousness, we will pick up their child and place him/her on the operating room table. They can then kiss their child and proceed to the family waiting area. If there is a language barrier, I will ask a translator to help explain this process and allow the translator in the operating room to assist in the communication that is needed to perform a nontraumatic mask induction.

Rectal Induction of Anesthesia

A number of medications may be administered rectally for induction/premedication of anesthesia (methohexital, thiopental, ketamine, midazolam). The main advantage of this approach is that the child falls asleep in the parent's arms or, as is the case with midazolam, separates atraumatically from the parents. This technique is no more intimidating than taking a rectal temperature but is generally reserved for children still in diapers. Care must be taken to not allow the child to see the rectal catheter or syringe, which would appear very large to the child. Rectal administration of 10% methohexital (20 to 30 mg/kg) reliably induces anesthesia within 8 to 10 minutes in 85% of young children and toddlers. Oxygen desaturation is not usually a problem unless the child's head is allowed to flex forward and cause obstruction of the airway. The main disadvantage of this technique is that there can be either markedly delayed or very rapid drug absorption. Other drugs administered rectally include 10% thiopental (20 to 30 mg/kg), midazolam (1 mg/kg up to 20 mg), and ketamine (6 mg/kg).

Intramuscular Induction of Anesthesia

Many medications, such as methohexital (10 mg/kg), ketamine (2 to 10 mg/kg combined with atropine [0.02 mg/kg] and midazolam [0.5 mg/kg]), or midazolam alone (0.15 to 0.2 mg/kg), are administered intramuscularly for premedication or induction of anesthesia. The main advantage of this route of administration is its reliability; its main disadvantage is that it is painful.

Intravenous Induction of Anesthesia

Intravenous induction of anesthesia is the most reliable and rapid technique. The main disadvantage is that starting an intravenous line can be painful and threatening for the child. Intravenous induction may be preferable when induction by mask is contraindicated (e.g., in the presence of a full stomach). A two-needle technique using a butterfly-type catheter with a 25-gauge needle is suitable for induction of anesthesia, followed by placement of an intravenous catheter once anesthesia is safely induced. Older children will often allow insertion of an intravenous catheter after the administration of 50% nitrous oxide and local anesthetic; topical anesthetic creams (e.g., EMLA, ELA-Max) are also well received. It is important to emphasize to the child that this procedure will not be excessively painful. Occasionally, children will cry with infiltration of local anesthetic and become hysterical when they see the intravenous catheter. Two maneuvers help minimize this response: (1) do not allow the child to see the catheter, and (2) puncture the anesthetized area with a needle, ask the child to look at the needle, and then ask if there is any sensation. Frequently the child is astounded at the lack of pain and stops crying.

Pediatric Airway Management

Endotracheal Tubes

For most children, the proper size of endotracheal tube and the proper distance of insertion relative to the alveolar ridge of the mandible or maxilla are moderately constant (also see Chapter 50). Published formulas are estimates that may need to be modified based on physical examination or unusual child size. Table 82-6 provides a guide to choosing the proper size of endotracheal tube and the recommended distance for insertion (from the alveolar ridge). Uncuffed endotracheal tubes were traditionally preferred for children younger than 6 years (see earlier discussion). Figure 82-4 illustrates a new cuffed endotracheal tube that may offer specific advantages over traditional cuffed endotracheal tubes. If one uses a cuffed endotracheal tube, a half-size smaller

Table 82-6 Recommended Sizes and Distance of Insertion of Endotracheal Tubes and Laryngoscope Blades for Use in Pediatric Patients

Age of Patient	Internal Diameter of Endotracheal Tube (mm)	Recommended Size of Laryngoscope Straight Blade	Distance of Insertion* (cm)
Preterm (<1250 g)	2.5 uncuffed	0	6-7
Full term	3.0 uncuffed	0-1	8-10
1 yr	3.5-4.0 cuffed	1	11
2 yr	4.5-5.0 cuffed	1-1.5	12
6 yr	5.0-5.5 cuffed	1.5-2	15
10 yr	6.0-6.5 cuffed	2-3	17
18 yr	7-8 cuffed	3	19

*Inserting the endotracheal tube this distance from the alveolar ridge of the mandible or maxilla places the distal end of the tube in the midtrachea.

than for an uncuffed endotracheal tube should be selected, and cuff pressure should be adjusted so that there is a small leak around the cuff at a peak inflation pressure of 20 to 30 cm H_2O. Cuff pressure should be checked periodically during anesthesia involving nitrous oxide. If an uncuffed endotracheal tube is used, the appropriate size allows a small gas leak at peak inflation pressures of 20 to 30 cm H_2O. If an uncuffed endotracheal tube (or a cuffed tube without the cuff inflated) does not leak at 40 cm H_2O, I will replace it with the next smaller size and recheck for a leak. It is always important to make this leak assessment to determine the size of the larynx. On average, several children per year in my practice have undiagnosed subglottic stenosis detected by the anesthesiologist at the time of intubation (Fig. 82-11).

Laryngoscope Blades

Any hospital that takes care of children must have a full selection of laryngoscope blades so that the blade most appropriate for the child is readily available. In general, straight blades are used in neonates and toddlers because of anatomic differences from older children (see earlier); the Wis-Hippel 1.5 is a particularly versatile blade because its surface is flat. Older children can be managed with either curved or straight blades. In some children a straight blade may offer advantage over curved blades because of midfacial hypoplasia or other anatomic deformity (Table 82-6). A laryngoscope blade with built-in oxygen delivery is available in sizes 0 and 1 and offers specific advantage for awake or sedated intubation of neonates (Fig. 82-12).

The Child with a Full Stomach

A child with a full stomach must be treated the same as for an adult with a full stomach; that is, both should undergo rapid-sequence induction of anesthesia with the application of cricoid pressure (also see Chapters 29 and 50). Because oxygen consumption is much greater, hemoglobin desaturation occurs more rapidly in a child than in an adult and more rapidly in an infant than in a child. Additionally, a child may be uncooperative and refuse to breathe oxygen before induction of anesthesia—that is, refuse preoxygenation. In this circumstance, the best that can be done is to enrich the environment with a high flow of oxygen because upsetting the child further is not desirable. Additional equipment that should be available includes two suction catheters (if one becomes blocked, another would be available immediately) and two appropriately sized laryngoscope blades (e.g., a Macintosh 2 and a Miller 2) with two handles (if the bulb, contact, or battery fails, another would be available immediately). While the child is breathing oxygen, atropine (0.02 mg/kg) is administered intravenously to prevent reflex- or succinylcholine-induced

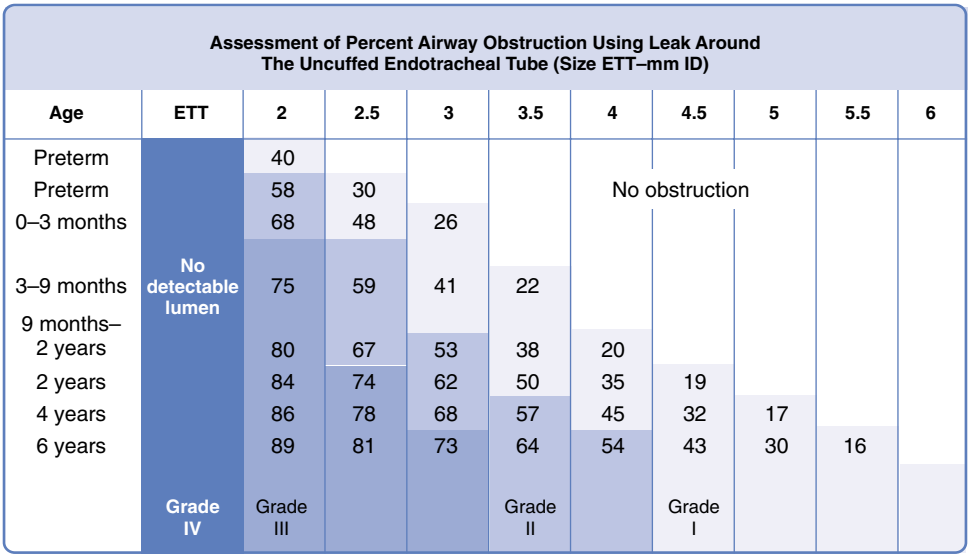

Figure 82-11 Method of determining the percentage of airway obstruction. After easy passage of an uncuffed endotracheal tube (ETT), a manometer is placed at the connection of the elbow of the anesthesia circuit and the ETT. A stethoscope is placed over the larynx and the circuit slowly pressurized. The pressure at which a leak is auscultated is matched with the age of the child and the size of the ETT to assess the degree of laryngeal narrowing. It should be noted that this chart is based on one institution's experience and the manufacturer of the ETTs was not described, so the actual external diameter of the ETTs used is unknown. *(Reproduced and modified with permission from Myer CM 3rd, O'Connor DM, Cotton RT: Proposed grading system for subglottic stenosis based on endotracheal tube sizes. Ann Otol Rhinol Laryngol 103:319-323, 1994.)*

Figure 82-12 The Oxyscope (Heine Optotechnik, D-82211 Herrsching, DE) is a Miller 1 laryngoscope blade with an insufflation channel along its length so that it may be attached to an oxygen source. An Oxyscope provides increased F_{IO_2} and is particularly useful for intubation in a conscious neonate whose oxygen consumption is high and in whom desaturation may develop rapidly.

bradycardia and to delay the bradycardia of hypoxemia should any of these events occur. Because of its rapid onset of neuromuscular blockade, succinylcholine is still the muscle relaxant of choice in this circumstance and should be administered at a dose of 1 to 2 mg/kg immediately after thiopental (5 to 6 mg/kg) or propofol (3 mg/kg). Cricoid pressure is gently applied after the child loses consciousness. Children should be told that they may "*feel someone touching you on the neck*" as they fall asleep and that this is "*normal*." In children, the head-up position does not significantly increase protection from pulmonary aspiration of acid gastric contents. If succinylcholine is contraindicated, rocuronium (1.2 mg/kg) will provide conditions for intubation similar to those provided with succinylcholine within 30 seconds of administration.[91] However, the duration of neuromuscular blockade will be 60 to 90 minutes (see earlier and Chapter 29). In the hypovolemic child, ketamine (2 mg/kg) may be used for induction, whereas in a child with hemodynamic instability, e.g., cardiomyopathy, etomidate (0.2-0.3 mg/kg) may be a better choice.

The Difficult Airway

The approach to a difficult airway depends in part on whether it is a known difficult airway and previous records are available for review or whether the child has an unexpectedly difficult airway. In the former situation, a difficult-airway cart with age- and size-appropriate airway equipment (Table 82-7) is brought into the operating room, and the assistance of a colleague with pediatric airway skills is arranged. In the latter situation, the difficult-airway cart may need to be brought into the room and skilled help summoned. The most common errors that I have observed in a number of malpractice cases are lack of equipment or inappropriately sized equipment, inadequate skilled help, failure or delay in calling for help, and failure of the anesthesiologist to attempt cricothyrotomy soon enough. Accordingly, the importance of having a dedicated pediatric difficult-airway cart, the need to be familiar with its contents and how to use the devices that it contains, and the availability of skilled help cannot be overemphasized.

A child facing a potentially difficult laryngoscopic procedure should receive, at most, light sedation before induction of anesthesia by mask to maintain spontaneous respirations. In this way the airway can be secured before "burning bridges" by administering a muscle relaxant and losing the help of spontaneous respirations. With the child breathing spontaneously, breath sounds can be used to guide successful tracheal intubation. When normal airway anatomy cannot be confirmed visually, placing a stylet in the endotracheal tube and bending the tip of the endotracheal tube acutely (90 degree bend) allows placement of the tip

Table 82-7 Suggested Equipment for a Difficult-Airway Cart

Equipment Category	Recommended Equipment
Airways	Oral and nasopharyngeal (trumpet) airways in all sizes for preterm infants to adults
Endotracheal tubes	Cuffed and uncuffed endotracheal tubes of various size (uncuffed down to size 2.0 mm ID)
Stylets	Stylets in several sizes
Laryngoscopy	Laryngoscope blades in multiple sizes and configurations Several handles, extra batteries Oxyscope (Heine Optotechnik, D-82211 Herrsching)
Laryngeal mask airways	All sizes 1.0 to 6.0 ProSeal LMAs for patients with a full stomach or those who require higher peak inflation pressure for successful ventilation Large-volume syringes for the larger masks
Fiberoptic intubation	Fiberoptic scopes—several sizes, including one that will fit through a 2.5-mm ID endotracheal tube Light source Teeth protectors Oral airways designed for fiberoptic intubation Silicon lubricant
Retrograde equipment	Retrograde intubation equipment (needle with guidewire)
Optical stylet	Available in a variety of sizes, including one that will fit through a 2.5-mm ID endotracheal tube (Storz, Karl Storz GmbH & Co. KG, Tuttlingen, Germany) or a 3.0-mm ID endotracheal tube (Shikani, Clarus Medical, Minneapolis, MN)
Endotracheal tube exchangers	Various sizes for the full array of pediatric patients
Cricothyrotomy equipment	Percutaneous cricothyrotomy kits designed for older and larger children (needles, guidewire, and dilator) Jet ventilation–type device, which is similar to an intravenous catheter (18, 14, and 13 gauge) and useful in infants
Jet ventilation equipment	Jet ventilation stylets and jet injector with an appropriate hookup for wall oxygen
Carbon dioxide detector	For use in non–operating room venues

ID, internal diameter.

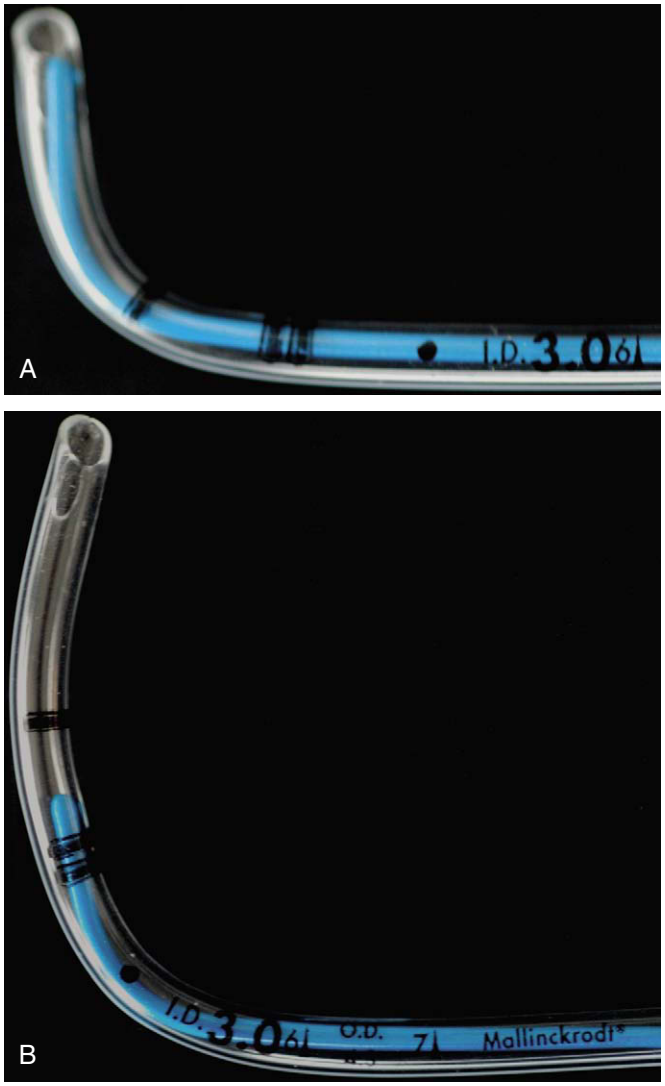

Figure 82-13 In patients with midfacial hypoplasia or those in a cervical collar, it is necessary to make a nearly 90-degree bend around the base of the tongue to enter the larynx. If one inserts a stylet into an endotracheal tube with a 90-degree bend (**A**), listens for breath sounds emerging from the proximal end of the endotracheal tube, and then when good breath sounds are heard, threads the endotracheal tube off the stylet (not advancing the stylet), the tube will make the bend around the base of the tongue and pass into the trachea (**B**).

of the endotracheal tube in the midline just posterior to the epiglottis. One can then listen for breath sounds exiting from the end of the endotracheal tube, and once good air exchange is heard, the endotracheal tube is advanced off the stylet (not inserted with the stylet) (Fig. 82-13). This technique allows advancement of the endotracheal tube at an acute angle without causing trauma to anatomic structures. If the child is not breathing spontaneously, this advantage may be lost. Spontaneous respiration with a facemask designed to allow fiberoptic intubation is another approach. Having a skilled assistant pull the tongue forward out of the mouth with a dry gauze or plastic retractor will also aid visualization of the glottic opening. Fiberoptic intubation through an LMA requires the use of two endotracheal tubes threaded on the fiberoptic scope (the second to hold the first in position while removing the LMA). The LMA is perhaps the most important adjunct to airway management because it can

Laryngeal Mask Size	Patient Weight
1	≤5 kg
1.5	5-10 kg
2	10-20 kg
2.5	20-30 kg
3	30-50 kg
4	50-70 kg
5	70-100 kg
6	>100 kg

*Manufacturer's recommendations (LMA North America).

establish a patent airway before the airway is secured more definitively with an endotracheal tube or a cricothyrotomy (Table 82-8). In neonates with difficult airways such as those with Goldenhar, Treacher-Collins, or Pierre Robin syndrome, awake topicalization of the airway with lidocaine (1% nebulized to avoid excessive doses) followed by placement of an LMA is very helpful in guiding awake/sedated fiberoptic intubation. A skilled assistant who can hold the head in proper position and assist with the difficult airway is critical to the success of most of these approaches to a difficult airway. It should be noted that in children the ProSeal LMA will allow ventilation at significantly higher peak inflation pressures (~25 cm H_2O) than possible with the classic LMA (~15 cm H_2O); thus, this device may be preferable in a difficult airway situation, especially since the stomach can be suctioned.[113]

If the child should progress to a "cannot ventilate, cannot intubate" situation, one must immediately establish a surgical airway. It is vital to properly position the child with a roll of towels under the shoulders to force the larynx anteriorly so that the best access to the larynx is provided. It is also important to have a variety of cricothyrotomy devices available, because some are appropriate for infants, whereas others are appropriate only for older children and teenagers. Devices appropriate for older children include some using the Seldinger technique (cricothyroid puncture, passing a guidewire, skin incision, then passing a dilator/catheter over the wire) (e.g., Arndt and Melker kits, Cook Critical Care, Inc., Bloomington IN) or use of an armored transtracheal catheter (Cook Critical Care). The simplest cricothyrotomy devices that can be used in children of all ages, including infants, is an intravenous catheter, which can then be interfaced with the 15-mm connector of a 3-mm internal diameter (ID) endotracheal tube.[114] Alternatively, a preformed device designed exactly like an intravenous catheter but with a built-in 15-mm connector is available. This device comes in three sizes (18, 14, and 13 gauge) and also has a Luer-Lok connection to allow transtracheal jet ventilation (Fig. 82-14) (Ventilation-Catheter, VBM Medical, Noblesville, IN). Other emergency airway devices include a stiletted endotracheal tube changer (used as a bougie) that has both 15-mm and Luer-Lok adapters (Cook, Inc., Bloomington, IN) (Fig. 82-15). A simple method for administering oxygen to the Luer-Lok without the high pressure of a jet ventilator is to use standard oxygen tubing with a hole cut in the side; occlusion and unocclusion of the hole will direct oxygen (1 to 5 L/min) through the catheter. Note that whenever

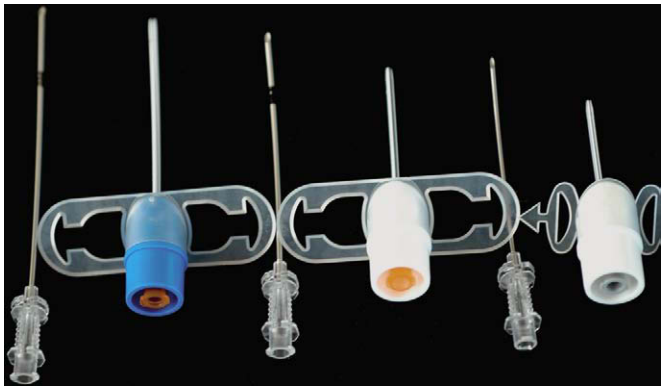

Figure 82-14 This device designed for transtracheal ventilation provides one of the best systems for emergency airway management in a child with a "cannot ventilate, cannot intubate" airway situation (Ventilation-Catheter, VBM Medical, Noblesville, IN). Note that the design is similar to that of an intravenous catheter, which means that the principles for use are familiar to all anesthesiologists, and the device is small enough to allow use even in neonates. In addition to a secure 15-mm adapter for interface with any standard bag ventilation device, there is a Luer-Lok connection that allows jet ventilation. Three sizes are available: 16 gauge (infant), 14 gauge (child), and 13 gauge (adult).

such a technique is applied, it is vital to ensure that the catheter is correctly positioned within the trachea to avoid barotrauma and that the chest is deflating between breaths.

The Child with Stridor

A child with intrathoracic airway obstruction has expiratory stridor and prolonged expiration (bronchiolitis, asthma, intrathoracic foreign body). In contrast, a child with extrathoracic upper airway obstruction has inspiratory stridor (epiglottitis, laryngotracheobronchitis, laryngeal or subglottic foreign body). When agitated or crying, such children exhibit dynamic collapse of the airway (Fig. 82-16), which can markedly worsen airway obstruction and lead to respiratory failure and hypoxemia. Therefore, events that can upset the child (drawing of blood for analysis of gases, venipuncture for blood tests, and separation from parents) must be minimized. The difficult-airway cart should also be present in the room. The surgical team should be mobilized and be prepared to perform an emergency tracheotomy should total airway obstruction occur and mask ventilation or endotracheal intubation not be possible.

I have found the following procedure to be effective for inducing anesthesia in a child with stridor. To minimize upsetting the child, the child is brought to the operating room with the mother or father, who holds the child during induction. Induction of anesthesia with halothane or sevoflurane in oxygen by mask is the preferred method because maintaining spontaneous respirations is critical. As soon as the child loses consciousness, the parent is escorted out of the operating room. With the child lightly anesthetized and after infiltration of local anesthetic, an intravenous line is inserted. This allows withdrawal of blood samples if indicated. Hydration is begun with lactated Ringer's solution (15 to 30 mL/kg), and atropine (0.02 mg/kg) is given. At this point the plane of anesthesia can be deepened with greater safety. If the stridor worsens or mild laryngospasm occurs, the pop-off valve is closed sufficiently to develop 10 to 15 cm H_2O of PEEP. This procedure relieves most instances of airway obstruction caused by dynamic collapse of the airway and loss of pharyngeal muscle tone when the child attempts to inspire against an obstructed airway (Fig. 82-17). As the level of anesthesia deepens, gentle assistance with ventilation may be necessary; however, maintaining spontaneous respiratory effort is important if possible.

Any child with airway obstruction will have a long, slow induction of anesthesia before becoming sufficiently anesthetized

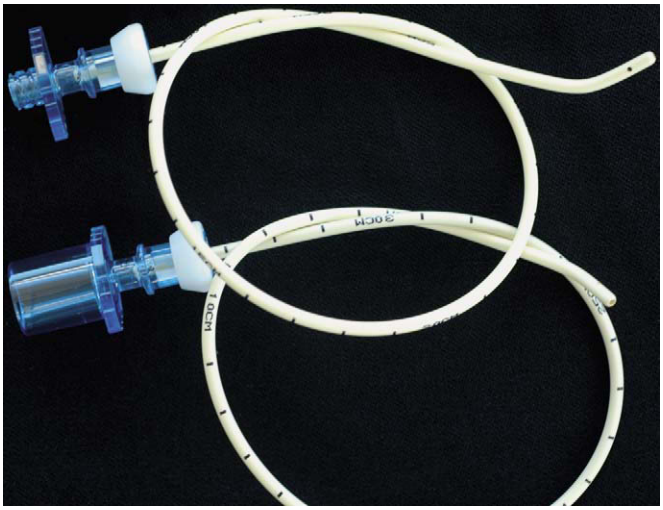

Figure 82-15 Endotracheal tube exchangers are available that will fit 3.0-mm internal diameter endotracheal tubes. They have side holes at the tip that allow delivery of oxygen and may be attached to either a jet ventilation system or standard adaptors with a 22-mm outside diameter. This device is also available with a stylet and slight bend to be used as an intubation bougie. *(Courtesy of Cook, Inc., Bloomington IN.)*

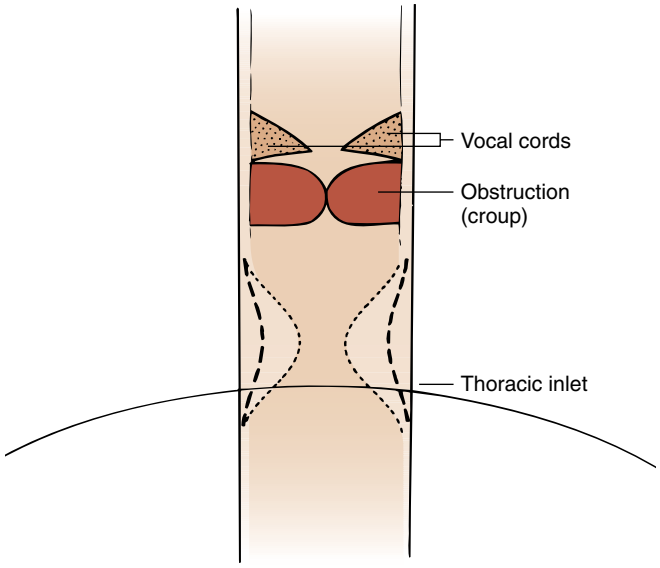

Figure 82-16 Infants and young children have highly compliant airway structures. With normal respiration, some dynamic collapse of the extrathoracic upper airway occurs (*broken line*). When a child has upper airway obstruction (as in epiglottis, laryngotracheobronchitis, or extrathoracic foreign body) (*dark orange*) and struggles to breathe against this obstruction, dynamic collapse of the trachea increases. This increase in dynamic collapse (*dotted line*) augments the mechanical obstruction of the airway. Therefore, until the airway is secured, it is important to avoid procedures that will upset the child. *(Modified from Coté CJ, Lerman J, Todres ID [eds]: A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, Saunders, 2008.)*

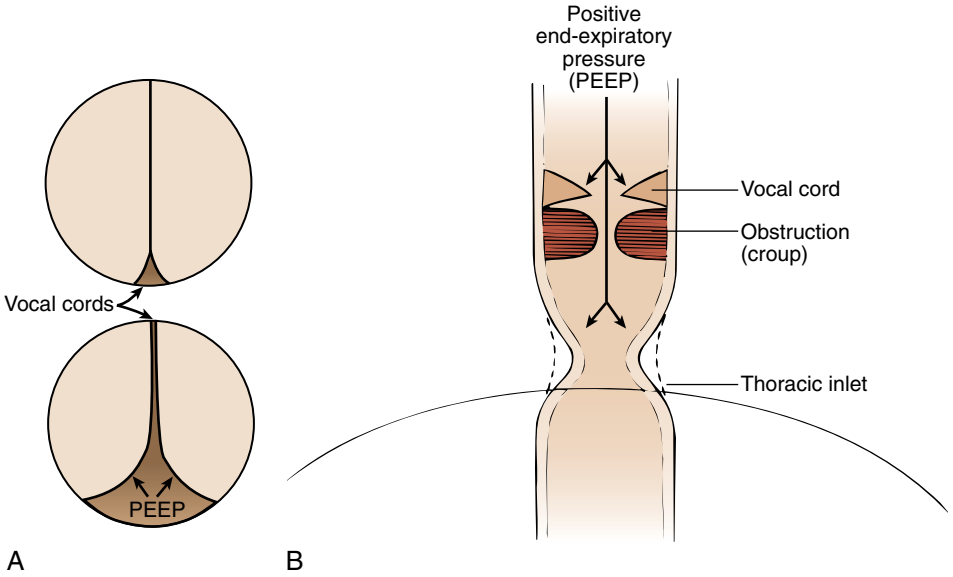

Figure 82-17 When a child has upper airway obstruction caused by laryngospasm (**A**) or mechanical obstruction (**B**), application of approximately 10-15 cm H_2O of positive end-expiratory pressure (PEEP) (*arrows*) during spontaneous breathing often relieves the obstruction. That is, PEEP helps keep the vocal cords apart (**A**) and the airway open (**B,** *broken lines*). If this simple maneuver does not relieve the obstruction, more vigorous positive-pressure ventilation may be necessary. Airway obstruction caused by the tongue requires insertion of an appropriately sized oral airway.

to permit laryngoscopy and endotracheal intubation. Because a sevoflurane vaporizer allows only 2.5 to 3 MAC concentrations to be delivered whereas a halothane vaporizer allows 5 to 6 MAC concentrations, halothane would be my drug of choice in this circumstance (if available). In addition, the slower excretion of halothane than of sevoflurane would also provide better conditions for airway manipulation for a longer time. The issue of a full stomach is secondary to the airway problem; rapid induction of anesthesia is contraindicated in these children. A child with laryngotracheobronchitis or epiglottitis usually requires an uncuffed endotracheal tube that is 0.5 to 1.0 mm (ID) smaller than normal; use of a stylet facilitates its insertion. Management of a difficult airway is also discussed in Chapter 50.

Intravenous Fluid and Transfusion Therapy

Intravenous Fluids

The approach to intravenous fluid therapy in children must consider their high metabolic demands and high ratio of body surface area to weight (also see Chapters 54 and 55). The basis for calculating maintenance fluids derives from data by Holliday and Segar,[115] who found that daily fluid requirements depend directly on metabolic demand—specifically, that 100 mL of water is required for each 100 calories of expended energy. Relating this to weight produces hourly fluid requirements of 4 mL/kg for children up to 10 kg, an additional 2 mL/kg for each kilogram above 10 kg up to 20 kg, and an additional 1 mL/kg for each kilogram above 20 kg (Table 82-9). Thus, a 25-kg child would require 65 mL/hr—that is, $(10 \times 4) + (10 \times 2) + (5 \times 1) = 65$ mL. This amount does not include fluid deficits, third-space losses, modifications because of hypothermia or hyperthermia, or requirements caused by unusual metabolic demands. In general, deficits caused by restriction of food and fluids are calculated by multiplying the hourly maintenance rate by the number of hours of restriction; 50% of the resulting deficit is replaced in the first hour and 25% in each of the next 2 hours. Third-space losses are replenished according to the surgical procedure and may vary from 1 mL/kg/hr for a minor surgical procedure to as much as 15 mL/kg/hr for major abdominal procedures (e.g., surgical repair of gastroschisis).

The composition of the intravenous fluid is also a concern. Because greater hypoxic brain damage was found to occur in animals with high blood glucose levels, we no longer recommend routine use of glucose-containing solutions, especially for brief operative procedures. However, a concern about unrecognized hypoglycemia was the motivating factor regarding the routine use of glucose-containing solutions in children, particularly those who have not had food or fluids for a longer than usual time or those who have diminished glycogen stores. Data are inadequate to eliminate glucose completely because the relevance of the animal data is not clear and the true incidence of hypoglycemia is not known in all populations of food-restricted children. This issue is further complicated by the fact that different values are used to define hypoglycemia, depending on the child's age.

Despite limited data, a balanced salt solution (e.g., lactated Ringer's solution) should be used for all deficits and third-space losses. If a child is thought to be at risk for hypoglycemia, 5% dextrose in 0.45% normal saline should be administered by "piggyback" infusion at maintenance rates. This minimizes the chance of a bolus administration of glucose and satisfies the concern for unrecognized hypoglycemia or accidental hyperglycemia. The routine use of 5% dextrose or 5% dextrose in 0.45% normal saline as the initial replacement for fluid deficit, third-space losses, and

Table 82-9 Calculation of Maintenance Fluid Requirements for Pediatric Patients

Weight (kg)	Hourly Fluid Requirements (mL)
<10	4 mL/kg
11-20	40 mL + 2 mL/kg for each kilogram above 10
>20	60 mL + 1 mL/kg for each kilogram above 20

blood loss is discouraged. For most children, lactated Ringer's solution is the only fluid required.

Children receiving intravenous alimentation present a special problem. Transition to 10% glucose is often recommended to avoid intraoperative hyperglycemia with continuation of the current alimentation fluid and to avoid hypoglycemia if it is stopped suddenly. However, this change to 10% glucose has not been adequately studied. In my practice I reduce the established intravenous alimentation fluid infusion rate by 33% to 40% (to account for the reduced metabolic rate under anesthesia) and periodically check blood glucose values. This then does not waste the current alimentation fluid and involves only a simple change in infusion rate. Another population of children who will require specific intravenous fluid management consists of those with mitochondrial disease. In general, glucose-containing solutions are administered at maintenance rates and lactate-containing solutions are avoided. Some children with mitochondrial disease have enormous glucose requirements that may necessitate the use of 10% glucose. Management of such patients must be individualized.

Fluid management of term and preterm infants must take into account other variables. The amount of insensible water loss is inversely proportional to gestational age. The younger and more physically immature the infant, the higher the skin permeability, the ratio of body surface area to weight, and the metabolic demand. In addition, the use of radiant warmers and phototherapy increases insensible water loss. On the other hand, preservation of body heat with warming devices reduces insensible water loss.

The fact that the neonatal kidney is unable to excrete large amounts of excess water or electrolytes must also be considered. As described earlier, the volume of extracellular fluid in a newborn is very large. During the first days of life, some of this excess water is excreted. Therefore, term newborns have reduced fluid requirements for the first week of life. The daily fluid requirements for a term newborn in the days after birth are 70 mL/kg on day 1, 80 mL/kg on day 3, 90 mL/kg on day 5, and 120 mL/kg on day 7. Daily fluid requirements would be slightly higher for preterm infants. Sodium and potassium concentrations are usually kept at 2 to 3 mEq/100 mL. Newborns are generally started on 10% glucose to prevent hypoglycemia. This fluid is continued for the first several days of life until glucose values are stable. Infants of diabetic mothers or those given large amounts of glucose just before delivery may require greater concentrations of glucose for protection against rebound hypoglycemia. Infants unable to tolerate oral feeding may continue to receive 10% glucose solutions and may even require peripheral or central alimentation. A number of infants have been transferred to our institution with severe and potentially life-threatening hyperglycemia (i.e., blood glucose levels of 700 to 900 mg/dL) as a result of overzealous use of this type of glucose therapy. This solution should be administered with a rate-limiting device and used with caution if infants require surgery; every effort should be made to reduce bolus administration of glucose. Blood sugar levels should be periodically monitored and the solution infused at maintenance rates only.

Packed Red Blood Cells

The use of blood products in pediatric surgical patients has diminished greatly because of the fear of transmission of disease—particularly human immunodeficiency virus (HIV). Because HIV, hepatitis B virus (HBV), hepatitis C virus (HCV), and a number of other disease-causing viruses can be transmitted with as little as 10 mL of packed red blood cells (PRBCs), administration of any blood product requires clear, medically defensible clinical indications that are preferably recorded on the anesthetic record (also see Chapter 55). The current estimated risk for transmission of HIV, HBV, or HCV is 1 in 81,000 to 1 in 1,600,000 units (see www.aabb.org/All_About_Blood/FAQs/aabb_faqs.htm). Because of these concerns it is common for families to donate blood for their child or relative; in this situation the blood product should be irradiated to prevent possible graft-versus-host disease.

When caring for children, it is very important to think in terms of blood volumes and portions of blood volumes lost rather than units because a unit of blood may constitute several blood volumes in a preterm infant but only a fraction of the blood volume of a robust teenager. These considerations govern calculation of the maximal allowable blood loss (MABL) resulting in an acceptable hematocrit. MABL takes into account the effect of patient age, weight, and starting hematocrit on blood volume. In general, blood volume is approximately 100 to 120 mL/kg for a preterm infant, 90 mL/kg for a full-term infant, 80 mL/kg for a child 3 to 12 months old, and 70 mL/kg for a child older than 1 year. These are merely estimates of blood volume. The individual child's blood volume is calculated by simple proportion by multiplying the child's weight by the estimated blood volume (EBV) per kilogram. Although several formulas are available, a simple relationship is easiest to remember:

$$\text{MABL} = \frac{\text{EBV} \times (\text{Starting hematocrit} - \text{Target hematocrit})}{\text{Starting hematocrit}}$$

Thus, if a 3-year-old child weighs 15 kg and has a starting hematocrit of 38% and if clinical judgment estimates the desired postoperative hematocrit to be 25%, the calculation would be as follows:

$$\text{MABL} = (15 \times 70) \times (38 - 25)/38 = 1050 \times 13/38 = \sim 360 \text{ mL}$$

MABL would be replaced with 3 mL of lactated Ringer's solution per milliliter of blood loss; that is, 3 mL of lactated Ringer's solution times the 360 mL of blood loss equals approximately 1080 mL of lactated Ringer's solution. If blood loss is less than or equal to MABL and no further significant blood loss occurs or is anticipated in the postoperative period, there is no need for transfusion of PRBCs. If, however, significant postoperative bleeding occurs or is anticipated, discussion of potential transfusion needs with the surgeon is very important. Normally, a child who has had adequate replacement of intravascular volume deficits will tolerate anemia very well. There is sufficient time to make the decision to transfuse by observing postoperative urinary output, heart rate, respiratory rate, and overall cardiovascular stability. Unfortunately, no one formula permits a definitive decision. The development of lactic acidosis is a late sign of inadequate oxygen-carrying capacity.

If the child has reached the MABL and significantly more blood loss is expected during surgery, the child should receive PRBCs in sufficient quantity to maintain the hematocrit in the 20% to 25% range. The entire loss of red cell mass should not be replaced unless clinically indicated if these additional PRBCs would expose the child to additional units of blood products. Hematocrit values in the low 20% range are generally well tolerated by most children, the exception being preterm infants, term

newborns, and children with cyanotic congenital heart disease or those with respiratory failure in need of high oxygen-carrying capacity. Because the incidence of apnea is higher in neonates and preterm infants who have hematocrit values below 30%, it would be prudent to discuss with both the surgeon and neonatologist the minimal target hematocrit for such children and to document the discussion in the child's record.[116] Older children with a history of sickle cell disease may require preoperative transfusion and should be managed in conjunction with their attending hematologist. A simple formula for intraoperative or postoperative estimation of the volume of PRBCs needed in a 15- kg child with a hematocrit of 20% as an example is

$$\text{Volume of PRBCs to be transfused} = \frac{\left[\text{Desired Hct}\,(35) - \text{Present Hct}\,(20) \times \text{EBV}\left(70\ \text{mL/kg} \times 15\ \text{kg}\right)\right]}{\text{Hematocrit of PRBCs}\left(\sim 60\%\right)}$$

$$\frac{(35-20)\times(70\times15)}{60} = \sim 262\ \text{mL PRBCs}$$

Fresh Frozen Plasma

Fresh frozen plasma (FFP) is administered to replenish clotting factors lost during massive blood transfusion (usually defined as blood loss exceeding one blood volume), for disseminated intravascular coagulopathy, or for congenital clotting factor deficit. The anesthesiologist initiates and guides therapy with FFP during massive blood loss, whereas the hematologist's advice is sought when either of the other two conditions exists.

Children with known clotting factor deficits, such as those with massive thermal injury or coagulopathy, may require transfusion of FFP before blood loss exceeds one blood volume. In contrast, healthy children who do not have coagulation factor deficits at the beginning of surgery do not need FFP until blood loss exceeds 1 and probably 1.5 blood volumes.[117,118] This generalization applies to children given PRBCs; children given whole blood will not need FFP, even when blood loss exceeds several blood volumes. Despite loss of one blood volume, prolongation of the prothrombin time (PT) and the partial thromboplastin time (PTT) will only be minor.[119,120]

Blood loss exceeding 1 to 1.5 blood volumes (replaced entirely with PRBCs and crystalloid, albumin, or other non–blood-related products) often necessitates transfusion of FFP. However, the decision to administer FFP should be based on observed coagulopathy and documented prolongation of the PT and PTT. Obtaining these test results from the laboratory often takes longer than desired. In this circumstance, a note should be written that blood loss has exceeded one blood volume and that abnormal oozing has occurred in the surgical field. A child should never be given FFP to correct bleeding that is surgical in nature.

No studies on children have yet clearly defined what values of PT and PTT are associated with pathologic bleeding requiring transfusion of FFP to replace clotting factors. However, if associated with abnormal oozing, a PT exceeding 15 seconds (international normalized ratio [INR] >1.4) or a PTT greater than 60 seconds (>1.5 times baseline) seems to warrant correction. If these abnormalities exist but oozing does not occur and the surgical field is relatively safe from the complications of hematoma formation (e.g., as in orthopedic surgery versus neurosurgery), it seems appropriate to observe the child and withhold transfusion of FFP.

The volume of FFP required to correct prolongation of the PT and PTT depends on the severity of the clotting factor deficit and the presence or absence of consumptive coagulopathy. In general, FFP therapy may require replacement of 30% or more of the child's blood volume. Transfusion of FFP at rates exceeding 1.0 mL/kg/min is sometimes followed by severe ionized hypocalcemia and cardiac depression with hypotension, especially if FFP is administered during anesthesia with a potent inhaled anesthetic (Fig. 82-18).[121,122] Therefore, exogenous calcium chloride (2.5 to 5 mg/kg) or calcium gluconate (7.5 to 15 mg/kg) should be administered during rapid transfusion of FFP.[123] Ionized hypocalcemia occurs very frequently in neonates given FFP, possibly because of their decreased ability to mobilize calcium and metabolize citrate; children undergoing liver transplantation or those with compromised hepatic function or perfusion may also be at increased risk because of a decreased ability to metabolize citrate.

Platelets

Thrombocytopenia may occur as a result of disease processes (idiopathic thrombocytopenic purpura, chemotherapy, infection, disseminated intravascular coagulopathy) or dilution during massive blood loss. Children whose platelet count has fallen because of idiopathic thrombocytopenic purpura or chemotherapy generally tolerate platelet counts as low as 15,000/mm^3 without a need for platelet transfusion. In contrast, children whose platelet count has decreased because of dilution (massive blood loss) generally require platelet transfusion when the count is 50,000/mm^3 or less (also see Chapter 55). The reason for this disparity is not known. However, in my experience, the preoperative platelet count has been extremely valuable in predicting intraoperative platelet requirements.[124] Children who begin surgery with elevated platelet counts may not require platelet transfusion despite blood loss of four or more blood volumes. Conversely, children who begin surgery with low platelet counts (approximately 100,000/mm^3) may require platelet transfusion when blood loss is one or two blood volumes. Children who begin surgery with a normal platelet count (150,000 to 350,000/mm^3) usually do not require platelet transfusion until two blood volumes or more is lost (Fig. 82-19).

Whenever platelets are administered, the anesthesia record should document the reason for the transfusion, and every effort should be made to obtain a platelet count before transfusion. Clinical oozing is the typical indication for platelet transfusion, unless the potential for bleeding would be critical to survival, such as during neurosurgery, cardiac surgery, or major organ transplantation. The initial volume of platelets transfused is approximately 0.1 to 0.3 U/kg; the increase in platelet count achieved with this amount of transfusion varies considerably and depends on the presence or absence of platelet antibodies and the rate of platelet consumption.

Blood Warmers

A fluid/blood warmer is essential for any child who might require rapid correction of intravascular volume. There is no benefit in using such devices for maintenance intravenous fluid therapy because the rate of infusion is so slow that the intravenous fluid returns to room temperature between the time that it exits the warmer and enters the child. New warming devices that use countercurrent or microwave warming methods are superior to the older water bath coiled tubing devices. Low-capacity passive flow

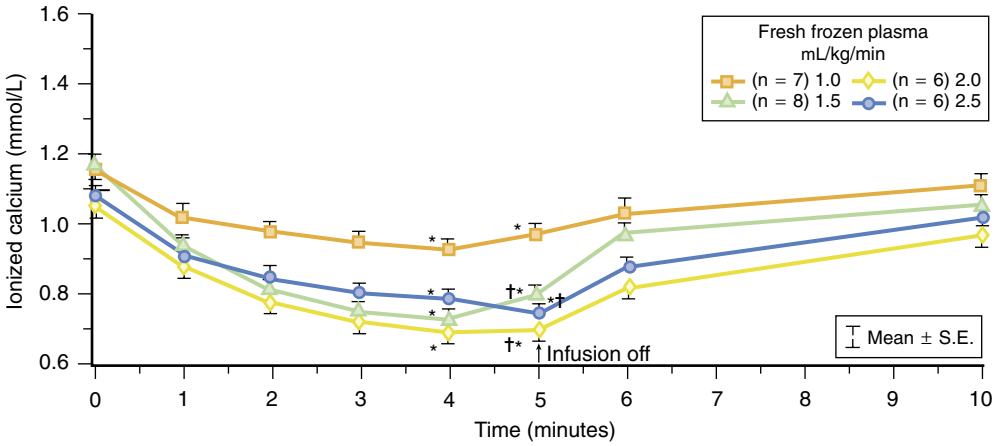

Figure 82-18 Ionized hypocalcemia always accompanies the administration of citrated blood products (fresh frozen plasma, citrated whole blood). Fresh frozen plasma has the highest concentration of citrate per unit volume of any blood product and is the most likely to cause ionized hypocalcemia during rapid infusion. Studies in children with severe thermal injuries suggest that rates exceeding 1.0 mL/kg/min produce severe ionized hypocalcemia. If there is no further administration of citrated blood products, this abnormality corrects itself because of metabolism of the citrate. However, children with impaired hepatic blood flow (infants, liver transplant patients, trauma patients) may need exogenous calcium therapy. *$P < .001$; †$P < .0021$ versus baseline. *(From Coté CJ, Drop LJ, Hoaglin DC, et al: Ionized hypocalcemia after fresh frozen plasma administration to thermally injured children: Effects of infusion rate, duration, and treatment with calcium chloride. Anesth Analg 67:152-160, 1988, with permission.)*

through devices such as the Hot Line (Level 1 Technologies, Inc., Rockland, MA) is useful but not for warming a patient with maintenance rate administration. One exception might be the Belmont Buddy fluid warmer (Belmont Instrument Corp., Billerica, MA). The manufacturer claims a warming capacity of "cold fluids to 38°C at flow rates as low as keep vein open (KVO) and as high as 100 mL/min." High-capacity systems such as the Level 1 System 1000 (Level 1 Technologies, Inc.), which uses countercurrent warming technology, is capable of warming blood starting at 5°C to 6°C to 33°C at rates as high as 250 mL/min. Another high-capacity blood warmer, the Belmont FMS (Belmont Instrument Corp.) uses microwave warming and is capable of fluid delivery at rates of 10 to 750 mL/min. This device is simple to set up. A comparison of several devices used with pediatric intravenous catheters found that technology similar to the Belmont FMS was superior to the Level 1 for maintaining temperature and high-volume transfusions through intravenous catheters larger than 18 gauge.[125] Thus, the Hot Line or Belmont Buddy seems appropriate for neonates and infants, the Level 1 would appear to be appropriate for massive rapid transfusion in children less than 30 kg, but the Belmont FMS would be superior for larger children.

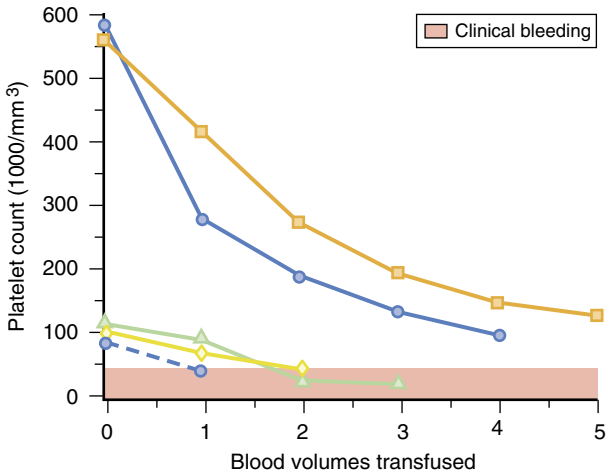

Figure 82-19 Dilutional thrombocytopenia occurs whenever massive blood loss takes place. The need for platelet transfusion, however, depends on the starting platelet count. In children who started with low platelet counts, dilutional thrombocytopenia developed after blood loss of one or two blood volumes, whereas children who started with very high platelet counts did not require transfusions of platelets. The *blue dashed*, *solid yellow*, and *solid green lines* represent three children with initial low platelet counts; the *blue* and *orange lines* represent two children with initial high platelet counts. *(Data from Coté CJ, Liu LM, Szyfelbein SK, et al: Changes in serial platelet counts following massive blood transfusion in pediatric patients. Anesthesiology 62:197-201, 1985.)*

Monitoring and Safety Issues for Pediatric Patients

The complexity of monitoring applied to pediatric patients must be consistent with the severity of the underlying medical condition and the planned surgical procedure. My philosophy is that if I would place an arterial line or central venous line in an adult undergoing a particular operation, the same should be carried out for a child or an infant.

Routine Monitoring and Safety Issues

Minimal monitoring during anesthesia should include a precordial or esophageal stethoscope, a blood pressure cuff, an electrocardiogram, a temperature probe, a pulse oximeter, an end-tidal carbon dioxide monitor, and if possible, an anesthetic agent analyzer. The noninvasive blood pressure cuff (NIBP) is particularly useful because frequent blood pressure measurements can be made even when the anesthesiologist is preoccupied with other tasks. The end-tidal carbon dioxide monitor, NIBP, and pulse oximeter all provide an early warning of impending disaster that may go unobserved until the appearance of late clinical signs such as cyanosis, bradycardia, severe hypotension, or absence of breath

sounds. Simultaneous loss of the pulse oximeter signal and inability to measure blood pressure usually indicate low or no cardiac output. If the pulse oximeter continues to function but the NIBP has changed from measuring to nonmeasuring, the likelihood of hypovolemia or anesthetic overdose must be addressed immediately, but one can have some assurance that perfusion is still taking place.

The pulse oximeter carries a high incidence of false alarms from movement artifact, light interference, and other factors. The newest generation of pulse oximetry software and new devices minimize these artifacts, but because they continue to function in very low-flow states and the software is designed to read through motion, it may no longer be possible to use the pulse oximeter as a rapid determinant of perfusion, and some devices may continue to indicate a pulse for some seconds even when no pulse is present (personal observation). It is therefore vitally important to understand the pluses and minuses of the devices used in one's institution.

Capnography is the gold standard for confirmation of successful endotracheal intubation. However, the capnograph is useful in a number of other ways as well. Changes in the shape or magnitude of the CO_2 waveform may indicate bronchospasm, endobronchial intubation, a kinked endotracheal tube, or low pulmonary blood flow. One of the main drawbacks of capnography in small children is the inaccuracy of the recording obtained with use of non-rebreathing circuits. The best method of avoiding artifacts is to sample the expired gases at some point within the endotracheal tube or to use the circle system, even in small infants but at lower fresh gas flow rates. In general, the concentration of carbon dioxide in expired gas is within 2 to 3 mm Hg of that in arterial blood. However, severe pulmonary disease or atelectasis may produce a large difference in these two values. In this type of child, the gradient between arterial and expired carbon dioxide levels may be used to estimate the severity of the shunting. When such shunts exist, measurement of expired carbon dioxide levels may be used only to monitor trends. Ultimately, the most important monitors are the eyes, ears, and hands of the anesthesiologist, who must gather all the information provided by observation of the child and by the monitors applied to the child, consolidate the information into an accurate picture, and respond accordingly.

Prospective studies have shown that children younger than 6 months have a higher incidence of critical events.[20,126-129] The incidence of critical events is higher in ASA physical status 3 and 4 children than in ASA physical status 1 and 2 children. A number of factors may account for these results: the high metabolic rate of small children, the technical difficulty of caring for infants, the difficulty of estimating actual delivered ventilation when a variety of circuit configurations are available, and unfamiliarity with the care of small children. The POCA registry, a voluntary reporting system, estimated that the incidence of pediatric cardiac arrest was 1.4 ± 0.45 per 10,000 cases. Of the 289 cases, 83 occurred in children younger than 12 months. Emergency procedures and ASA status of 3 or greater were predictive of death. Of the anesthesia-related cardiac arrests, 55 were thought to be related to medications, and halothane alone or in combination with other drugs was associated with 37 of these events. It should be noted that two were associated with sevoflurane and that at the time of data collection sevoflurane had not been widely used in the United States. The use of high inspired concentrations of halothane (≥3%) accounted for 14 of the arrests, and other associated factors were controlled ventilation ($n = 18$) and difficult intravenous access ($n = 4$). The most common preceding events were bradycardia and hypotension ($n = 25$). Three infants had an unrecognized cardiomyopathy and one had congenital heart disease. Airway-related events accounted for only 20% of cases, and most involved airway obstruction and laryngospasm. Several lessons can be taken from these data: (1) Children younger than 1 year are particularly vulnerable to adverse events in the perioperative period, (2) the combination of high inspired concentrations of an inhaled agent and controlled ventilation contributed to the critical event, (3) high inspired concentrations of an inhaled agent should be avoided until intravenous access is established, (4) it is not the inhaled agent but the way that the agent is used that is most likely the major contributing factor to these arrests, (5) particular attention should be paid to frequent monitoring of blood pressure and heart rate during induction, (6) monitoring with pulse oximetry and capnography may have reduced the incidence of airway-related events that were avoidable when compared with earlier studies, and (7) children with congenital heart disease are particularly vulnerable to the cardiac depressant effects of potent inhaled agents. One study that supports these conclusions was a multi-institutional, highly controlled drug trial that compared remifentanil-based anesthesia and halothane-based anesthesia for pyloromyotomy.[80,81] In that study of 60 infants (38 receiving remifentanil and 22 receiving halothane), there were no cases of significant bradycardia, no differences in hemodynamic variables, and no differences in extubation times, PACU time, or rate of adverse events. There basically was no difference between halothane (a slow-onset, slow-offset potent anesthetic) and remifentanil (a very potent opioid with rapid onset and rapid offset). This study suggests that when anesthesiologists pay careful attention to details, adverse outcomes and severe adverse events can be avoided. The presence of an intravenous line before induction also probably provided an additional measure of safety.

Invasive Monitoring

Arterial and central venous catheters should be used in pediatric patients whenever such monitors contribute to the management of safe anesthesia. Placement of these monitors should not be avoided simply because the child is small or the anesthesiologist is uncomfortable applying the technique to a child. A variety of manufactured kits are available, most often using a thin-walled needle and a guidewire for venous access. If these monitors are indicated, the anesthesiologist, surgeon, cardiologist, or neonatologist should insert them. Peripherally inserted central catheters (PICC lines) offer a less invasive procedure that can provide accurate measures of central venous pressure.

Multilumen catheters are very valuable in the care of critically ill children. These devices facilitate the simultaneous intravenous administration of a variety of fluids, vasopressors, and antibiotics. However, these catheters can also lead to a false sense of security created by having three intravenous ports. Specifically, if a rapid infusion of colloid or even crystalloid is necessary, the long, narrow lumen would severely limit the rate of infusion preventing adequate rapid volume replacement. If the need for rapid volume expansion arises, a separate large-bore intravenous catheter should be inserted. Short-term cannulation of the femoral or brachiocephalic vein is reasonable and may be lifesaving.

Pediatric Equipment

The Dedicated Pediatric Equipment Cart

Anesthesiologists caring for pediatric patients must be prepared for the unexpected, particularly an undiagnosed congenital malformation or difficult endotracheal intubation. Having designated pediatric carts containing pediatric equipment is a convenient way of providing optimal care in a variety of locations in and outside the operating room. These carts contain pediatric-specific intravenous administration sets, intravenous catheters of various size, butterfly needles (scalp vein needles), electrocardiographic pads, various infant- to adult-sized blood pressure cuffs, precordial stethoscopes, adult and pediatric esophageal stethoscopes, armboards, intravenous fluids in pediatric-size containers, preterm infant– to adult-sized laryngoscope blades and handles, preterm infant– to adult-sized oral airways, endotracheal tubes (2.5 to 6.0 mm ID uncuffed and 3.0 to 7.0 mm ID cuffed), stylets, facemasks in preterm to adult size, size 1 to 5 LMAs, tape, drugs for resuscitation as well as commonly administered medications, and syringes, especially tuberculin syringes, for more precise administration of drugs. An intraosseous needle can be a lifesaving means of establishing emergency venous access for administration of drug or crystalloid and should be present in the pediatric cart. In addition, an interface that allows the administration of albuterol down an endotracheal tube should be readily available and preferably in the drug drawer (Fig. 82-20).

Anesthesia Circuits

Much has been written about the advantages and disadvantages of various anesthesia circuits for use in pediatric patients (also see Chapter 25).[130] Most of the attention has been directed to neonates and ways of reducing the work of breathing while preventing rebreathing. Non-rebreathing circuits provide the advantage of minimal work of breathing because they have no valves to be opened by the child's respiratory effort. The rate of induction of anesthesia may be more rapid because the volume of the non-rebreathing circuit is less, no equilibration with the carbon dioxide canister is required, and anesthetic gases are delivered immediately at the airway. Additionally, because the volume of the non-rebreathing circuit is small in comparison to the circle system, the compression and compliance volume will be significantly less.[130] This improves the ability to observe respiratory effort, as reflected by movement of the anesthesia bag, as well as the ability to estimate pulmonary compliance. Thus, the actual delivered ventilation, when used in conjunction with a ventilator, may be greater with a Mapleson D system than with a circle system if no compensatory adjustment in tidal volume is made (Fig. 82-21). The Mapleson D circuit will be more sensitive to changes in fresh gas flow (i.e., an increase or decrease in minute ventilation) or to the addition of a humidifier (decreased minute ventilation because of added compression volume) during mechanical ventilation. The most recent generation of ventilators are less susceptible to these types of issues because they automatically compensate for changes in fresh gas flow.

A pediatric circle system can be used safely in neonates as long as one understands the clinical implications: large compression volume losses, longer time to equilibrate, and perhaps a decreased ability to determine changes in compliance. I have used pediatric circle systems exclusively for the past 14 years, and as long as pressure-limited ventilation with the same peak inflation pressure is used, the same tidal volume is delivered as with a non-rebreathing system.[131-133]

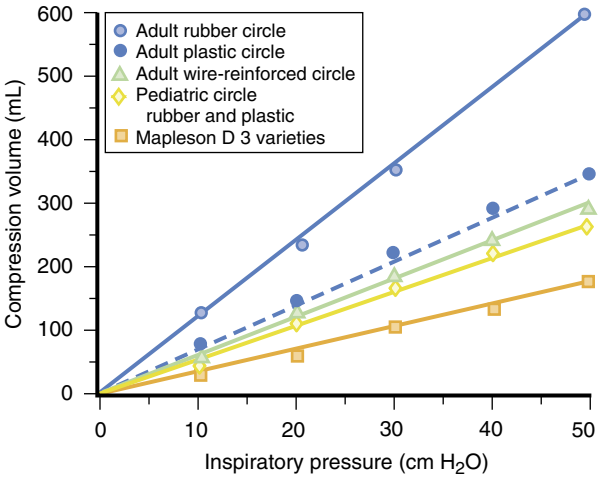

Figure 82-21 Eight types of anesthesia circuits were compared regarding ventilatory losses (circuit efficiency) as a result of compression of anesthetic gases (compression volume) and stretching of the circuit (compliance volume). Compression volume and compliance volume losses vary by as much as a factor of 5, depending on the volume of the circuit and the material from which it is constructed. Low-volume, low-compliance circuits (Mapleson D systems) are the most efficient and give the anesthesiologist the greatest amount of tactile feedback on tidal volume and lung compliance in small children. Although large-volume, high-compliance circuits (adult circle systems) can be used in small children, it is very difficult to estimate tidal volume and lung compliance because circuit-related losses in compression and compliance volume are so large. *(From Coté CJ, Petkau AJ, Ryan JF, Welch JP: Wasted ventilation measured in vitro with eight anesthetic circuits with and without inline humidification. Anesthesiology 59:442-446, 1983, with permission.)*

Figure 82-20 Adaptor that allows the administration of albuterol through an endotracheal tube and timing of that dose with inspirations to provide maximum delivery; note that use of a long intravenous catheter that extends beyond the tip of an endotracheal tube may further improve drug delivery. *(From Coté CJ, Lerman J, Todres ID [eds]: A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, WB Saunders, 2008.)*

Considerations for Neonatal Anesthesia

The neonate has unique requirements for equipment, intravenous access, fluid and drug therapy, anesthetic dosage, and environmental control. The many possible neonatal procedures are too numerous to describe in this limited space. However, the basic anesthetic management is the same for all neonates. An understanding of the basic differences in physiology, pharmacologic and pharmacodynamic responses, and the underlying pathology of the surgical problem is essential for the development of a safe anesthesia plan. Most of the complications that arise are attributable to a lack of understanding of these special considerations before induction of anesthesia. Care of neonates is fraught with danger, sudden changes, unexpected responses, and unknown congenital problems. If anesthesiologists are to deliver optimum pediatric anesthesia care, they must always be prepared for the unexpected, have the proper size and variety of equipment available, and obtain the highest level of support, both in the operating room and in the ICU. If the anesthesiologist only occasionally cares for infants, the likelihood of a problem increases dramatically.

Children younger than 1 year have a higher incidence of complications than older children.[20,126-129,134,135] These complications relate to oxygenation, ventilation, airway management, and response to anesthetic agents and medications; they also occur more frequently in ASA physical status 3 and 4 children. Neonates—particularly preterm infants—function on a marginal basis, so any type of stress is usually poorly tolerated. This vulnerability may relate to the technical difficulty of taking care of small children, the immaturity of their organ systems (especially the cardiovascular, pulmonary, renal, hepatic, and nervous systems), their high metabolic rate, the large ratio of body surface area to weight, and the ease of miscalculating a drug dose.

When caring for infants and neonates, special attention must be paid to all aspects of anesthesia and surgical management. The anesthesiologist must devote particular care to the calculation of drug dosage and dilution of drugs. Prevention of paradoxical air emboli requires that all air be vented from intravenous devices and syringes before use (aspirate each intravenous injection port to remove air trapped at these junctions and eject some drug before intravenous administration to clear air from the dead space of the needle). A volume of air that is clinically unimportant in an adult may prove catastrophic in an infant. Warming of skin preparation solutions and irrigation fluids before application minimizes heat loss. Intravenous fluids should be administered with volume-limiting devices; infusion pumps are particularly helpful in preventing overadministration of intravenous fluid. The composition and infusion rate of flush solutions should be noted and calculated into maintenance fluid therapy.

Every effort must be made to maintain the infant's temperature so that thermal stress is minimized. The operating room environment should be warmed so that the whole operating room constitutes a giant incubator. Heated air mattress devices are particularly useful for maintaining temperature.

Monitoring of expired concentrations of carbon dioxide can be less accurate in small infants but is still very useful for diagnosing changes over time and issues such as bronchospasm, a kinked endotracheal tube, or endobronchial intubation. Pulse oximetry is useful not only for the usual data that it provides but also for preventing extreme hyperoxia. Maintaining oxygen saturation at 93% to 95% keeps preterm infants on the steep side of the oxygen-hemoglobin dissociation curve. This consideration may be important to infants still susceptible to retinopathy of prematurity (ROP), that is, those younger than 44 weeks PCA, although a multicenter trial of tight control of supplemental oxygen failed to show any change in risk for the development of ROP.[136] However, because these infants have the highest oxygen consumption, oxygen saturation in the 93% to 95% range can change to severe hypoxemia within seconds. When managing such a delicate balance and in view of the slight inaccuracies of these monitors, the anesthesiologist must be extremely vigilant and prepared to respond rapidly to changes in oxygen saturation. Keeping arterial carbon dioxide values within the normal range (35 to 45 mm Hg) may also be important in preventing ROP. Many other factors well beyond the control of the anesthesiologist contribute to the development of this condition.

Apoptosis

One very important concern that must be mentioned is the fear of apoptosis caused by medications used to provide sedation, analgesia, and anesthesia for infants and toddlers (~2- to 3-year-olds), a population still undergoing rapid brain growth. Anesthesiologists must be up to date on this issue because with the current widespread use of the Internet, more and more parents are asking "*Is it safe for my baby to have anesthesia?*" and specifically mention apoptosis! All of the potent inhaled agents—nitrous oxide, ketamine, propofol, etomidate, barbiturates, benzodiazepines, chloral hydrate, ethanol—and others have been associated with an increased rate of apoptosis in laboratory animals.[137-140] The majority of animal studies have examined drugs doses far outside the clinical range. Others have not controlled for blood pressure, ventilation, or oxygenation. To further confound the issue, the period of rapid brain growth is different in each animal species, and the time of exposure in some is longer than what would occur in clinical practice. To date, there are limited data in primates (monkeys) and none that have convincingly demonstrated that these observations are transferable to humans. In fact, the preliminary data that have focused on ketamine "suggest that there might be a margin of safety for the use of ketamine in vivo and that there may be safety margins for other anesthetics currently used in the clinical setting."[138] Given the fact that thousands of infants and toddlers undergo general anesthesia for diagnostic and therapeutic procedures each year, certainly if this were a major issue for humans, by now we would have evidence that our most vulnerable children, neonates, infants, and toddlers, would demonstrate adverse developmental outcomes consistent with the animal models. In addition, many preterm and term infants receive these same medications for days and often weeks in the neonatal ICU without obvious adverse outcomes.[139]

At present, I believe the issue of drug-induced apoptosis to be a very valid concern and an area of research that must be vigorously pursued. However, what is quite unclear is at what age or what developmental level this is no longer a concern. Is it just preterm infants, full-term infants, toddlers, teenagers, or even adults? Is the plasticity of the human brain able to overcome a (potential) short-term insult? If we remove this list of drugs from our armamentarium, how are we to provide adequate amnesia,

analgesia, and anxiolysis? Until more convincing data are available, it is prudent to continue our current level of care with the drugs now available to us.[141,142] It would not make sense and it would be irresponsible to change current practice without adequate science to support such a drastic change in child care.

The Stress Response

There is little doubt that neonates, even extremely preterm infants, are capable of feeling pain and responding to painful stimuli; however, what actually constitutes a state of "anesthesia" has yet to be proved. No child should be denied analgesia or anesthesia because of size or age. Clearly, the cardiovascular system of a preterm infant rarely tolerates the cardiovascular depressant effects of potent inhaled anesthetics. However, the synthetic narcotics (e.g., fentanyl, sufentanil, alfentanil, remifentanil) are usually well tolerated by even critically ill infants. These potent narcotics must be carefully titrated to response, and the anesthesiologist must always be wary of narcotic-induced bradycardia and its consequences on cardiac output. Low concentrations of potent inhaled anesthetics can be used with narcotics to provide a means of controlling hemodynamic responses without significantly depressing the myocardium. The relative merits of one anesthetic technique over another are not clear, and the few studies examining this issue are poorly controlled. Narcotics and inhaled anesthetics suppress the hormonal responses to pain. The important result of the provocative studies undertaken to clarify this issue is that they have heightened everyone's awareness of the need to provide adequate anesthesia and analgesia to neonates. As described earlier, it is not so much the drugs but how they are used that make the difference in terms of outcomes. In the hands of skilled pediatric anesthesiologists, no differences were found in adverse events or recovery from anesthesia for pyloromyotomy managed with halothane or remifentanil.[80]

Specific Neonatal and Surgical Procedures

Meningomyelocele

Meningomyelocele (hernial protrusion of a part of the meninges and spinal cord through a defect in the vertebral column) is a relatively common neonatal abnormality. The following should be considered in addition to the usual concerns for the management of neonates: (1) special positioning for endotracheal intubation (defect placed on a "doughnut" and towels under the head), (2) the possibility of underestimating fluid and blood loss from the defect, (3) the high association of this condition with hydrocephalus, (4) the possibility of cranial nerve palsy resulting in inspiratory stridor, and (5) the potential for brainstem herniation. The anesthesiologist must establish adequate intravenous access and invasive monitoring if appropriate; replace all fluid deficits, including loss from the defect (usually with normal saline); and ensure that crossmatched blood is available. Latex allergy precautions should be used with these children for their first and all subsequent anesthetics.

Omphalocele and Gastroschisis

Omphalocele and gastroschisis are major defects in closure of the abdominal wall that result in exposure of viscera that are either covered (omphalocele) or not covered (gastroschisis) by peritoneum (Fig. 82-22A and B; Table 82-10). The major problems with these defects include (1) severe dehydration and massive fluid loss, both from the exposed visceral surfaces (gastroschisis—chemical peritonitis) and from third-space losses caused by partial bowel obstruction; (2) heat loss; (3) the difficulty of surgical closure; and (4) the high association of this condition with prematurity and other congenital defects, including cardiac abnormalities (with omphalocele, ~20%). These children should not be rushed to the operating room without an echocardiogram before anesthesia.

Infants with omphalocele or gastroschisis must be cared for expeditiously to reduce the potential for infection and compromise of bowel function and to minimize the loss of fluid and heat; optimizing fluid and electrolyte balance before surgery is

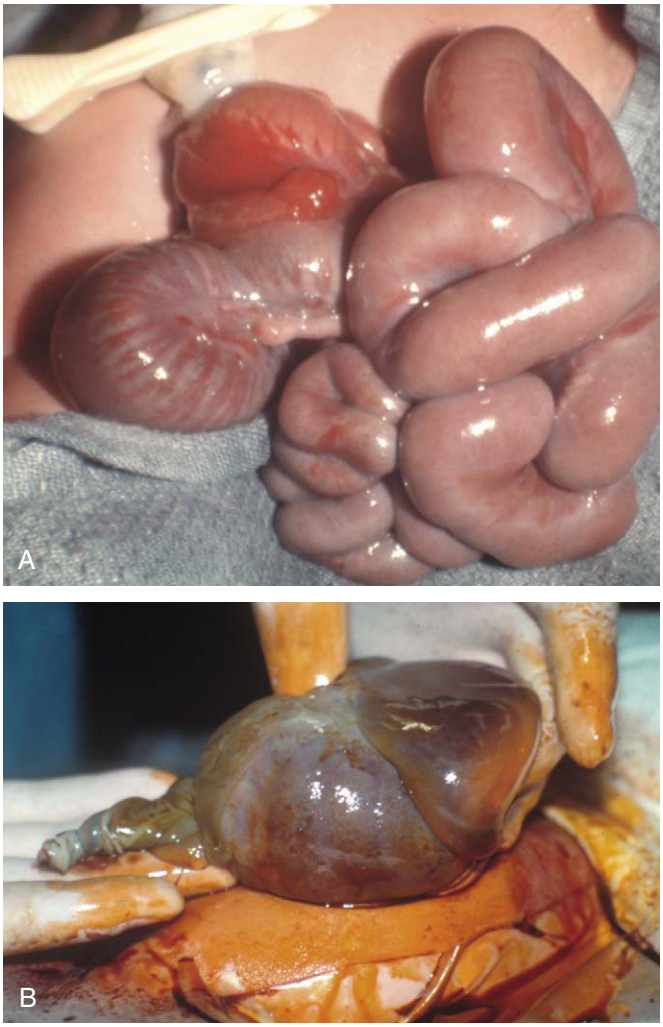

Figure 82-22 **A,** Gastroschisis malformation. Note that the viscera have herniated outside the peritoneum. **B,** Omphalocele malformation. Note that the viscera are still covered by peritoneum.

Table 82-10 Comparison of Gastroschisis and Omphalocele Malformations

	Gastroschisis	Omphalocele
Pathophysiology	Occlusion of the omphalomesenteric artery	Failure of gut migration from the yolk sac into the abdomen
Incidence	~1 in 15,000 births	~1 in 6000 births
Incidence of associated anomalies	~10%-15%	~40%-60%
Location of defect	Periumbilical	Within the umbilical cord
Problems associated with the defect	Inflammation of exposed gut Edema Dilated and foreshortened gut (chemical peritonitis)	Congenital heart disease (~20%) Exstrophy of the bladder Beckwith-Wiedemann syndrome (macroglossia, gigantism, hypoglycemia, hyperviscosity)

From Coté CJ, Lerman J, Todres ID (eds): A Practice of Anesthesia for Infants and Children, 4th ed. Philadelphia, WB Saunders, 2008.

recommended. Adequate intravenous access must be ensured, and occasionally invasive monitoring is necessary if an associated cardiac defect is present. The liberal use of muscle relaxants provides optimal surgical conditions for closure of the defect; hypotension secondary to tension on a major organ (liver) or caval compression is common. If the surgeon is unable to close the defect in one procedure, a staged procedure is planned, usually in the neonatal ICU. In either situation, postoperative ventilation will be necessary until the abdominal wall has had time to stretch to accommodate the viscera. Intravenous alimentation may also play a vital role in the rapid recovery of these children.

A small percentage of children with omphalocele will also have Beckwith-Wiedemann syndrome, a condition characterized by profound hypoglycemia, hyperviscosity syndrome, and associated visceromegaly. It should be noted that increased abdominal pressure after a tight closure may compromise hepatic function and markedly alter drug metabolism. Staged closure with a premade spring-loaded Silastic silo is being used with increasing frequency, thus minimizing repeat trips to the operating room and the need for postreduction ventilation.

Tracheoesophageal Fistula Anomaly

A tracheoesophageal fistula anomaly can have five or more configurations, most of which are manifested as an inability to swallow because of esophageal atresia (ending of the esophagus in a blind pouch). The characteristic diagnostic test is an inability to pass a suction catheter into the stomach. Neonates may have aspiration pneumonitis from a distal fistula connecting the stomach to the trachea through the esophagus or from a proximal connection of the esophagus with the trachea. Additionally, this anomaly may be a part of a larger constellation of anomalies known as the VATER association (V, vertebral; A, anal; TE, tracheoesophageal; R, renal) or the VACTERL association (VATER + C, cardiac; and L, limb). Any child with a tracheoesophageal fistula or esophageal atresia should be suspected of having the other anomalies described. An echocardiogram to examine for a right-sided aortic arch and the presence of congenital heart disease should be performed before anesthesia.[143]

The major anesthetic issues include (1) evaluation for aspiration pneumonia; (2) overdistention of the stomach from entry of air directly into the stomach through the fistula; (3) inability to ventilate the child because of the large size of the fistula; (4) problems associated with other anomalies, particularly a patent ductus arteriosus (shunting) and other forms of congenital heart disease; and (5) the need for postoperative intensive care.

For management of anesthesia the infant's feedings are withheld, a catheter is placed in the esophagus to drain saliva, and the infant is placed prone in a head-up position. If the infant has pneumonia, treatment should be initiated; surgery may be postponed until the pneumonitis improves or clears. The infant may be a candidate for gastrostomy to provide a means of nutrition during recovery from pneumonitis. Anesthesia evaluation centers on the pulmonary and cardiovascular systems. Generally, an "awake sedated" intubation is performed. I usually administer 0.5 to 1 μg/kg of fentanyl and 25 to 50 μg/kg of midazolam and topicalize the tongue, larynx, and vocal cords with no more than 5 mg/kg of lidocaine (1.0%). The endotracheal tube is intentionally passed into the right main bronchus and then slowly withdrawn until breath sounds are heard on the left. Often this technique ensures that the tip of the endotracheal tube is placed beyond the origin of the fistula, thus avoiding massive distention of the stomach. Care must be taken to avoid rupturing the stomach, so spontaneous and gently assisted ventilation may be appropriate until the fistula is ligated or a gastrostomy is completed. A change in the distance of insertion of the endotracheal tube of as little as 1 to 2 mm may determine whether the anesthesiologist is ventilating both lungs, one lung, or the fistula. Therefore, because a change in oxygen saturation may be the first indication that all is not well, the pulse oximeter is one of the most useful monitors in managing these children. A preductal and postductal location (two pulse oximeters) will diagnose intracardiac shunting. Taping the stethoscope to the left side of the chest in the axilla also decreases the possibility of unrecognized endobronchial intubation. Some surgeons prefer that the infant remain intubated postoperatively, whereas others prefer an attempt at extubation; it should be noted that approximately 30% will require reintubation for clearing of secretions.

Postoperative pain may be managed with a caudal catheter threaded up to the thoracic level and either intermittent bupivacaine (1 to 2 mL of 0.125% with epinephrine 1:200,000) administered every 6 to 8 hours or a continuous infusion of chloroprocaine (1.5%) with fentanyl (0.4 μg/mL) infused at 0.3 to 0.8 mL/kg/hr. Note that such management may be undertaken only with the full support of a pediatric pain service.

Diaphragmatic Hernia

A diaphragmatic hernia is usually manifested on the first day of life by respiratory distress and a scaphoid abdomen. The abnormality consists of herniation of the abdominal viscera through a defect in the diaphragm, most commonly the foramen of

Bochdalek on the left side. Almost all of the abdominal viscera, including the liver and spleen, may be above the diaphragm. The gestational age at which herniation occurs may determine the degree of lung hypoplasia.

Anesthesia concerns include (1) hypoxemia and hypotension caused by overdistention of the stomach and herniation across the midline, (2) hypoxemia due to primary pulmonary hypoplasia, (3) hypoxemia due to pulmonary hypertension, (4) pneumothorax of the contralateral lung during attempts at high-pressure ventilation, and (5) systemic hypotension caused by kinking of major blood vessels, particularly those of the liver. In general, the anesthesiologist's ability to control arterial carbon dioxide tension ($Paco_2$) reflects the severity of the lung pathology and therefore survival. An inability to reduce $Paco_2$ is associated with a poor prognosis. Extracorporeal membrane oxygenation (ECMO) and the use of nitric oxide have reduced the mortality associated with this condition, and the urgency for surgical intervention has diminished and given way to a desire to stabilize the infant and minimize stress. It is common practice to postpone surgery on infants with a diaphragmatic hernia until their condition has been stabilized for several days. In some centers the closure is accomplished at the bedside in the neonatal ICU.

Anesthestic management of children with a diaphragmatic hernia includes the following: (1) Awake intubation without bag-and-mask ventilation prevents overdistention of the stomach and herniation across the midline (now uncommon because they generally do not come to the operating room for several days); (2) insertion of an arterial line for heartbeat-to-heartbeat blood pressure monitoring and close observation of the surgical field are most helpful in diagnosing impairment of venous return or cardiac output; (3) blunting of the stress response is accomplished by providing analgesia with narcotics (usually high-dose fentanyl, 25 μg/kg or more) and by controlling respirations with a muscle relaxant (usually pancuronium); (4) careful control of ventilation and oxygenation prevents sudden increases in pulmonary artery pressure ($Paco_2$ is kept below 40 mm Hg and Pao_2 above 100 mm Hg); pulse oximetry is helpful in diagnosing subclinical episodes of hypoxemia; (5) hypothermia is avoided to decrease the oxygen consumption needed for thermogenesis; (6) anesthetic agents that might depress the myocardium are avoided until the chest is decompressed; (7) to prevent bowel distention, nitrous oxide is not given; (8) awareness for the development of barotrauma-induced pneumothorax on the ipsilateral or contralateral side should be heightened; (9) adequate intravenous access for maintenance of a constant circulating blood volume should be ensured; and (10) postoperative intensive care is necessary.

In most centers the approach to these children has changed to supportive care initially with permissive hypercapnia, ECMO, high-frequency ventilation, and inhaled nitric oxide.[144,145] The infant is no longer rushed to the operating room soon after birth, and this approach appears to have reduced mortality.[145,146] Review of long-term outcomes seems to indicate that all of these measures have not significantly improved mortality.[147]

Pyloric Stenosis

Pyloric stenosis is normally manifested in the first 3 to 6 weeks of life. The following are major concerns for the anesthesiologist: (1) a full stomach, occasionally filled with contrast material; (2) metabolic alkalosis with hypochloremia and hypokalemia; and (3) severe dehydration.

This operation is never a surgical emergency. Children should be evaluated carefully, and severe metabolic imbalance should be corrected before surgery. Even if the child arrives with a nasogastric tube in place and although the diagnosis is now most commonly made by ultrasound rather than barium swallow, the stomach should still be suctioned with a wide-bore catheter in the supine and the right and left lateral positions immediately before induction of anesthesia and as much of the stomach contents removed as possible.[148] This suctioning technique will remove 98% of the gastric contents![149] Children with pyloric stenosis can be managed with awake endotracheal intubation followed by low-dose rocuronium (0.3 mg/kg) or rapid-sequence induction of anesthesia with cricoid pressure after atropine (0.02 mg/kg), propofol (3 mg/kg), and succinylcholine (2 mg/kg). Arguments can be made for either type of induction, and selection depends on the skill and familiarity of the anesthesiologist with that technique, but one study in a teaching institution demonstrated fewer attempts and half the time for successful intubation when a muscle relaxant was used.[150] Postoperative analgesia is generally provided by local infiltration of the skin incision with bupivacaine (maximum dose, 1 mL/kg of 0.25% bupivacaine) and acetaminophen (40-mg/kg initial dose followed by 20 mg/kg every 6 hours rectally or 10 to 15 mg/kg by mouth every 4 to 6 hours for a total 24-hour dose of ~100 mg/kg). There have been conflicting reports of apnea events after pyloromyotomy.[151,152] One well-controlled clinical trial described new-onset apnea after halothane anesthesia in 3 of 13 children.[81] Until larger studies are carried out, it may be prudent to observe these children with apnea monitors and pulse oximetry postoperatively.

The Former Preterm Infant

Since the early retrospective reports noting a high incidence of postoperative apnea in former preterm infants (gestational age less than 37 weeks), a number of studies have tried to define the population at risk. Most studies have found that the majority of infants in whom postanesthesia apnea develops are younger than 46 weeks PCA; however, apnea has been reported up to 60 weeks PCA.[153] The conclusions reached by each of these studies were limited by the relatively small number of children. I had the opportunity to obtain and analyze the original data from eight prospective studies. A combined analysis examining risk for apnea included only children undergoing inguinal hernia repair and not receiving special treatment such as caffeine or regional anesthesia.[116] The only two risk factors that stood out across all ages were gestational age and PCA. The incidence of apnea was inversely related to both postconceptual and gestational age. For example, if two infants were now 42 weeks PCA yet one was born at 28 and the other at 36 weeks gestational age, the 28-week gestational age infant would have approximately twice the potential for apnea (Fig. 82-23). In addition, the younger the child at the time of surgery (weeks PCA), the higher the incidence of apnea. The incidence of apnea was higher in institutions that collected data with continuous recording devices than in those that relied on impedance pneumography or nursing observations. Anemia (hematocrit <30%) is an independent risk factor associated with apnea in former preterm infants (see Fig. 82-23). What makes this risk factor unique is the fact that the risk for apnea in anemic

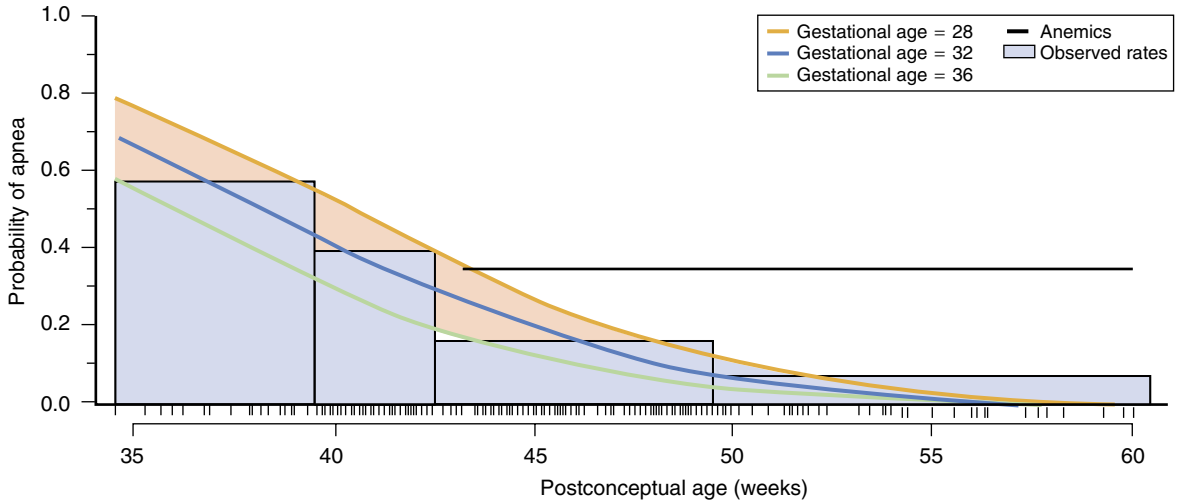

Figure 82-23 Predicted probability of apnea for all children by gestational age and weeks postconceptual age. Children with anemia are shown as the *horizontal hatched line*. *Bottom marks* indicate the number of data points by postconceptual age. The risk for apnea diminishes in infants born at a later gestational age. The *shaded boxes* represent the overall rates of apnea for infants within that gestational age range. The probability of apnea was the same regardless of postconceptual age or gestational age for infants with anemia (*horizontal hatched line*). *(Reproduced with permission from Coté CJ, Zaslavsky A, Downes JJ, et al: Postoperative apnea in former preterm infants after inguinal herniorrhaphy. A combined analysis. Anesthesiology 82:809-802, 1995.)*

former preterm infants is not altered by postconceptual or gestational age; that is, the risk for apnea would appear to be the same for an anemic 60-week PCA infant as for an anemic 45-week one. Even after eliminating infants with an obvious apnea spell in recovery and infants who were anemic, the risk for apnea does not decrease to less than 1% (with 95% statistical confidence) until a PCA of 56 weeks with a gestational age of 32 weeks or until a PCA of 54 weeks with a gestational age of 35 weeks. In general, it is simplest to just admit all former preterm infants younger than 60 weeks PCA to monitored beds and to be aware that anemic former preterm infants are at particular risk.

Although the risk of apnea may be less with regional anesthesia, apnea may still occur and may even be increased if regional anesthesia is combined with sedation (ketamine, midazolam).[154-161] There are insufficient numbers of well-controlled studies of regional versus general anesthesia to determine whether the risk is significantly reduced. It is also clear that apnea still occurs even with sevoflurane or desflurane anesthesia, so the more modern inhaled agents have not eliminated this concern.[162]

Part of the problem of how to treat these children is the fact that we do not know the clinical importance of brief apnea/bradycardia spells that do not require intervention. Because cerebral blood flow is markedly reduced at heart rates below 80 beats/min, even brief apnea associated with bradycardia may have adverse effects.[163] The dilemma faced by the clinician is how to manage former preterm infants scheduled for outpatient procedures. More prospective studies need to address whether regional techniques are safer than general anesthesia. Pulse oximetry would help define the severity of desaturation and electrocardiographic monitoring would help define episodes of bradycardia, which may reduce cerebral blood flow. It would seem reasonable that the combination of desaturation and bradycardia is of more physiologic importance than simple documentation of pauses in respiration.

If appropriate monitoring facilities are not available postoperatively, a preterm infant who is less than 60 weeks PCA should be referred to an institution that has such facilities. High-dose caffeine (10 mg/kg) has been recommended.[164] This may be an effective therapy, but the half-life of caffeine in older former preterm infants is only 6 hours and the first apnea spells after anesthesia may not be manifested until 12 hours.[116] Therefore, one cannot administer caffeine and then send the infant home and assume that the problem is treated.

To make the issue even more complex, I have observed a full-term infant who became apneic after general anesthesia. This infant had periodic breathing, which is distinctly unusual in a full-term infant.[165] We still do not know with certainty which children are truly anesthetized safely on an outpatient basis and at what postconceptual and gestational age. Because most organ systems are still rapidly developing during the first month of life (44 weeks PCA), it is reasonable to delay elective surgery during the first month of life and consider postoperative admission and apnea monitoring even in full-term infants younger than 1 month. Alternatively, performing the case as the first of the day and then observing for an extended period may permit safe discharge in the late afternoon or early evening.

Children with Repaired Heart Disease

Frequently, anesthesiologists assume that children have normal cardiac function after "correction" of congenital heart defects. Although the circulation may be normal, there is never assurance that cardiac function is normal. Any child who has undergone a ventriculotomy would be expected to have some ventricular dysfunction caused by the incision; there is less potential for dysfunction if the surgical approach was through an atriotomy.[166] Likewise, even relatively benign procedures such as closure of ventricular or atrial septal defects can be associated with the later develop-

ment of dysrhythmias.[166] Some children, particularly those with repaired single-ventricle physiology, have a marked predisposition to sudden death as a result of pathologic arrhythmias; a careful history is particularly important in these children. Should an arrhythmia develop intraoperatively, consultation with the child's cardiologist is essential because this may be the first indication of a serious underlying arrhythmogenic foci. A radiofrequency ablation procedure may be life saving. Cardiac transplant children need particular attention to rule out small vessel coronary artery disease.[167,168]

Children with Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is defined as a "disorder of breathing during sleep characterized by prolonged upper airway obstruction and/or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep." Children at particular risk include those with craniofacial abnormalities, neuromuscular disorders, obesity, and adenotonsillar hypertrophy.[169-176] The difficulty that we face is determining which children are at risk because not all children will undergo formal polysomnogram evaluation, which is considered the gold standard.[169] Abnormal sleep oximetry values (clusters of desaturation to <80%) have also been shown to correlate with the severity of OSA.[171,177] Even children undergoing surgery in the afternoon may be at greater risk than those operated on in the morning.[178] The apnea index (AI) and the respiratory disturbance index are measurements of the presence and severity of OSA syndrome. These indices reflect the frequency of occlusive and partially occlusive respiratory events per hour of sleep. OSA syndrome is considered to be present if the AI is 1 or greater (i.e., one or more apnea events per hour of sleep) and can be classified as mild if the AI is between 1 and 5, moderate if the AI is between 5 and 10, and severe if the AI is greater than 10 events per hour of sleep. Of particular concern are children in whom cardiac dysfunction (cor pulmonale) has developed and those in whom postobstructive pulmonary edema could develop. These children may require overnight ventilation in an ICU. In general, risk factors for postoperative complications include (1) age younger than 3 years; (2) abnormal coagulation values; (3) evidence of OSA; (4) systemic disorders that place the child at increased perioperative risk (e.g., cor pulmonale, metabolic diseases); (5) presence of craniofacial or other airway abnormalities; (6) performance of the procedure is for peritonsillar abscess; and (7) living a long distance from an adequate health care facility, adverse weather conditions, or home conditions not consistent with close observation, cooperativeness, and ability to return quickly to the hospital (e.g., substance-abusing parents, teenage mother).[179] The main problems that we face as anesthesiologists are when it is safe to send these children home and what we should do to provide postoperative analgesia. Some day-surgery centers send tonsillectomy children home immediately; others hold the children for at least 4 hours (the interval most likely for bleeding or respiratory compromise to occur). Hospitals tend to admit the children to a 23-hour unit (to avoid the 24-hour "hospital admission"), thus observing the child for an extended time (usually not the full 23 hours) while minimizing expense to the insurance provider. Though inefficient in cost, this provides the best safety net for these children. Analgesia is generally provided with a combination of oral acetaminophen given preoperatively or rectally after induction and low-dose morphine (50 μg/kg). Some anesthesiologists prefer short-acting opioids such as fentanyl to minimize respiratory depression and then supplement the analgesia with an additional longer-acting opioid in the PACU. Ketorolac provides analgesia without adverse respiratory effects, but it is associated with an increased incidence of postoperative bleeding if given before achieving hemostasis.[180] Postoperative nausea and vomiting are generally treated with serotonin 5-HT_3 antagonists, whereas postoperative swelling (plus vomiting) is treated with dexamethasone (0.0625 to 0.15 mg/kg).[181] The most common at-home analgesic is acetaminophen with codeine. One issue that requires further evaluation is the possibility of alteration of opioid receptors (upregulation of μ-receptors) in response to repeated minor hypoxemic events, as well as of response to carbon dioxide.[182-185] These altered responses result in increased sensitivity to the respiratory depressant effect of opioids.[186] It addition to these factors, it has been shown that children with OSA have a structurally narrowed airway because of an increased propensity for upper airway collapsibility.[187] These factors explain in part why children with OSA are at markedly increased risk for postoperative respiratory complications.[170,177,188,189]

Regional Anesthesia and Analgesia

Most regional anesthesia techniques used in adults can be administered safely to pediatric patients so long as strict attention is paid to the dose of local anesthetic, the dose of epinephrine, the route of administration, and the use of proper equipment. Perhaps the greatest advance in pediatric anesthesia has been the development of methods producing postoperative analgesia (also see Chapters 81 and 87). Caudal anesthesia, caudal narcotics, regional blocks, and child-parent-nurse–controlled analgesia have all been accepted by anesthesiologists and children. Recent advances in ultrasound equipment have further improved the accuracy of nerve blocks. Even pediatric patient–controlled epidural analgesia has been used successfully in children as young as 5 years.[190] Each institution and practitioner must decide which method works best given each particular practice setting. Obviously, until dosage guidelines and safety standards for monitoring are well established, some of these techniques must be limited to medical centers familiar with their use in children.[191]

It is my practice to supplement the analgesia of either opioid or regional techniques with 40 mg/kg of acetaminophen rectally at the beginning of the procedure. Several studies have demonstrated that 40 mg/kg of acetaminophen rectally will place a majority of children in the therapeutic range for antipyresis (we do not know the plasma levels associated with analgesia in children) within 60 to 180 minutes, hence the need to insert the suppositories at the beginning of the procedure rather than at the end.[192] It should be noted that suppositories should not be cut open because the drug may not be evenly distributed within the matrix; combinations of suppository doses are the best means of achieving a dose close to 40 mg/kg. Repeat rectal dosing should be approximately 20 mg/kg every 6 hours until transition to oral acetaminophen (total 24-hour limit, ~100 mg/kg either orally or rectally).[192]

Regional nerve blocks and direct local infiltration of surgical wounds with long-acting local anesthetics are simple yet very effective methods of providing pain relief for all children. In most institutions it is now rare for a pediatric patient to awaken from anesthesia without some form of regional block. This practice has been especially helpful in the outpatient population; parents are encouraged to start analgesics when they observe their child becoming irritable but before complete dissipation of the block. This approach usually provides a smooth transition from general anesthesia and a pain-free child. Chapters 51 to 53 discuss regional anesthesia and analgesia in detail, and in Chapter 81 special emphasis is placed on pediatrics.

83 Anesthesia for Pediatric Cardiac Surgery

Key Points

1. Organ system maturation, from birth through adolescence (e.g., cardiovascular, central nervous system [CNS], pulmonary, renal, hematologic), affects physiologic function and therefore anesthetic and surgical management and outcome.
2. Physiologic understanding of congenital heart disease and consequent anesthetic management are based on the pathophysiologic determinants of four categories of defects: shunts, mixing lesions, stenotic lesions, and regurgitant lesions.
3. The chronic sequelae of congenital heart disease—repaired, palliated, or unrepaired—affect anesthetic management: ventricular failure, residual hemodynamic effects (e.g., valve stenosis), arrhythmias, and pulmonary blood flow changes (e.g., pulmonary artery hypertension).
4. Preoperative assessment of cardiac status (e.g., review of history and physical examination, echocardiography, and catheterization data and consulting with the patient's cardiologist) and planning are the keys to a successful anesthetic outcome.
5. Intraoperative transesophageal echocardiography and CNS monitoring enhance surgical outcome and reduce morbidity.
6. Selecting an induction technique is dependent on the degree of cardiac dysfunction, the cardiac defect, the degree of sedation provided by the premedication, and the presence or absence of an indwelling venous catheter. The maintenance of anesthesia depends on the age and condition of the patient, the nature of the surgical procedure, the duration of cardiopulmonary bypass (CPB), and the need for postoperative ventilation.
7. The physiologic effects of CPB on neonates, infants, and children are significantly different from the effects on adults. During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (18°C), hemodilution (threefold to fivefold greater dilution of circulating blood volume), low perfusion pressures (20 to 30 mm Hg), and wide variation in pump flow rates (ranging from 200 mL/kg/min to total circulatory arrest).
8. After the repair of complex congenital heart defects, the anesthesiologist and surgeon may have difficulty separating patients from CPB. Under these circumstances, the underlying cause must be determined, which may be (a) an inadequate surgical result with a residual defect requiring repair, (b) pulmonary artery hypertension, or (c) right or left ventricular dysfunction.
9. The use of modified ultrafiltration (MUF) reverses the deleterious effects of hemodilution and the inflammatory response associated with CPB in children. Perioperative blood loss and blood use are significantly reduced when MUF is used. MUF also improves left ventricular function and systolic blood pressure and increases oxygen delivery. Pulmonary compliance and brain function after CPB are also improved.
10. Neonates, infants, and children undergoing cardiac surgery with CPB have a higher rate of postoperative bleeding than that seen in older patients. This is due to several factors: (a) There is disproportionate exposure to the nonendothelialized extracorporeal circuit, which produces an inflammatory-like response. This inflammatory response to CPB is inversely related to patient age; the younger the patient, the more pronounced the response. (b) The type of surgery performed in neonates and infants usually involves more extensive reconstruction and suture lines, creating more opportunities for surgical bleeding than in adult cardiac patients. (c) Operations are frequently performed using deep hypothermia or circulatory arrest, which may further impair hemostasis. (d) The immature coagulation system in neonates may also contribute to impaired hemostasis. (e) Patients with cyanotic heart disease demonstrate an increased bleeding tendency before and after CPB.
11. The guiding principle in the management of the postoperative patient is an understanding of both

normal and abnormal convalescence after anesthesia and cardiac surgery. The immediate postoperative period, even that of normal convalescence, is one of continuous physiologic change because of the pharmacologic effects of residual anesthetic agents and the ongoing physiologic changes secondary to abrupt alteration in hemodynamic loading conditions, surgical trauma, and extracorporeal circulation.

12. There are additional anesthetic considerations in patients with congenital heart disease who undergo transplantation, closed heart operations without CPB, cardiac interventional procedures, and noncardiac surgery.

Cardiac surgery is an established and effective treatment for children with congenital heart defects. Early successes in surgical treatment have led to a new therapeutic era in the management of congenital heart disease and have fostered the development of the subspecialties pediatric cardiology and cardiac surgery and their collaboration. Through this cooperative effort, tremendous progress in medical diagnosis and surgical treatment has been achieved. In turn, these accomplishments gave rise to the development of pediatric cardiac anesthesiologists, individuals who understand the pathophysiology of congenital heart malformations, the diagnostic and surgical procedures used to treat heart disease, and the principles of pediatric and cardiac anesthesia as well as of intensive care medicine. Pediatric cardiac anesthesia continues to evolve as an exciting and technically demanding subspecialty in which anesthetic management is based on physiologic principles.

Congenital cardiovascular surgery and anesthesia are often performed under unusual physiologic conditions. Rarely in clinical medicine are patients exposed to such biologic extremes as during congenital heart surgery. Commonly, patients are cooled to 18°C, are acutely hemodiluted by more than 50% of their extracellular fluid volume, and undergo periods of total circulatory arrest lasting up to 1 hour. Management of patients under these physiologic extremes is a vital function of the pediatric cardiovascular anesthesiologist. As with other areas of medicine, the application and management of technology preceded a comprehensive understanding of its physiologic effects.

Clearly, the perioperative management of these complex cases requires a group of physicians (surgeon, anesthesiologist, cardiologist, critical care specialist), nurses, and perfusionists to work as a team. This team orientation is essential to the achievement of an optimal outcome. Although the quality of the surgical repair, the effects of cardiopulmonary bypass (CPB), and postoperative care are the major determinants of outcome, meticulous anesthetic management is also imperative. Ideally, despite the complexity of the cases and the marked physiologic changes attributed to CPB and the surgical procedures, anesthetic care should never contribute substantially to morbidity or mortality.[1] The challenge is to understand the principles underlying the management of patients with congenital heart disease and to apply them to clinical anesthesia. We assume that the reader already understands the fundamentals of adult cardiac (see Chapter 60) and general pediatric anesthesia (see Chapter 82).

Unique Features of Pediatric Cardiac Anesthesia

Pediatric cardiovascular management is unique. Important differences from adult cardiac surgery do exist (Table 83-1). These differences are attributable to normal organ system maturation in the neonate and young infant, differing pathophysiologic conditions in congenital heart disease, the diversity of surgical repairs, and the use of specialized CPB techniques such as deep hypothermia and total circulatory arrest.

Table 83-1 Unique Characteristics of Pediatric Cardiac Anesthesia

Patient
Normal organ system development and maturational changes of infancy
Cardiovascular: blood flow patterns of circulation at birth, myocardial compliance, systemic and pulmonary vasculature, and β-adrenergic receptors
Pulmonary: respiratory quotient, closing capacity, chest compliance
Central nervous system: brain growth, cerebral blood flow, autonomic regulation
Renal: glomerular filtration rate, creatinine clearance
Hepatic: liver blood flow, microsomal enzyme activity
Disease/growth interrelationship
Effects of systemic disease alter somatic and organ growth
Compensatory ability of developing organs to recover from injury
Immunologic immaturity of the infant
Obligatory miniaturization (i.e., small patient size and body surface area)
Congenital Heart Disease
Diverse anatomic defects and physiologic changes
Altered ventricular remodeling owing to myocardial hypertrophy and ischemia
Chronic sequelae of congenital cardiac disease
Surgical Procedures
Diversity of operations
Frequent intracardiac and right ventricular procedures
Use of deep hypothermia and circulatory arrest during repair
Trend toward repair in early infancy
Evolution of surgical techniques to avoid residua and sequelae
Trend toward wider application of certain operations

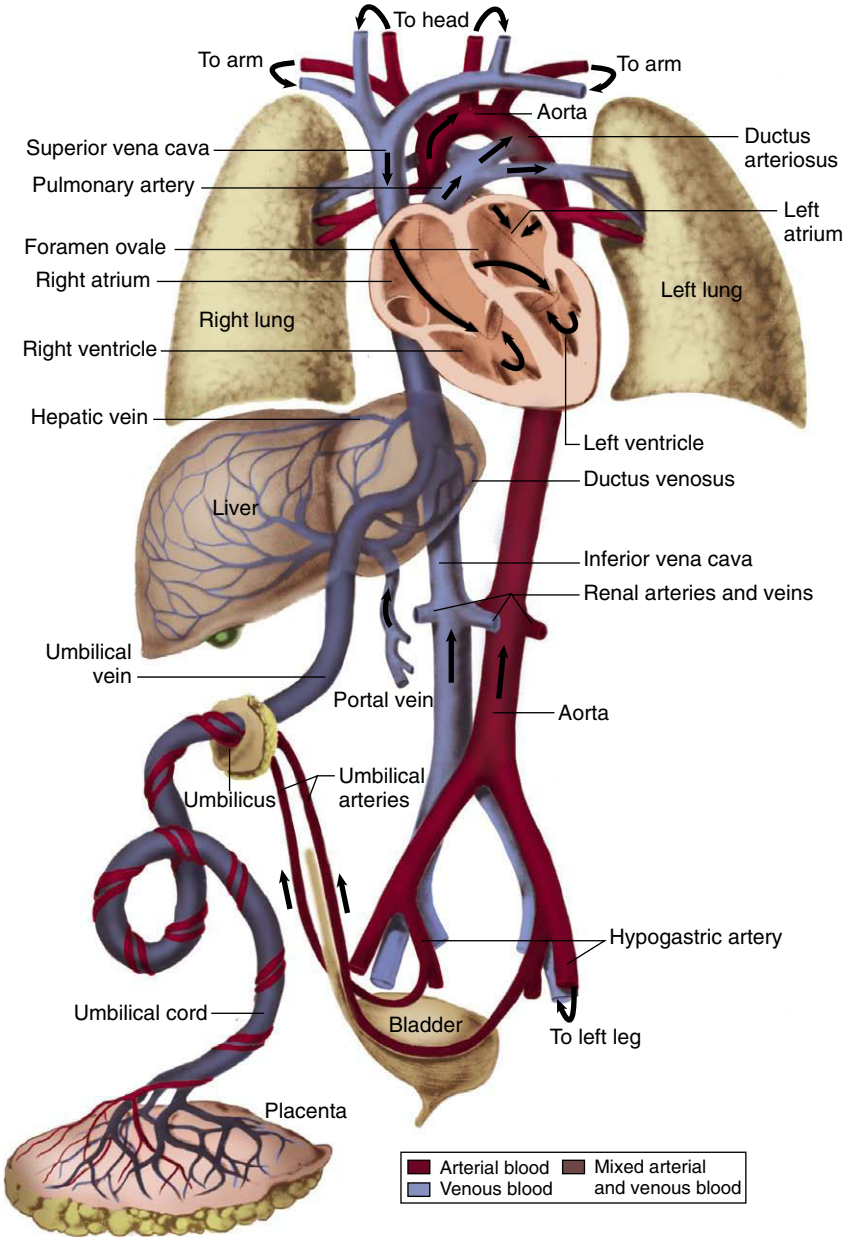

Figure 83-1 Course of the fetal circulation in late gestation. Note the selective blood flow patterns across the foramen ovale and the ductus arteriosus.

Physiologic Considerations and Maturational Features of the Pediatric Patient

The cardiovascular system changes markedly at birth because of a dramatic alteration in blood flow patterns (Fig. 83-1). During fetal life, blood flow returning to the right atrium bypasses the unventilated fluid-filled lungs. Blood is then preferentially shunted across the patent foramen ovale into the left atrium or passes from the right ventricle (RV) across the patent ductus arteriosus (PDA) to the systemic circulation. At birth, physiologic closure of the PDA and of the foramen ovale brings about the normal adult circulatory pattern. The presence of certain congenital heart defects or pulmonary disease can disrupt this normal adaptive process, creating a transitional circulation in which right-to-left shunting persists across the foramen ovale or the PDA. Under such circumstances, the continued presence of a transitional circulation can lead to severe hypoxemia, acidosis, and hemodynamic instability, which are poorly tolerated in the neonate. In contrast, when initially treating some forms of congenital heart disease, the prolongation of this transitional circulation is actually beneficial, promoting systemic or pulmonary blood flow (PBF) and postnatal viability. An example of the latter is pulmonary atresia, in which PBF is supplied via the PDA. In the absence of collateral vessels, closure of the PDA eliminates the principal source of PBF, resulting in hypoxemia and death. Ductal patency can be maintained with the administration of prostaglandin E_1. Importantly, the transitional circulation can be manipulated by pharmacologic ventilatory strategies, thereby promoting hemodynamic stability in the young patient.

Another unique feature of the normal neonatal and infant cardiovascular system is the reduced myocardial reserve compared with that in the healthy adult. The newborn left ventricular

function is restricted by a reduced number of α-adrenergic receptors, high resting levels of circulating catecholamines, limited recruitable stroke work, an immature calcium transport system, and decreased ventricular compliance.[2] This limits contractile reserve and results in a left ventricle (LV) with a high level of resting tone. Although the resting performance of the neonatal myocardium may be greater than in adults and older children, there is a greater sensitivity to β-blockade and only modest increases in cardiac performance after administration of the β-agonist drugs dobutamine and isoproterenol.[3]

On the ultrastructural level, a variety of cellular synthetic functions are occurring in immature myofibrils that dominate the newborn heart. Large nuclei, mitochondria, and surface membranes predominate within the myofibrils. In neonates, there is a 50% reduction in the number of myofibrils and the myofibrils are arranged in a nonlinear, disordered array. As a direct result, the contractile mass of the heart is effectively reduced, resulting in a ventricle with low compliance.[4] Preload augmentation is effective at low filling pressures (1 to 7 mm Hg). However, when left-sided filling pressures exceed 7 to 10 mm Hg, further increases in left ventricular stroke volume are minimal.[2] As a consequence, neonates are more dependent on heart rate and, to a lesser extent, on preload, to maintain cardiac output at filling pressures of 7 to 10 mm Hg or greater.[5]

In addition to a reduced contractile mass, the calcium transport system in the neonatal myocardium is underdeveloped. The transverse tubular system is absent, and the sarcoplasmic reticulum, which has to store and release calcium, is small and inefficient. The neonatal heart is therefore more dependent on extracellular calcium levels than the adult myocardium.[6-9] Because intracellular calcium concentrations play a central role in myocardial contractility, normal or even elevated plasma levels of ionized calcium may be necessary to augment or maintain an effective stroke volume.[10] This is in contrast to adult cardiac patients in whom calcium use during cardiac surgery has fallen into some disfavor, owing to direct concerns over myocardial ischemia and reperfusion injury.

Another unique feature relates to the pulmonary circulation. The pulmonary circulation undergoes significant changes during the first months of life. These changes are largely characterized by regression of the hypertrophied medial smooth muscular layer in the pulmonary arteries that exists in utero, resulting in a concomitant drop in pulmonary vascular resistance (PVR). In the immediate newborn period, the large decrease in PVR is due to lung expansion and the vasodilatory effects of a higher Pao_2 than existed in utero. Further decline in PVR throughout the next 2 months of life is attributable to regression of the smooth muscle layer in the pulmonary arterioles. A corresponding decrease in pulmonary artery pressure occurs as PVR declines. Acute physiologic stress in the newborn period, such as hypoxemia or acidosis, can increase pulmonary artery pressure and thus PVR. If the resulting right ventricular hypertension causes reduced right ventricular compliance, right-to-left shunting can occur at the foramen ovale. Once PVR exceeds systemic vascular resistance (SVR), right-to-left shunting develops at the PDA. Either phenomenon will worsen the hypoxemia and eventually limit tissue oxygen delivery to the point of lactic acidosis. In contrast, left-to-right shunts, such as with a ventricular septal defect (VSD), produce intimal changes in the pulmonary vasculature and delay regression of medial muscle hypertrophy. This results in persistent elevation of PVR.

Size differences between adult and pediatric cardiac patients require different anesthetic techniques and miniaturization. Anatomically, pediatric patients have small upper and lower airways, small veins and arteries, and a decreased body surface area, as compared with adult patients. There are several anesthetic implications related to patient size. Some centers believe that the placement of arterial catheters by cutdown in neonates and infants represents the most expedient approach, particularly when optimal sites are limited. Pulmonary artery catheters are used infrequently, both because of the technical difficulties in positioning the tip in the pulmonary artery and because of the fundamental fact that pulmonary flow bears no obligatory relationship to systemic output in children with either intra- or extracardiac communications. Transthoracic catheters for pressure monitoring and delivery of vasoactive substances are commonly placed from the surgical field instead of percutaneous approach via the neck. Adequacy of the repair and function can be assessed by transesophageal echocardiography with Doppler color flow imaging with miniaturized probes.[11,12] CPB serves as another example of the influence of patient size on management. The ratio of pump priming volume to patient blood volume is considerably higher in small children than in adults, resulting in a greater degree of hemodilution. Several studies have demonstrated a heightened inflammatory response to CPB in children compared with adults.[13] This effect is related to the disproportionate exposure to the nonendothelialized surfaces of the pump circuit per body surface area. Greater damage to the formed blood elements and plasma proteins is incurred, resulting in activation of mediators of inflammation.

In pediatric patients with congenital heart disease, the cardiovascular system often represents the sole cause of the medical problem. This is in contrast with the multiplicity of diagnoses and organ system involvement frequently found in adults with acquired cardiovascular disease. Moreover, there is a special disease/growth interrelationship unique to growing infants and children that does not exist in adults. This special interrelationship permits developing organs to compensate for and modify existing disease processes. Reparative and recuperative processes in children are greater as a result of this compensatory ability of developing organ systems. Adult cardiac patients unfortunately do not exhibit the same recuperative ability. Although children adapt well to cardiovascular pathology, there are some negative aspects to long-standing heart disease. Congenital heart disease has detrimental effects on somatic growth as well as on the growth and development of the brain, myocardium, and lung.

Other unique considerations are issues surrounding the premature infant (see Chapter 84). Premature infants are classified as low birth weight infants (31-34 weeks, 1-1.5 kg), very low birth weight infants (26-30 weeks, 600 g–1 kg) and extremely low birth weight infants (<26 weeks, 400-600 g). This population of infants manifests unique anesthetic challenges. Cardiorespiratory failure is common and multifactorial. The small airways are prone to obstruction, which results in increased airway resistance and work of breathing with easy fatigability. Diseases of the upper airway such as subglottic stenosis, tracheomalacia, and tracheal stenosis are poorly tolerated, and the use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) is often necessary to stent open the airway. Lung compliance is reduced because of a deficiency of surfactant, resulting in intrapulmonary shunt and ventilation-perfusion mismatch. Mechanical ventilation prevents alveolar collapse, maintains

patency of the airway, and maintains lung volume, preventing hypoxia. Premature lungs are susceptible to barotrauma and oxidant injury. Ventilation should utilize measures to reduce peak inspiratory pressures and barotrauma, and the inspired oxygen concentration should be reduced to avoid generation of free radicals. Premature infants are also prone to perioperative periods of apneas. Such apneas might be central in origin or obstructive, both of which can be aggravated by anesthetic agents. Apnea can be precipitated by abrupt changes in oxygenation, pulmonary mechanics, brain hemorrhage, and hypothermia. Sustained apnea can result in desaturation and usually begins after emergence from anesthesia and persists for up to 48 hours. Continuous apnea and saturation monitoring with correction of anemia (hematocrit > 30) and intravenous administration of caffeine are therapeutic options. The incidence of postoperative apnea is related to postconceptional and gestational age, the presence of anemia, and the type of surgical procedure. The premature heart is a poorly contractile organ, sensitive to changes in intracellular calcium, with poor diastolic function. Cardiac output is dependent on heart rate, with marginal reserve. The premature infant also has a relatively low absolute blood volume and tolerates blood loss poorly. Autoregulation is not well developed and blood loss compromises cerebral and coronary flow prior to other manifestations of hypovolemia. It is also imperative to avoid fluid overload in these patients. Patency of the ductus arteriosus results in pulmonary overcirculation with heart failure and a large left-to-right shunt. If uncorrected, this would result in pulmonary hypertension secondary to the development of pulmonary vascular occlusive disease. Thermoregulation by nonshivering thermogenesis is also poor owing to inadequate stores of brown fat in prematurity. It is critical to maintain normothermia by increasing the operating room temperature, using incubators for transport, warming and humidification of respiratory gases, and warming all intravenous fluids. Glycemic control is poor with a tendency to hypoglycemia and hyperglycemia. It is important to monitor and maintain euglycemia. Typically, these infants receive higher concentrations of parenteral glucose solutions, which need to be continued in the perioperative period. Premature infants are also prone to retinopathy of prematurity with high inspired oxygen concentrations and intraventricular hemorrhage. Every attempt should be made to avoid hemodynamic perturbances and fluctuation in oxygen saturations. In general, immaturity of organ systems results in both increased drug effect and duration of action, warranting careful titration of drugs.

Prematurity is associated with a twofold increase in cardiovascular malformations compared with infants born at term.[14] One in 6 infants with congenital heart disease not including those with PDA or ASD are born prematurely. Some malformations such as tetralogy of Fallot, pulmonary stenosis, pulmonary atresia with ventricular septal defect, complete atrioventricular septal defect, large ventricular septal defects in isolation or associated with coarctation, and aortic stenosis are more prevalent in this population.[15] There is a significant increase in the likelihood of being small for gestational age among infants with tetralogy of Fallot, complete atrioventricular septal defect, hypoplastic left heart, pulmonary stenosis, or large ventricular septal defect.[16]

Cardiac catheterization, intervention, and complete surgical repair in the very-low-birth-weight newborn (<1.5 kg) can be successfully undertaken with low risk, although longer-term follow-up remains necessary to determine growth and development patterns. However, because of the complexity of premature organ systems and superimposed cardiorespiratory pathophysiology, morbidity and mortality are increased.[17-19] Surgical adaptations have been described that enable the use of CPB in low-birth-weight infants. However, low birth weight remains a significant risk for mortality in neonates with complex single ventricle disease undergoing surgical palliation.[20,21] Interventional catheterization is associated with higher risk of complications, especially related to problems with vascular access, arrhythmias, and respiratory compromise.[18] Premature infants are electively intubated and ventilated for both catheterization and surgical procedures. Adequate intravenous access and invasive monitoring can be challenging but are necessary in most cases. Maintenance of euglycemia and normothermia and attention to fluid and electrolyte balance are important. Oxygen delivery should be optimized by maintaining age-appropriate blood pressures, adequate intravascular volume, and hematocrit. Any acidosis must be sought and aggressively corrected. Generally, such infants should recover in a specialized pediatric cardiac intensive care unit.

Congenital Heart Disease

The marked array of anatomic and physiologic conditions seen with congenital heart disease distinguish these processes from acquired adult cardiac disease. The spectrum of intracardiac shunts, valve pathology (stenoses, regurgitation, or atresia), and disrupted great artery connections and the absence of one or more chambers of the heart preclude a uniform anesthetic approach to patients with congenital heart disease. Moreover, there are myocardial changes resulting from the hemodynamic impact and increased cardiac work incurred by these defects. Functionally, these myocardial changes place the ventricles at great risk for the development of intraoperative ischemia and failure. Therefore, an understanding of the isolated defect, associated myocardial changes, and hemodynamic consequences is fundamental to planning an appropriate anesthetic regimen.[4] Too often, because of the complexity and diversity of the defects, the anesthesiologist, cardiologist, and surgeon are focused on the specific anatomic considerations and the physiologic implications are overlooked. Distilling congenital heart disease into a finite number of physiologic categories enables the anesthesiologist to construct a strategy that employs the qualitatively predictable impact of pharmacologic agents, ventilatory management, and fluid administration to optimize cardiovascular performance. Although an isolated heart malformation may be identified, the entire cardiopulmonary system is usually affected.

Physiologic Approach to Congenital Heart Disease

Although the structural variations seen in congenital heart disease constitute an encyclopedic list of malformations, anesthetic management is more logically designed to achieve physiologic goals. A general physiologic classification is listed in Table 83-2. Fortunately, although structurally complex, these defects can be understood within a more limited physiologic spectrum. Identification and classification on the basis of physiology provide an organized framework for the intraoperative anesthetic management and postoperative care of children with complex congenital cardiac defects. In general, congenital heart lesions fit into one of four categories: shunts, mixing lesions, flow obstruction, and regurgitant valves (see Table 83-2). Each category imposes at least one

Table 83-2 Classification of Congenital Heart Defects

Physiologic Classification	Pulmonary Blood Flow	Comments
Left-to-right shunts		
VSD	↑	Volume-overloaded ventricle
ASD		Development of CHF
PDA		
AV canal		
Right-to-left shunts		
Tetralogy of Fallot	↓	Pressure-overloaded ventricle
Pulmonary atresia/VSD		Cyanotic
Eisenmenger complex		Hypoxemia
Mixing lesions		
Transposition/VSD	Generally ↓ but variable $\dot{Q}p/\dot{Q}s$	Variable pressure versus volume loaded
Tricuspid atresia		Usually cyanotic
Anomalous venous return		
Univentricular heart		
Obstructive lesions		
Interrupted aortic arch		Ventricular dysfunction
Critical aortic stenosis		Pressure-overloaded ventricle
Critical pulmonic stenosis		Ductal dependence
Hypoplastic left heart syndrome		
Coarctation of the aorta		
Mitral stenosis		
Regurgitant lesions		
Ebstein's anomaly		Volume-overloaded ventricle
Other secondary causes		Development of CHF

ASD, atrial septal defect; AV canal, atrioventricular canal; CHF, congestive heart failure; PDA, patent ductus arteriosus; $\dot{Q}p$, pulmonary blood flow; $\dot{Q}s$, systemic blood flow; VSD, ventricular septal defect.

of three pathophysiologic states: ventricular volume overload, ventricular pressure overload, or hypoxemia. Ultimately, these pathophysiologic conditions can result in myocardial failure or pulmonary vascular disease. Medical and surgical perioperative management strategies should be focused on minimizing the pathophysiologic consequences of these lesions.

Shunt Lesions

Shunts are intracardiac connections between chambers or extracardiac connections between a systemic and pulmonary artery; examples are an atrial septal defect (ASD), a VSD, and a PDA. The direction of blood flow through the shunt is dependent on the relative resistances on either side of the shunt and on the size of the shunt orifice.[22] With a nonrestrictive VSD or PDA that does not impede blood flowing freely in each direction, the main determinant of blood flow is the resistance of the pulmonary and systemic vascular beds. The direction and magnitude of shunt at the atrial level are governed by the relative differences in ventricular compliance and respective atrioventricular (AV) valve function. The effect that a shunt lesion has on the cardiovascular system depends on its size and direction, either right-to-left or left-to-right. Left-to-right shunts occur when the PVR is lower than the SVR and blood flow is preferentially directed toward the lungs, resulting in increased PBF.

In patients with large left-to-right shunts and low PVR, a substantial increase in PBF can occur. This results in three pathophysiologic problems: (1) congestion of the pulmonary circulation; (2) volume overload with resulting increased cardiac work for the LV, which is required to increase stroke volume and heart rate to ensure adequate systemic perfusion; and (3) excessive PBF, resulting in progressive elevation in PVR. Volume overload causes ventricular dilation that places the heart at a mechanical and physiologic disadvantage, resulting in reduced diastolic compliance. These diastolic changes lead to engorgement of the respective venous beds, which produces the signs and symptoms of clinical congestive heart failure early in the natural history of volume-overload condition. The demand for increased cardiac output placed on the LV is limited in the infant by virtue of its immature structure, so that large left-to-right shunts may outstrip the capacity of the left side of the heart to maintain adequate systemic perfusion, and congestive heart failure will result. Surgical closure of a hemodynamically significant VSD usually provides immediate benefit by dramatically lowering left ventricular volume output demands.

Occasionally, the sudden increase in wall stress imposed on a dilated ventricle that must now pump solely against SVR can produce worsening ventricular failure during the early postoperative period after eliminating the low resistance "popoff" into the pulmonary circulation. If the left-to-right shunt is not repaired, prolonged exposure to increased PBF results in progressive elevations in PVR. Fixed changes in pulmonary arterioles may occur, leading to pulmonary vascular obstructive disease. Table 83-2 lists common left-to-right shunt lesions.

Right-to-left shunts occur when pulmonary vascular or right ventricular outflow tract resistance exceeds SVR, thereby reducing PBF. The systemic circulation receives an admixture of

deoxygenated blood via the shunt and manifests clinically as cyanosis and hypoxemia. Pure right-to-left shunting due to increased PVR is seen in the Eisenmenger complex and in persistent pulmonary hypertension of the newborn with atrial and ductal level shunting. More commonly, PVR is low, and a more complex lesion with obstruction of pulmonary outflow, proximal to the pulmonary vasculature, produces right-to-left shunting. Defects such as tetralogy of Fallot represent classic right-to-left shunts. The shunting occurs through the VSD because of pulmonary outflow obstruction. Systemic perfusion is generally normal with right-to-left shunting lesions unless hypoxemia becomes severe enough to impair oxygen delivery to tissue. Thus, there are two pathophysiologic problems: (1) reduced PBF resulting in systemic hypoxemia and cyanosis and (2) an increased impedance to right ventricular ejection resulting in pressure overload, which may ultimately lead to ventricular dysfunction and failure of the RV. However, the physiologic mechanisms designed to compensate for pressure overload rarely create abnormalities in systolic or diastolic function early in the natural history of the disease process. In contradistinction to lesions that produce ventricular volume overload, ventricular dysfunction and failure typically take years to develop in the context of isolated pressure overload.

Mixing Lesions

Mixing lesions constitute the largest group of cyanotic congenital heart defects (see Table 83-2). In these defects, the mixing between the pulmonary and the systemic circulation is so large that the systemic and pulmonary artery oxygen saturations approach each other. The pulmonary-to-systemic flow ratio $\left(\dot{Q}p/\dot{Q}s\right)$ is independent of shunt size and totally dependent on vascular resistance or outflow obstruction. The pulmonary and systemic circulations tend to be in parallel with one another rather than in series (see Table 83-2). In patients with no outflow obstruction, flow to the systemic or pulmonary circulation is dependent on the relative vascular resistances of both circuits, such as with univentricular hearts or double-outlet RV. If SVR exceeds PVR, as in the typical circumstance, the tendency is toward excessive PBF, and the predominant pathophysiologic process is left-to-right shunting. These patients have increased PBF, ventricular volume overload, and a gradual elevation of PVR over time. If PVR exceeds SVR, as may occur episodically in ductal-dependent lesions such as hypoplastic left heart syndrome, systemic blood flow predominates and PBF dramatically decreases, causing progressive hypoxemia (Table 83-3).

In patients with a mixing lesion and left ventricular outflow obstruction, PBF may be sufficiently excessive to impair systemic perfusion. In patients with mixing lesions and a right ventricular outflow obstruction such as a single ventricle with subpulmonic stenosis, systemic-to-pulmonary flow can vary from balanced flow to significantly decreased PBF in which the severity of hypoxemia depends on the degree of obstruction. Typical mixing lesions include truncus arteriosus, univentricular heart, total anomalous pulmonary venous return, pulmonary atresia with large VSD, and single atrium.

Table 83-3 Ductal-Dependent Lesions

PDA Provides Systemic Flow	PDA Provides Pulmonary Flow
Coarctation of the aorta	Pulmonary atresia
Interrupted aortic arch	Critical pulmonary stenosis
Hypoplastic left heart syndrome	Severe subpulmonic stenosis with VSD
Critical aortic stenosis	Tricuspid atresia with pulmonic stenosis

PDA, patent ductus arteriosus; VSD, ventricular septal defect.

Obstructive Lesions

Obstructive lesions range from mild to severe. Severe lesions present in the newborn period with a pressure-overloaded, diminutive, or profoundly dysfunctional ventricle proximal to the obstruction. These lesions include critical aortic stenosis, critical pulmonic stenosis, coarctation of the aorta, and interrupted aortic arch. Although aortic and pulmonary atresia represent the most extreme variants of outflow tract obstruction, they are associated with such extreme hypoplasia of the ventricle (hypoplastic left heart syndrome and pulmonary atresia with intact ventricular septum, respectively) that the ventricle's function does not contribute to the circulatory physiology. As with other critical obstructive lesions, these extreme variants have ductal-dependent circulations, but beyond that similarity they are perhaps better understood as univentricular hearts for which the management characteristics of a mixing lesion dominate in importance. In critical neonatal left-sided obstructive defects, systemic perfusion is dependent on blood flow (desaturated) from the RV via the PDA and the coronary perfusion is supplied by retrograde flow from the descending aorta (see Table 83-3). In right-sided lesions, PBF is supplied from the aorta via the PDA and right ventricular function is impaired.

Pathophysiologic problems in critical neonatal left-sided heart obstructive lesions include (1) profound left ventricular failure, (2) impaired coronary perfusion with an increased incidence of ventricular ectopy, (3) systemic hypotension, (4) PDA-dependent systemic circulation, and (5) systemic hypoxemia. The pathophysiologic problems in critical neonatal right-sided heart obstructive lesions include (1) right ventricular dysfunction, (2) decreased PBF, (3) systemic hypoxemia, and (4) PDA-dependent PBF. Apart from the most extreme variants that become evident in the neonatal period, infants and children with outflow obstruction (e.g., mild to moderate aortic or pulmonary stenosis, coarctation of the aorta) manifest the effective compensatory mechanisms for pressure overload, often remaining clinically asymptomatic for many years.

Regurgitant Valves

Regurgitant valves are uncommon as primary congenital defects. Ebstein's malformation of the tricuspid valve is the only pure regurgitant defect presenting in the newborn period. However, regurgitant lesions are frequently associated with an abnormality of valve structure, such as incomplete or partial AV canal defect, truncus arteriosus, and tetralogy of Fallot with an absent pulmonary valve. The pathophysiology of regurgitant lesions includes (1) volume-overloaded circulation and therefore (2) progression toward ventricular dilation and failure.

In summary, when considering the incidence of all the congenital heart defects, three uncomplicated left-to-right shunts (VSD, ASD, PDA) and two obstructive lesions (pulmonic stenosis, coarctation) constitute 60% of all congenital cardiac defects. Mixing lesions, complicated obstructive defects, and right-to-left

shunting lesions account for the vast majority of the remaining 40%. The latter group of defects, which are more difficult to manage, are more labor intensive and have a significantly higher morbidity and mortality rate. This observation is directly attributed to the complexity of the cardiovascular abnormalities seen in this group, in which there is an absence of a chamber or a major ventricular-arterial connection.

Chronic Consequences of Congenital Heart Disease

The chronic effects of congenital heart disease are a consequence of the imposed hemodynamic stress of the defect or the residua and sequelae after cardiac surgery. These effects continue to alter normal growth and development of the cardiovascular system as well as other organ systems throughout life. Complete surgical cures are rarely achieved, and some repairs are palliative rather than corrective; therefore, abnormalities before and after repair produce long-term effects in patients with congenital heart disease.[23] Although the overall outlook for these patients is good in most instances, every defect has associated myocardial changes and every repair leaves certain obligatory abnormalities. Many of the abnormalities are trivial and have no major import. Others affect major organ system processes, such as ventricular function, central nervous system growth, the conduction system of the heart, or PBF. Under these circumstances, the long-term quality of life is affected. Whether anesthetizing these patients for their primary or subsequent cardiac repair or for noncardiac surgery, these chronic changes should be ascertained and reflected in the anesthetic plan.

The myocardium is continually remodeled by specific hemodynamic stresses in utero and throughout life. Right ventricular growth and development are influenced by the low-resistance afterload of the pulmonary circulation. The LV is coupled to the high-resistance systemic circulation, which accelerates its rate of growth and development. This situation gives rise to the adult condition in which left ventricular dominance of myocardial muscle mass occurs. This entire developmental process is referred to as dynamic ventricular modeling.[4] Abnormal hemodynamic loading conditions associated with congenital heart disease interrupt the normal ventricular modeling process (Fig. 83-2).[24] Abnormal ventricular remodeling typically begins in utero and stimulates an increase in ventricular mass. Increased ventricular mass is due to both hyperplasia and hypertrophy of myocytes in response to altered wall stress on the developing ventricle. The resultant biomechanical deformation of the ventricle alters its geometry, affecting normal systolic and diastolic function.

Abnormalities of ventricular performance at rest and with exercise can be detected in patients with chronic hemodynamic overload and complex cyanotic lesions. These abnormalities in ventricular function are the consequences of chronic ventricular overload, repeated episodes of myocardial ischemia, and residua or sequelae of surgical treatment (ventriculotomy, altered coronary artery supply, inadequate myocardial protection). The physiologic adaptive responses to chronic hypoxemia and ventricular pressure or volume overload are the primary stimuli producing the long-term ventricular dysfunction. Although chronic volume overload of the LV as seen with left-to-right shunts or a chronic pressure-loaded LV due to left-sided obstructive lesions results in congestive heart failure, the compensatory mechanisms for pressure overload create less physiologic disturbance, particularly in diastolic function. Consequently, congestive heart failure occurs later in the natural history of isolated obstructive lesions that do not require treatment in the neonatal period. Similarly, chronic right ventricular volume overload as seen in pulmonic insufficiency after tetralogy of Fallot repair is more likely to be associated with chronic ventricular dysfunction and failure than a pressure-loaded RV that manifests with residual pulmonic stenosis. In fact, the most potent combination for inducing ventricular dysfunction and failure occurs when a pressure overload is superimposed on a dilated, volume-overloaded ventricle (e.g., postoperative tetralogy of Fallot with pulmonary insufficiency and branch pulmonary artery stenosis). The mechanism for the dysfunction and failure is multifactorial.

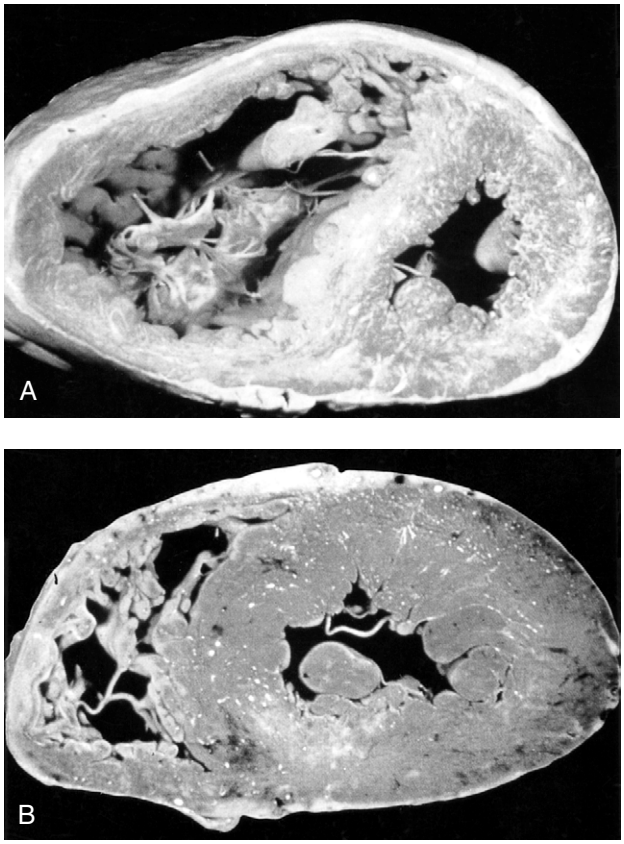

Figure 83-2 Comparison of ventricular hypertrophy patterns demonstrating altered ventricular remodeling in two different congenital heart defects. **A,** Note the right ventricular hypertrophy and the diminutive left ventricle in tetralogy of Fallot. **B,** Note the severe left ventricular hypertrophy and septal bulging into the right ventricle in aortic stenosis.

Initial manifestations of congestive heart failure reflect alterations in ventricular compliance that result from a variety of biophysical responses to abnormal loading conditions. The ventricular dilation and compensatory hypertrophy that accompany volume overload provide effective compensation to preserve normal systolic wall stress, but alterations in diastolic wall stress become evident (Fig. 83-3). Ultimately, chronic or severe pressure loads manifest similar changes as the resultant myocardial hypertrophy outgrows vascular supply and results in ischemia and fibroblast proliferation. Permanent changes in myocardial structure and function are the end result.

In patients with cyanotic conditions, the long-term compensation for chronic hypoxemia shows a major redistribution of

	Normal	Pressure overload	Volume overload
LVp	117 ± 7 / 10 ± 1	220* ± 6 / 23* ± 3	139 ± 7 / 24* ± 2
h	.8 ± .1	1.5* ± .1	1.1* ± .1
r	2.4 ± .1	2.8 ± .2	3.3* ± .1
h/r	.34 ± .02	.58* ± .05	.34 ± .02
σ_s	151 ± 14	161 ± 24	175 ± 7
σ_p	17 ± 2	23 ± 3	41* ± 3

Figure 83-3 Changes in ventricular physiology that accompany abnormal pressure and volume loading in human adolescents and adults. Schematic diagram represents the changes in cross-sectional ventricular geometry that accompany abnormal pressure and volume loads. Data are measured and derived from catheterization and echocardiography of 30 adolescent and adult human subjects. Pressure overload triggers significant increases in wall thickness and wall thickness : radius ratio (h/r), but these compensatory mechanisms preserve σ within normal limits. Whereas volume overload causes dilation and enough hypertropy to preserve normal σ_s, diastolic function deteriorates significantly. LVp, left ventricular pressure; r, radius of the LV chamber; σ_D, end-diastolic wall stress; σ_S, peak systolic wall stress; *$P = .01$. (*From Grossman W, Jones D, McLaurin LP: Wall stress and patterns of hypertrophy in the human left ventricle. J Clin Invest 56:56, 1975.*)

organ perfusion with selected blood flow to the heart, brain, and kidney and decreased flow to the splanchnic circulation, skin, muscle, and bone. Chronic hypoxemia is associated with increased work of breathing in an attempt to increase oxygen uptake and delivery. The most dramatic complications are decreased rate of somatic growth, increased metabolic rate, and an increase in hemoglobin concentration seen in children with palliated or unrepaired defects.

There may also be congenital syndromes with associated congenital heart disease that will influence long-term outcome (Table 83-4).

Surgical Procedures and Special Techniques

The ultimate objectives for congenital heart surgery are (1) physiologic separation of the circulation, (2) relief of outflow obstruction, (3) preservation or restoration of ventricular mass and function, (4) normalization of life expectancy, and (5) maintenance of quality of life. The available surgical procedures to accomplish these objectives are diverse and complex (Table 83-5). Compared with cardiac operations in adult patients, pediatric congenital heart repairs involve more intracardiac surgery, with a greater preponderance performed via the right atrium and RV. In general, operations performed for congenital heart defects can be divided into palliative and corrective procedures. The type and timing of repair depend on the age of the patient, the specific anatomic defect, and the experience of the surgeon and the team (see Table 83-5).

Palliation in infancy is usually performed when there are missing anatomic parts, as in pulmonary atresia (absent RV and pulmonary artery), tricuspid atresia (absent RV and tricuspid valve), hypoplastic left heart syndrome (aortic atresia and hypoplastic LV), univentricular heart (absent RV or LV), and mitral atresia (absent LV). These palliative procedures can be further subdivided into those that will increase PBF, those that decrease PBF, and those that increase mixing (see Table 83-5). Palliative procedures that increase PBF include shunts (Blalock-Taussig, central, and Glenn), outflow patch, and enlargement of the VSD. Those that decrease PBF include pulmonary artery banding and ligation of a PDA. Those that improve intracardiac mixing include atrial septostomy (balloon, blade, and Blalock-Hanlon).

The improvements in surgical technique, coupled with advancements in anesthetic and technologic support, make repair in early infancy not only feasible but in many cases preferable.[25] Currently, repair in infancy can be offered for a number of congenital heart defects, as shown in Table 83-5. The timing of surgical intervention reflects medical necessity, physiologic and technical feasibility, and optimal outcome. Cardiac defects that require a PDA to sustain sufficient systemic blood flow or PBF (e.g., pulmonary atresia, hypoplastic left heart syndrome, interrupted aortic arch, critical aortic stenosis, and critical pulmonic stenosis) require an intervention in the neonatal period. A variety of defects are optimally repaired in early infancy. Lesions such as transposition of the great arteries may exhibit better left ventricular function if the arterial switch operation is performed in the first few weeks of life when the PVR has recently been high enough to increase left ventricular systolic pressure, whereas other repairs may manifest less volatile postoperative physiology if deferred a few weeks or months until PVR has consistently fallen (e.g., tetralogy of Fallot, AV canal defect). Each defect may have mitigating factors for which deferred definitive repair will enable optimal surgical result (e.g., tetralogy of Fallot with aberrant coronary branching pattern or multiple VSDs; transposition of the great arteries with VSD and severe left ventricular outflow tract obstruction).

Although some lesions merit repair whenever they are diagnosed (e.g., total anomalous pulmonary venous return, coarctation of the aorta), others exhibit such a wide spectrum of physiologic disturbance that the timing of an intervention must be made individually (e.g., VSD, aortic stenosis, pulmonic stenosis). A few cardiac malformations produce pathophysiologic changes that are sufficiently mild that repair is typically deferred to later infancy or childhood (e.g., isolated ASD). Palliative surgery is entertained when a physiologic derangement requires intervention but circumstances preclude definitive repair.

In general, the recent trend in pediatric cardiovascular surgery has been to repair defects in infancy rather than palliate.[24] This trend reflects improved technical capabilities coupled with a desire to limit the morbidity and mortality associated with long-term medical management and the sequelae of multiple palliative operations. Early corrective surgery is expected to decrease the incidence of the chronic complications of congenital heart disease, such as the problems associated with ventricular overload, cyanosis, and pulmonary vascular obstructive disease.[26] Early infant repair may also have the selective advantage of enhancing organ system protection during repair because of poorly understood factors promoting resistance to injury and enhanced recovery potential (i.e., enhanced plasticity). With the continued improvement in surgical techniques and the early treatment of congenital heart disease, specific organ systems such as the brain, heart, and

Table 83-4 Syndromes Associated with Congenital Heart Disease (CHD)

Syndrome	Lesion	Cardiac Lesion	Comments
Syndromes with Airway Issues and CHD			
CHARGE association		VSD, ASD, PDA, TOF	Micrognathia, possible difficult airway
Edwards' syndrome	Trisomy 18	VSD, ASD, PDA	Micrognathia, small mouth, difficult intubation
Di George sequence	Microdeletion 22q11.2	Aortic arch and conotruncal lesions	Short trachea—tendency to endobronchial intubation
Goldenhar's syndrome		VSD, PDA, TOF, CoA	Maxillary and mandibular hypoplasia, C-spine anomalies—difficult intubation
Hurler's syndrome	MPS 1, storage disorder	Multivalvular disease, CAD, cardiomyopathy	Macroglossia, short neck—extremely difficult intubation
Noonan's syndrome		PS, ASD, cardiomyopathy	Short webbed neck, macrognathia—difficult intubation
Turner's syndrome	Monosomy X	LVOT O, AS, HLHS, CoA	Micrognathia, webbed neck—difficult intubation
VATER association		VSD, TOF, ASD, PDA	Potential for difficult intubation
Syndromes with Risk of Arrhythmias			
Long QT syndrome (LQTS)		Torsades de pointes, SCD	
Brugada's syndrome		VT/VF/SCD	
Arrhythmogenic right ventricular dysplasia (ARVD)		VT/SCD	
Catecholaminergic polymorphic ventricular tachycardia		Polymorphic VT/SCD	
Wolff-Parkinson-White syndrome		SVT	
Maternal lupus		CCHB in the newborn	
Chromosomal Disorders Associated with CHD			
Down syndrome	Trisomy 21	VSD, ASD, CAVC	
Edwards' syndrome	Trisomy 18	VSD, ASD, PDA	
Patau's syndrome	Trisomy 13	VSD, PDA, ASD	
Turner's syndrome	Monosomy X	LVOT O, AS, HLHS, CoA	
3p– syndrome	Deletion 3p	CAVC	
Cri du chat syndrome	Deletion 4p	Variable	
8p– syndrome	Deletion 8p	CAVC	
9p– syndrome	Deletion 9p	VSD, PDA, PS	
Williams syndrome	Microdeletion 7q11	SVAS, SVPS, branch PS	
Smith-Magenis syndrome	Microdeletion 17p11.2	ASD, VSD, PS, AV valve malformations	
Miller-Dieker syndrome	Microdeletion 17p13.3	TOF, VSD,PS	
CHARGE association		VSD, ASD, PDA, TOF	Coloboma, heart, choanal atresia, retardation, genital and ear anomalies

lungs will be spared the detrimental effects of chronic derangements of hemodynamics and oxygen delivery.

Procedures for the treatment of congenital heart disease continue to evolve to decrease long-term morbidity and enhance survival. For example, the long-term problems with right ventricular dysfunction and failure associated with the Mustard procedure for repair of transposition of the great arteries encouraged many surgical groups to develop the neonatal arterial switch operation.[27] Early indications suggest that the latter procedure provides an anatomic correction with better long-term results. A second example of the continuing evolution of technique is surgery for tetralogy of Fallot. Long-standing pulmonary insufficiency after right ventricular outflow repair for tetralogy of Fallot is associated with right ventricular dysfunction and failure. Preservation of the pulmonary valve at initial repair using a combined transatrial and transpulmonary approach during correction and the early insertion of a pulmonary homograft in the setting of pulmonary insufficiency are techniques being used in an attempt to avoid the long-term problems of right ventricular dysfunction and failure.[28]

Surgery for hypoplastic left heart syndrome, once considered a fatal disease, has achieved significant long-term survival in a growing number of institutions after a series of staged reconstructive procedures.[29,30] The use of right ventricular to pulmonary artery (RV-PA) conduits as an alternative to traditional systemic-to-pulmonary shunts has been shown to confer some advantage in survival after stage 1 palliation owing to elimination of diastolic runoff into the pulmonary circulation with concurrent unloading of the systemic RV. There seems to be an improvement in myocardial perfusion, with higher diastolic pressures, lower aortic saturations, and decreased myocardial work. The long-term impact of a right ventriculotomy in a univentricular

Table 83-5 Congenital Cardiac Defects and Their Repair

Anatomic Defects	Palliation	Complete Repair
Tetralogy of Fallot		VSD closure and RVOT patch
With PA atresia	Shunt	
With anomalous right coronary artery	Rastelli	
HLHS	Norwood I/transplant	
Transposition of the great arteries		Arterial switch
Unfavorable coronary anatomy	Atrial switch (Senning)

ASD, atrial septal defect; HLHS, hypoplastic left heart syndrome; PAs, pulmonary artery; RV, right ventricle; RVOT, right ventricular outflow tract; VSD, ventricular septal defect.

heart is unknown.[31-33] The use of a low-resistance strategy has been advocated for a stable postoperative course with use of vasodilators such as phenoxybenzamine on CPB and optimal reduction of PVR with inhaled nitric oxide and 100% oxygen after CPB.[34,35]

Several factors considered to be associated with an increased risk for single ventricle palliation include anatomic variants such as aortic atresia, mitral atresia, ascending aorta less than 2.0 to 2.5 mm, restrictive atrial septum, obstructed pulmonary venous return, the presence of other congenital anomalies, prematurity, birth weight less than 2.5 kg, older age at time of surgery (>14 days), surgical inexperience, and prolonged CPB and arrest times. Perioperative factors can adversely affect outcome and include preoperative metabolic acidosis, preoperative inotrope support, morphologic RV in the systemic circuit, right ventricular dysfunction, presence of severe tricuspid regurgitation, pulmonary valve regurgitation (beyond mild), and low $S\bar{v}O_2$ (<30%) after a Norwood procedure.[36-42] Neurologic outcome after surgical repair is an ongoing concern. Preoperative cerebral blood flow (CBF) was shown to be diminished in patients with a variety of congenital heart defects, and low CBF values were associated with periventricular leukomalacia.[43] Some centers routinely advocate regional low-flow cerebral perfusion and measurement of regional cerebral oxygen saturation index and CBF velocity using transcranial Doppler during arch reconstruction in this population. Reductions in the regional cerebral oxygen saturation index or CBF greater than 20% of baseline are treated aggressively in an attempt to increase cerebral oxygen delivery by increasing the mean perfusion pressure, red blood cell transfusion, and maintenance of high normal levels of $PaCO_2$ to achieve cerebral vasodilation.

Surgical management has evolved in a broader application of certain surgical procedures initially designed for a specific defect. For example, modifications of the Fontan operation, which was originally devised for patients with tricuspid atresia, are now being used to repair a variety of univentricular hearts, including hypoplastic left heart syndrome.[44,45] Initially, the wider application of the Fontan operation to include complex defects once considered inoperable was associated with a rise in morbidity and mortality. However, this trend has been reversed in recent years by several groups who have demonstrated improved outcome with the staging of the operation (superior cavopulmonary anastomosis, subsequent completion of the Fontan operation), the creation of a fenestration between the right and left atrium at the time of the Fontan operation, and the use of modified ultrafiltration (MUF) (see later).[46] The communication allows for right-to-left shunting, thereby preserving cardiac output at lower systemic venous pressure in the early postoperative period. When necessary, once the patient has convalesced from the acute postoperative changes, the fenestration can be closed at the bedside with a snare placed at the time of the operation or in the catheterization laboratory with a clamshell device. In a substantial proportion of cases, these fenestrations close spontaneously without further intervention.

Ingenuity and innovation such as demonstrated with the difficult Fontan procedure have permitted continued improvements in survival for all patients with congenital heart disease. As incisions in the myocardium become smaller and sutures more precisely placed, and as improvements in surgical techniques continue to evolve, the complications of ventricular dysfunction, arrhythmias, and residual obstruction should decline, contributing to improved patient quality of life.

One final difference unique to congenital heart surgery that has a major impact on anesthetic management relates to the type of cardiopulmonary support. Because of the complexity of repair in small patients, surgery often requires significant alterations in the bypass techniques, such as the use of deep hypothermic CPB at temperatures of 18°C and total circulatory arrest. Many operations are undertaken in this setting of extreme biologic conditions of temperature and perfusion. Current methods of CPB management in neonates, infants, and children involve extensive alterations in temperature, hemodilution, systemic perfusion pressure, and flow. Despite widespread use of these techniques during CPB, their physiologic effects on major organ system function are just beginning to be understood. These effects are discussed in subsequent sections.

In summary, there are unique features that need to be considered in caring for children with congenital heart disease who are undergoing pediatric cardiac surgery. These features include the patient's growth and development, the developing cardiovascular system of the young, the pathophysiology of congenital heart disease, the surgical procedures, and the CPB techniques. A basic understanding of these differences coupled with the fundamental knowledge of adult and pediatric cardiac anesthesia principles underlies the approach to the perioperative management of these patients.

Anesthetic Management

Preoperative Management

Anesthetic Evaluation

Caring for children with congenital heart disease presents the anesthesiologist with a wide spectrum of anatomic and physiologic abnormalities. Patients range from young, healthy, asymptomatic children who are having closure of a small ASD to the neonate with hypoplastic left heart syndrome requiring aggressive perioperative hemodynamic and ventilatory support. Intertwined with the medical diversity of these patients are the psychological factors affecting both the patient and the parents. Preparation of the patient and the family is time-consuming, but omitting or compromising this aspect of patient care is a major deterrent to a successful outcome and patient/parental satisfaction. This team-oriented approach also serves as a safeguard to prevent errors and omissions in the exacting perioperative care necessitated by the complexity of cardiac surgery for congenital heart disease. The preoperative visit offers the family the opportunity to meet the surgeon and anesthesiologist.

Parents should be questioned about the general health and activity of their child. Fundamentally, a child's general health and activity will reflect cardiorespiratory reserve. Deficiencies may point toward cardiovascular or other systems that may influence anesthetic or surgical risk. It is important to determine whether the child has an impaired exercise tolerance. Is he or she gaining weight appropriately or exhibiting signs of failure to thrive on the basis of cardiac cachexia? Does the child exhibit signs of congestive heart failure (diaphoresis, tachypnea, poor feeding, recurrent respiratory infections)? Is there progressive cyanosis or new onset of cyanotic spells? Any intercurrent illness such as a recent upper respiratory tract infection or pneumonia must be ascertained. Lower respiratory tract infections may require a delay in proposed surgery, based on the negative impact that airway reactivity and elevations in PVR may have on surgical outcome. Recurrent pneumonia is frequently associated with pulmonary overcirculation and altered lung compliance in patients with increased PBF.

A good history must delineate previous surgical and cardiologic interventions. These may have an impact on both surgical and anesthetic plans for the current procedure. Patients who have had their subclavian artery sacrificed for a subclavian flap angioplasty to correct coarctation or a Blalock-Taussig shunt will not accurately display systemic arterial pressure or perhaps even pulse oximetry readings when the monitoring is applied to the left arm. Likewise, children who have femoral venous occlusion after catheterization are not candidates for femoral venous access, particularly for femoral CPB should sternotomy prove impossible. It is equally important to ascertain current medications, previous anesthetic problems, or family history of anesthetic difficulties.

In the modern era of echocardiography and cardiac catheterization, physical examination rarely contributes additional anatomic information about the underlying cardiac lesion. However, it is extremely useful in assessing the overall clinical condition of the child. For example, an ill-appearing, cachectic child in respiratory distress has limited cardiorespiratory reserve and the use of excessive premedication or a prolonged inhalational induction could result in significant hemodynamic instability.

Concurrent Medications and Drug Interactions

Drug interactions are common both among the co-therapeutic cardiovascular agents and between the cardiovascular drugs and anesthetic drugs. An understanding of the mechanisms and of the interactions is useful to the pediatric cardiovascular anesthesiologist. Some common cardiovascular medications and anesthesia considerations are shown in Table 83-6.

Pediatric oncology patients presenting for cardiac or noncardiac procedures may manifest higher cardiovascular risk due to cardiotoxic chemotherapy.[47] Common cardiotoxic agents include the antimetabolite 5-fluorouracil, the anthracycline antibiotics doxorubicin and daunorubicin, and the alkylating agent cyclophosphamide. The acute form is characterized by acute ST segment/T wave changes on the electrocardiogram (ECG), serious dysrhythmias, and congestive heart failure associated with pericardial effusion. Chronic cardiotoxic heart failure is cumulative, dose related, and unresponsive to digoxin therapy. Serious cardiomyopathy can occur and is related to dose, irradiation, and use of an anthracycline. Mortality rate can exceed 50%. These patients should undergo thorough preoperative evaluation, including a full blood cell count, assessment of renal and hepatic function and coagulation parameters, and an echocardiogram. An isoflurane/N_2O-based anesthetic might confer better hemodynamic stability than opioid-based anesthesia in such patients.[48]

Anesthetic agents can cause torsades de pointes, a malignant arrhythmia. Risk factors for torsades de pointes include female gender, electrolyte imbalances such as hypokalemia and hypomagnesemia, genetic ion channel polymorphisms of congenital long QT syndrome (LQTS), subclinical LQTS, baseline QT prolongation, and use of QT-prolonging drugs especially in high concentrations or as rapid intravenous infusions. Conditions

Table 83-6 Common Perioperative Cardiovascular Medications and Considerations

Cardiac Drug Class	Interactions	Considerations
Angiotensin-converting enzyme inhibitors	Hypotension with induction of general anesthesia	Consider withholding AM dose, or reducing dosage, in hypotensive patients; avoid fixed dose induction regimens with drugs having a profound vagomimetic effect
β-Blockers	Acute withdrawal can precipitate tachycardia and arrhythmias; can potentiate hypotension with volatile anesthesia; can decrease response to inotropic agents	Continue in the perioperative period
Calcium channel blockers	May augment the negative inotropic and chronotropic effects of volatile anesthesia	Continue in the perioperative period
Diuretics	Hypovolemia/hypokalemia; may augment effect of neuromuscular blocking agents	Discontinue preoperatively
Antiarrhythmics	Can be proarrhythmic with inotropes, electrolyte disturbances; high catecholaminergic states; can interact with other antiarrhythmics and precipitate bradycardia	Avoid electrolyte imbalance Avoid drugs that are proarrhythmic Monitor carefully
α_2-Agonists	Reduces perioperative shivering, ischemia, anesthetic and analgesic requirements	Continue into the perioperative period with appropriate monitoring

with reduced repolarization reserve such as congestive cardiac failure or digoxin toxicity can precipitate torsades de pointes. Drugs that may cause torsades in patients with congenital LQTS are shown in Table 83-7.

Laboratory evaluation should include analysis of hemoglobin, hematocrit, pulse oximetry, and, in selected patients (e.g., those on diuretics or with renal impairment), serum electrolytes. An elevated hematocrit in a normovolemic child gives an indication of the magnitude and chronicity of their hypoxemia. Levels above 60% may predispose to capillary sludging and secondary end organ damage, including stroke. Despite these risks, liberalized nothing-by-mouth guidelines that permit children to consume clear liquids up to 2 hours before anesthetic induction have virtually eliminated the need to admit these patients for preoperative intravenous hydration.[49,50]

Echocardiography with Doppler color flow imaging (echo-Doppler) is an invaluable tool that provides a noninvasive means of assessing intracardiac anatomy, blood flow patterns, and estimates of physiologic data.[51] For many cardiac defects, more invasive studies are generally not required if a good echocardiographic assessment is made. Echo-Doppler is especially helpful for defining intracardiac abnormalities. Extracardiac abnormalities, such as pulmonary artery or vein stenosis, are more difficult to define by echo-Doppler and often require cardiac catheterization. The ability to interpret anatomy and physiology accurately requires a skilled echocardiographer, reaffirming the need for a well-integrated interactive team. Although the complexities posed by extreme anatomic variation and changing loading conditions render intraoperative echo-Doppler challenging even for experienced echocardiographers, the pediatric cardiac anesthesiologist should develop some familiarity with its capabilities and limitations so as to participate in critical intraoperative management decisions.

Magnetic resonance imaging (MRI) of the heart and major vessels has become a very useful noninvasive imaging tool in children with heart disease. Typically, MRI is used for segmental description of cardiac anomalies; evaluation of thoracic aortic anomalies; noninvasive detection and quantification of shunts, stenoses, and regurgitations; evaluation of conotruncal malformations and complex anomalies; identification of pulmonary and

systemic venous anomalies; and postoperative studies and evaluation of congenital heart disease in adult patients.[52] MRI is particularly useful in quantifying ventricular function, regional wall motion, valvar competence, and velocity flow mapping. It is especially useful for imaging the aortic arch, pulmonary arteries, and the mediastinal vessels in children with complex congenital heart disease. Lesions for which MRI provides accurate and useful information include coarctation of the aorta, anomalies of the pulmonary arteries, anomalous pulmonary venous connections and persistent left superior vena cava, and intracardiac baffles, conduits, and shunts. MRI is also useful in older patients with poor acoustic windows and patients with chest wall deformities.[52] It can be used as an alternative to cardiac catheterization in select patients. However, physiologic data such as oxygen saturations cannot be obtained. Adenosine stress cardiac MRI is used to delineate areas of inducible ischemia.

Cardiac catheterization remains the gold standard for assessing anatomy and physiologic function in congenital heart disease. Although many anatomic questions can now be reliably answered noninvasively, cases that present complex anatomic questions or those for which physiologic data are required, catheterization remains a vital tool. Important catheterization data for the anesthesiologist include the following:

1. Child's response to sedative medications
2. Pressure and oxygen saturation in all chambers and great vessels
3. Location and magnitude of intracardiac and extracardiac shunt $\left(\dot{Q}p/\dot{Q}s\right)$
4. Pulmonary vascular resistance, systemic vascular resistance
5. Chamber size and function
6. Valvular anatomy and function
7. Distortion of systemic or pulmonary arteries related to prior surgery
8. Coronary artery anatomy
9. Anatomy, location, and function of previously created shunts
10. Acquired or congenital anatomic variants that might have an impact on planned vascular access or surgery

Careful review of the cardiac catheterization data and an understanding of their potential impact on the operative and anesthetic plan are essential. Not all the medical problems can be evaluated and corrected preoperatively; the surgeon, cardiologist, and anesthesiologist must discuss the potential management problems and any need for further evaluation or intervention before arrival in the operating room. Appropriate communication and cooperation between the two physicians will optimize patient care and facilitate perioperative clinical management. Typically, institutions have a regularly scheduled combined cardiology/cardiac surgery meeting to discuss candidates for surgery, during which all essential information is displayed and discussed. Such a meeting provides an invaluable opportunity for learning about specific patients proposed for surgery as well as a continuing educational forum that promotes an interdisciplinary exchange directed at contemporary concepts in congenital heart disease and its treatment, both medical and surgical.

Premedication

See Chapter 82.

Intraoperative Management

Operating Room Preparation

Advance, careful preparation of the operating room is essential. The anesthesia machine must have the capacity to provide air, oxygen, carbon dioxide, and nitric and nitrous oxide to help balance pulmonary and systemic blood flow. Intravenous tubing must be free from air bubbles to prevent paradoxical air embolism. Resuscitative drugs, labeled and ready for administration, should include succinylcholine, calcium gluconate or calcium chloride, sodium bicarbonate, atropine, phenylephrine, lidocaine, and epinephrine. An inotropic infusion, usually dopamine, should be premixed and ready for administration in high-risk cases, but additional infusions are prepared if their need is strongly suspected. For all pediatric cases, certain anesthetic drugs should be available (thiopental, propofol, ketamine). In pediatric cardiac anesthesia, many patients have limited reserve as well as high endogenous catecholamine levels released in an adaptive response to their underlying cardiac disease. The resuscitative drugs should therefore be prepared and immediately available before anesthetic induction.

For congenital heart surgery, the ability to alter body temperature rapidly for cooling and rewarming is essential. During deep hypothermic CPB, patients are cooled to 18°C. Surface cooling with a heating/cooling water mattress and an efficient room/ambient temperature control system is important in the operative management of these patients.

Physiologic Monitoring

The monitoring used for any specific patient should depend on the child's condition and the magnitude of the planned surgical procedure. The perioperative monitoring techniques available are listed in Table 83-8. Noninvasive monitoring is placed before induction of anesthesia. In the crying pediatric patient, the anesthesiologist may elect to defer application of monitoring devices until immediately after the induction of anesthesia. Standard monitoring includes an electrocardiographic system, pulse oximetry, capnography, precordial stethoscope, and an appropriate-sized blood pressure cuff (either oscillometric or Doppler). Additional monitoring includes an indwelling arterial catheter, temperature probes, and an esophageal stethoscope. Foley catheters are generally employed when surgical intervention entails CPB or might produce renal ischemia or when the anesthetic management includes a regional technique associated with urinary retention. Some centers routinely employ central venous pressure (CVP) monitoring for major cardiovascular surgery. Alternatively, we typically use directly placed transthoracic atrial lines to obtain that information for separation from CPB and the postoperative period. In that setting, the benefits of the information or access provided by percutaneous CVP catheters in the pre-bypass period must be weighed against the risks they pose.

Continuous monitoring of arterial pressure is only possible through an indwelling intra-arterial catheter. In young children, cannulation of the radial artery with a 22- or 24-gauge catheter

is preferred. In older children and adolescents, a 20-gauge catheter may be substituted. Careful inspection, palpation, and four-extremity noninvasive blood pressure determinations help ensure that previous or currently planned operative procedures (e.g., a previous radial artery cutdown, subclavian flap for coarctation repair, or Blalock-Taussig shunt) do not interfere with the selected site of arterial pressure monitoring. Other sites available for cannulation include the ulnar, femoral, axillary, and umbilical (in neonates) arteries. Cannulation of the posterior tibial or dorsalis pedis arteries is not usually sufficient for complex operative procedures. Peripheral arterial catheters, principally of the distal lower extremities, function poorly after CPB and do not reflect central aortic pressure when distal extremity temperature remains low.[53]

Myocardial and cerebral preservation is maintained principally through hypothermia; therefore, the accurate and continuous monitoring of body temperature is crucial. Rectal and nasopharyngeal temperatures are monitored because they reflect core temperature and brain temperature, respectively. Monitoring of esophageal temperature is a good reflection of cardiac and thoracic temperature. Tympanic probes, although a useful reflection of cerebral temperature, can cause tympanic membrane rupture.

Pulse oximetry and capnography provide instantaneous feedback concerning adequacy of ventilation and oxygenation. They are useful guides in ventilatory and hemodynamic adjustments to optimize $\dot{Q}p/\dot{Q}s$ before and after surgically created shunts and pulmonary artery bands. Peripheral vasoconstriction in patients undergoing deep hypothermia and circulatory arrest renders digital oxygen saturation probes less reliable. In the newborn, the use of a tongue sensor has been advocated to provide a more central measure of oxygen saturation, with less temperature-related variability.[54]

The use of transthoracic (in the right or left atrium, pulmonary artery) or transvenous pulmonary artery catheters is determined on an individual basis based on the disease process, physiologic state, and surgical intervention. For example, in children undergoing a Fontan procedure for tricuspid atresia or a univentricular heart, catheters in the Fontan pathway and the pulmonary venous atrium are especially useful. After a Fontan operation, PBF must occur without benefit of a ventricular pumping chamber. Subtle changes in preload, PVR, and pulmonary venous pressure will influence PBF and thus systemic cardiac output. Data derived from systemic venous pressure and left atrial pressure (LAP) help identify the relative importance of intravascular volume (CVP), PVR (CVP-LAP gradient), or ventricular compliance (LAP), each of which requires a different therapeutic approach.

As a general guideline, a transvenous pulmonary artery catheter may be placed using the internal jugular approach in children weighing more than 7 kg. A 5.0-Fr catheter is used for children weighing between 7 and 25 kg, and a 7.0-Fr one is used for children weighing more than 25 kg. For infants weighing less than 7.0 kg, percutaneous placement of a pulmonary artery catheter can be performed from the femoral vein. Occasionally, the latter technique will require fluoroscopy. The use of intraoperative transthoracic monitoring lines and echo-Doppler limits the need for transvenous pulmonary artery catheters in most cases.

Special Monitoring

Intraoperative Echocardiography

Of the newer techniques available for monitoring patients during pediatric cardiovascular surgery, the most promising is echo-Doppler imaging. Several reports have described the usefulness of intraoperative echo-Doppler imaging during congenital heart surgery.[55-57] Two-dimensional echocardiography combined with pulsed-wave Doppler ultrasonography and color flow mapping is able to provide detailed morphologic as well as physiologic information in the majority of operative cases. Using echo-Doppler in the operating room, anatomic and physiologic data can be obtained before CPB, thus refining the operative plans. Prebypass echo-Doppler precisely defines anesthetic and surgical management.[12,56] Because of the unrestricted epicardial and transesophageal echocardiography (TEE) approaches in anesthetized patients, new findings are frequently discovered and management plans changed accordingly (Fig. 83-4).

Postbypass echo-Doppler evaluation is able to immediately assess the quality of the surgical repair as well as assess cardiac function by examining ventricular wall motion and systolic thickening.[12,56] This technique can show residual structural defects after bypass, which can be immediately repaired in the same operative setting and avoids leaving the operating room with significant residual structural defects that will require reoperation at a later time (Fig. 83-5). By identifying patients with new right ventricular and left ventricular contraction abnormalities after bypass, as determined by a change in wall motion or systolic thickening, echo-Doppler provides guidance for immediate phar-

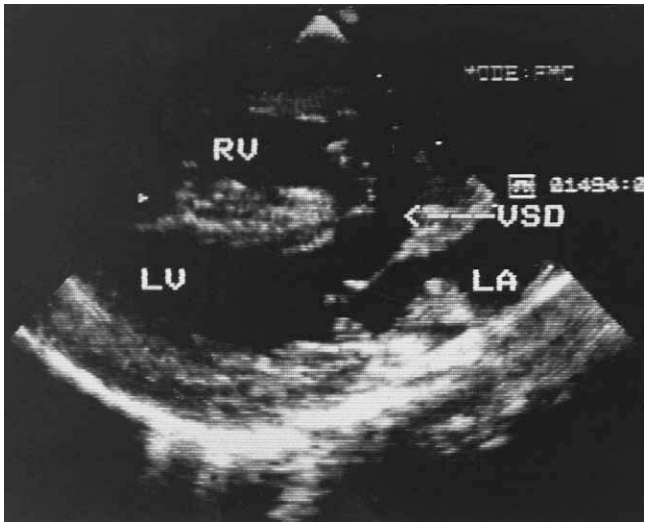

Figure 83-4 Intraoperative pre–cardiopulmonary bypass epicardial echocardiogram in the long-axis view. Note the insertion of the papillary muscle of the tricuspid valve on the interventricular septum. On the basis of this view, the surgeon decided that ventricular septal defect (VSD) closure was possible in a child thought preoperatively to be only a candidate for palliation. LA, left atrium; LV, left ventricle; RV, right ventricle.

macologic interventions. Importantly, postbypass ventricular dysfunction and residual structural defects identified by echo-Doppler are associated with an increased incidence of reoperation and higher morbidity and mortality rate.[58] Thus, this monitoring tool is helpful in assessing surgical outcome and identifying operative risk factors. Whether early identification of these abnormalities, which directs appropriate medical and surgical interventions, will improve outcome remains to be determined.

Two techniques for intraoperative echo-Doppler have been described: epicardial and transesophageal echocardiography (TEE). Using TEE, the probe is placed after induction of anesthesia and intubation and is then available for monitoring of the patient. The advantage of this technique is its utility as a continuous monitor of cardiac structure and function, without interrupting surgery.[12,59] Because of its ideal imaging location, TEE has been especially helpful in evaluating pulmonary venous return and the integrity of the left AV valve after mitral valvuloplasty, complete AV valve repair, and correction of complex congenital heart disease. Early limitation in views has been virtually eliminated as a result of clinical experience and improved biplane images. Pediatric biplane TEE probes have now extended the patient weight limits to neonates between 2.5 and 3 kg.[60] Potential hazards of TEE that merit particular vigilance include descending aorta and airway compression due to probe size or during probe flexion. If a pre-repair TEE is indicated, the probe is removed during the procedure because of concerns about esophageal damage during hypothermia and low or no flow states.

A second technique for intraoperative echocardiographic analysis in children is the epicardial approach.[56,60] This approach requires passing a clean, short-focused 5.0- or 7.0-MHz transducer over the anesthesia screen into a sterile sheath, where it then can be placed on the epicardial surface of the heart. This technique best facilitates the probe manipulations necessary for thorough interrogation of the major structures and dynamic function of the heart. The advantage of this approach is that all views can be obtained in patients of any size. Among the disadvantages are the need for sufficient operator skill and experience to perform the manipulations,[58] the need to interrupt surgery to manipulate the probe, and the possible deleterious impact of direct myocardial mechanical manipulation. With the current TEE capabilities, epicardial imaging is rarely employed.

Specialized Central Nervous System Monitoring

The primary goal of brain monitoring is to improve our understanding of cerebral function and dysfunction during cardiac surgery so that effective brain protection strategies can be developed. Because many of the determinants of normal brain perfusion become externally controlled by the cardiac team during CPB, such as flow rate (cardiac output), perfusion pressure, temperature, hematocrit, and $Paco_2$, a knowledge of the effect of these factors on the brain in neonates, infants, and children is essential. Furthermore, the examination of the brain under unusual biologic circumstances, such as after deep hypothermic circulatory arrest (DHCA) or during continuous-flow CPB at deep hypother-

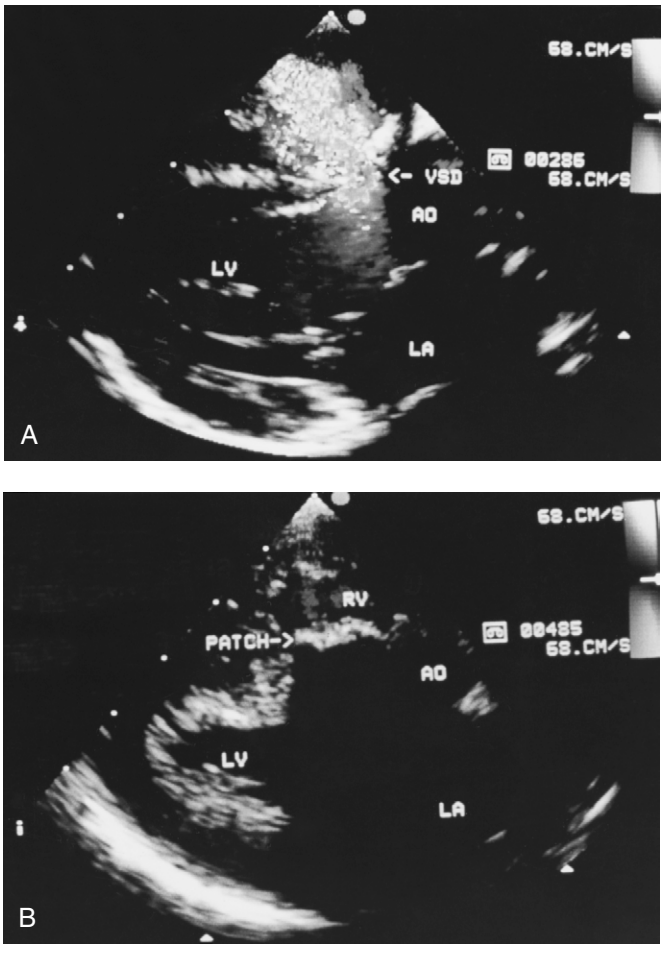

Figure 83-5 **A,** Echocardiogram with a Doppler flow map in the long-axis view illustrating a residual ventricular septal defect (VSD) resulting from patch dehiscence after initial repair. Turbulent flow through the VSD appears as a mosaic of white particles (*arrow*). This finding necessitated immediate reinstitution of cardiopulmonary bypass and re-repair. **B,** Repeat Doppler flow map in the long-axis view illustrates patch closure (*arrow*) of the VSD after re-repair. Note the absence of turbulent flow with the loss of the mosaic of white particles. AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

mia (18°C), permits a unique opportunity to describe cerebrovascular physiology and pathophysiology. Numerous intraoperative techniques have been used for monitoring the brain to prevent secondary brain injury due to hypoxia, ischemia, emboli, and electrophysiologic derangements (see Chapter 46). These have primarily included the following three modalities in isolation or combination: (1) near-infrared spectroscopy (NIRS) to provide a measure of venous-weighted, tissue oxyhemoglobin saturation; (2) transcranial Doppler to measure arterial flow and resistance; and (3) electroencephalography (EEG) to assess perfusion-related changes in cortical activity.[61] Additionally, the measurement of CBF and metabolism with specialized clinical research tools has been very important in furthering our understanding of brain function during and after surgery. Multimodal neurologic monitoring is also used to guide the conduct of CPB, DHCA, and regional low flow cerebral perfusion (RLFP) techniques in neonatal arch reconstruction.[62-64]

Electroencephalographic monitoring allows detection of ischemia or recognition of an adequate decrease in cerebral metabolic activity during hypothermia before DHCA. Electroencephalography is helpful in monitoring physiologic functions of the CNS during deep hypothermic bypass and total circulatory arrest. For example, during deep hypothermia and before total circulatory arrest, the processed electroencephalogram (EEG) can identify residual cerebral electrical activity.[65] Isoelectric silence can then be induced by further cooling and any further brain activity detected by electroencephalography. Because this residual electrical activity during arrest is associated with ongoing cerebral metabolism, an isoelectric state may prevent ischemic injury to the brain during circulatory arrest. Electroencephalography may also be useful in detecting the level and depth of anesthesia. Postoperative electroencephalographic analysis has demonstrated subclinical seizure activity in a number of high-risk patients, potentially linking these abnormalities to poorer neuropsychologic outcome. The value of intraoperative electroencephalographic monitoring after CPB and the significance of the findings remain to be determined.

Transcranial Doppler imaging has been used primarily for research purposes in infants and allows detection of venous or arterial flow abnormalities and the detection of microemboli.[66] This technology uses the Doppler principle to detect shifts in the frequency of reflected signals from blood in the middle cerebral artery to calculate blood flow velocity.[67] Because the diameter of this large cerebral artery is relatively constant, flow velocity should approximate that of CBF. Transcranial Doppler imaging has several advantages: (1) It is noninvasive, (2) it does not require radiation exposure, and (3) it is a continuous monitor. An additional advantage of this technique is the capability of assessing rapid alterations in blood flow velocity caused by temperature or perfusion changes, as commonly occur during cardiac surgery. The limitations of transcranial Doppler monitoring include (1) reproducibility, especially at low flows, when minute movement of the patient's head can dramatically alter signal intensity and alter baseline measurements, and (2) the lack of validating studies during hypothermic CPB, when temperature, reduced flow rates, and the laminar flow characteristics of nonpulsatile perfusion may limit the accuracy of CBF velocity measurements. CBF velocity measurements by TCD have reasonable correlation with more standard measures of CBF during normothermia, and some studies have examined its validity during hypothermic CPB.[68]

Transcranial Doppler imaging has been used to investigate the effect of CPB and deep hypothermic circulatory arrest on cerebral hemodynamics in children, as well as to assess the incidence of cerebral emboli. Recent studies examining the brain using TCD have enabled several investigative groups to provide important information regarding questions of normal and abnormal brain perfusion during cardiac surgery in children. Questions regarding cerebral perfusion pressure, autoregulation, effect of $Paco_2$, and temperature have been addressed using transcranial Doppler imaging in children and are discussed subsequently.[68-70] This technique has also provided qualitative information regarding the presence of gaseous emboli in the middle cerebral artery during cardiac surgery.[71,72] Quantification of this important mechanism of cerebral injury during cardiac surgery would be instructive. Future investigations using transcranial Doppler should address this mechanism of injury as well.

Centers with excellent outcomes may report "never" or "always" using NIRS during the perioperative care of neonates with congenital heart disease. Given that cerebral NIRS values have been shown to correlate with jugular venous bulb saturations, the interest in using NIRS as a way to noninvasively assess oxygen delivery to the brain is sensible.[73] Austin and associates have reported the value of monitoring cerebral NIRS intraoperatively. They noted that cerebral oxyhemoglobin desaturation accounted for a majority of neurophysiologic abnormalities during multimodality neuromonitoring using NIRS, transcranial Doppler, and electroencephalography.[74] Over two thirds of the patients in their study had detectable neuromonitoring events, and a similar percentage of these events required intervention by the perfusionist, surgeon, or anesthesiologist. Surgical interventions, such as cannula repositioning, were performed in one fourth of the events, and the perfusionist intervened in over one half of the events. The incidence of postoperative neurologic sequelae was also higher in those patients who had untreated events. During some specific surgical techniques, such as regional cerebral perfusion, NIRS monitoring has also been reported to be of benefit in guiding intraoperative care.[75,76] However, no studies have yet shown that use of NIRS in the postoperative period is associated with improved neurodevelopmental outcomes.

CBF studies using xenon clearance technology have improved the understanding of cerebrovascular dynamics in young children during CPB and especially during deep hypothermia and after periods of circulatory arrest.[77-80] In general, this investigational tool has described the effects of CPB, temperature, and various perfusion techniques on CBF and, indirectly, on brain metabolism (Fig. 83-6). Studies using this methodology have shown that some of the mechanisms of CBF autoregulation, such as pressure-flow regulation, are lost with deep hypothermia and that cerebral reperfusion is impaired after a period of total circulatory arrest.

Induction and Maintenance of Anesthesia

The principles of intraoperative management of cardiothoracic surgical procedures are based on an understanding of the pathophysiology of each disease process and a working knowledge of the effects of the various anesthetic and other pharmacologic interventions on a particular patient's condition. Selecting an induction technique is dependent on the degree of cardiac dysfunction, the cardiac defect, the degree of sedation provided by

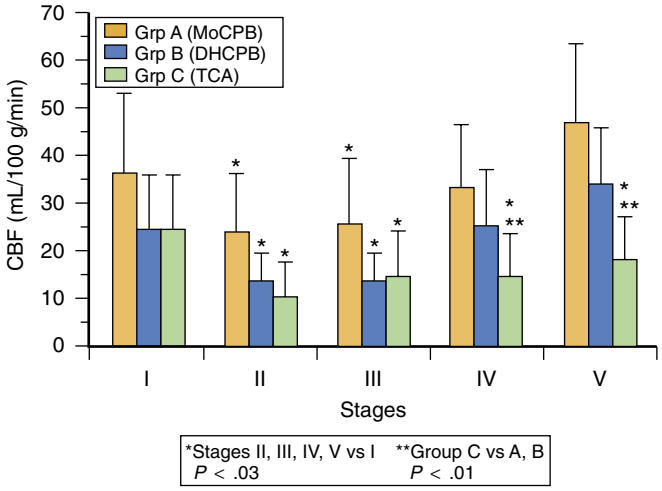

Figure 83-6 Bar chart of the changes in cerebral blood flow (CBF) before, during, and after cardiopulmonary bypass (CPB) in 67 infants and children (mean ± SD). Group A underwent repair with moderate hypothermic bypass (MoCPB) at 28° to 32°C; group B, with deep hypothermic bypass (DHCPB) at 18° to 22°C; and group C, with total circulatory arrest at 18°C. Note the impaired cerebral reperfusion after total circulatory arrest (group C). Stage I, pre-bypass; stages II and III, during hypothermic bypass; stage IV, rewarmed on bypass; stage V, after bypass. (*From Greeley WJ, Brusino FG, Ungerleider RM, et al: The effects of cardiopulmonary bypass on cerebral blood flow in neonates, infants, and children. Circulation 80:I209, 1989.*)

the premedication, and the presence or absence of an indwelling catheter. In children with good cardiac reserve, induction techniques can be quite varied so long as induction is careful and well monitored. The titration of anesthetics for induction of anesthesia is more important than the specific anesthetic technique in patients with reasonable cardiac reserve. A wide spectrum of anesthetic induction techniques have been used safely and successfully, such as sevoflurane, isoflurane, and nitrous oxide; intravenous and intramuscular ketamine; and intravenous propofol, fentanyl, midazolam, and thiopental.[81] For neonates undergoing open-heart surgery, opioid-relaxant inductions are most prevalent, whereas older children with sufficient cardiac reserve typically receive inhalation inductions with either sevoflurane or halothane. Ketamine is often used in anesthetic induction in patients with cyanotic conditions because it increases SVR and cardiac output, thereby diminishing the magnitude of right-to-left shunting. Administration of ketamine can be intravenous or intramuscular. An intramuscular injection may result in pain, agitation, and subsequent arterial desaturation.

Inhalation inductions are generally well received and tolerated by most children. An inhalation induction with sevoflurane can easily and safely be performed even in cyanotic patients such as those with tetralogy of Fallot (Fig. 83-7). In these patients, who are at risk for right-to-left shunting and systemic desaturation, oxygenation is well maintained with a good airway and ventilation despite halothane-induced reduction in systemic arterial pressure.[82] Skilled airway management and efficiency of ventilation are equally essential components of anesthetic induction. Although it is essential to understand the complexities of shunts and vascular resistance changes, airway and ventilation effects on the cardiovascular system are of primary importance during the induction of anesthesia.

After anesthetic induction, intravenous access is established or augmented as appropriate. A nondepolarizing muscle relaxant is usually administered and an intravenous opioid or inhalation agent or both chosen for maintenance anesthesia. The child is preoxygenated with 100% F_{IO_2}, and a lubricated nasal endotracheal tube is carefully positioned. A nasal tube is usually selected because in most patients who require an intraoperative TEE or postoperative mechanical ventilation or both a nasotracheal tube provides greater stability and patient comfort compared with the oral route. Some degree of alveolar preoxygenation is recommended, even in the infant whose systemic perfusion might be jeopardized by lowering PVR with resulting increase in PBF. This maneuver delays desaturation during intubation. If the child arrives in the operating room with an endotracheal tube in place, it is our practice to change it. Inspissated secretions in a tube with a small internal diameter can cause significant obstruction to gas flow. During periods of bypass when humidified ventilation is discontinued, significant endotracheal tube obstruction can occur. This can be minimized by placing a new endotracheal tube at the beginning of the procedure.

Because of the diverse array of congenital heart defects and surgical procedures, an individualized anesthetic management plan is essential. The maintenance of anesthesia in these patients depends on the age and condition of the patient, the nature of the surgical procedure, the duration of the CPB, and the need for postoperative ventilation. An assessment of the hemodynamic objectives designed to lessen the pathophysiologic loading conditions should be developed for each patient, taking advantage of the known qualitative effects of specific anesthetic agents and ventilatory strategies. These individualized plans must also be integrated with the overall perioperative goals to configure the optimal anesthetic. In patients with complex defects requiring preoperative inotropic and mechanical ventilatory support, a carefully controlled hemodynamic induction and maintenance

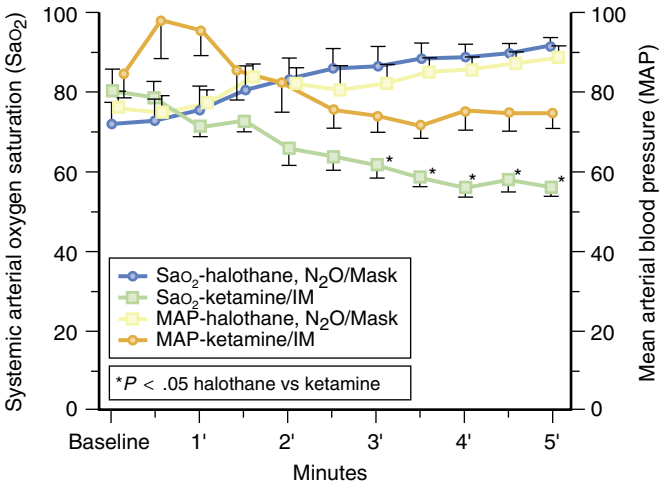

Figure 83-7 Comparative changes in arterial oxygen saturation (Sao_2) and mean arterial pressure (MAP) during mask halothane N_2O ($n = 7$) and intramuscular ketamine ($n = 7$) inductions in children with tetralogy of Fallot at risk for right-to-left shunting. Note the maintenance of Sao_2 in the halothane group despite the significant drop in MAP. (*From Greeley WJ, Bushman GA, Davis DP, Reves JG: Comparative effects of halothane and ketamine on systemic arterial oxygen saturation in children with cyanotic heart disease. Anesthesiology 65:666, 1986.*)

anesthetic with a potent opioid is generally chosen. In patients with a simple ASD or VSD, a potent inhalation agent is preferred as the principal anesthetic agent. This allows for early postoperative extubation and a less prolonged period of intensive care monitoring. More important than the specific anesthetic techniques and drugs is the skilled execution of the anesthetic plan, taking into account patient response to drugs, the changes associated with surgical manipulation, and early recognition of intraoperative complications.

The reported changes in arterial blood pressure and heart rate from the inhaled anesthetic in normal children are observed in pediatric cardiac surgical patients as well. Although both halothane and isoflurane decrease blood pressure in neonates, infants, and children, the vasodilatory properties of isoflurane may improve overall myocardial contractility, compared with the effects of halothane.[83] Despite improved cardiac reserve with isoflurane, the incidence of laryngospasm, coughing, and desaturation during induction of anesthesia limits its use as an induction agent in children with congenital heart defects.[84] The use of potent inhalation agents as primary anesthetics should be reserved for the child with adequate cardiovascular reserve who is a candidate for early postoperative extubation. In these patients, the myocardial depression and hypotension associated with the use of inhalation agents are well tolerated. Examples include closure of an ASD or VSD, excision of a discrete subaortic membrane, pulmonic or aortic stenosis, tetralogy of Fallot, shunts, ligation of a PDA, and repair of coarctation of the aorta.

Desflurane has cardiorespiratory properties similar to those of isoflurane.[85] Its main advantage is low blood gas and tissue solubility. This allows for rapid equilibration between the inspired and alveolar concentrations and rapid decrease of alveolar concentrations during elimination.[86] This provides greater precision in drug dosing during the operative period and may make desflurane a more titratable adjunctive drug for pediatric cardiac anesthesia. The three main disadvantages of desflurane are potency, pungency, and negative inotropic effect.[87,88] Studies in normal infants and children suggest that 1 minimum alveolar concentration (MAC) of desflurane requires concentrations of 8% to 10%.[89,90] Desflurane is also quite pungent and, although its uptake is rapid, early experience with this drug for inhalation induction in children has reported a fairly high incidence of airway reactivity and laryngospasm.[89,91,92] Although its negative inotropic effect is significantly less potent than that of halothane, desflurane should not be used as the sole anesthetic in patients with significant cardiac dysfunction.[92]

Sevoflurane offers a more tolerable aroma without the magnitude of myocardial depression that accompanies halothane.[93] In addition, its blood gas solubility is nearly as low as that of desflurane. Hemodynamically, sevoflurane tends to produce some tachycardia, particularly in older children, and preserve systemic arterial pressure.[94] Reductions in heart rate and systemic arterial pressure are more modest in infants anesthetized with sevoflurane than in control subjects anesthetized with halothane, and the former exhibit echocardiographic evidence of normal contractility and cardiac index.[95,96] Controversies continue to surround the potential toxic by-products of sevoflurane anesthesia, related both to patient metabolism and to the production of Compound A in the anesthesia breathing circuit. Although the importance of Compound A in adult practice remains uncertain, evidence suggests that production of this toxin is significantly diminished in children.[97]

Children with complex congenital heart disease and limited cardiac reserve demand an anesthetic technique that provides hemodynamic stability. Inhalation agents are less well tolerated as a primary anesthetic in patients who have limited cardiac reserve, especially after CPB. Fentanyl is an excellent induction and maintenance anesthetics for this group of patients. Low to moderate doses of this opioid can be supplemented with inhalation anesthetics. Adding low concentrations of inhalation agents to smaller doses of opioids shortens or eliminates the need for postoperative mechanical ventilation while maintaining the advantage of intraoperative hemodynamic stability. Postoperative mechanical ventilation will be required when a high-dose opioid technique is used. The hemodynamic effects of fentanyl at a dose of 25 μg/kg with pancuronium given to infants in the postoperative period after operative repair of a congenital heart defect include no change in LAP, pulmonary artery pressure, PVR, and cardiac index and a small decrease in SVR and mean arterial pressure.[98] Higher doses of fentanyl at 50 to 75 μg/kg with pancuronium result in a slightly greater fall in arterial pressure and heart rate in infants undergoing repair for complex congenital heart defects.[99] Despite the wide safety margin exhibited by this opioid, a selected population of infants and children with marginally compensated hemodynamic function sustained by endogenous catecholamines may manifest more extreme cardiovascular changes with these doses. Fentanyl has also been shown to block stimulus-induced pulmonary vasoconstriction and contributes to the stability of the pulmonary circulation in neonates after congenital diaphragmatic hernia repair.[100] Thus, the use of fentanyl may be extrapolated to the operating room, where stabilizing pulmonary vascular responsiveness in newborns and young infants with reactive pulmonary vascular beds is crucial to weaning from CPB and stabilizing shunt flow.

Sufentanil and pancuronium provide the same cardiovascular stability as with fentanyl and pancuronium in pediatric cardiovascular patients. Children receiving a sufentanil induction as a single dose of 5 to 20 μg/kg have a stable preintubation period.[101,102] Intubation and other stimuli such as sternotomy do not produce clinically significant alterations in hemodynamics, although changes are greater than with equipotent doses of fentanyl. The use of fentanyl as an infusion (0.1 μg/kg/min) produces fewer alterations in heart rate and blood pressure. This is particularly important in infants, in whom significant hemodynamic changes are poorly tolerated. For neonates with critical congenital heart disease, sufentanil anesthetic and postoperative infusion have been shown to reduce morbidity after cardiac surgery when compared with a halothane anesthetic and routine morphine postoperatively.[103] The blunting of the stress response observed in this study probably accounted for the differences in morbidity; there was no comparison group representing a more typical dose of a phenylpiperidine opioid (e.g., fentanyl, 0-75 μg/kg) to permit conclusions as to whether such large opioid doses are optimal.

Compared with other agents in its class, remifentanil, a newer ultrashort-acting opioid, offers the unique advantage of metabolism via nonspecific and tissue esterases, thereby limiting the potential for accumulation related to protracted elimination.[104] Remifentanil may provide advantages in the selected group of patients for whom the blunting of endogenous responses is desirable intraoperatively but potentially deleterious at the end of the procedure. A randomized controlled trial comparing equipotent doses of alfentanil and remifentanil for outpatient pediatric surgery revealed delayed emergence, requiring naloxone only

in the alfentanil group.[105] In both adults and children, remifentanil is associated with qualitative hemodynamic changes similar to other opioids, a variable tendency to bradycardia, and a small reduction in systolic blood pressure.[105-107]

Because of the widespread use of the opioids for pediatric cardiac surgery and the availability of invasive monitoring, the pharmacokinetics and pharmacodynamics of these drugs have been well studied.[102,108] In general, the clinical pharmacology of fentanyl and sufentanil share the same age-related pharmacokinetic and pharmacodynamic features. For example, sufentanil has increased clearance in patients aged 1 month to 12 years, comparable adult clearance in adolescents (12 to 16 years of age), and decreased clearance during the neonatal period (newborn to 1 month) (Table 83-9).[91,96] Furthermore, sequential sufentanil anesthetics in neonates with congenital heart disease show marked increases in clearance and elimination between the first week and the third or fourth week of life (Fig. 83-8).[97] The latter observation is most likely attributable to maturational changes in hepatic microsomal activity and improved hepatic blood flow from closure of the ductus venosus. The variability in clearance and elimination, coupled with limited cardiovascular reserve in the neonate during the first month of life, makes opioid dosing difficult in this age group. Careful titration of 5 to 10 µg/kg of fentanyl or 1 to 2 µg/kg of sufentanil or a continuous infusion technique provides the most reliable method of achieving hemodynamic stability and an accurate dose response. CPB, different institutional anesthetic practices, and individual patient differences influence pharmacokinetic and pharmacodynamic disposition of the opioids in ways that are not predictable. Even certain disease states such as tetralogy of Fallot[98] or pathophysiologic conditions such as increased intra-abdominal pressure[99] alter pharmacokinetic processes.

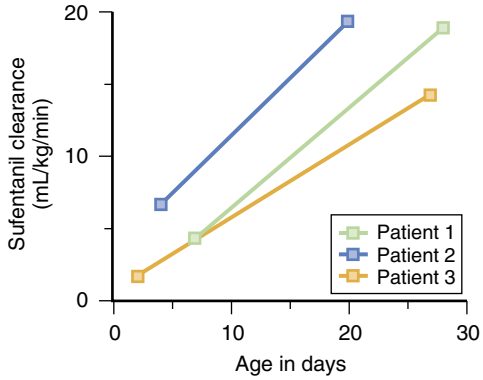

Figure 83-8 Sequential sufentanil clearance during the first month of life in three neonates with congenital heart disease. Clearance of sufentanil increases above adult rates within the neonatal period. (*Data from Greeley WJ, de Bruijn NP: Changes in sufentanil pharmacokinetics within the neonatal period. Anesth Analg 67:86, 1988.*)

Cardiopulmonary Bypass

Differences between Adult and Pediatric Cardiopulmonary Bypass

The physiologic effects of CPB on neonates, infants, and children are significantly different than the effects on adults (Table 83-10). During CPB, pediatric patients are exposed to biologic extremes not seen in adults, including deep hypothermia (18°C), hemodilution (threefold to fivefold greater dilution of circulating blood volume), low perfusion pressures (20 to 30 mm Hg), wide variation in pump flow rates (ranging from highs of 200 mL/kg/min to total circulatory arrest), and differing blood pH management techniques (α-stat or pH-stat, or both sequentially). These parameters significantly differ from those of normal physiology and affect preservation of normal organ function during and after CPB. In addition to these prominent changes, subtle variations in glucose supplementation, cannula placement, presence of aortopulmonary collaterals, and patient age may be important factors affecting organ function during CPB.

Adult patients are infrequently exposed to these biologic extremes. In adult cardiac patients, temperature is rarely lowered below 25°C, hemodilution is more moderate, perfusion pressure is generally maintained at 50 to 80 mm Hg, flow rates are maintained at 50 to 65 mL/kg/min, and pH management strategy is less influential because of moderate hypothermic temperatures and rare use of circulatory arrest. Variables such as glucose supplementation rarely pose a problem in adult patients owing to large hepatic glycogen stores. Venous and arterial cannulas are larger and less deforming of the atria and aorta, and their placement is more predictable. Although superficially similar, the conduct of CPB in children is considerably different from that in adults. One would therefore expect marked physiologic differences in the response to CPB in children. Additionally, there are several modifiable intraoperative factors that can influence neuropsychologic morbidity (Table 83-11).

Table 83-9 Sufentanil Pharmacokinetics in Pediatric Cardiovascular Patients*

Age Group	t½α (min)	t½β (min)	Clearance (mL/kg/min)	Vd_{ss} (L/kg)
1-30 days	23 ± 17	737 ± 346	6.7 ± 6.1	4.2 ± 1.0
1-24 mo	16 ± 5	214 ± 41	18.1 ± 2.7	3.1 ± 1.0
2-12 yr	20 ± 6	140 ± 30	16.9 ± 2.2	2.7 ± 0.5
12-18 yr	20 ± 6	209 ± 23	13.1 ± 0.4	2.7 ± 0.5

t½α, slow distribution half-life; t½β, elimination half-life; Vd_{ss}, volume of distribution at steady state.
*All values are mean ± standard deviations (see reference 39).

Priming Volume

The priming solutions used in pediatric CPB take on great importance because of the disproportionately large priming volume/blood volume ratio in children. In adults, the priming volume is equivalent to 25% to 33% of the patient's blood volume, whereas in neonates and infants the priming volume may exceed the patient's blood volume by 200%. With contemporary low-volume bypass circuits (e.g., small volume oxygenators, smaller tubing), priming volume is not more than one blood volume in a small neonate. Care must be taken, therefore, to achieve a physiologically balanced priming solution and limit the volume as much as possible. Most pediatric priming solutions, however, have quite

Table 83-10 Differences between Adult and Pediatric Cardiopulmonary Bypass

Parameter	Adult	Pediatric
Hypothermic temperature	Rarely below 25-30°C	Commonly 15-20°
Use of total circulatory arrest	Rare	Common
Pump prime Dilution effects on blood volume Additional additives in pediatric primes	 25-33%	 150-300% Blood, albumin
Perfusion pressures	50-80 mm Hg	20-50 mm Hg
Influence of α- vs. pH-stat management strategy	Minimal at moderate hypothermia	Marked at deep hypothermia
Measured $Paco_2$ differences	30-45 mm Hg	20-80 mm Hg
Glucose regulation Hypoglycemia Hyperglycemia	 Rare—requires significant hepatic injury Frequent—generally easily controlled with insulin	 Common—reduced hepatic glycogen stores Less common—rebound hypoglycemia may occur

variable levels of electrolytes, calcium, glucose, and lactate. Electrolytes, glucose, and lactate levels may be quite high if the solution includes large amounts of banked blood or quite low if a minimal amount of banked blood is added. Calcium levels are generally very low in pediatric priming solutions; this may contribute to the rapid slowing of the heart with the initiation of bypass.

The main constituents of the priming solution include crystalloid, banked blood (to maintain a temperature-appropriate hematocrit), and colloid. Other supplements that may be added to the prime are mannitol, a buffer (sodium bicarbonate or trishydroxymethylaminomethane [THAM]), and steroids. Many institutions add colloid or fresh frozen plasma to the pump prime in neonates and small infants or use whole blood in the priming solution. Low concentrations of plasma proteins have been shown experimentally to impair lymphatic flow and alter pulmonary function by increasing capillary leak.[109] Although adding albumin to the pump prime has not been shown to alter outcome in adults during CPB, one study suggested that maintaining normal colloid osmotic pressure may improve survival in infants undergoing CPB.[110,111]

Table 83-11 Central Nervous System Injury and Potential Modifiable Intraoperative Factors

Deep hypothermic circulatory arrest (if utilized)
Reperfusion injury and inflammation
Rate of core rewarming/hyperthermia
Hyperglycemia
Hyperoxia
pH management during cardiopulmonary bypass
Hematocrit management during cardiopulmonary bypass

The addition of fresh frozen plasma or whole blood (see Chapter 55) is an attempt to restore the level of procoagulants, which are severely diluted with CPB in infants. For neonates and infants, blood must be added to the priming solution. Most institutions use packed red blood cells, but some use whole blood. The use of whole blood supplements both red blood cells and the coagulation factors with a single donor exposure. In fact, low-volume bypass circuits may enable perfusionists and anesthesiologists to share a single unit of whole blood, thereby limiting the donor exposure to one throughout the entire perioperative course.

The addition of any blood products will cause a much higher glucose load in the priming solution. Hyperglycemia may increase the risk of neurologic injury if brain ischemia occurs. Mannitol is added to promote an osmotic diuresis and to scavenge oxygen free radicals from the circulation. Steroids are added to stabilize membranes to produce the theoretical advantage of reducing ion shifts during periods of ischemia. Steroids, however, may raise glucose levels, and this may be detrimental if there is a period of cerebral ischemia. Steroids remain one of the more controversial additives in priming solutions.

Temperature

Hypothermic CPB is used to preserve organ function during cardiac surgery. Three distinct methods of CPB are used: moderate hypothermia (25°C to 32°C), deep hypothermia (18°C), and DHCA. The choice of method of bypass is based on the required surgical conditions, patient size, the type of operation, and the potential physiologic impact on the patient.

Moderate hypothermic CPB is the principal method of bypass employed for older children and adolescents. In these patients, venous cannulas are less obtrusive and the heart can easily accommodate superior and inferior vena cava cannulation. Bicaval cannulation reduces right atrial blood return and improves the surgeon's ability to visualize intracardiac anatomy. Moderate hypothermia may also be chosen for less demanding cardiac repairs in infants, such as an ASD or an uncomplicated VSD. Most surgeons are willing to cannulate the inferior and superior venae cavae in neonates and infants. In these patients, however, this approach is technically more difficult and likely to induce

brief periods of hemodynamic instability. Additionally, the pliability of the venae cavae and the rigidity of the cannulas may result in caval obstruction, impaired venous drainage, and elevated venous pressure in the mesenteric and cerebral circulation.

Deep hypothermic CPB is generally reserved for neonates and infants requiring complex cardiac repair. However, certain older children with complex cardiac disease or severe aortic arch disease benefit from deep hypothermic temperatures. For the most part, deep hypothermia is selected to allow the surgeon to operate under conditions of low-flow CPB or total circulatory arrest. Low pump flows (50 mL/kg/min) improve the operating conditions for the surgeon by providing a nearly bloodless field. DHCA allows the surgeon to remove the atrial or aortic cannula. If this technique is used, surgical repair is more precise because of the bloodless and cannula-free operative field. Arresting the circulation, even at deep hypothermic temperatures, introduces the concern of how well deep hypothermia preserves organ function, with the brain being at greatest risk.[112]

Hemodilution

Hemodilution has been used during CPB to decrease homologous blood use and has been thought to improve microcirculatory flow by reducing blood viscosity. Although hemoconcentrated blood has an improved oxygen-carrying capacity, its viscosity reduces efficient flow through the microcirculation. With hypothermic temperatures, blood viscosity increases significantly and flow decreases. Hypothermia, coupled with the nonpulsatile flow of CPB, impairs blood flow through the microcirculation. Blood sludging, small vessel occlusion, and multiple areas of tissue hypoperfusion may result. Therefore, hemodilution is an important consideration during hypothermic CPB. The appropriate level of hemodilution for a given hypothermic temperature, however, is not well defined. However, hemodilution also reduces perfusion pressure, increases CBF thereby potentially increasing the microembolic load to the brain, and reduces the oxygen-carrying capacity of blood.[113] Using an animal model, one group of investigators found that extreme hemodilution to a hematocrit less than 10% resulted in inadequate oxygen delivery, but with higher hematocrit levels of 30% there was improved cerebral recovery after DHCA.[114] Jonas and colleagues[115] confirmed these findings in a randomized trial using two hemodilution protocols (20% versus 30% hematocrit) in infants younger than 9 months of age. Developmental outcomes were assessed at follow-up at 1 year of age with the Bayley Scales of Infant Development. In the short term, the lower-hematocrit group had lower nadirs of cardiac index, higher serum lactate levels 1 hour after CPB, and a greater increase in total body water on the first postoperative day. At 1 year of age, mental development index scores were similar but psychomotor development index scores were significantly lower in the lower hematocrit group. Also, infants in the lower hematocrit group had psychomotor development scores that were 2 standard deviations below the mean. Because red blood cells serve as the major reservoir of oxygen during circulatory arrest, especially during rewarming, hematocrit values closer to 30% are generally preferred for deep hypothermia when this technique is contemplated. Currently, most centers maintain hematocrit levels around 25% to 30% during CPB, enhancing oxygen delivery to vital organs such as the brain. Cerebral oxygen delivery is an especially important consideration, because cerebral autoregulation is impaired at deep hypothermic temperatures and after DHCA.

To achieve a hematocrit level of 25% to 30% in neonates and infants, banked blood should be added to the priming solution. The mixed hematocrit level on CPB (the hematocrit level of the total priming volume plus the patient's blood volume) can be calculated by the following formula:

$$HCT_{CBP} = \frac{BV_{pt} \cdot HCT_{pt}}{BV_{pt} + TPV}$$

where Hct_{CPB} is the mixed hematocrit (TPV + BV_{pt}), BV_{pt} is the patient's blood volume (weight in kilograms × estimated blood volume in milliliters per kilogram), TPV is the total priming volume, and Hct_{pt} is the starting hematocrit level of the patient. This calculation allows an estimate of the hematocrit level of the patient using an asanguineous priming solution and is therefore useful for older children and adolescents. In neonates and infants, the perfusionist must add blood to the pump prime to achieve a desired hematocrit level during hypothermic CPB. The following formula estimates the amount of packed red blood cells (RBCs) in mL that must be added to the prime volume to achieve this hematocrit level:

$$\text{Added RBCs (mL)} = \left(BV_{pt} + TPV\right)\left(Hct_{desired}\right) - \left(BV_{pt}\right)\left(Hct_{pt}\right)$$

where BV_{pt} is the patient's blood volume, TPV is the total priming volume, $Hct_{desired}$ is the desired hematocrit level on CPB, and Hct_{pt} is the starting hematocrit level of the patient.

Currently, no evidence exists for defining the optimal hematocrit level after weaning from CPB. Decisions concerning post-CPB hematocrit levels are made based on the patient's post-repair function and anatomy. Patients with residual hypoxemia or those with moderate to severe myocardial dysfunction benefit from the improved oxygen-carrying capacity of hematocrit levels of 40% or higher. Patients with a physiologic correction and excellent myocardial function may tolerate hematocrit levels of 25% to 30%.[116] In children with mild to moderate myocardial dysfunction, accepting hematocrit values between these levels seems prudent. Therefore, in patients with physiologic correction, moderately good ventricular function, and hemodynamic stability, the risks associated with blood and blood product transfusion should be strongly considered during the immediate postbypass period.

Blood Gas Management

The theoretical benefit of α-stat versus pH-stat blood gas management during hypothermic CPB has been a topic of great debate (see Chapter 49). Although the pH-stat strategy may not be optimal for adults in whom the principal risk for brain injury is microembolism, this risk is thought to be lower in infants due to the lack of atherosclerotic disease. With pH-stat management, the addition of CO_2 to the inspired gas mixture during cooling on CPB increases CBF and may improve cerebral tissue oxygenation and outcomes.

The controversial issue of pH management during CPB has been addressed in a large study from Boston Children's Hospital. In this study, infants younger than 9 months of age were randomized to α-stat versus pH-stat during deep hypothermic CPB with excellent long-term follow-up.[117,118] Neurodevelopmental

outcomes were evaluated in infants undergoing biventricular repair for a variety of cardiac defects when younger than 9 months of age. The short-term benefits identified with the pH-stat strategy included a trend toward less postoperative morbidity and shorter recovery time to first electroencephalographic activity. In patients with transposition of the great arteries, there was a shorter duration of intubation and intensive care unit stay in patients.[118] However, the use of either the α-stat or pH-stat strategies was not consistently related to either improved or impaired neurodevelopmental outcomes at 2- and 4-year follow-up.[117]

Initiation of Cardiopulmonary Bypass

Arterial and venous cannula in the heart before initiating CPB may result in significant problems in the peri-bypass period. A malpositioned venous cannula has the potential for vena cava obstruction. The problems of venous obstruction are magnified during CPB in the neonate because arterial pressures are normally low (20 to 40 mm Hg), and large, relatively stiff cannulas easily distort these very pliable venous vessels.[109,110] A cannula in the inferior vena cava may obstruct venous return from the splanchnic bed, resulting in ascites from increased hydrostatic pressure or directly reduced perfusion pressure across the mesenteric, renal, and hepatic vascular beds. Significant renal, hepatic, and gastrointestinal dysfunction may ensue and should be anticipated in the young infant with unexplained ascites. Similar cannulation problems may result in superior vena cava obstruction. This condition may be more ominous during bypass. Under these circumstances, three problems may ensue: (1) cerebral edema, (2) a reduction in regional or global CBF, and (3) reduced proportion of pump flow reaching the cerebral circulation, causing inefficient brain cooling.

In the operating room, superior vena cava pressures via an internal jugular catheter should be monitored by examining the patient's head for signs of suffusion after initiating bypass. Discussions with the perfusionist regarding adequacy of venous return and large cooling gradients between the upper and lower body should alert the anesthesiologist and the surgeon to potential venous cannula problems. Patients with anomalies of the large systemic veins (persistent left superior vena cava or azygous continuation of an interrupted inferior vena cava) are at particular risk for problems with venous cannulation and drainage.

Problems with aortic cannula placement can also occur. The aortic cannula may slip beyond the takeoff of the innominate artery and therefore selectively flow to the right side of the cerebral circulation. Also, the position of the tip of the cannula may promote preferential flow down the aorta or induce a Venturi effect to steal flow from the cerebral circulation. This problem has been confirmed during CBF monitoring by the appearance of large discrepancies in flow between the right and left hemispheres after initiating CPB. The presence of large aortic to pulmonary collaterals, such as a large PDA, may also divert blood to the pulmonary circulation from the systemic circulation, thereby reducing CBF and the efficiency of brain cooling during CPB. The surgeon should gain control of the ductus either before or immediately after instituting CPB to eliminate this problem and, if possible, large aortopulmonary collaterals should be embolized in the cardiac catheterization laboratory before the operative procedure. Neonates with significant aortic arch abnormalities (e.g., aortic atresia, interrupted aortic arch) may require radical modifications of cannulation techniques, such as placing the arterial cannula in the main pulmonary artery and temporarily occluding the branch pulmonary arteries to perfuse the body via the PDA, or even dual arterial cannulation of both the ascending aorta and main pulmonary artery. Such adaptations require careful vigilance to ensure effective, thorough perfusion and cooling of vital organs.

Once the aortic and venous cannulas are positioned and connected to the arterial and venous limb of the extracorporeal circuit, bypass is initiated. The arterial pump is slowly started, and, once forward flow is ensured, venous blood is drained into the oxygenator. Pump flow rate is gradually increased until full circulatory support is achieved. If venous return is diminished, arterial line pressure high, or mean arterial pressure excessive, pump flow rates must be reduced. High line pressure and inadequate venous return are usually caused by malposition or kinking of the arterial and venous cannulas, respectively. The rate at which venous blood is drained from the patient is determined by the height difference between the patient and the oxygenator inlet and the diameter of the venous cannula and line tubing. Venous drainage can be increased by using vacuum-assisted drainage under certain circumstances.

In neonates and infants, deep hypothermia is commonly used. For this reason, the pump prime is kept cold (18°C to 22°C). When the cold perfusate contacts the myocardium during the institution of CPB, heart rate slows immediately and contraction is impaired. The contribution of total blood flow pumped by the infant's heart rapidly diminishes. Therefore, to sustain adequate systemic perfusion at or near normothermic temperatures, the arterial pump must reach full flows quickly.

CPB is initiated in neonates and infants by beginning the arterial pump flow first. Once aortic flow is ensured, the venous line is unclamped and blood is siphoned out of the right atrium into the inlet of the oxygenator. Flowing before unclamping the venous line prevents the potential problem of exsanguination if aortic dissection or misplacement of the aortic cannula occurs. Neonates and infants have a low blood volume/priming volume ratio, and intravascular volume falls precipitously if the venous drainage precedes aortic inflow. Once the aortic cannula position is verified, pump flow rates are rapidly increased to maintain effective systemic perfusion. Because coronary artery disease is rarely a consideration, the myocardium should cool evenly unless distortion caused by the cannulas compromises the coronary arteries. When a cold prime is used, caution must be exercised in using the pump to infuse volume before initiating CPB. Infusion of cold perfusate may result in bradycardia and impaired cardiac contractility before the surgeon is prepared to initiate CPB.

Once CPB is begun, careful observation should be focused to ensure appropriate circuit connections, myocardial perfusion, and optimal cardiac decompression. Ineffective venous drainage can rapidly result in ventricular distention. This is especially true in infants and neonates, in whom ventricular compliance is low and the heart is relatively intolerant of excessive preload augmentation. If ventricular distention occurs, pump flow must be reduced and the venous cannula repositioned. Alternatively, the heart may be decompressed by placing a cardiotomy suction catheter or small vent in the appropriate chamber.

Pump Flow Rates

Recommendations for optimal pump flow rates for children have historically been based both on the patient's body mass and on evidence of efficient organ perfusion as determined by arterial blood gases, acid-base balance, and whole-body oxygen consumption during CPB.[65,119] At hypothermic temperatures, metabolism is reduced, and CPB flow rates can therefore be reduced and still meet or exceed the tissue's metabolic needs (see the discussion of low-flow CPB in the following section).

Special Techniques

Deep Hypothermic Circulatory Arrest

There are a certain subset of neonates, infants, and children with congenital heart disease who require extensive repair of complex congenital heart defects using DHCA. This technique facilitates precise surgical repair under optimal conditions and free of blood or cannulas in the operative field, providing maximal organ protection and often resulting in shortened total CPB time. The scientific rationale for the use of deep hypothermic temperatures rests primarily on a temperature-mediated reduction of metabolism. Whole-body and cerebral oxygen consumption during induced hypothermia decreases the metabolic rate for oxygen by a factor of 2 to 2.5 for every 10°C reduction in temperature.[120] These results are consistent with in-vitro models, which relate temperature reduction to a decrease in the rate constant of chemical reactions, as originally described by Arrhenius using the equation $k = Ae^{-RT}$. The reduction in oxygen supply during deep hypothermic low-flow CPB is associated with preferential increases in vital organ perfusion (e.g., to the brain) and increased extraction of oxygen.[121] Therefore, to some extent, deep hypothermic low-flow CPB exerts a protective effect by reducing the metabolic rate for oxygen, promoting preferential organ perfusion, and increasing tissue oxygen extraction.

The duration of the safe period of DHCA has not clearly been delineated.[122] Although all organ systems are at risk for the development of ischemic and reperfusion injury, as manifested by lactate and pyruvate production during DHCA, the brain appears to be the most sensitive to and the least tolerant of these effects. Brainstem and cortical evoked potentials as well as processed electroencephalograms are altered after DHCA.[122-124] The abnormalities in the evoked potentials appear to be related to the duration of DHCA and are attributed to altered metabolism. During reperfusion after the arrest period, CBF and metabolism remain depressed in neonates and small infants (Fig. 83-9; also see Fig. 83-6).[77] Importantly, during the use of these extremes of temperature, it appears that autoregulation is lost and cerebral perfusion becomes highly dependent on the conduct of extracorporeal perfusion and presumably post-bypass hemodynamic performance.

The potentially deleterious effects of prolonged DHCA in infants and neonates are well described. In general, it is agreed that very prolonged periods of uninterrupted DHCA may have adverse neurologic outcomes. However, there is considerable disagreement if a "safe" period of DHCA exists and whether patient-specific, procedure-specific, or postoperative management strategies may attenuate or promote CNS damage from DHCA. There are some reports of detrimental effects of DHCA

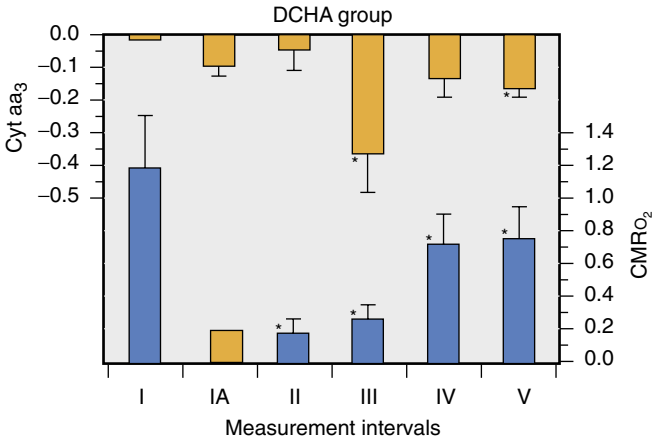

Figure 83-9 Bar graph of variations in cytochrome oxidase (cyt aa_3) near-infrared spectroscopic signals and cerebral metabolic rate for oxygen ($CMRO_2$) in subjects with deep hypothermic circulatory arrest (DHCA). Each point of cyt aa_3 represents mean ± SE in six subjects; $CMRO_2$ values are mean ± SD. Negative values in cyt aa_3 represent relative decreases in quantity of oxidized enzyme. *, $CMRO_2$ and cyt aa_3 are significantly different from control, $P \pm .05$.

on a variety of outcomes regarding the central nervous system and others on either an inconsistent effect or no effect.[118,125-128] Three issues have become clear over time: (1) The effects of short durations of DHCA are inconsistently related to adverse outcomes, (2) the effect of DHCA is not a linear phenomenon, and (3) the effects are most likely modified by other patient-related, preoperative, and postoperative factors.[128-130] Because many studies suggest a negative effect, some surgeons have developed innovative and challenging strategies to provide continuous cerebral perfusion during complex reconstruction of the aortic arch or intracardiac repair to avoid or minimize the use of DHCA. It should be emphasized that by avoiding DHCA, the duration of CPB is necessarily lengthened and longer durations of CPB have been shown to adversely effect both short- and long-term outcomes.[130] The relative risks and benefits of longer CPB versus less (or no) DHCA remain a subject of continued controversy.

Regional Cerebral Perfusion

Some surgeons have developed innovative and challenging strategies to provide continuous cerebral perfusion during complex reconstruction of the aortic arch or intracardiac repair to avoid or minimize the use of DHCA. However, avoiding DHCA, the duration of CPB is necessarily lengthened and longer durations of CPB have been shown to adversely effect both short and long-term outcomes.[59,60] The relative risks and benefits of longer CPB versus less (or no) DHCA remain a subject of continued controversy. In efforts to study this newer strategy, two recent studies have evaluated the technique of regional cerebral perfusion. In one nonrandomized study from Boston, Wypij and colleagues followed 29 infants who underwent a stage I palliation, 9 of whom received regional cerebral perfusion at 30 to 40 mL/kg/min.[131] The authors reported no difference in mental or psychomotor developmental indices at 1 year of age between the regional cerebral perfusion group and those who received DHCA as a primary strategy. A group from the University of Michigan has published a larger, randomized trial of DHCA ± regional cerebral perfusion

at 20 mL/kg/min in patients with a functional single ventricle, with long-term studies that are in the planning stages.[132] A total of 77 patients were enrolled with similar survival to hospital discharge (88%) and at 1-year follow-up (75%). No significant difference was seen in either the psychomotor development index or the mental development index scores between the two groups at any time points, although the scores tended to be lower in the regional cerebral perfusion group.

Glucose Regulation

A substantial amount of clinical and experimental data has shown conclusive evidence of the detrimental effects of hyperglycemia during complete, incomplete, and focal cerebral ischemia.[133,134] The role of glucose in potentiating cerebral injury appears to rest on two factors: adenosine triphosphate (ATP) utilization and lactic acidosis.[135,136] The anaerobic metabolism of glucose requires phosphorylation and the expenditure of two molecules of ATP before ATP production can occur. This initial ATP expenditure may result in a rapid depletion of ATP and may explain why hyperglycemia worsens neurologic injury. Lactic acidosis is also important in glucose-augmented cerebral injury. Its important role, however, may be as a glycolytic enzyme inhibitor. Lactate slows anaerobic ATP production by inhibiting glycolysis immediately after ATP is consumed in the phosphorylation of glucose.[137]

A strong scientific argument can be made for the detrimental effects of hyperglycemia during ischemia, but there is very little evidence supporting a relationship between a worsening neurologic outcome and hyperglycemia during CPB or DHCA in children. Although a retrospective review of 34 children undergoing DHCA suggested a worse neurologic outcome in the hyperglycemic children, the results were reported as a nonsignificant statistical trend.[138] A review of acquired neurologic lesions in patients undergoing the Norwood stage I procedure for hypoplastic left heart syndrome suggested hyperglycemia as a significant associated finding in patients with extensive cerebral necrosis or intraventricular hemorrhage. A host of other potentially damaging factors (e.g., periods of hypoxia, low diastolic and systolic pressure, thrombocytopenia) were statistically associated with the observed neuropathology.[139] Because hyperglycemia accompanies a generalized stress response, this literature failed to distinguish whether glucose directly contributes to neurologic injury or merely serves as a marker for a high-risk population that ultimately suffers neurologic insult as a result of other factors.

Hypoglycemia is a frequent concern in neonates during the perioperative period. Reduced hepatic gluconeogenesis coupled with decreased glycogen stores places the newborn at increased risk for hypoglycemic events. In newborns with congenital heart disease, reduced systemic perfusion (e.g., critical coarctation, hypoplastic left heart syndrome, critical aortic stenosis) may result in worsening hepatic biosynthesis, further impairing glucose production. These patients may be fully dependent on exogenous glucose; therefore, it is not uncommon for them to require 20% to 30% dextrose infusions to maintain euglycemia in the pre-bypass period. Older children are not immune to hypoglycemic events and are therefore susceptible to hypoglycemia-induced neurologic injury. Patients with low cardiac output states (cardiomyopathies, pretransplant patients, critically ill postoperative patients) requiring reoperation and when on substantial inotropic support are at risk for reduced glycogen stores and intraoperative hypoglycemia.[140]

The impact of hypoglycemia during CPB is further complicated by the consequences of hypothermia, CO_2 management, and other factors that may modify normal cerebrovascular responses during bypass. In a dog model, insulin-induced hypoglycemia to 30 mg/dL did not alter the electroencephalographic findings. However, after 10 minutes of hypocapnic hypoglycemia, the EEG became flat.[141] When regional blood flow was examined in these animals, cortical and hippocampal blood flow remained normal whereas other regions of the brain had reduced flow. The loss of electroencephalographic activity from hypoglycemia alone does not normally occur above glucose levels of 8 mg/dL.[142]

During deep hypothermic CPB and DHCA, CBF and metabolism are altered. The additive effect of hypoglycemia, even if mild, may cause alterations in cerebral autoregulation and culminate in increased cortical injury.[139] The common practice of using hyperventilation to reduce PVR in neonates and infants during weaning from CPB and in the early post-bypass period can further exacerbate hypoglycemic injury. Glucose monitoring and rigid maintenance of euglycemia are an important part of CPB management in the patient with congenital heart disease.

Renal Effects

After CPB, the combined effects of hypothermia, nonpulsatile perfusion, and reduced mean arterial pressure cause release of angiotensin, renin, catecholamines, and antidiuretic hormones.[143-145] These circulating hormones promote renal vasoconstriction and reduce renal blood flow. However, despite the negative impact of CPB on renal function, studies have been unable to link low-flow, low-pressure, nonpulsatile perfusion with postoperative renal dysfunction (Table 83-12).[143] The factors that best correlate with postoperative renal dysfunction are preoperative renal dysfunction and profound reductions in post-CPB cardiac output. Preoperative factors include primary renal disease,

Table 83-12 Sequelae of Pediatric Cardiopulmonary Bypass

End-Organ Injury	Etiology/Signs
Renal injury	Organ immaturity, preexisting renal disease Post-cardiopulmonary bypass low CO, use of DHCA Renal dysfunction characterized by reduced GFR and ATN
Pulmonary injury	Endothelial injury, increased capillary leak, complement activation, and leukocyte degranulation Pulmonary dysfunction characterized by reduced compliance, reduced FRC, and increased A-a gradient
Cerebral injury after DHCA	Loss of autoregulation, suppressed metabolism and cerebral blood flow, cellular acidosis, and cerebral vasoparesis CNS dysfunction characterized by seizures, reduced developmental quotients, choreoathetosis, learning disabilities, behavioral abnormalities

A-a, alveolar-arterial; ATN, acute tubular necrosis; CNS, central nervous system; CO, cardiac output; DHCA, deep hypothermic circulatory arrest; FRC, functional residual capacity; GFR, glomerular filtration rate.

low cardiac output, and dye-related renal injury after cardiac catheterization.[145]

The incidence of acute renal insufficiency after pediatric cardiac surgery is approximately 8%. Multiple causative factors are involved, and the final common result is oliguria and an elevated serum creatinine. Diuretics have been the mainstay of promoting urine flow after pediatric CPB. Furosemide in a dose of 1 to 2 mg/kg or ethacrynic acid 1 mg/kg every 4 to 6 hours, or both, induces a diuresis and may reverse renal cortical ischemia associated with CPB. After DHCA, it is not unusual to observe a 24-hour period of oliguria or anuria that resolves over the next 12- to 24-hour period. The use of diuretics is effective only after spontaneous urine output has been initiated in these patients.

Glomerular filtration rate, creatinine clearance, and medullary concentrating ability are substantially reduced in neonates and young infants. Therefore, the use of CPB in these patients is associated with greater fluid retention than is typically seen in older children and adult patients. The net result may be increased total body water, increased organ weight (e.g., lungs, heart), and greater difficulty with postoperative weaning from ventilatory support. The use of ultrafiltration during rewarming or after CPB is effective in reducing total body water, limiting the damaging effects of CPB, and decreasing the postoperative ventilation period.[146,147]

Pulmonary Effects

Cardioplegia protects the heart, but there is no parallel protection afforded the lung during bypass. Pulmonary dysfunction is common after CPB, and its pathogenesis is poorly understood (see Table 83-12). In the broadest terms, lung injury is mediated in one of two ways: first, by an inflammatory response due to leukocyte and complement activation and, second, by a mechanical effect culminating in surfactant loss, atelectasis with resultant ventilation-perfusion mismatch, loss of lung volumes, and altered mechanics of breathing.

Pulmonary function after CPB is characterized by reduced static and dynamic compliance, reduced functional residual capacity, surfactant deficiency, and an increased A-a gradient.[148,149] Atelectasis and increased capillary leak due to hemodilution and hypothermic CPB are the most likely causes. Hemodilution reduces circulating plasma proteins, reducing intravascular oncotic pressure, and favors water extravasation into the extravascular space. Hypothermic CPB causes complement activation and leukocyte degranulation.[150] Leukocytes and complement are important in causing capillary-alveolar membrane injury and microvascular dysfunction through platelet plugging and release of mediators, which increase PVR. The technique of modified ultrafiltration (MUF) is highly effective in reducing lung water and pulmonary morbidity during the postoperative period.

Stress Response and Cardiopulmonary Bypass

The release of a large number of metabolic and hormonal substances, including catecholamines, cortisol, growth hormone, prostaglandins, complement, glucose, insulin, endorphins, and other substances, characterizes the stress response during hypothermic CPB.[13,151] The likely causes of the elaboration of these substances include contact of blood with the nonendothelialized surface of the pump tubing and oxygenator, nonpulsatile flow, low perfusion pressure, hemodilution, hypothermia, and light anesthesia depth. Other factors that may contribute to elevations of stress hormones include delayed renal and hepatic clearance during hypothermic CPB, myocardial injury, and exclusion of the pulmonary circulation from bypass. The lung is responsible for metabolizing and clearing many of these stress hormones. The stress response generally peaks during rewarming from CPB. There is strong evidence that the stress response can be blunted by increasing the depth of anesthesia.[13,151]

It is unclear at what level elevated circulating stress hormones, a normal neonatal adaptive response, become detrimental. There is little question that these substances could mediate undesirable effects such as myocardial damage (catecholamines), systemic and pulmonary hypertension (catecholamines, prostaglandins), pulmonary endothelial damage (complement, prostaglandins), and pulmonary vascular reactivity (thromboxane). The benefits of controlling the stress response with fentanyl in premature infants undergoing PDA ligation and with sufentanil in neonates with complex congenital heart disease have been demonstrated.[103,152] Although blunting the stress response seems warranted, there is additional evidence suggesting that the newborn stress response, especially the endogenous release of catecholamines, may be an adaptive metabolic response necessary for survival at birth.[153] Thus, the complete elimination of an adaptive stress response may not be desirable. To what extent acutely ill neonates with congenital heart disease are dependent on the stress response for maintaining hemodynamic stability is currently unknown.

It is, therefore, prudent to maintain a depth of anesthesia adequate to attenuate the stress response but to attempt to block the response altogether may not be necessary. Acceptable anesthesia during CPB may be best accomplished by the continuous administration of an inhalation anesthetic via a vaporizer connected to the pump oxygenator, careful titration of incremental doses of opioids, or the precise administration of an opioid or opioid and benzodiazepine by a continuous infusion technique. Primary opioid anesthetic techniques result in reduced stress hormone release and decreased postoperative metabolic acidosis and lactate production compared with primary halothane anesthesia and may therefore be a preferred technique in complex congenital heart disease.[103] If an adequate depth of anesthesia is accomplished by the administration of excessively large doses of opioids (e.g., fentanyl or sufentanil), postoperative mechanical ventilation will be necessary. By contrast, residual levels of inhalation anesthetic drugs (e.g., halothane or isoflurane) can produce transient myocardial depression at the termination of CPB, complicating separation from CPB. Because of the improved surgical techniques coupled with the reduced morbidity of CPB, the use of high doses of an opioid anesthetic is infrequent in our current practice.

Discontinuation of Cardiopulmonary Bypass

In separating the patient from CPB, blood volume is assessed by direct visualization of the heart and monitoring right atrial or left atrial filling pressures. When filling pressures are adequate, the patient is fully warmed, acid-base status is normalized, heart rate is adequate, and sinus rhythm has been achieved, the venous drainage is stopped and the patient can be weaned from bypass. The arterial cannula is left in place so that a slow infusion of

residual pump blood can be used to optimize filling pressures. Myocardial function is assessed by direct cardiac visualization and by a transthoracic left or right atrial catheter, by a percutaneous internal jugular catheter, or by the use of intraoperative echocardiography. Pulse oximetry can also be used to assess the adequacy of cardiac output.[154] Low systemic arterial saturation or the inability of the oximeter probe to register a pulse may be a sign of very low output and high systemic resistance.[155]

After the repair of complex congenital heart defects, the anesthesiologist and surgeon may have difficulty separating patients from CPB. Under these circumstances, a diagnosis must be made and includes (1) an inadequate surgical result with a residual defect requiring repair, (2) pulmonary artery hypertension, and (3) right or left ventricular dysfunction.

Two general approaches are customarily used, either independently or in conjunction. An intraoperative "cardiac catheterization" can be performed to assess isolated pressure measurements from the various great vessels and chambers of the heart (i.e., catheter pullback measurements or direct needle puncture to evaluate residual pressure gradients across repaired valves, sites of stenosis and conduits, and oxygen saturation data to examine for residual shunts).[156] Alternatively, echo-Doppler imaging may be used to provide an intraoperative image of structural or functional abnormalities to assist in the evaluation of the postoperative cardiac repair.[12,157] If structural abnormalities are found, the patient can be placed back on CPB and residual defects can be repaired before the patient leaves the operating room. Leaving the operating room with a significant residual structural defect adversely affects survival and increases patient morbidity (see Fig. 83-5).[12,157] Echo-Doppler imaging can rapidly identify right and left ventricular dysfunction and suggest the presence of pulmonary artery hypertension. In addition, echo-Doppler imaging can identify regional wall motion abnormalities caused by ischemia or intramyocardial air that will direct specific pharmacologic therapy and provide a means of assessing the results of these interventions (Fig. 83-10).[158]

Ultrafiltration

Institution of CPB in neonates, infants, and young children results in a profound proinflammatory response as well as significant hemodilution. This may lead to post-CPB morbidity and mortality resultant from poor organ function. The organ systems most affected by this are the heart, lungs, and brain. Although contact between the patient's blood and the foreign surface of the bypass circuit is a potent stimulus to trigger the inflammatory cascade, other factors including ischemia, profound hypothermia, rewarming, and surgical trauma are also important in its genesis. These inflammatory mediators include complement anaphylotoxins, vasoactive amines, and cytokines (e.g., tumor necrosis factor-α [TNF-α]) that lead to an increase in vascular permeability.[159] Hemodilution occurs at the onset of CPB despite the use of physiologically balanced priming solutions that include blood, crystalloid, albumin, and buffer and smaller volume circuits. Hemodilution may, however, be advantageous in those patients where the surgery is performed under hypothermic conditions ranging from mild hypothermia down to deep hypothermic circulatory arrest. Initiation of CPB will change the viscoelastic properties of blood, and these changes have been shown to continue into the post-CPB period.[160] Although the mode of perfusion, cardiotomy suction, arterial roller pump type, and shear forces of the CPB circuit are important, it is the temperature and hematocrit of the blood that play the most important role in changing viscoelasticity. It has been shown that low temperature with a high hematocrit leads to a higher viscosity.[161] This elevated viscosity may lead to altered organ perfusion particularly in the brain. It is thus for the reason of these alterations in blood viscosity that hemodilution is tolerated in the cooling phases of CPB. Although advantageous early, this hemodilution combined with the inflammatory response will lead to transudation of fluid into the extravascular space, which in turn leads to the potential for organ dysfunction as eluded to earlier. Prevention of organ dys-

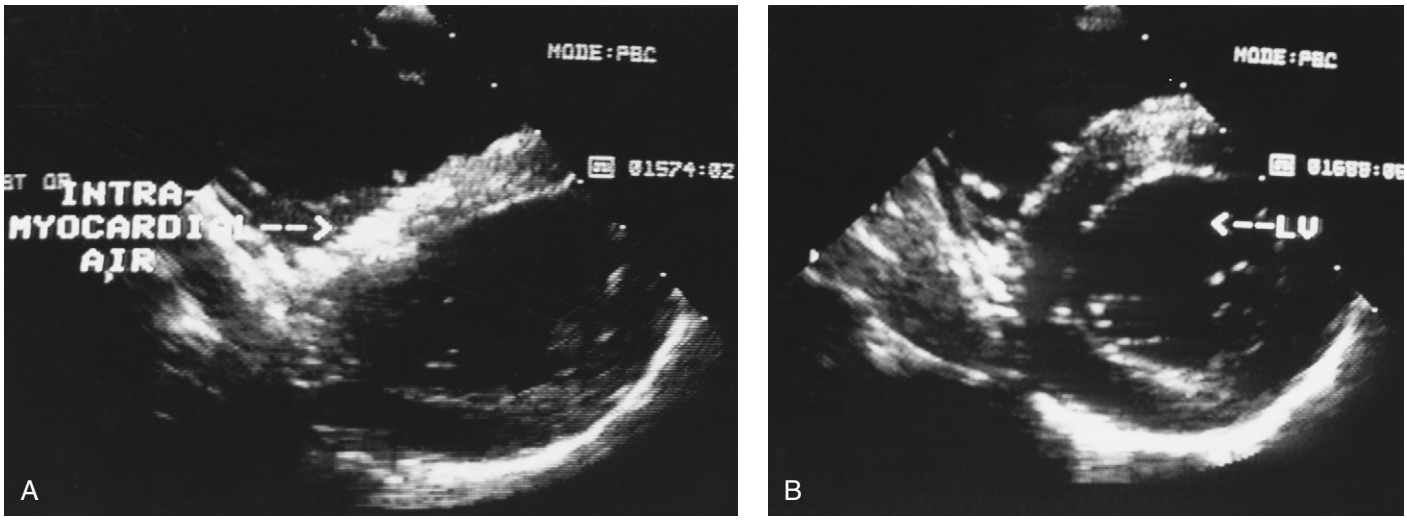

Figure 83-10 A, Two-dimensional echocardiogram in the short-axis view across the ventricles demonstrating the presence of intramyocardial air (*arrow*) in the ventricular septum and right ventricular wall. The intramyocardial air appears as a dense, "snowy" echogenic area. Note the associated wall motion abnormality appearing as flattening of the ventricular septum. **B,** The patient was treated with phenylephrine, increasing systemic and coronary perfusion pressure, resulting in clearance of the air, normalization of the echogenic density, and restoration of normal left ventricular (LV) wall motion and configuration.

function and improved oxygenation by the removal excess fluid and inflammatory mediators are the rationale, therefore, in the use of ultrafiltration. The end result thus is the removal of plasma water and low-molecular-weight solutes across a semipermeable membrane.

Essentially, five forms of ultrafiltration are utilized in modern perfusion practice, three of which are while the patient is on CPB. Prime ultrafiltration (PUF) is utilized when packed red blood cells are added to the prime solution and is performed in the pre-bypass phase. Its aim is to replace crystalloid prime with blood prime, adjust pH, alter electrolyte concentration to safer levels, and remove inflammatory mediators potentially present in the donor blood.[162] Conventional ultrafiltration (CUF) involves the removal of fluid at any time while the patient is being supported by CPB. A common use for this method is the removal of the volume of clear fluid equal to the volume of cardioplegia used. Conventional ultrafiltration can be performed during all phases of CPB. It involves the placement of an ultrafilter within the circuit and connected either to the venous line or to the venous reservoir. The problems associated will be the removal of an excess of ultrafiltrate, resulting in low reservoir volumes. In zero balance ultrafiltration (ZBUF), once fluid has been removed it is replaced with crystalloid to avoid the problems of inadequate reservoir volumes, and thus there is no net removal of volume. The third method of on-bypass ultrafiltration is dilutional ultrafiltration (DUF), which is employed when the concentration of a given electrolyte (e.g., potassium) is deemed elevated. The method thus involves removal of ultrafiltrate with its replacement by one-half normal saline, thus diluting the concentration of the given electrolyte to safer levels. From the description of on-bypass ultrafiltration it can be appreciated that although these methods have different names their end point is similar, that is, attempted removal of excess clear fluid resulting in hemoconcentration, removal of inflammatory mediators, and manipulation of electrolyte concentrations to safe levels.

First described by Nakik and associates[146] in 1991, MUF involves filtration of blood once the patient has been weaned from bypass. This can be achieved either by a venovenous technique in which blood is removed and returned to the atrium once concentrated or by an arteriovenous technique in which blood is removed via the aortic cannula and returned via the venous line.[147,163-165] In more detail, in this technique blood is removed in a retrograde fashion via the aortic cannula and passes through the ultrafilter along with remaining circuit volume from the venous reservoir and oxygenator. Flow through the ultrafilter is maintained by a roller pump at flows of between 10 and 30 mL/kg, with the slower rates resulting in a more gradual change in the intravascular fluid compartment and thus potentially better tolerated. A constant atrial pressure is maintained throughout the procedure by adding crystalloid into the venous reservoir as needed. Suction is applied to the filtrate port to achieve a maximal transmembrane pressure, thus allowing for ultrafiltration rates of between 100 and 150 mL/min.[166] End points for the process of MUF are time (15-20 minutes) and reaching of a target hematocrit (usually 40%) once the circuit volume has been replaced by crystalloid or should the patient's hemodynamics not tolerate the procedure.

Cardiac surgeries in the very young may be complex with potentially protracted CPB and cross-clamp times. It is not surprising, therefore, that myocardial performance is depressed after weaning from CPB. Although ultrafiltration is used during CPB in an attempt to remove excess body water, it appears from studies

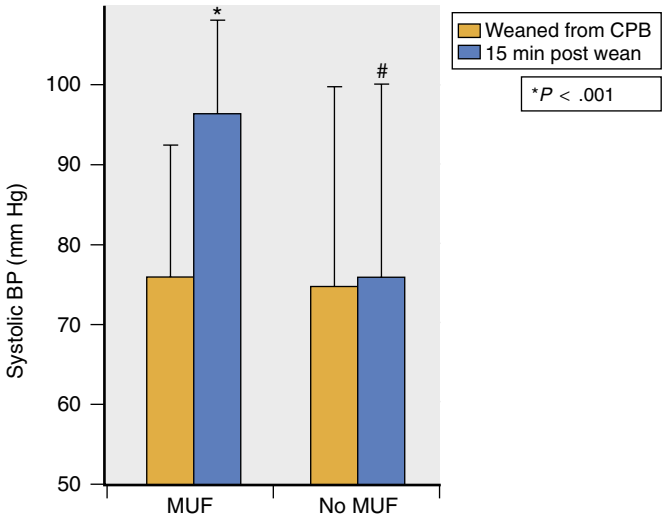

Figure 83-11 Systolic blood pressure (BP) after separating from cardiopulmonary bypass (CPB) and 15 minutes after separating with and without modified ultrafiltration (MUF). Note the significant improvement in systolic BP with the use of MUF. (*From Ungerleider RM: Effects of cardiopulmonary bypass and use of modified ultrafiltration. Ann Thorac Surg 65:S35, 1998; reprinted with permission from the Society of Thoracic Surgeons.*)

that it is the use of MUF that significantly improves myocardial performance (Fig. 83-11).[166-168] Using echocardiographic measurements in a study of infants undergoing corrective surgery under nonhypothermic arrested conditions, Davies and associates found that there were improvements in both systolic and diastolic function in the children studied.[169] They found that the preload recruitable stroke work, which is load independent, improved after MUF and was thus a good indicator of improved systolic function. The same study showed that after MUF there was a decrease in the myocardial wall thickness and cross-sectional area that was not present in the control group of patients who received no ultrafiltration. These reductions result in an increase in end-diastolic length and a fall in end-diastolic pressure, both of which are indicators of improved diastolic function. Although presumably it was the decrease in myocardial edema that was the cause for these improvements, the increased hematocrit also observed could well have also contributed, owing to the associated improvement in oxygen-carrying capacity. Of interest, however, in the Davies study was that these positive effects were not seen past 24 hours, when urine output and inotropic support were the same in both treatment groups. This has led some commentators to question the absolute benefit of MUF.[169]

Pulmonary dysfunction is one of the most common negative effects of CPB.[170] The use, therefore, of ultrafiltration and MUF is to improve oxygenation and decrease the effects of inflammatory mediators on the alveolar capillary membrane and pulmonary vascular reactivity. Studies have demonstrated that in patients in whom ultrafiltration and MUF were used improvements in pulmonary compliance, decreased airway resistance, pulmonary arterial reactivity, and improved oxygenation were demonstrated.[171-175] It is therefore obvious why these methods have thus found such wide acceptance in pediatric cardiac surgery, particularly in those patients in whom normal compliance with low PVR is vital (i.e., those with single-ventricle physiology).

Although these studies commonly find that there is improvement in pulmonary function immediately after weaning from CPB and the completion of MUF, there is disagreement as to whether these effects result in improved function much beyond 6 hours, with some showing little if any benefit at 24 hours. A conclusion, however, from these studies is that combination of on-bypass ultrafiltration coupled with MUF has the best results in the early postbypass period.

Studies into the long-term effects of CPB and indeed DHCA on the brain of children are ongoing. As has been mentioned previously, the initiation of CPB will affect the major organs. In a study performed on a piglet model of DHCA, the use of MUF after CPB improved hematocrit, cerebral oxygen delivery, and cerebral oxygen consumption, thus representing a potential reduction in cerebral injury.[27] Further studies have made similar conclusions. In these studies it was shown that four variables are of importance in improving cerebral oxygenation: P_{CO_2}, mean arterial pressure, hematocrit, and MUF flow rate.[176,177] Increasing all except MUF flow rate improved oxygen delivery. Increasing the flow rate appeared to cause a steal-like phenomenon in which there was an apparent diastolic runoff into the MUF circuit from the aortic cannula. Thus, although the process of MUF is important for recovery of normal cerebral function, care must be used not to negate the benefits by decreasing the time on MUF by increasing the flow rates (Fig. 83-12).

Common to the improvement in cardiac and pulmonary function are the associated decrease in inflammatory mediators seen after ultrafiltration. Studies have shown that the ultrafiltrate contains a wide variety of low-molecular-weight inflammatory mediators, including C3a, C5a, interleukin (IL)-6, IL-8, TNF, myocardial depressant factor, and endothelin.[172,174,178] It is the removal of endothelin-1 after MUF that results in the improvement of pulmonary vascular reactivity, which is of great importance particularly in infants younger than 4 to 6 months of age when pulmonary vascular reactivity is high and in those patients who are having staged cavopulmonary reconstructions. TNF, a potent inflammatory mediator implicated in the development of capillary leak syndrome seen after CPB, has been shown to be removed best by MUF. Despite these positive effects of MUF the literature does not give a clear advantage of one form of ultrafiltration over the other, and it may be the combination of these methods that once again shows the best potential results.

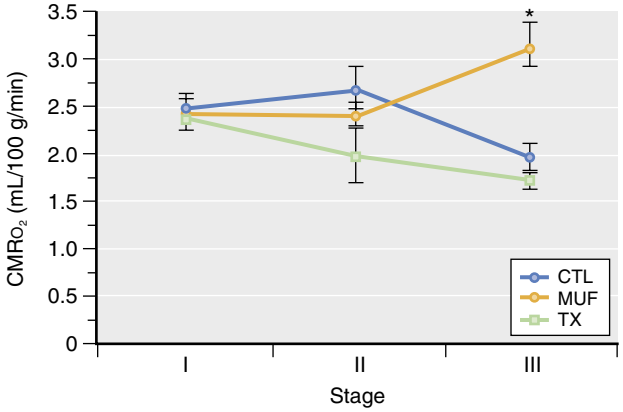

Figure 83-12 Cerebral metabolic rate for oxygen measurements ($CMRO_2$) before and after deep hypothermic circulatory arrest. Note the significant increase in $CMRO_2$ in the MUF animals compared with the control and transfusion groups at stage 3. CTL, control; MUF, modified ultrafiltration; TX, transfusion. (*From Skaryak LA, Kirshbom PM, DiBernardo LR, et al: Modified ultrafiltration improves cerebral metabolic recovery after circulatory arrest. J Thorac Cardiovasc Surg 109:744, 1995.*)

Another important post-CPB issue is ongoing blood loss. There is little doubt that the use of MUF will result in an elevation of the patient's hematocrit secondary to the removal of the excess body water, as already discussed. This further results in decreased blood use and the observation that there is less postoperative bleeding.[179] Indeed, in older children attempts can thus be made to avoid the use of donor blood altogether.

Disadvantages to these techniques are noted. The addition of an ultrafilter to the CPB circuit adds a level of complexity to the circuitry and, thus, another potential area in which circuit-related complications may occur. Antagonists of MUF note also the following potential problems: the potential for air entrainment into the arterial cannula, additional time in which the patient is anticoagulated, potential for hypovolemia as volume is drawn off from the patient, hypothermia as the filtered volume does not pass through the heater/oxygenator, and the potential for the increase in the plasma concentration of drugs (e.g., fentanyl).[180] Another interesting complication potentially associated with ultrafiltration was the reduction in thyroid hormone. This acute hypothyroidism may lead to depressed function, manifesting as decreased contractility, heart rate, cardiac output, and elevated SVR, all of which will clearly effect the immediate post-CPB period.[181] As with other techniques in medicine the benefit versus risk must be seriously considered, but from the presented evidence the use of ultrafiltration both on and off CPB is extremely beneficial and these methods are thus commonly used in modern pediatric cardiac surgery with good result and little complication.[165,168,182,183]

In the preceding paragraphs the discussion has concluded that there is no clear advantage of one method of ultrafiltration over the other. Unfortunately, comparing a wide range of patients having different surgeries under different conditions is difficult, and thus it appears that from the articles referenced the best strategy would include both the use of on-CPB ultrafiltration and the use of MUF once the patient has been separated from bypass to achieve the goals of decreasing total-body water, removal of inflammatory mediators, improved hematocrit, and thus oxygen-carrying capacity, and the preservation of vital organ function.

Specific Problems Encountered in Discontinuing Cardiopulmonary Bypass

Left Ventricular Dysfunction

The contractile state of the LV may be reduced after pediatric cardiac surgery. This is due to surgically induced ischemia during the repair, the preoperative condition of the myocardium, the effects of deep hypothermia and circulatory arrest on myocardial compliance, and new, altered loading conditions on the LV caused by the repair.[184,185] Left ventricular dysfunction can be treated by optimizing preload, increasing heart rate, increasing coronary perfusion pressure, correcting ionized calcium levels, and adding inotropic support. The neonate's heart rate–dependent cardiac output, reduced myocardial compliance, and diminished response to calcium and catecholamines are factors influencing the need for inotropic support. Inotropic support is usually begun with

dopamine (3-10 μg/kg/min). Several studies suggest that the effect of dopamine in children is age dependent. After cardiac surgery in young children, dopamine increases cardiac output, which correlates more with elevations in heart rate than augmentation of stroke volume, whereas, in young adults, dopamine clearly increases stroke volume.[10] Nonetheless, infants and neonates respond favorably to dopamine infusions with increased systemic blood pressure and cardiac output and improved systemic perfusion.

Calcium supplementation is important in augmenting cardiac contractility. Although calcium supplementation has fallen into some disfavor because of concerns over reperfusion injury, it remains an important therapy after pediatric cardiac surgery. Fluctuations in ionized calcium levels occur commonly in the immediate post-CPB period in children. This is most often due to the relatively large transfusions of citrate- and albumin-rich blood products, such as whole blood, fresh frozen plasma, platelets, and cryoprecipitate necessary for hemostasis, all of which bind calcium.[186] Routine calcium supplementation during the early post-CPB period is especially helpful in patients with diminished left ventricular function. In patients with a slow sinus or junctional rate, calcium must be administered cautiously because marked slowing of AV conduction may occur.

Epinephrine (0.02-0.2 μg/kg/min) is useful in patients with significant left ventricular dysfunction who remain hypotensive with high left atrial filling pressures or echo-Doppler imaging evidence of reduced contractility or regional ischemia.[187]

Milrinone, a potent phosphodiesterase-3 inhibitor, is also an effective inotrope-vasodilator in infants and children. Studies in neonates after open-heart surgery reveal significant reductions in SVR and PVR and increases in cardiac index, primarily due to larger stroke volume.[188] Infants and children demonstrate a larger volume of distribution and clearance of milrinone compared with adults; thus, the loading dose necessary to achieve therapeutic levels may be as high as 100 μg/kg.[189] In neonates, the loading dose of milrinone on CPB is 100 μg/kg, followed by a continuous infusion to be started within 90 minutes of the load dose at a rate of 0.2 μg/kg/min to maintain a therapeutic level. In older infants and children, the rate of continuous infusion is higher, usually 0.5 to 1.0 μg/kg/min.

Dobutamine is an effective, albeit weaker, inotropic agent in children. Although it is reported to have fewer chronotropic effects than dopamine in neonates, significant tachyarrhythmias may occur. This may be related to structural similarities between dobutamine and isoproterenol.[187] In children after cardiac surgery, dobutamine increases cardiac output primarily through increased heart rate. The efficacy of dobutamine seems to be reduced in immature animals. This is consistent with reduction in α-receptors and a higher level of circulating catecholamines in newborns.

Right Ventricular Dysfunction

Primary right ventricular dysfunction is a common finding after CPB in neonates, infants, and children. For example, after repair of tetralogy of Fallot, preexisting right ventricular hypertrophy, a right ventriculotomy, and the placement of a transannular patch across the right ventricular outflow tract, resulting in acute pulmonary regurgitation and right ventricular volume overload, are common causes of postoperative right ventricular dysfunction.[23] The treatment of right ventricular dysfunction consists of measures directed at lowering PVR and preserving coronary perfusion without distending the RV. Metabolic acidosis should be addressed and inotropic agents selected for their vasodilating properties (e.g., dopamine, amrinone, or milrinone). In cases of extreme ventricular dysfunction, low-dose epinephrine (0.01 to 0.03 μg/kg/min) may provide inotropy without vasoconstriction.[184,190] Mechanical ventilation should be adjusted to assist right ventricular function and minimize PVR.

In contrast with the LV, the low intracavitary pressure of the normal RV receives two thirds of its coronary filling during ventricular systole.[191] In patients with right ventricular dysfunction, maintaining a normal or slightly elevated systolic arterial pressure maximizes coronary perfusion to the RV and augments contractility. If the need for inotropic support persists after the early post-CPB period, a critical evaluation for other structural and functional abnormalities should be aggressively pursued. Preload should be maintained at a normal to slightly elevated level. Because right ventricular contractility is reduced, it is important to maximize preload to the highest portion of the Starling curve. Overdistention of the RV, however, is not well tolerated, owing to diminished ventricular compliance and diastolic dysfunction. Excessive volume loading may result in significant diastolic dysfunction, tricuspid regurgitation, and worsening forward flow. Generally, CVP much above 12 to 14 mm Hg is poorly tolerated in neonates and infants with right ventricular dysfunction.[192] If right ventricular dysfunction is severe, the sternum should be left open.[193] This eliminates the impedance imposed by the chest wall and mechanical ventilation, allowing the RV to maximize its end-diastolic volume. An additional strategy in neonates, infants, and children with significant post-CPB right ventricular dysfunction is to allow right-to-left shunting at the atrial level. Typical patients who would benefit from this strategy include neonates undergoing repairs for tetralogy of Fallot and truncus arteriosus. Allowing an atrial communication to remain open, with blood shunting in a right-to-left direction, preserves cardiac output and oxygen delivery to the systemic circulation. Although these patients have somewhat diminished systemic oxygen saturation, as their effective cardiac output and tissue oxygen delivery are enhanced, systemic perfusion pressure improves and coronary perfusion of the RV is maintained. As right ventricular function improves, right atrial pressure falls, right-to-left shunting decreases, and systemic arterial saturation rises.

If right ventricular dysfunction persists to the extent that systemic cardiac output is compromised, consideration should be given to extracorporeal life support (extracorporeal membrane oxygenation [ECMO]). When ECMO is used for circulatory support, venoarterial cannulation is preferred. Venous and arterial access may be achieved through a large central artery and vein, usually the carotid artery and internal jugular vein, or by direct chest cannulation. Recovery from severe ventricular dysfunction is predicated on the concept that the myocardium has sustained a transient injury (i.e., "stunned myocardium") and is capable of recovery with time.[194,195] ECMO is used to decrease ventricular wall tension, increase coronary perfusion pressure, and maintain systemic perfusion with oxygenated blood. ECMO may also be used for left ventricular failure, although success with this condition is less common than that seen with right ventricular dysfunction or pulmonary artery hypertension. Patients placed on ECMO because they fail to separate from CPB demonstrate significantly greater mortality than do those for whom ECMO was instituted later in the postoperative course.[196] The children

who consistently have the lowest survival rate are those who require ECMO after a Fontan operation.[197] The role of ECMO in patients with myocardial injury or pulmonary hypertension is to provide adequate systemic oxygen transport and systemic perfusion while allowing the ventricles to rest and recover. ECMO may even provide an effective means of resuscitation for postoperative cardiac patients, particularly if instituted promptly.[198] In larger infants and children with predominantly right ventricular dysfunction and satisfactory pulmonary function, a selective right ventricular assist device may be preferable to ECMO.[199]

Pulmonary Artery Hypertension

Primary pulmonary hypertension is a devastating disease. The progressive and sustained elevation in PVR eventually leads to right-sided heart failure and death.[200,201] Pulmonary arterial hypertension (PAH) is defined by the presence of mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg during exercise.[202] In two recent studies, presence of PAH was shown to be a significant predictor of major perioperative cardiovascular complications including pulmonary hypertensive crises, cardiac arrest, and death in patients undergoing cardiac catheterization or noncardiac surgery under anesthesia.[203,204] Suprasystemic pulmonary artery pressure was predictive of major complications. Complications, however, were not associated with age, etiology, type of anesthetic, or airway management. Preanesthesia evaluation should evaluate disease severity. A history significant for chest pain, syncope, and dizziness, with signs of dyspnea at rest, low cardiac output state, metabolic acidosis, hypoxemia, and signs of right-sided heart failure warrants caution. Acute increases in PVR resulting in pulmonary hypertensive crises cause an increase in right ventricular afterload, right ventricular dysfunction, and hemodynamic decompensation. Suprasystemic pulmonary artery pressure results in inadequate PBF, inadequate left ventricular preload, low cardiac output, and biventricular failure. The associated hypotension results in coronary ischemia, which worsens this cycle. Perioperative factors thought to precipitate a pulmonary hypertensive crisis include hypoxia, hypercarbia, acidosis, hypothermia, pain, and airway manipulations in patients with pulmonary hypertension. Such patients present for hemodynamic catheterization, drug study, and noncardiac and cardiac surgical procedures. Although each anesthetic has to be tailored to the patient's pathophysiology and surgical procedure, certain common principles remain. Pulmonary vasodilator therapy and inotropes must be continued in the perioperative period. Investigations include a comprehensive echocardiogram with occasional chest CT angiography to exclude pulmonary thromboembolic disease. In our center, premedication is avoided and intravenous induction is performed with carefully titrated doses of ketamine. Procedures with potential for blood loss, hemodynamic instability, and changes in ventilatory status mandate invasive arterial monitoring. Care should be taken to avoid systemic hypotension while achieving general anesthesia. Ventilation and oxygenation are controlled, and acidosis is treated aggressively. Hypotension in the presence of euvolemia may need to be treated with inotropes and, if necessary, with α_1-agonists.[205,206]

Therapy for elevated pulmonary artery pressures is directed at lowering PVR and unloading the RV. Reduction of PVR is accomplished by altering ventilation pattern, inspired oxygen concentration, and blood pH. Specifically, manipulating the pulmonary vascular bed in newborns and infants is a matter of regulating $Paco_2$, pH, Pao_2, PAo_2, and ventilatory mechanics.[207,208] $Paco_2$ is a potent mediator of PVR, especially in the newborn and young infant. Reducing $Paco_2$ to 20 mm Hg and increasing pH to 7.6 produces a consistent and reproducible reduction in PVR in infants with pulmonary artery hypertension. Manipulating serum bicarbonate levels to achieve a pH of 7.5 to 7.6 while maintaining a $Paco_2$ of 40 mm Hg has equal salutary effects on PVR.[209] Both the Pao_2 and the PAo_2 decrease PVR as well. In the circumstance of intracardiac shunts, changes in Fio_2 have little effect on Pao_2. Thus, by inference, a reduction in PVR induced by increasing the inspired oxygen concentration is probably a direct pulmonary vasodilatory effect of PAo_2 rather than Pao_2.

Ventilatory mechanics also play a major role in reducing PVR. Neonates and infants have a closing volume above functional residual capacity. Thus, at the end of a normal breath, some airway closure occurs. This process results in areas of lung that are perfused and yet underventilated. As these lung segments become increasingly hypoxemic, secondary hypoxic vasoconstriction occurs. The net effect is an increase in PVR. Therefore, careful inflation of the lungs to maintain functional residual capacity will selectively reduce PVR. In practice, this is accomplished with relatively large tidal volumes and low respiratory rates, which produce an exaggerated chest excursion. Generally, tidal volumes of 15 to 25 mL/kg are required. Respiratory rates of 15 to 25 breaths/min are used for neonates and infants. A reduced ventilatory rate with large tidal volumes reduces mean airway pressure and provides a longer expiratory phase of ventilation.

Because PBF occurs predominantly during the expiratory phase of the respiratory cycle, the ventilatory pattern should be adjusted to allow an adequate distribution of gas throughout the lung during inspiration and a more prolonged expiratory phase to promote blood flow through the lungs. End-expiratory pressure must be applied cautiously during the post-CPB period. Low positive end-expiratory pressure (3 to 5 mm Hg) prevents narrowing of the capillary and precapillary blood vessels, thereby reducing PVR. Higher positive end-expiratory pressure or excessive mean airway pressure results in alveolar overdistention and compression of the capillary network in the alveolar wall and interstitium. This condition elevates PVR and reduces PBF.[148]

The final and perhaps the least well-recognized use of the mechanical ventilator is to assist in unloading the RV. During inspiration, intrathoracic pressure increases and creates an increased pressure gradient from the lung to the left atrium, promoting cardiac output. This ventilatory assist is commonly seen in patients with PAH or right ventricular dysfunction. An augmentation of the arterial pressure trace during inspiration is seen. The use of the ventilator to augment systemic blood flow is very similar to the thoracic pump concept used to explain blood flow during CPR.[210] The inspiratory assist must be balanced by the potential negative effects of increased mean airway pressure on PVR and right ventricular afterload. To maximize these cardiopulmonary interactions, high tidal volume with low respiratory rates should be employed.

Attempts to manipulate PVR through pharmacologic interventions have been generally unsatisfactory. Drugs that have shown the greatest promise in decreasing PVR both clinically and experimentally have been the phosphodiesterase inhibitors. Amrinone and milrinone are the only drugs of this class currently available in the United States. Both reduce PVR and SVR and increase RV contractility.[211,212] Isoproterenol has mild pulmonary

artery–vasodilating properties in the normal pulmonary circulation.[213] It reduces PVR in adults after cardiac transplantation, but there are very few data to support PVR reduction in infants and young children after cardiac surgery. In immature animals, the myocardium is less responsive to isoproterenol and causes tachycardia and increased myocardial oxygen consumption. These latter effects may reduce coronary perfusion and result in relative myocardial ischemia. Both prostaglandin E_1 and prostacyclin have a pulmonary vasodilating effect[214,215]; however, both drugs produce systemic hypotension, which severely limits their use.

Because of the lack of specificity of vasodilator drugs on the pulmonary bed, newer pharmacologic methods of controlling pulmonary artery hypertension and elevated PVR are being sought. Two new concepts include ultrashort-acting intravenous vasodilators and inhaled vasodilating agents such as nitric oxide. Ultrashort-acting intravenous vasodilators are nonspecific potent vasodilators, with a half-life measured in seconds. Infusion of these drugs into the right side of the circulation produces a potent short-lived relaxation of the pulmonary artery smooth muscle.[216] Once the drug reaches the systemic circulation it is no longer functional. Adenosine and ATP-like compounds have these properties and may have clinical applicability in pulmonary artery hypertension in the future.[217]

Beginning in the past decade, several potent therapies for pulmonary hypertension have evolved.[207,208] A continuous intravenous infusion of prostacyclin improves pulmonary vascular hemodynamics, exercise tolerance, and survival in pulmonary hypertension.[218] Sildenafil is a selective phosphodiesterase type 5 inhibitor. Phosphodiesterase type 5 breaks down cyclic guanosine monophosphate. Sildenafil produces acute and relatively selective pulmonary vasodilatation and acts synergistically with nitric oxide.[219-221] Bosentan is a dual endothelin receptor blocker. Preliminary reports indicate that bosentan improves symptoms, exercise tolerance, and hemodynamics in patients with pulmonary hypertension. The drug is well tolerated and free of side effects apart from a dose-dependent increase in liver enzymes.[222] Lung transplantation is the only available surgical therapy for primary pulmonary hypertension; however, the 5-year survival remains less than 50%, and bronchiolitis obliterans remains the single most common cause of death.[223,224] Prior to listing for transplantation all patients undergo a hemodynamic cardiac catheterization and drug study in which reversibility of pulmonary hypertension with increased inspired oxygen concentrations and nitric oxide is determined.[225] Inhaled iloprost, although used in adult centers, has not become routine in pediatric practice.

CPB with associated endothelial injury predisposes to the development of postoperative pulmonary hypertension in patients with congenital heart disease. Anatomic factors that impose either obstruction to PBF or residual left-to-right shunting need to be surgically addressed. Elevated LAP resulting from mitral valve disease or left ventricular dysfunction, pulmonary venous obstruction, branch pulmonary artery stenosis, or surgically induced loss of the pulmonary vascular cross-sectional area all raise right ventricular pressure and impose a burden on the right side of the heart.

Nitric oxide, an endothelium-derived vasodilator that is administered as an inhaled gas, represents the most promising development in the therapy for elevated PVR in patients with congenital heart disease (see Chapter 31). Although nonselective, it is rapidly inactivated by hemoglobin and, when inhaled, produces no systemic vasodilation.[226] Nitric oxide reduces pulmonary artery pressure in adult patients with mitral valve stenosis and in selected pediatric cardiac patients with PAH.[227-229] The congenital cardiac patient population in whom nitric oxide appears to be effective is those patients with acute PVR elevation after open-heart surgery, as well as preoperative pulmonary hypertension accompanying specific anatomic conditions (e.g., total anomalous pulmonary venous return, congenital mitral stenosis).[228,229] Because it acts directly on vascular smooth muscle, nitric oxide remains effective despite the post-CPB endothelial injury frequently encountered in children.[230] Some centers routinely employ nitric oxide in low dose (1 to 5 ppm) after a Fontan operation when the CVP-LAP gradient exceeds 10 mm Hg.[231] Finally, nitric oxide can provide diagnostic information that helps distinguish reactive pulmonary vasoconstriction from fixed anatomic obstructive disease either in the postoperative surgical patient or in the patient undergoing pretransplant evaluation.[232,233] In the latter, the distinction between pulmonary vasoconstriction and advanced pulmonary vascular occlusive disease will influence the prediction as to whether a child with pulmonary hypertension in association with either congenital heart disease or cardiomyopathy will survive a heart transplant or requires replacement of both heart and lungs.

Management strategies for postoperative pulmonary hypertension and treatment of pulmonary hypertensive crises include sedation, moderate hyperventilation (maintaining P_{CO_2} between 30 and 35 mm Hg), moderate alkalosis (pH > 7.5), increased inspired oxygen, optimization of positive end-expiratory pressure (to maximize functional residual capacity), pulmonary vasodilators (e.g., nitric oxide), and the creation or maintenance of an intracardiac right-to-left shunt in an attempt to maintain cardiac output.[234-236] Nitric oxide is also useful in the manipulation of PVR after Fontan-type procedures.[237] Care should be exercised in weaning nitric oxide in patients, because abrupt withdrawal can precipitate rebound pulmonary hypertension and pulmonary hypertensive crises.[237,238]

Anticoagulation, Hemostasis, and Blood Conservation

Modern pediatric cardiac anesthesia must include the principles and practice of effective anticoagulation, hemostasis, and blood conservation. Bleeding after CPB remains a significant problem in pediatric cardiac surgery.[239] Continuing blood loss after CPB requiring blood component replacement is associated with hemodynamic compromise as well as morbidity from multiple donor exposures. In pediatric patients, restoration of hemostasis has proved difficult; diagnosis of the problem and treatment are marginally effective.

Neonates, infants, and children undergoing cardiac surgery with CPB have a higher rate of postoperative bleeding than that seen in older patients.[239] This is due to several factors. First, there is disproportionate exposure to the nonendothelialized extracorporeal circuit, which produces an inflammatory-type response. This inflammatory response to CPB is inversely related to patient age; the younger the patient, the more pronounced the response.[13] Because complement and platelet activation are linked to the activation of other protein systems in the blood (i.e., fibrinolytic), it is probable that this hemostatic activation, which results in

impaired hemostasis and increased bleeding tendency, plays a major role during pediatric cardiac surgery. Second, the type of operation performed in neonates and infants usually involves more extensive reconstruction and suture lines, creating more opportunities for surgical bleeding than in adult cardiac patients. Operations are also frequently performed using deep hypothermia or circulatory arrest, which may further impair hemostasis.[240] Third, the immature coagulation system in neonates may also contribute to impaired hemostasis.[241] Although procoagulant and factor levels may be reduced in young patients with congenital heart disease due to immature or impaired hepatosynthesis,[242] functional bleeding tendencies are usually not present before surgery. Finally, patients with cyanotic heart disease demonstrate an increased bleeding tendency before and after CPB.

CPB is a significant thrombogenic stimulus requiring anticoagulation with heparin before its initiation. Heparin is usually administered empirically based on patient weight, and its effect is followed by activated clotting time monitoring. Because the heparin effect is primarily due to coupling with antithrombin III and because there are age-related differences and quantitative differences in procoagulants and inhibitors, variability of heparin dosing and its effect has been a concern. High heparin sensitivity is observed in the first week of life and then decreases progressively until about 3 years of age, when values approach those observed in adults.[243] These findings are consistent with evidence in infants of variable quantities of both procoagulants and inhibitors, especially prothrombin and antithrombin III.[244] Heparin administration must also include a consideration of the quantity and composition of the priming volume for CPB, especially if fresh frozen plasma is added. The authors recommend a heparin dose of 200 U/kg plus an additional dose of 1 to 3 U/mL of priming solution and maintaining the activated clotting time above 480 seconds.

Heparin is neutralized with protamine dosed according to the quantity of heparin administered or based on body weight. Protamine excess may actually contribute to postoperative bleeding.[245] It appears that the protamine dose requirement is high for neonates and decreases with increasing age of the patient. The relatively increased protamine requirement for young as compared with older children and adults is indicative of higher circulating heparin levels after CPB.[246] Delayed hepatic clearance of heparin due to organ immaturity and the predominant use of hypothermic circulatory arrest in the young will decrease metabolism and excretion of heparin. We typically administer 4 mg/kg protamine in neonates, whereas 2 mg/kg usually restores the activated clotting time to baseline values in adolescents and adults. Interpatient variability mandates some form of individual assessment to guide drug dose, in order to prevent excess protamine.[245]

Neonates and young infants with congenital heart disease will have low circulating levels of procoagulants and inhibitors. The thrombogenic and dilutional effects of CPB further contribute to hemostatic abnormalities after CPB. Formed blood elements such as leukocytes and platelets may be activated, and procoagulants may be diluted by CPB. Furthermore, deep hypothermic circulatory arrest causes increased clotting and fibrinolytic activity. The lower the temperature, the higher the degree of hemostatic activation. Therefore, the causes of bleeding after CPB are many. Injudicious use of blood products to correct individual coagulation abnormalities separately can further exacerbate dilution of existing procoagulants, as well as carrying the risks of multiple donor exposure. Because the transfusion of blood products is associated with numerous complications, transfusion is to be assiduously avoided, unless specifically indicated by an impairment in tissue oxygenation or documented coagulopathies with clinically significant bleeding. All efforts at blood conservation during cardiac surgery should be routinely employed by all members of the operative team, intraoperatively as well as postoperatively.

Bleeding after CPB is not an unusual occurrence. The surgeon should first attempt to identify any obvious source of surgical bleeding at the sites of repair. Next, adequate protamine reversal of heparin is assessed by measuring an activated clotting time. In general, standard coagulation tests show a prolongation of the partial thromboplastin time, prothrombin time, hypofibrinogenemia, and dilution of other procoagulants as well as a prolonged bleeding time in many pediatric patients, with and without bleeding (Fig. 83-13). The most common reason for persistent bleeding is platelet dysfunction.[247,248] Under such circumstances, administration of platelets is warranted in the presence of bleeding. Routine administration of blood products to correct laboratory coagulation abnormalities in the absence of bleeding is never clinically indicated. After platelets have been given and if bleeding is still present, reassessment and repeat platelet infusion or the administration of cryoprecipitate or fresh frozen plasma may be beneficial. Under most circumstances, meticulous surgical technique, appropriate administration of protamine, adequate patient temperature, and platelet infusion will correct excessive bleeding. In neonates, excessive bleeding, as well as the escalating dilutional effects of selective component therapy on the remaining procoagulants, makes the treatment of bleeding difficult. The use of fresh whole blood may be warranted under these

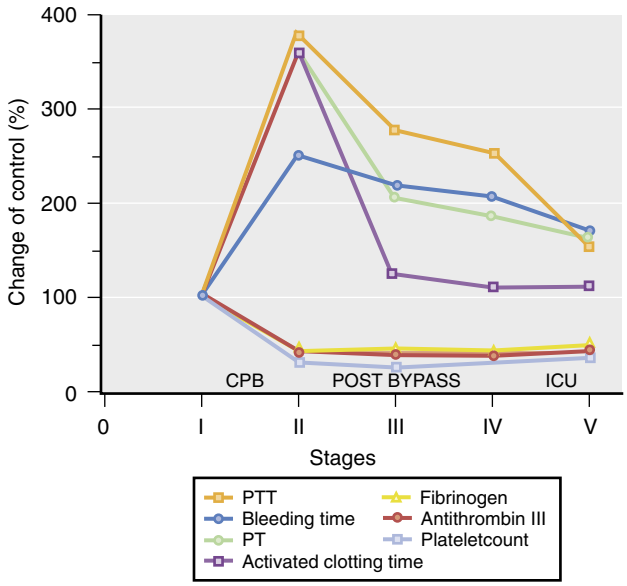

Figure 83-13 Plot of blood coagulation profile changes before, during, and after cardiopulmonary bypass (CPB) in 25 children. Clotting times and coagulant factors are shown as percent change from control. Stage I, baseline, before CPB; stage II, post-CPB, before protamine reversal of heparin; stage III, after protamine; stage IV, just before leaving the operating room; stage V, after 3 hours in the intensive care unit (ICU). PTT, partial thromboplastin time; PT, prothrombin time.

circumstances. The administration of fresh whole blood (<48 hours old) after CPB can meet all the hematologic requirements with minimum donor exposure. The efficacy of whole blood in restoring hemostasis and reducing blood loss after CPB has been demonstrated in patients younger than 2 years of age undergoing complex surgical repairs.[239]

Many attempts have been made to reduce bleeding after CPB by pharmacologic interventions. Desmopressin acetate[249,250] and the antifibrinolytics aminocaproic acid and tranexamic acid[251] have been tried with variable success in significantly reducing postoperative blood loss after cardiac surgery. Royston and associates have demonstrated this with the use of aprotinin.[252] A proteinase inhibitor, aprotinin has antifibrinolytic properties in low concentrations and acts as a kallikrein inhibitor at higher levels. CPB causes increased kallikrein by contact activation, promoting thrombus and fibrin generation, which promotes fibrinolysis. The inhibition of kallikrein results in inhibition of the contact phase of coagulation, and the inhibition of fibrinolysis reduces bleeding. Reduced thrombin generation leads to a diminished platelet stimulation. Better-preserved platelet function has been described in patients receiving aprotinin.[252] Aprotinin has been demonstrated to reduce the intraoperative and postoperative blood loss in cardiac surgery.[253-256] Aprotinin use during pediatric cardiac surgery attenuates fibrinolytic activation in a dose-dependent fashion, reducing the formation of fibrin-split products.[240,257] Higher doses of aprotinin reduce thrombin/antithrombin III complex and F1/F2 fibrin fragments, supporting the hypothesis of suppression of clotting activation with higher aprotinin doses and plasma concentrations. To date, the use of aprotinin for congenital heart surgery has been generally confined to certain patients requiring reoperation, patients undergoing a Ross procedure, and patients undergoing cardiac/lung transplantation procedures. Of note, because of current concerns about aprotinin being associated with increased thrombosis and morbidity, we no longer use this drug in our practice.

The techniques of blood conservation must be continued during the postoperative period. Isolated coagulation abnormalities are often present in the uncomplicated postoperative cardiac patient (see Fig. 83-13). Usually, these coagulation abnormalities self-correct during the first postoperative day and are not associated with excessive bleeding. Therefore, routine correction of these abnormalities with infusion of blood products is not warranted. Administration of blood products should not occur in the absence of clinical evidence of bleeding and the identification of a specific defect requiring targeted component therapy. Routine use of blood products for volume replacement is also to be avoided; lactated Ringer's or saline solution can be satisfactorily administered at a reduced cost without the hazards associated with transfusion.

Postoperative Management

Immediate postoperative care of the pediatric patient who has undergone cardiothoracic surgery is an important period in the overall sequence of anesthetic and surgical management. Although the primary influence on outcome is determined by the conduct of the operation, postoperative care is an important factor. As a member of the operative team, it is necessary that the anesthesiologist understand and become involved during the immediate postoperative period. Detailed principles of postoperative management of the pediatric cardiac surgical patients are beyond the scope of this chapter. However, a few general guiding principles and approaches are given to provide fundamental knowledge for the anesthesiologist.

The postoperative period can be characterized by a series of physiologic and pharmacologic changes as the body convalesces from the abnormal biologic conditions of CPB and cardiac surgery. During this period, the effects of the cardiac operation, any underlying disorders, the effects of hypothermic CPB, and special techniques such as DHCA may create special problems. In the immediate postoperative setting, abnormal convalescence and specialized problems must be recognized and managed appropriately. Fortunately, most patients are able to balance the cost imposed by the physiologic trespass created by the surgical repair and the effects of CPB against the benefit of reduced pathophysiologic loading conditions, resulting in low morbidity and mortality.

Therefore, the guiding principle in the management of the postoperative patient is an understanding of both normal and abnormal convalescence after anesthesia and cardiac surgery. The immediate postoperative period, even that of normal convalescence, is one of continuous physiologic change because of the pharmacologic effects of residual anesthetic agents and the ongoing physiologic changes secondary to abrupt alteration in hemodynamic loading conditions, surgical trauma, and extracorporeal circulation. Anesthesia and surgery affect not only the patient's conscious state but also cardiovascular, respiratory, renal, and hepatic function; fluid and electrolyte balance; and immunologic defense mechanisms. Despite all these changes, postoperative care should be predictable and standardized for most patients undergoing cardiac procedures.

In general, there are four temporal phases of postoperative management in the cardiac patient: (1) transport to the intensive care unit (ICU), (2) stabilization in the ICU, (3) weaning from inotropic and ventilatory support, and (4) mobilization of fluids. Patients proceed through these phases at variable rates based on such factors as the underlying disease process, preoperative medical condition, sequelae of the surgical procedure, duration of CPB, and presence or absence of intraoperative complications. One of the most important functions of the ICU team is to identify postoperative complications in the patient who convalesces abnormally and to provide interventional therapy. Because physiologic change after cardiac surgery is dramatic but self-limiting during normal convalescence, recognition of abnormal processes can be difficult. Under such circumstances a uniform, multidisciplinary approach with experienced clinicians and nurses facilitates the identification of any abnormalities in convalescence. These abnormalities often are indications for closer observation, more invasive monitoring, pharmacologic intervention, and increased cardiopulmonary technical support. Complications include hypovolemia, residual structural heart defect, right and left ventricular failure, hyperdynamic circulation, pulmonary artery hypertension, cardiac tamponade, arrhythmias, cardiac arrest, pulmonary insufficiency, oliguria, seizures, and brain dysfunction. It is critical to detect these departures from the normal convalescent course and to treat them aggressively.

One important area in which the anesthesiologist can aid the recovery of the cardiac patient is pain control. Pain and sedation are among the most common problems requiring ICU intervention. Many factors influence the onset, incidence, and severity

of postoperative pain. The attenuation of the stress response in the immediate postoperative period using infusions of potent opioids in the critically ill infant reduces morbidity.[103] Attenuation of postoperative pain can be attempted with a preoperative medication and an intraoperative anesthetic management technique that includes the use of potent opioids. Patients who receive no opioids preoperatively or during the operative procedure will require analgesics in the immediate postoperative period once the inhalation anesthetic is eliminated. Most cases of postoperative pain can be managed by the administration of small intravenous doses of opioids, usually morphine. This is important in a patient being weaned from the ventilator during the early postoperative period. Patients who are intubated and ventilated overnight should receive adequate sedation and pain control until ventilatory weaning is begun. This is usually accomplished by a continuous infusion of a benzodiazepine and an opioid. Continuous infusion of sedatives and analgesics results in a more consistent and reliable control of postoperative pain. When separated from mechanical ventilation, the patient is concurrently weaned from the sedatives and analgesics. Under these circumstances, careful titration of opioids often results in prompt pain relief. In patients with reactive pulmonary artery hypertension, opioids have been shown to prevent hypertensive crisis.[100]

Regional anesthesia may be used for postoperative pain control in infants and children after thoracotomy (see Chapter 81). This method avoids opioid-induced respiratory depression from intravenous doses of these drugs. The administration of opioids in the epidural space is a very effective approach to pain management. This technique is used in children for postoperative pain control when given in the epidural space via the caudal route as a "single shot" or via a small caudal catheter. Morphine or hydromorphone provides effective analgesia with a duration of 6 to 12 hours, with no significant respiratory depression. Caudal morphine diluted in 0.05 to 0.075 mg/kg delivered in a total volume of 1.25 mL/kg of sterile saline has been used with good success in our practice. The use of regional anesthesia for postoperative pain appears to be best suited for the child extubated in the early postoperative period. Relative contraindications of this technique include hemodynamic instability and patients with abnormal clotting profiles with continued active bleeding. Using this regional technique, better arterial oxygenation, a more rapid ventilator weaning, and decreased postoperative respiratory complications may be expected. However, urinary retention occurs frequently in patients without a bladder catheter. Generally, no treatment is required.

Children requiring large thoracotomies or a bilateral thoracosternotomy (i.e., "clamshell") incision merit consideration for thoracic epidural analgesia. This technique significantly reduces the respiratory depression and pulmonary mechanics abnormalities that accompany the quantity of systemic opioids that would be necessary to provide adequate analgesia for these excruciatingly painful incisions. If the procedure requires systemic heparinization, we will typically defer placement of these catheters until the heparin effect is neutralized. For the patient undergoing coarctation repair via a left thoracotomy, we place the caudal or epidural catheter after demonstration of motor function in the lower extremities. For patients undergoing heart/lung transplantation, a thoracic epidural catheter is placed at a time in the postoperative period when the patient can be weaned from intravenous medications that will adversely impact on the patient's ability to breathe in close proximity to the planned extubation. It is common for these patients to need a functioning thoracic epidural catheter for several days.

Postoperative Neuropsychologic Morbidity

Neurologic morbidity has been identified to be increasingly problematic in neonates and infants with congenital heart disease as surgical mortality rates have improved. Although early postoperative CNS sequelae such as stroke and seizures occur in a small percentage of neonates with congenital heart disease, the importance of more subtle neurologic abnormalities at long-term follow-up is being increasingly recognized.[223,258-266]

These findings may include fine and gross motor impairments, speech and language delays, disturbances in visual-motor and visual spatial abilities, attention-deficit disorders, learning disorders, and impaired executive functioning. The presence of "congenital brain disease" in patients with congenital heart disease represents a challenge in improving long-term neurologic outcomes. Many neonates with CHD have congenital structural brain abnormalities or chromosomal abnormalities or both, as well as physiologic abnormalities that may impair brain development. Brain abnormalities on head ultrasonography have been noted in one fifth of full-term infants undergoing heart surgery, with half of the abnormalities being present preoperatively.[266]

Postoperatively, secondary neurologic injury may be related to post-CPB alterations in cerebral autoregulation and additional hypoxic-ischemic insult, seizures, or other issues associated with prolonged ICU stay. In addition to prenatal and modifiable perioperative factors, genetic and environmental factors are known to be important. Unfortunately, modifiable perioperative factors may explain less of the variability in long-term outcomes than do patient-specific factors.

New, postoperative neurologic injury may be detected clinically in over 10% of infants,[7] and in over 50% using more sensitive brain imaging techniques such as MRI.[267,268] Given that new neurologic injury can occur at various time points during the neonate's hospitalization, perioperative attention to reducing known risk factors is critical. Mechanisms of CNS injury in infants undergoing cardiac surgery include hypoxia-ischemia, emboli, reactive oxygen species, and inflammatory microvasculopathy. Preoperatively, the primary focus is on preventing hypoxic-ischemic injury and thromboembolic insults. Modifiable intraoperative factors associated with CNS injury include, but are not limited to, pH management, hematocrit during CPB, regional cerebral perfusion, and the use of DHCA. The adverse effects of CPB may be greater in infants compared with larger children or adults given their immaturity in organ function and tissues as well as the size of the CPB circuit relative to their body size.[269] However, a significant amount of research has been conducted in the area of intraoperative prevention of neurologic injury. With ongoing changes in technology and new therapies, the conduct of CPB and other support techniques have been actively under investigation

Mechanical Assist Devices

Survival in children with congenital cardiac as well as pulmonary defects has improved over recent decades due to improved preoperative management, surgical techniques, anesthesia

management, drug therapies, and postoperative management. Despite these advances patients may still require therapies for both acute and chronic heart failure that are refractory to medical therapy. Mechanical support in the form of ECMO or ventricular assist devices (VADs) may then need to be instituted. Examples of conditions that may require support include failure to wean from CPB, acute cardiac arrest, malignant arrhythmia, and worsening myocardial function secondary to the underlying congenital defect or related to acquired cardiomyopathy. Fortunately, however, the numbers are small, with less than 2% of post-CPB patients requiring this intervention.[270] Mechanical support can thus be used as a treatment option to allow for recovery of ventricular function, as a bridge to transplant, or to support the heart in those with marginal functional reserve requiring invasive diagnostics or treatments (e.g., Williams' syndrome with severe supravalvar pulmonary or aortic stenosis). As with any therapy, contraindications must be excluded before embarking on the use of a mechanical assist device. These contraindications may include extreme prematurity, severe and irreversible multiorgan failure, incurable malignancy, and preexisting neurologic devastation.[270] Anesthetic management in the use of ECMO is supportive with management limited to assistance in the resuscitative efforts and hemorrhage associated with the cardiac surgery that was ongoing at the time of conversion to ECMO. Once the patient is on full ECMO support, ventilation is continued but at a slower rate of ventilation in the order of 10 breaths/min with peak pressure of 20 cm H_2O with PEEP set at 5 to 10 cm H_2O and F_{IO_2} also decreased to about 40%. These settings will aid in the prevention of atelectasis with management of CO_2 and O_2 related to flow across the circuit membrane. This is very different from the patient into whom a VAD is placed. Here the anesthesiologist continues to manage the patient as for routine CPB weaning. Obviously differences exist in this scenario. If a systemic VAD is placed, careful attention must be given to the ventricle pumping blood into the pulmonary bed because failure of this ventricle will have disastrous consequences. Thus, management tailored to unload this pulmonary ventricle is vitally important and will include inodilators in the form of phosphodiesterase inhibitors, inotropic support, and possibly even inhaled nitric oxide to decrease PVR and promote forward flow. In association with the perfusionist, intravascular volume loading is assessed and maintained for effective functioning of the VAD and thus adequate offloading of the assisted ventricle. Careful attention to pulmonary function is also vital. Adequate pulmonary toilet, recruitment maneuvers, and appropriate ventilatory parameters must be utilized. As will be alluded to later, bleeding is a potential in the implantation of the VAD and thus a clear strategy must be planned for in the form of antifibrinolytics, adequate volumes of blood and blood products, and even possibly the use of activated clotting factors (e.g., factor VII).[271]

As can be seen from Table 83-13 there are a number of differences that can be appreciated between the just-mentioned assist devices. The potential for bleeding exists at the time of insertion of both of these modalities; however, it would seem from clinical experience that due to the extensive dissection and need for sizeable ventriculotomy that implantation of a VAD (and especially Bi-VAD) is more problematic. That being said, however, the requirements of anticoagulation to keep the activated clotting time in the range of 180 to 200 for ECMO may also lead to ongoing and significant bleeding, especially if placed into a patient who requires support in the immediate perioperative phase. The use of an ECMO circuit with a membrane oxygenator requires ongoing intravenous anticoagulation with maintenance of the ACT in the aforementioned range. Apart from the immediate postoperative phase, patients with VAD systems can be transitioned to oral agents. A two-part therapy is recommended. Antiplatelet therapy includes aspirin or clopidrogel. The second part of the therapy will entail the use of anticoagulation with either warfarin (Coumadin) or subcutaneous low-molecular-weight heparin.[270]

Table 83-13 Comparison of ECMO versus VAD

	ECMO	VAD
Bleeding at insertion	++	++
Sternotomy	Not required	Required
Left atrial venting	±	–
Blood product use	+++	+
Number of cannulae for biventricular support	2	4
Pulmonary support	+	–
Intravenous anticoagulation	+	±
Duration of support	Weeks	Months
Emergent support	Yes	No
Patient mobility	–	+

ECMO, extracorporeal membrane oxygenation; VAD, ventricular assist device.

As previously mentioned these modalities are used as a potential bridge to transplant and, as such, exposure to donor antigens is of great importance. In a study by Stiller and associates comparing the volume of blood products used, it was shown that the volume was less in those treated with a VAD in a period up to 8 days after insertion. Importantly, the authors pointed out that this difference remained even when support was started at a time remote from surgery.[272]

Three potential disadvantages exist in the use of the VAD system. There is no pulmonary support when using the VAD, and this limits its use to patients whose lung function is adequate. From Table 83-13, when biventricular support is needed the patient will require two separate VAD devices necessitating the placement of four cannulae that may be technically difficult in a very young child. The third disadvantage is that VAD placement cannot be performed in a code situation or at the bedside as with ECMO.

Important advantages of the VAD system are the ability of patients to ambulate while on support and that VAD support can be maintained for months in comparison to the weeks only of ECMO support. Another important advantage over ECMO is that these patients will not require further venting of the left atrium. In ECMO patients this is achieved by the placement of a left atrial vent at the time of sternotomy or a balloon atrial septectomy, which may require transfer to the catheterization laboratory with the possible complications associated with transport of a patient on an ECMO circuit.

Despite successful resuscitation and placement onto mechanical assist devices, morbidity and mortality remain high, with ECMO appearing to have worse outcomes. The mortality rate for ECMO in the 1990s was on the order of 47%, with survival in series published in the early 2000s not showing much

improvement.[274-277] In contrast, the survival in those into whom a VAD is placed appears to be superior within the quoted series up to 80% of patients surviving to transplantation or being successfully weaned from support.[274,278] In the study by Blume and coworkers,[275] it was, however, noted that associated congenital heart disease, and patients who are younger and smaller, have a higher mortality when compared with those with fulminant myocarditis and cardiomyopathy. Alongside survival data, the next most important marker is neurologic outcome and it appears that this is better in the VAD group.[279,280] Risk factors for poor neurologic outcome were once again low weight and duration of DHCA, both of which place ECMO patients at a survival disadvantage because ECMO patients will be smaller and a number of those who undergo DHCA for repair of congenital anomalies will require emergent ECMO support to wean from CPB or in the immediate postoperative phase.[281]

Survival predictors are important in our management of these patients. It appears that one common variable that can predict survival is the return of ventricular function between 3 and 5 days after the initiation of support; and should the support be required for longer periods of time, morbidity and mortality increases.[276,281] As mentioned earlier, both of these modalities have been used successfully as a bridge to transplantation, with VAD patients having a greater than 80% survival to transplantation and ECMO patients showing a less than 60% survival. These data, however, may be skewed because ECMO is used often in the infant population and in those with complex congenital heart disease, both of which are factors known to increase mortality among VAD patients.[278] The important causes of morbidity and mortality in patients on both of these modalities include cerebrovascular events secondary to either hemorrhagic or embolic phenomena, circuit-related issues (e.g., circuit thrombosis), renal failure requiring hemofiltration, sepsis, ongoing hemorrhage, and multiple-organ failure.

Although these modalities are often compared alongside each other, they both have unique places in the care of children with cardiac disability. ECMO has a great advantage in that it can be employed rapidly in a code situation for a patient of any age or size. In the past, size has been the limiting factor for implantation of VAD systems into pediatric patients. The Berlin Heart VAD (Berlin Heart AG, Berlin, Germany) is available for use even in neonates. The system has been employed in Europe for over 10 years and has pump sizes from 10 to 80 mL. At this time the device is available only for emergency compassionate use in the United States. From this, however, it can be appreciated that these two modalities can certainly complement each other, with ECMO being used acutely; once the patient is physiologically stable, but still requiring support, a VAD can be used should long-term support be warranted.

Anesthesia for Heart and Lung Transplantation

Although perioperative management for thoracic organ transplantation is considered elsewhere in this text, the application of these procedures to children requires some specific modification. Differences include the characteristics of the candidates, preparation of these children, anesthetic management, surgical considerations, post-CPB management, and outcome. Even though some of the earliest heart transplant procedures were performed for congenital heart malformations, this indication became rare by the early 1980s. In 1984, over 60% of the few pediatric heart transplant procedures were performed in patients with cardiomyopathy, usually adolescents. In the next decade, a dramatic rise in the number of infants and young children with congenital heart malformations treated with heart transplantation resulted in a marked shift in the demographics (Fig. 83-14).[282] By 1995, over 70% of the children receiving heart transplants were younger than 5 years of age, with half of those younger than age 1. The overwhelming majority of these infants received transplants for congenital heart malformations for which reconstructive options either had failed or were not believed to exist (Fig. 83-15).[282] The implications of this shift reach into every element of perioperative management.

Children considered for heart transplantation are more likely to have pulmonary hypertension than adults. Most adult transplant programs will not offer heart transplant therapy to patients with PVR over 6 Wood units/m^2.[283] The exclusion threshold in infants and children remains controversial. Some programs accept patients with PVR as high as 12 Wood units/m^2, particularly if the pulmonary vasculature responds to vasodilators such as oxygen, nitric oxide, calcium channel blockers, or prostacyclin.[284] Neonates are generally assumed to have elevated PVR, but outcome data from some programs suggest that the importance

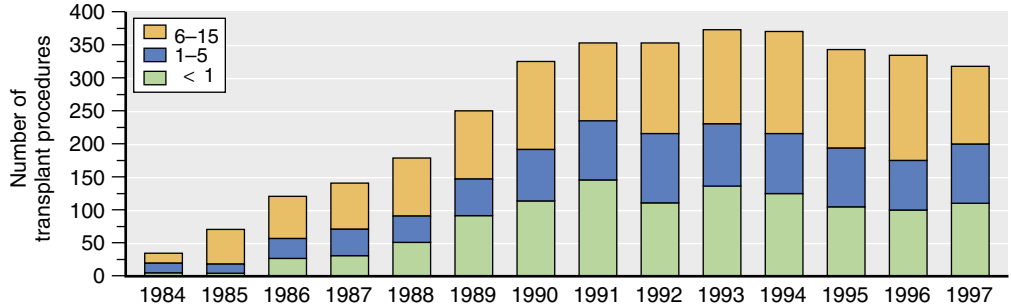

Figure 83-14 Demographic data for pediatric heart transplantation by age. Stacked bar graph illustrates the total number and age distribution for heart transplantation in patients younger than 16 years of age. Note the rapid rise in transplant procedures performed during the late 1980s, with particular growth in the population of children aged 5 years and younger. Having peaked in the mid 1990s, the total number of transplant procedures (both adult and pediatric) has declined slightly, but the relative age proportions within the pediatric population remain relatively constant. (*Data from the Registry of the International Society for Heart and Lung Transplantation.*[282])

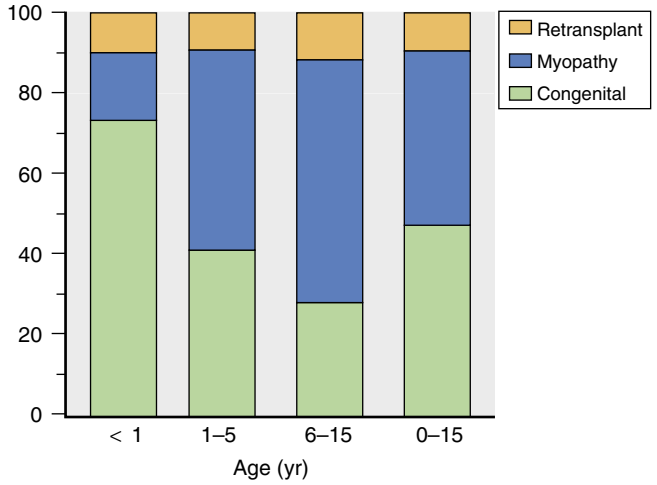

Figure 83-15 Indication for heart transplantation in children. Over the past 2 decades, the major indications for pediatric heart transplantation were nearly equally divided between congenital malformation and cardiomyopathy. In later years, pediatric recipients with congenital malformations assumed a slight plurality due to shifting age demographics. As illustrated, younger children are more likely to undergo heart transplantation because of congenital malformation. (*Data from the Registry of the International Society for Heart and Lung Transplantation.*[282])

of this factor for postoperative outcome is substantially less in the first year of life, perhaps because the infant donor hearts, having recently undergone transitional circulation, are better prepared to cope with the right ventricular pressure load that elevated PVR imposes.[285]

The anesthetic plan for pediatric heart transplantation must accommodate a wide spectrum of pathophysiology. Recipients with congenital heart malformations benefit from the analysis of loading conditions and optimizing hemodynamics discussed previously. Although a few of these patients undergo heart transplantation because the natural history of reconstructive heart surgery poses greater risk despite reasonable ventricular function, most candidates exhibit some manifestations of impaired ventricular performance. Accordingly, they require careful titration of anesthetic agents with minimal myocardial depressant characteristics to avoid cardiovascular collapse. In this fragile population, even modest doses of opioids can be associated with marked deterioration in systemic hemodynamics, presumably by reducing endogenous catecholamine release. As with most congenital heart patients, skilled management of the airway and ventilation represents crucial elements in a satisfactory induction, particularly in the presence of elevated PVR. No matter how elegant the anesthetic plan in conception and implementation, a certain proportion of these children will decompensate on induction, necessitating resuscitative therapy.

Although orthotopic heart transplantation poses some technical challenges in neonates and young infants, the replacement of an anatomically normal heart is less complex than several reconstructive heart procedures commonly performed in patients at this age. However, the need to adapt this procedure to incorporate repair of major concurrent cardiovascular malformations requires the consummate skill and creativity that remain the province of a few exemplary congenital heart surgeons.[286,287]

Having withstood extended ischemic periods, heart grafts are extraordinarily intolerant of superimposed residual hemodynamic loads that may accompany imperfect vascular reconstruction. The extensive vascular repair and, particularly in older children with longstanding hypoxemia, the propensity to coagulopathy together elevate hemorrhage to a major cause of morbidity and even mortality in pediatric heart transplantation. Nevertheless, once successfully implanted, these grafts will respond to physiologic factors that stimulate growth and adaptation in the developing infant and child.[288]

Management considerations during separation from CPB and the early postoperative period are primarily focused on three pathophysiologic conditions: myocardial preservation, denervation, and PVR. Even expeditious transplant procedures usually force the heart to endure ischemic periods that exceed those encountered during reconstructive surgery. Although some researchers believe the infant heart is more tolerant of extended ischemia,[285] these hearts will demonstrate a period of reperfusion injury, and virtually all require pharmacologic and, in some cases, mechanical support. In addition, endogenous adaptive responses and exogenous pharmacologic agents that act via myocardial sympathetic activation are ineffective in the denervated graft. Because the majority of children presenting for heart transplantation exhibit some element of elevated PVR, even with isolated end-stage cardiomyopathy, the RV of a newly implanted heart is particularly vulnerable to failure.

As such, ventilatory and pharmacologic interventions are usually configured to exert a favorable impact on PVR and provide inotropic and chronotropic support. Once the lungs are fully expanded, we ventilate to $Paco_2$ values in the low 30s using an Fio_2 of 1. Virtually all recipients receive low-dose dopamine (3-5 μg/kg/min) and isoproterenol (0.02-0.05 μg/kg/min) to promote inotropy, chronotropy, and lower PVR. In the event that these do not provide sufficient inotropy in the presence of more significant postischemic dysfunction, additional agents are added (e.g., milrinone, epinephrine). Most transplant centers have a specific regimen for immunosuppression to be initiated in the perioperative period. As with adults, pediatric transplant programs typically employ triple-drug immunosuppression with a calcineurin inhibitor (e.g., cyclosporine, tacrolimus), antimetabolite (e.g., azathioprine), and steroid. After an interval without rejection, some pediatric programs will taper and discontinue one or even two of these agents, particularly in neonates, in whom some element of tolerance is thought to develop.[289,290]

National statistics indicate that the outcome from pediatric heart transplantation is slightly less favorable than comparable adult results.[282] The principal risk factors are age younger than 1 year and congenital heart defects. Because these factors are closely related (i.e., the vast majority of infants younger than age 1 undergo transplantation for a congenital heart defect), it is difficult to determine the independent effect of age. Concurrent repair of structural cardiovascular anomalies substantially increases perioperative risk of hemorrhage, residual hemodynamic loading conditions, and right-sided heart failure from elevated PVR. When these two factors are taken together, infants younger than 1 year of age have an operative mortality rate of 24%, more than twice that of older children.[282] Beyond the early postoperative period, mortality rates are quite comparable for all age groups. Nevertheless, the sequelae of rejection and the consequences of the requisite immunosuppression result in significant ongoing morbidity and mortality. Because even the best transplant recipi-

ents have achieved only a 28% 14-year survival rate, these procedures must be considered palliative for children.[282]

Lung and heart-lung transplantation have achieved respectable operative survival rates in children.[291,292] They remain the only viable surgical therapy for infants and children with severe pulmonary vascular disease and selected progressive pulmonary diseases. These remain uncommon procedures in pediatrics. Lung transplantation carries the additional morbidity of obliterative bronchiolitis, a debilitating small airway disease that results in gradual deterioration in flow-related pulmonary functions over time. Despite an operative mortality rate that is currently less than 20%, the 3-year survival rate is only 50% to 60%.[282,292]

Patients with transplanted hearts also present for surveillance cardiac catheterizations, biopsies, and other procedures.[270,293-295] The anesthesia plan in these patients should take into effect the physiologic and pharmacologic problems of allograft denervation, the side effects of immunosuppression, the risk of infection, and the potential for rejection.[293-295] Cardiac allograft vasculopathy is the leading cause of morbidity and mortality after transplantation, leading to progressive graft dysfunction with heart failure, an increased risk of dysrhythmia, and the possibility of arrhythmogenic sudden death. Conventional revascularization procedures are ineffective because cardiac allograft vasculopathy is caused by intimal proliferation; thus, retransplantation is the only therapeutic option. Hyperlipidemia after heart transplantation is a common occurrence in both adults and children and is aggravated by chronic steroid therapy and other immunosuppressive agents. Statins are used with good results in controlling hyperlipidemia after transplantation and are likely to manifest inherent immunosuppressive effects. Risk factors for post-transplant renal dysfunction are the use of calcineurin inhibitors, mechanical circulatory support, prolonged inotropic support, and preexisting renal dysfunction. Newer, more potent immunosuppressive agents (e.g., tacrolimus) have led to steroid-sparing regimens late after transplantation, eliminating the detrimental effects of long-term steroid administration. Agents such as sirolimus may now be used in combination with lower levels of calcineurin inhibitors, thus minimizing long-term nephrotoxicity. Post-transplant lymphoproliferative disorders represent a pathologic spectrum of abnormal lymphoid proliferation ranging from localized early lesions to polymorphic disease or, in some cases, monomorphic lymphomatous disease. From a clinical perspective, the most common sites of disease and presenting symptoms included the gastrointestinal tract and pulmonary systems. Patients with polymorphic disease are treated primarily by a reduction or temporary cessation of immunosuppression along with adjunctive surgical therapy for tissue diagnosis or obstructive lesions. Most centers reserve traditional chemotherapeutic regimens for patients with nonresponsive polymorphic disease and monomorphic disease. As a result of cardiac denervation, autonomic regulatory mechanisms are not available to prevent the wide swings in a patient's hemodynamic state, and the stress response is slower than usual. Cardiac parameters are significantly altered, and patients may experience a decrease in systemic blood pressure and cardiac filling pressures. Compensatory mechanisms are delayed, and reductions in cardiac output lead to decreased coronary and cerebral perfusion, especially on the background of hypertension. Drugs with direct myocardial and vascular effects are the mainstay of therapy. Most immunosuppressive agents affect hepatic and renal functions and interact with anesthetic drugs.

Anesthesia for Closed-Heart Operations

Early corrective repair in infancy has significantly reduced the number of noncorrective, palliative closed-heart operations. Corrective closed-heart procedures include PDA ligation and repair of coarctation of the aorta. Noncorrective closed-heart operations include pulmonary artery banding and extracardiac shunts such as the Blalock-Taussig shunt. These procedures are performed without CPB. Therefore, venous access and intra-arterial monitoring are important in evaluating and supporting these patients. A pulse oximeter remains an invaluable monitor during intraoperative management.

Ligation of a PDA is typically performed through a left thoracotomy, although video-assisted thoracoscopic techniques are increasingly common.[296,297] Physiologic management is that of a left-to-right shunt producing volume overload. Patients with a large PDA and low PVR generally present with excessive PBF and congestive heart failure. Neonates and premature infants also run the risk of having substantial diastolic runoff to the pulmonary artery, potentially impairing coronary perfusion. Thus, patients range from an asymptomatic healthy young child to the sick ventilator-dependent premature infant on inotropic support. The health of the former patient allows a wide variety of anesthetic techniques culminating in extubation in the operating room. The latter patient requires a carefully controlled anesthetic and fluid management plan. Generally, a trial of medical management with indomethacin and fluid restriction is attempted in the premature infant before surgical correction. Transport of the premature infant to the operating room can be especially difficult and potentially hazardous, requiring great vigilance to avoid extubation, excessive patient cooling, and venous access disruption. For these reasons, many centers are now performing ligation in the neonatal ICU.

There is a subset of premature infants with PDAs at institutions without cardiac surgical teams. Ligation of the PDA in these patients requires either transfer of these high-risk neonates to a center that has a team that routinely performs the procedure or the availability of a team capable of performing the procedure that is willing to travel to perform the procedure in the neonate's home neonatal intensive care unit (NICU). Gould and associates[298] reviewed the experience with on-site and off-site ligations of a team composed of a pediatric cardiac attending anesthesiologist, a certified registered nurse anesthetist, an attending pediatric cardiothoracic surgeon and fellow, and cardiac operating room nurses. There were no anesthetic-related complications in their group. No differences were found in the incidence of perioperative complications in the procedures in the two sites. This study showed PDA ligations can be performed safely in the NICUs of hospitals lacking on-site pediatric cardiac surgical units, without incurring the risk inherent in transport of critically ill infants. In addition, patient care is continued by the neonatology team most familiar with the child's medical and social history and the patient's family is minimally inconvenienced.

Complications of PDA ligation include inadvertent ligation of the left pulmonary artery or descending aorta, recurrent laryngeal nerve damage, and excessive bleeding due to inadvertent PDA disruption. After ductal ligation in premature infants, worsening pulmonary compliance can precipitate a need for increased

ventilatory support; and manifestations of an acute increase in left ventricular afterload should be anticipated, especially if left ventricular dysfunction has developed preoperatively. PDA ligation has been performed in infants and children using thoracoscopic surgical techniques. This approach has the advantage of limited incisions at thoracoscopic sites, promoting less postoperative pain and discharge from the hospital the same day of surgery.

Coarctation of the aorta is a narrowing of the descending aorta near the insertion of the ductus arteriosus. Obstruction to aortic flow results and may range from severe obstruction with compromised distal systemic perfusion to mild upper extremity hypertension as the only manifestation. Associated anomalies of both the mitral and aortic valves can occur. In the neonate with severe coarctation, systemic perfusion is dependent on right-to-left shunting across the PDA. In these circumstances, left ventricular dysfunction is very common and prostaglandin E_1 is necessary to preserve sufficient systemic perfusion. Generally, a peripheral intravenous line and an indwelling arterial catheter, in the right upper extremity, are recommended for intraoperative and postoperative management. In patients with left ventricular dysfunction, a central venous catheter may be desirable for pressure monitoring and inotropic support.

The surgical approach is through a left thoracotomy, whereby the aorta is cross-clamped and the coarctation repaired with an end-to-end anastomosis, patch aortoplasty, or subclavian patch. During cross-clamping, we usually allow significant proximal hypertension (20% to 25% increase over baseline), based on evidence that vasodilator therapy may jeopardize distal perfusion and promote spinal cord ischemia. Intravascular volume loading with 10 to 20 mL/kg of crystalloid is given just before removal of the clamp. The anesthetic concentration is decreased, and additional blood volume support is given until the blood pressure rises. Post-repair rebound hypertension due to heightened baroreceptor reactivity is common and often requires medical therapy. After cross-clamping, aortic wall stress due to systemic hypertension is most effectively lowered by institution of β-blockade with esmolol or α/β-blockade with labetalol.[299] Recent work indicates that patients younger than 6 years of age should receive a loading dose of 250 to 500 μg/kg of esmolol, followed by an infusion of 250-750 μg/kg/min, depending on the blood pressure. Despite an esmolol infusion, 25% to 50% of patients have a blood pressure that is above the targeted range, requiring a second drug. Sodium nitroprusside, which increases the calculated aortic wall stress in the absence of β-blockade, is usually chosen as the second drug. Other agents that may have a greater likelihood of achieving the targeted pressure include nitroglycerin and nicardipine. Propranolol is useful in older patients but can cause severe bradycardia in infants and young children. Although it actually increases calculated aortic wall stress in the absence of β-blockade by accelerating dP/dT (contractile force), the addition of sodium nitroprusside may be necessary to control refractory hypertension. Captopril or an alternative antihypertensive regimen is begun in the convalescent stage of recovery in those patients with persistent hypertension.

The management of infants undergoing placement of extracardiac shunts without CPB centers on goals similar to those of other shunt lesions: balancing pulmonary and systemic blood flow by altering $Paco_2$, Pao_2, and ventilatory dynamics. Central shunts are usually performed through a median sternotomy, whereas Blalock-Taussig shunts may be performed through a thoracotomy or sternotomy. In patients in whom PBF is critically low, partial cross-clamping of the pulmonary artery required for the distal anastomosis causes further reduction of PBF and desaturation, necessitating meticulous monitoring of pulse oximetry. Careful application of the cross-clamp to avoid pulmonary artery distortion will help maintain PBF. Under circumstances in which severe desaturation and bradycardia occur with cross-clamping, CPB will be required for the procedure.

Intraoperative complications include bleeding and severe systemic oxygen desaturation during chest closure, usually indicating a change in the relationship of the intrathoracic contents that results in distortion of the pulmonary arteries or kink in the shunt. Pulmonary edema may develop in the early postoperative period in response to the acute volume overload that accompanies the creation of a large surgical shunt. Measures directed at increasing PVR, such as lowering inspired O_2 to room air, allowing the $Paco_2$ to rise, and adding positive end-expiratory pressure are helpful maneuvers to decrease PBF until the pulmonary circulation can adjust. Decongestive therapy such as diuretics and digoxin may alleviate the manifestations of congestive heart failure. Under such circumstances, early extubation is inadvisable.

Pulmonary artery banding is used to restrict PBF in infants whose defects are deemed uncorrectable for either anatomic or physiologic reasons. These patients are generally in congestive heart failure with reduced systemic perfusion and excessive PBF. The surgeon places a restrictive band around the main pulmonary artery to reduce PBF. Band placement is very imprecise and requires careful assistance from the anesthesia team to accomplish successfully. Many approaches have been suggested. We place the patient on 21% inspired oxygen concentration and maintain the $Paco_2$ at 40 mm Hg, to simulate the postoperative state. Depending on the malformation, a pulmonary artery band is tightened to achieve hemodynamic (e.g., distal pulmonary artery pressure 50%-25% systemic pressure) or physiologic (e.g., $\dot{Q}p:\dot{Q}s$ approaching 1) goals. Should the attainment of these objectives produce unacceptable hypoxemia, the band is loosened.

Anesthesia for Interventional or Diagnostic Cardiac Procedures

Advances in interventional and diagnostic cardiac catheterization techniques are significantly changing the operative and nonoperative approach to the patient with a congenital heart defect. Common interventions in the cardiac catheterization laboratory are shown in Table 83-14. Nonoperative interventional techniques are being used instead of procedures requiring surgery and CPB for safe closure of secundum ASDs, VSDs, and PDAs. Stenotic aortic and pulmonic valves, recurrent aortic coarctations, and branch pulmonary artery stenoses can be dilated in the catheterization laboratory, avoiding surgical intervention.[300,301] These techniques shorten the hospital stay and are particularly beneficial to patients with recurrent coarctation and muscular or apical VSDs, who are at a higher risk of operative intervention. Many patients

Table 83-14 Common Interventions in the Cardiac Catheterization Laboratory

Simple Interventions	
Device Closures	**Coil Embolization**
Atrial septal defect (ASD)	Decompressing veins
Ventricular septal defect (VSD)	Aortopulmonary (AP) collaterals
Patent ductus arteriosus (PDA)	Surgical shunts
Patent foramen ovale (PFO)	Coronary/atrioventricular fistulas
Balloon valvuloplasty	Balloon angioplasty
Aortic stenosis (AS)	Branch pulmonary artery stenosis
Pulmonary stenosis (PS)	Coarctation of the aorta
Complex Interventions	
Hypoplastic Left Heart Syndrome (HLHS)	
Post Norwood	
Pulmonary artery stenosis	Angioplasty
Shunt thrombosis	Dilation/thrombectomy
Restrictive ASD	Balloon septostomy
Aortic arch obstruction	Angioplasty
AP collaterals	Coil embolization
Post Glenn/Fontan	
Decompressing veins	Coil embolization
Baffle leaks	Device/coil embolization
Systemic vein stenosis/thrombosis	Angioplasty/thrombectomy
RV failure	Creation of fenestration
Exercise intolerance	Closure of fenestration
AP collaterals	Coil embolization
Obstructive Fontan pathway	PA angioplasty, balloon septostomy)
Transposition of Great Arteries	Balloon atrial septostomy
Tetralogy of Fallot	
Shunt thrombosis	Thrombectomy
Pulmonary artery stenosis	Angioplasty
AP collaterals	Coil occlusion
Miscellaneous Interventions	
Severe pulmonary hypertension	Atrial septostomy
ECMO left heart decompression	Atrial septostomy
Stenosis of pulmonary veins	Balloon angioplasty stent
Stenosis/thrombosis of systemic veins	Balloon angioplasty/thrombectomy

with complex cardiac defects are poor operative risks. Innovative interventional procedures improve vascular anatomy, reduce pressure loads on ventricles, and decrease the operative risk for these patients. For example, in tetralogy of Fallot with hypoplastic pulmonary arteries, balloon angioplasty and vascular stenting procedures create favorable pulmonary artery anatomy and reduce pulmonary artery pressure and right ventricular end-diastolic pressure. Complications are more common during interventional catheterization and include arterial thrombosis, arrhythmias (especially heart block), hemodynamic instability, embolization of devices or coils, bleeding, and perforation of the major vessels or heart.[302] Complications are more common in infants younger than 6 months and with smaller infants. Constant vigilance, correction of electrolyte imbalance, maintenance of acid-base status, and appropriate heparinization will mitigate some of the morbidity. Appropriate and early transfusion with deployment of rapid-response ECMO in the resuscitation of an infant in cardiac arrest improves outcome. High-risk patients undergoing diagnostic evaluation of pulmonary artery hypertension in anticipation of heart-lung transplantation also require anesthetic management. Despite the attendant high risks of the procedure in patients with suprasystemic right ventricular pressure, these patients are best managed with general anesthesia and controlled ventilation.

Anesthetic management of interventional or diagnostic procedures in the catheterization laboratory must include the same level of preparation that applies in caring for these patients in the operating room. These patients have the same complex cardiac physiology and, in some cases, greater physiologic complexity and less cardiovascular reserves. Interventional catheterization procedures can impose acute pressure load on the heart during balloon inflation. Large catheters placed across mitral or tricuspid valves create acute valvular regurgitation or, in the case of a small valve orifice, transient valvular stenosis. When catheters are placed across shunts, severe reductions in PBF and marked hypoxemia may occur. The anesthetic plan must consider the specific cardiology objectives of the procedure and the impact of anesthetic management in facilitating or hindering the interventional procedure. In general, there are three distinct periods involved in an interventional catheterization: the data acquisition period, the interventional period, and the postprocedural evaluation period.

During the data acquisition period, the cardiologist performs a hemodynamic catheterization to evaluate the need for and extent of the planned intervention. Catheterization data are obtained under normal physiologic conditions; that is, room air, physiologic $Paco_2$, and spontaneous ventilation are preferred. Increased Fio_2 or changes in $Paco_2$ may obscure physiologic data. During the procedural period, the patient is usually intubated and mechanically ventilated. A secured airway allows the anesthesiologist to concentrate on hemodynamic issues. Positive-pressure ventilation also reduces the risk of air embolism. During spontaneous ventilation, a large reduction in intrathoracic pressure can entrain air into vascular sheaths and result in moderate to large pulmonary or systemic air emboli. Precise device placement is also facilitated with muscle relaxants that eliminate patient movements and controlled ventilation, thereby reducing the respiratory shifting of cardiac structures. Substantial blood loss and changes in ventricular function occur commonly during the intervention. Blood volume replacement and inotropic support may be necessary during or immediately after the interventional procedure.

In the postprocedural period, the success and the physiologic impact of the intervention are evaluated. Blood pressure, mixed venous oxygen saturation, ventricular end-diastolic pressure, and cardiac output, when available, are used to assess the impact of the intervention. Persistent severe hemodynamic derangement indicates the need for ICU monitoring and respiratory or cardiovascular support. Because of the hemodynamic variability of many of these patients, as well as changing anesthetic requirements, continuous intravenous infusion with ketamine/midazolam or propofol is appropriate. Potent inhaled anesthetics are generally not used as the primary anesthetic and are reserved for adjunctive anesthesia.

A brief description of some of the interventional procedures and the associated anesthetic implications follows. The success of these interventions will undoubtedly result in widespread availability and use over the next few years.

Transcatheter Technique for Atrial Septal Defect Closures

In the transcatheter technique for ASD closures, a collapsed double-umbrella clamshell device is loaded into a large introducer sheath placed through the femoral vein, advanced to the right atrium, and placed across the ASD into the left atrial chamber. Each side of the device consists of a Dacron mesh patch suspended in six spring-loaded arms that open like an automatic umbrella. Using biplane fluoroscopy and TEE, the catheter is positioned in the left atrium away from the mitral valve.[303] The sheath is pulled back to open the six distal arms and its Dacron mesh cover into the left atrium. The sheath and device are then pulled back so the distal arms contact the left atrial septum. Fluoroscopy and TEE are used to confirm that the arms are on the left atrial side and do not interfere with mitral valve motion. Once adequately seated, the sheath is pulled farther back to expose the proximal side of the device and the proximal arms, which spring open to engage the right side of the atrial septum. When proper positioning is certain, the device is released.[303] In a review of data for 122 children undergoing transcatheter ASD closures, there was a 9% incidence of procedural complications that resulted in hemodynamic complications requiring treatment.[304]

Device closure of secundum ASD is the preferred therapeutic approach. Data continue to support closure of small to moderate size defects (<8-20 mm) in appropriate-size patients with appropriate septal length and device diameter.[305-307] The procedure is well tolerated with minimal long-term complications. Complications such as cardiac erosions and heart block can occur in patients who receive a large device for patient size, especially those who have a deficient anterosuperior rim.[308-309] Thrombus is a rare problem that can usually be treated medically, and its incidence appears to be device-dependent.[310] Despite nearly a decade of experience, these devices remain under investigational protocol and are therefore available only at a limited number of study centers.

Transcatheter Ventricular Septal Defect Closures

Most VSDs that are electively closed in the catheterization laboratory are mid-muscular or apical VSDs that are either difficult to close in the operating room or would require a left ventriculotomy. Left ventriculotomies are associated with a high incidence of left ventricular dysfunction and have been relegated to a position as the least desirable surgical option. The preferred therapeutic approach for VSD is surgical closure. Transcatheter closure of muscular VSDs can be performed safely. However, there is a significant incidence of complications including heart block, blood loss, and hemodynamic instability.[311,312] Device closure of membranous VSD is in early stages of investigation, and the incidence of complications remains to be determined.[313-314] The transcatheter approach requires a blade atrial septostomy and a retrograde catheter placed through the femoral artery and advanced to the left atrium. This catheter is pulled across the atrial septum into the right atrium and is used to guide a superior vena cava catheter (placed through the internal jugular vein) across the ASD into the left atrium, across the mitral valve, and into the LV. The VSD defect is approached from the left ventricular side. The large sheath containing the double-umbrella clamshell device prevents closure of the mitral valve, resulting in acute mitral regurgitation or, in cases in which the VSD is large or the mitral annulus small, acute severe mitral stenosis. In this latter case, systemic output is decreased and a period of severe hypotension is unavoidable. Judicious use of vasoconstrictors to maintain coronary perfusion may be required during the catheter placement, followed by volume and inotropic resuscitation after the VSD device is deployed. This highly specialized application of the clamshell device is confined to only a few pediatric centers in the United States.

Angioplasty of Branch Pulmonary Artery Stenosis

One of the most important areas of interventional catheterization has been the dilation and stenting of hypoplastic or stenotic branch pulmonary arteries. In patients with tetralogy of Fallot with hypoplastic pulmonary arteries, pulmonary atresia, or single ventricle with surgically induced peripheral stenoses, the use of balloon angioplasty and stenting procedures creates favorable pulmonary artery anatomy and reduces the risk of subsequent surgical repairs (Fig. 83-16). Peripheral pulmonary artery stenosis is not a surgically amenable lesion and is particularly suited to catheterization and angioplasty. Balloon angioplasty is accomplished by tearing the vascular intima and media, allowing the vessel to remodel and heal with a larger diameter. The balloon is placed across the stenotic lesion so that the middle of the balloon is at the stenosis. The balloon is inflated until the waist of the balloon is eliminated. Ideally, the most stenotic lesions are dilated first to minimize the impact on PBF and cardiac output. When the balloon is inflated, PBF is reduced, right ventricular afterload is increased, and cardiac output falls. In patients with an associated VSD or ASD, right-to-left shunting and desaturation occur with balloon inflation. In patients without a shunt, acute increase in right ventricular afterload can cause systemic hypotension and right ventricular failure. The large vascular sheaths required for these procedures can introduce tricuspid regurgitation, which is poorly tolerated in patients with severe RV hypertension. Occasionally, balloon catheters must be placed across aortopulmonary shunts, significantly reducing PBF.

The procedure is successful in approximately 60% of patients. In an early series, complications included hypotension (40%), pulmonary artery rupture (3%), unilateral reperfusion pulmonary edema (4%), aneurysmal dilation of the dilated pulmonary vessel (8%), death (1.5%), and transient postprocedural right ventricular dysfunction.[315] Improved techniques and patient selection have favorably influenced the results with superior balloon catheters and stents while significantly reducing serious complications. Anesthetic support minimizes hemodynamic compromise by anticipating changes in blood flow patterns, treat-

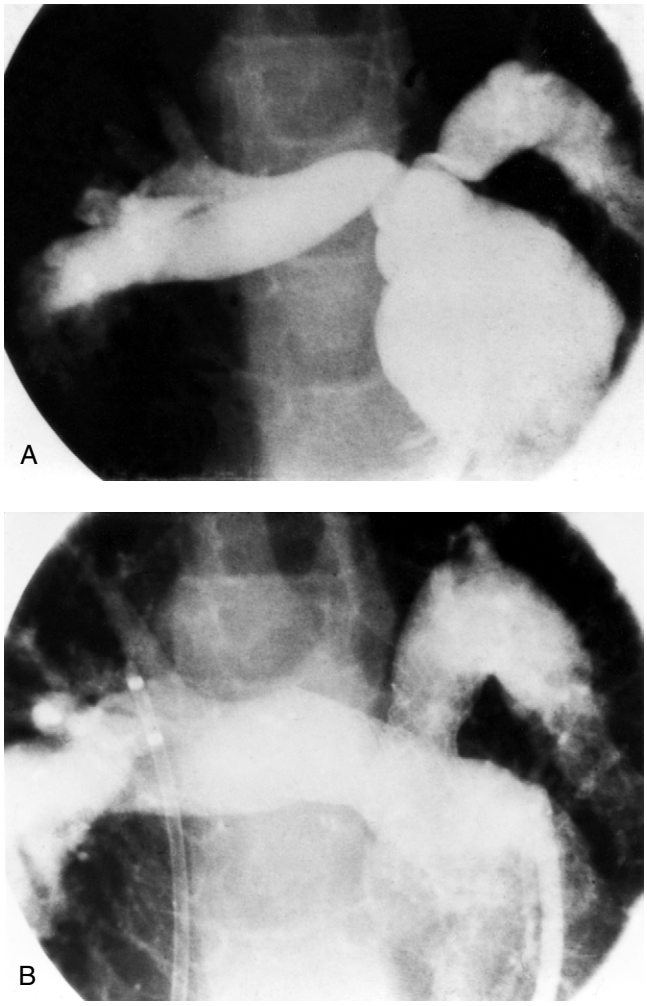

Figure 83-16 A, Severe bilateral branch pulmonary artery stenoses at the distal end of a conduit in a patient with pulmonary trunk atresia and ventricular septal defect. Stents were placed in the right and left pulmonary arteries. **B,** Follow-up angiogram in the same projection and magnification showed marked improvement of both right and left stenoses.

ing transient hypotension, and providing airway support to minimize the risks associated with pulmonary artery disruption and acute unilateral pulmonary edema.[315]

A unique group of patients are those with Williams' syndrome with supravalvar aortic and pulmonary stenosis. Such patients can have multiple areas of severe branch pulmonary artery stenosis, with resultant systemic or suprasystemic right ventricular pressures and right ventricular dysfunction. Patients can also have coronary stenosis and develop subendocardial ischemia from hemodynamic disturbances in the setting of biventricular hypertrophy. The presence of supravalvar aortic stenosis, biventricular outflow tract obstruction, and coronary stenosis is associated with increased perioperative risk. Typically, such patients undergo general anesthesia with positive-pressure ventilation and recover in the cardiac ICU for angioplasty of branch pulmonary artery stenosis.[316] Care must be exercised in maintaining SVR, myocardial oxygenation, and contractility. Tachycardia and subendocardial ischemia should be avoided in the presence of ventricular hypertrophy.

Balloon Valvulotomies

Balloon valvulotomies conducted in well-compensated infants and children can often be accomplished without anesthetic support. Exceptions include neonates with critical aortic or pulmonary stenosis and patients with significant ventricular dysfunction who exhibit unstable hemodynamics. Balloon valvuloplasty is indicated in valvular pulmonary or aortic stenosis with valvular gradients more than 50 mm Hg. Balloon dilation is effective in most patients except those with dysplastic valves (e.g., Noonan's syndrome); post-dilation pulmonary incompetence is anticipated and does not pose a problem in the immediate and intermediate period. There is a need for prophylaxis for subacute bacterial endocarditis long-term. Only 8% of patients require re-interventions. Typically, patients recover in the ICU and may require transfusion depending on hemodynamic stability. Valvular aortic stenosis is associated with poor surgical outcome in the neonatal period. All therapies are palliative with a high incidence of re-interventions, and balloon valvuloplasty is often the initial treatment. Residual obstruction or regurgitation is common after balloon dilatation and can require re-intervention. There is a real risk of damage to the aortic valve and subaortic septum with the consequence of acute aortic insufficiency and coronary ischemia. Hypotension and bradycardia commonly occur during valvuloplasty, and many centers have a policy of ECMO standby for these high-risk interventions in the catheterization laboratory. Ready availability of a surgical and perfusion team is crucial to a good outcome. Neonates with critical aortic stenosis often require stabilization with inotropes and prostaglandins to maintain systemic perfusion before the procedure. Balloon dilation of recurrent coarctation is often the therapy of choice in older children with re-coarctation after surgery. Such patients are often hypertensive. The procedure can be performed with the patient under deep sedation or general anesthesia. In infants after Norwood palliation for hypoplastic left heart syndrome, coarctation can occur in the distal arch anastomotic site. Catheters placed antegrade via the right side of the heart into the neoaorta can induce hemodynamically significant tricuspid and neoaortic regurgitation, resulting in hemodynamic instability. Careful monitoring and aggressive hemodynamic intervention result in a good outcome.

Coil Embolization

Transcatheter methods can be adapted to occlude undesired vascular structures. Intravascular coils have been used to close PDAs, aortopulmonary collaterals, surgical systemic/pulmonary artery shunts, venous collaterals in single ventricle lesions, coronary fistulas, and some arteriovenous malformations (e.g., vein of Galen malformation). In selected instances, to minimize the risk that coils may escape to threaten vital organ perfusion, cardiologists request the use of general anesthesia with a muscle relaxant.

Depending on the lesion, patients might manifest severe cyanosis, low or high output cardiac failure, or coronary ischemia. Extra care should be exercised in patients with coronary fistulas to maintain myocardial oxygen supply and reduce demand. Mate-

rials used for embolization can include surgical gel (Gelfoam), alcohol, and coils. Some of these substances can induce severe allergic reactions with hemodynamic collapse. Antibiotic prophylaxis is mandatory to prevent bacterial endocarditis. Angiography is used to demonstrate successful occlusion of the vascular structure and ascertain appropriate placement.

Valve Prostheses

Transcatheter bioprosthetic valve replacement of the pulmonary and aortic valves is being performed. The pulmonary valve is a bovine jugular venous valve mounted on a balloon-expandable Cheatham platinum stent. The technique is limited by the maximum size of 22 mm of the bovine jugular venous valve. Percutaneous placement of bioprosthetic valve in the pulmonary position is a reality, and further refinement and miniaturization will lead to its application in aneurysmal right ventricular outflow tract. The development of transcatheter placement in the aortic position is still in its very early stages, but animal studies and initial adult studies show that it is feasible.[317-318]

Emergent Procedures

Emergent interventions such as balloon atrial septostomy to ensure adequate mixing in patients with transposition physiology and in patients who have restrictive atrial septal defect with single ventricle physiology are lifesaving and enable planning surgery at a suitable time. The procedure can be performed at the bedside with echocardiography or in the catheterization laboratory with fluoroscopic confirmation of balloon position. Access is via the femoral or umbilical vein, and the balloon catheter is advanced through the foramen ovale into the left atrium. The balloon is inflated with contrast and pulled back via the septum until a satisfactory atrial septal defect is created. If the procedure is successful, the left and right atrial pressures should equalize and adequate mixing should occur. Oxygenation and pulmonary venous drainage should improve. Complications include atrial perforation, laceration of the mitral or tricuspid valves and pulmonary veins, and low cardiac output state. Balloon atrial septostomy is also performed emergently in patients receiving ECMO therapy for left-sided heart decompression.

Endomyocardial Biopsy

Typically, endomyocardial biopsies are performed both as part of post-transplant surveillance catheterizations at regular intervals to ascertain absence of rejection in patients after orthotopic heart transplantation. Right-sided heart catheterization is usually performed via access of the right internal jugular vein, through which the long sheath and biotome are introduced. Usually five to eight samples are taken. Endomyocardial biopsies are also used to confirm a diagnosis of myocarditis or cardiomyopathy; sedation or general anesthesia is required for smaller children, although older children can undergo this procedure with local anesthesia alone. Children who undergo catheterization during a period of acute rejection are at high risk of malignant arrhythmias during endomyocardial biopsy and might require resuscitation. A clinical history suggestive of an episode of rejection includes fever, gastrointestinal disturbances, and arrhythmias. Complications include perforation, tricuspid valve damage, and the development of coronary to right ventricular fistulas.

Cardiac Catheterization of Patients Supported by Extracorporeal Membrane Oxygenation

Booth and associates have reported on the Boston experience of cardiac catheterization in pediatric patients supported on ECMO. Indications included assessment of surgical repair, left-sided heart decompression, myocarditis/cardiomyopathy, hemodynamic assessment, catheter interventions, and ablation of arrhythmias.[319] The most common interventions were left-sided heart decompression in patients with left atrial hypertension, balloon angioplasty of the pulmonary arteries, and endomyocardial biopsy. The anesthesiologist coordinates safe transport of the patient on mechanical support with the perfusion and nursing team. The logistics of the transport, availability of surgeon, and blood need to be addressed before the transfer. Anesthesia is provided using isoflurane or sedatives on the ECMO circuit, and paralysis must be achieved before transport. Rest ventilation of the lungs is continued. The anesthesiologist's role is in managing a safe transport and attending to emergency mechanical, cardiorespiratory, and hematologic issues.

At present, hybrid techniques find a niche in lesions where cardiac surgery is problematic, such as apical muscular or anterior muscular VSDs or in high-risk patients with more complex lesions where immediate surgery is contraindicated or is associated with significant morbidity and mortality. Close collaboration is required so that a surgical approach is modified to facilitate subsequent interventional approach. The hybrid approach has been used in the management of hypoplastic left heart syndrome (HLHS). Stage 1 palliation is performed by creation of an atrial septal communication and stent placement in the ductus arteriosus during catheterization to maintain ductal patency with surgically applied external right and left pulmonary artery bands or transcatheter placed internal bands.[320,321] A modified Norwood procedure with a bidirectional Glenn anastomosis is performed with CPB during stage 2 palliation.[322] Stage 3 (Fontan operation) is performed entirely by transcatheter techniques.[323] In the current surgical climate, it seems difficult to promote ductal stenting as a method of choice but in patients with contraindications to immediate surgery this provides an attractive bridge.[324]

Pediatric Cardiac Electrophysiology

Diagnostic Evaluation

Cardiac Event Monitoring

Most patients with cardiac arrhythmias present with infrequent or episodic symptoms. These symptoms may include chest pain, palpitations, syncope, and presyncope. Transtelephonic

electrocardiographic event monitors (TTMs) may yield documentation of the arrhythmia because they are portable and patient activated.[325]

Insertable Cardiac Recorders

Insertable loop recorders implanted subcutaneously allow continuous rhythm monitoring that is stored either when manually activated by a patient/parent or automatically when high or low rate parameters are met.[326] These insertable loop recorders have value in correlating arrhythmias with symptoms when noninvasive means do not make a diagnosis. Typically, loop recorders are inserted under general anesthesia as an outpatient procedure and cause minimal pain.

Radiofrequency Ablation of Accessory Pathways

Radiofrequency ablation is a nonsurgical approach designed to eliminate atrial or ventricular reentrant tachyarrhythmias. The technique requires pathway mapping and precision ablation of the aberrant pathway, using a radiofrequency ablation catheter. Catheter ablation is offered to patients with refractory arrhythmias that are bothersome and the focus or pathway is amenable to ablation. In pediatrics, the EP catheters are introduced via femoral venous catheterization and the tips are positioned in the right atrial appendage, the His bundle area, right ventricular apex, and the coronary sinus. Occasionally, right internal jugular venous access is used for placement of the coronary sinus catheter. Rapid atrial pacing and, occasionally, an isoproterenol infusion are required during the mapping procedure to induce the arrhythmia. An ablation catheter is used to map the substrate, and, subsequently, the pathway is ablated. During the ablation, unexpected patient movement may result in catheter dislodgment and damage to normal conducting tissue; therefore, general anesthesia is usually required in younger children. Anesthetic agents and techniques should be chosen to maintain circulating catecholamines and avoid suppression of arrhythmogenesis, for identification of the aberrant pathway. Our current preference is a propofol continuous intravenous anesthetic, although low-dose volatile anesthetics are equally satisfactory. Rapid atrial pacing and, occasionally, an isoproterenol infusion are required during the mapping procedure.

Severe postprocedural cardiomyopathy has been described but is very unusual. An underlying cardiomyopathy from frequent episodes of supraventricular tachycardia and myocardial oxygen imbalance caused by prolonged periods of rapid atrial pacing and isoproterenol infusions are the presumed causative factors. An arterial line is helpful during these lengthy procedures for continuous monitoring of blood pressure and blood gases. Complications of the procedure include radiation exposure, tamponade, pericarditis, groin hematoma, arterial thrombosis, AV block, systemic embolization, coronary artery dissection, trauma to the mitral and tricuspid valves, and endocarditis.

Intra-atrial Reentrant Tachycardia

Intra-atrial reentrant tachycardia (IART) is associated with significant morbidity and mortality for many patients with repaired congenital heart disease, particularly after extensive atrial surgery, such as Fontan and atrial switch operations. Therapeutic options for IART include antiarrhythmic medications, catheter ablation, surgery, and pacing. The arrhythmia occurs along with long-standing myocardial dysfunction and residual lesions. Careful choice of anesthetic, monitoring, and early management of low cardiac output, especially in patients with single-ventricle physiology, are important. Prolonged periods of arrhythmia induction during mapping can result in low cardiac output state, necessitating inotropic therapy. Such patients may need to undergo recovery in the cardiac ICU. Despite reports of high acute success rates with catheter ablation, arrhythmia recurrence continues to be problematic in this population.[327] Acute success was reported in 93% of patients and was defined as no inducible, sustained IART. Recurrence occurred in 34% of patients, 88% within 1 year. Patients with Fontan physiology had the highest recurrence rate. Inadequate lesion size and depth with conventional radiofrequency ablation catheters are the principal reasons for recurrence. Intraoperative cryoablation within the right atrium for patients with IART and/or left atrium for atrial fibrillation using preoperative and intraoperative mapping can be used successfully. A new generation of antitachycardia pacemaker (AT500) has been used for treating IART. This device was able to successfully terminate 54% of treatable tachycardias by use of antitachycardia pacing, with no incidence of ventricular proarrhythmia.[328] In patients who are either unsuitable candidates for catheter ablation or in whom ablation has been unsuccessful, surgical ablation may be successfully combined with repair of congenital heart disease. This is particularly true of patients with complex physiology (e.g., Fontan revision with a maze procedure).[329-331]

Arrhythmias and Sudden Cardiac Death

Certain cardiomyopathies and channelopathies are associated with an increased risk of sudden cardiac death due to lethal arrhythmias. There is usually a history of syncope, near-syncope, or aborted sudden death. Such patients present for insertion of automated internal cardioverter-defibrillators (AICDs) for either primary or secondary prevention.

Implantation of Pacemakers and Defibrillators

Pacemakers are indicated for complete heart block or sinus node dysfunction with symptomatic bradycardia and hemodynamic decompensation. Children usually require general anesthesia with endotracheal intubation. It should be noted that the anesthetic can be associated with worsening bradycardia. Transthoracic pacing pads are applied before induction of anesthesia, and an isoproterenol (Isuprel) infusion might be required for chronotropic effect. External transthoracic, esophageal or emergent transvenous pacing might be necessary until placement of a permanent pacing device is achieved. In small children the pacemaker generator is typically placed in the upper abdomen, and in older children and teenagers it is placed in the subclavicular region. Epicardial leads are used in small children due to inadequate size of the veins, and in those in whom transvenous access to the heart is impossible (e.g., the Fontan circulation). Epicardial pacemaker placement usually is performed by a cardiac surgeon, with electrophysiologists readily available to program the device. Adequate peripheral venous access is mandatory in the event of

major hemorrhage, and blood should be readily available. A mode of monitoring mechanical capture of electrical pacing activity is also necessary and can include invasive arterial monitoring or pulse plethysmography. Transvenous pacing can be achieved in the operating room with surgical backup or in the cardiac catheterization laboratory by the cardiologists. In the latter situation it is important to address the need for surgical backup during case planning.

AICDs are placed for life-threatening ventricular arrhythmias, which include LQTS, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia. Of note, the device is tested after placement, with induction of ventricular fibrillation. It is absolutely essential to have external modes of defibrillation available, as well as antiarrhythmics such as amiodarone, magnesium, and lidocaine, in the event of device failure. These devices are placed with the patient under general anesthesia with endotracheal intubation and controlled ventilation. Invasive arterial pressure monitoring is typically used. Adequate analgesia can be provided with local infiltration with local anesthetics and short-acting intravenous opioids. Patients are admitted overnight with telemetry monitoring. Appropriate antibiotic therapy is provided for a 24-hour period.

Advances in Resynchronization Therapy

Bundle branch block or interventricular conduction delay often accompanies heart failure as well as some forms of congenital heart disease, either preoperatively or postoperatively, and may result in ventricular dysfunction caused by asynchronous myocardial contraction. Biventricular pacing is an attempt to resynchronize ventricular contraction by pacing both ventricles, thereby improving overall ventricular function. In patients with left bundle branch block, cardiac resynchronization therapy counteracts the underlying electrical and mechanical dyssynchrony, leading to improved contractility, function, exercise tolerance, and quality of life. Multisite pacing has been attempted in pediatric patients.[332] Two atrial and three ventricular epicardial leads were placed at the time of surgery, with the ventricular leads placed as far from one another as possible. Atrial synchronous ventricular pacing was established postoperatively, and the AV interval was adjusted to yield the narrowest QRS complex while simultaneously pacing two ventricular sites. Multisite pacing resulted in significant narrowing of the QRS complex, improved cardiac index, and increased systolic blood pressure overall. Multisite pacing after surgery for congenital heart disease in children may facilitate weaning from inotropic agents, thereby limiting side effects such as increasing myocardial oxygen consumption. There have also been reports of biventricular pacing with improved outcome in infants with dilated cardiomyopathy and complete AV block.[333,334] Long-term improvements need to be studied. Right bundle branch block is a common outcome after surgery for congenital heart lesions. Right ventricular pressure and/or volume loading may also be present, with attendant right ventricular enlargement and dyskinesis. The QRS duration decreased in all patients during dual-chamber pacing. Cardiac index also increased during resynchronization with dual-chamber pacing. The pacing site yielding the narrowest QRS duration also improved the cardiac index the most.[335,336]

Anesthesia for Noncardiac Surgery

Infective Endocarditis Prophylaxis: American Heart Association Guidelines

Guidelines for IE prophylaxis have been updated by the American College of Cardiology and the American Heart Association in 2008. A detailed discussion of the changes is beyond the scope of this chapter.

Procedures for which prophylaxis for infective endocarditis is recommended include the following:[337]

- Dental procedures involving manipulation of the gingival tissue or periapical region of the teeth or involving perforation of the oral mucosa
- Respiratory procedures that involve incision of the respiratory mucosa
- Infected skin, skin structure, or musculoskeletal tissue

Prophylaxis is no longer routinely recommended for gastrointestinal/genitourinary procedures. For elective procedures, coexisting enterococcal urinary tract infections should be treated before genitourinary/gastrointestinal procedures; for emergent procedures, in patients at highest risk of infective endocarditis, prophylaxis can be considered.

Conditions for which prophylaxis is recommended for dental procedures include the following (Table 83-15):

- Prosthetic cardiac valve
- Previous infective endocarditis
- Unrepaired congenital heart disease including palliative shunts/conduits
- Completely repaired congenital heart disease with prosthetic material or device within the first 6 months after the procedure
- Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or device
- Cardiac transplant recipients who develop cardiac valvulopathy

These are guidelines only. The authors' practice at the current time is to consult the child's cardiologist and make a decision based on the child's condition, the operative procedure, risk of bacteremia, and the cardiologist's opinion.

Magnetic Resonance Imaging of the Heart

Apart from the usual considerations of providing general anesthesia in a remote location, when working in a magnetic field necessitating the use of magnet-safe equipment, the anesthesiologist needs to be prepared to provide resuscitative care in these patients. Patients with implanted devices and hardware need to be assessed to ensure magnet compatibility and safety. Generally, pacemakers, implanted defibrillators, and aneurysm clips are contraindications to MRI. Other coils, stents, and surgical clips produce interference and artifact with imaging but do not constitute a

Table 83-15 Infective Endocarditis Prophylaxis

Situation	Drug	Single Dose 30-60 min before Dental Procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin *or*	2 g IM/IV	50 mg/kg IM/IV
	Cefazolin/ceftriaxone	1 g IM/IV	50 mg/kg IM/IV
Allergic to penicillins/oral	Cephalexin *or*	2 g	50 mg/kg IM/IV
	Clindamycin *or*	600 mg	20 mg/kg IM/IV
	Azithromycin/clarithromycin	500 mg	15 mg/kg
Allergic to penicillins/unable to take oral medication	Cefazolin/ceftriaxone *or*	1 g IM/IV	50 mg/kg IM/IV
	Clindamycin	600 mg	20 mg/kg

Vancomycin is an alternative for patients who are unable to tolerate a β-lactam or when the infective agent is considered to be methicillin-resistant *Staphylococcus aureus*.

threat to patient safety. Usually an MR screening form is part of the evaluation and needs to be discussed with the MR technologist/radiologist. In a majority of patients, the scan can be performed as an outpatient procedure. Patients who are younger, uncooperative, or claustrophobic require sedation or general anesthesia. Total intravenous anesthesia can be provided with a propofol infusion and a natural airway, avoiding the need for scavenging and allowing rapid recovery.[338] Anesthesia has been provided with a range of inhalational agents, such as dexmedetomidine, ketamine, and midazolam.[339] In patients in whom breath holding is necessary, or there is a potential for airway compromise, general endotracheal anesthesia with positive-pressure ventilation may be required. Irrespective of technique chosen it is mandatory to maintain continuous monitoring of heart rate, pulse oximetry, capnography, noninvasive blood pressure, and temperature. Supplemental oxygen should be delivered until the patient is fully recovered from the anesthetic. In the event of hemodynamic compromise, the patient needs to be removed from the MR scanner into a safe environment where resuscitation equipment can be safely used. With the development of compatible catheters and devices, MRI will be a useful tool in minimizing x-ray exposure, particularly in patients whose congenital heart disease necessitates numerous catheterization procedures. Razavi and associates have described their experience of MRI used in combination with fluoroscopy to decrease radiation exposure and improve soft tissue visualization during cardiac catheterization of congenital heart disease patients.[340]

Offsite Anesthesia in Cardiac Surgery Patients

Patients with cardiac disease are no different from any other group of patients who require procedures or investigations in areas outside the operating room. As such, anesthesiologists should always be prepared for any eventuality and follow guidelines such as those set out by the American Society of Anesthesiologists.[341] This discussion will exclude those procedures performed in the cardiac catheterization laboratory because this has already been addressed elsewhere. The nature of congenital cardiac surgery will result in a number of patients' requiring emergent chest exploration for ongoing hemorrhage or as part of resuscitation to relieve tamponade or for ECMO placement, all of which may take place in the ICU setting. It is obvious that we cannot predict which patients will have problematic postoperative courses with absolute certainty, but the practitioners who have participated in the operative phase will gain an accurate sense of which patients may require possible further exploration or surgery. Accordingly, it is best to plan ahead, and it cannot be stressed enough that even if as a group of practitioners we are overprepared, this is the best option to have. This being said, it is imperative that the patient have enough blood and blood products available to perform surgery at any given time. Successful treatment of these patients is dependent on a team approach to their care and thus surgeons, anesthesiologists, intensivists, perfusionists, and operating room nurses must be immediately available. When the decision is made to perform a procedure within the ICU, speed of preparation is of the essence. We are fortunate in our practice that we can obtain a set of premade drugs, electrolytes, and infusions within a 15-minute period. Invariably, if a patient is within a few hours' window from returning from the operating room this same set of drugs will have accompanied the patient from the operating room to the ICU and can thus be accessed. Emergent preparation includes ensuring that blood is checked and that a warmer is set up ready for use, emergency drugs are present as mentioned, and the code cart (with internal paddles) is readily available. The blood that will be used for these procedures will include fresh whole blood (<48 hours old and remaining from the operating room) or packed red blood cells, which in our practice is less than 7 days old, or for blood older than this we would prefer it to be washed to avoid the possibility of acute hyperkalemia with transfusion. An anesthesiologist's role here is thus one of facilitation of the entire procedure from sedation of the patient, positioning and preparation, readying the blood, and continuing ongoing volume resuscitation, resuscitative drug use, and airway management.

The premature infant with a patent ductus arteriosus poses an interesting management problem to cardiac surgery teams because frequently these ill neonates are at hospitals remote from major centers where the team is normally assembled. As referenced in an article by Gould and associates, our team has been

performing these ductal ligations with great success at hospitals remote from ours.[298] The philosophy is thus to take the cardiac team to the neonate instead of having these fragile infants transported to us. In this article neonates operated on in our home hospital NICU were used as the controls, and it was found that the success and complication rates were comparable in the two groups. Thus, from an anesthetic perspective we travel with a full complement of airway equipment and drugs as described earlier, with packed red cells being made available at the host hospital. The anesthetic regimen for this procedure comprises a high-dose narcotic, muscle relaxant, antibiotic, and a continuation of any preoperative vasoactive infusions. We have found that this is a stable and well-tolerated anesthetic regimen.

The requirement for anesthesia services is ever-widening and in patients with pediatric heart disease this is also the case. Thus the patients will require radiologic investigations, including computed tomography, MRI, and nuclear medicine scans; interventional radiology procedures; and gastrointestinal procedures, to name a few. Prior to discussion of the patient and the anesthetic it is important for the practitioners to have a thorough knowledge of the environment into which they are taking the patient with regard to magnetic fields, closest code cart, and the ability to get help quickly if needed. Without going into the specifics of every potential clinical scenario, a few basic points are discussed.

As with any anesthetic procedure, a thorough preoperative evaluation is vital. Most patients with pediatric heart disease have long and complex histories, so this assessment should include a detailed description of their cardiac status, including prior surgeries, catheterization findings, and associated conditions (e.g., neurocognitive function, pulmonary status, renal function). Depending on the patient's underlying condition a recent echocardiogram will give very important clinical details related to overall function, valve pathology, presence or absence of intracardiac shunt, patency of surgical shunts, and presence of pericardial fluid. Although this may be ideal, often the echocardiographic examination may be remote from the anesthetic encounter and thus the clinical history and examination are important. The group of heart transplant patients, however, requires an echocardiogram within a short time of the planned procedure because it will give vital information that may indicate worsening function in an otherwise asymptomatic patient. The last point is the nil per mouth period. Many patients in this group have physiology in which dehydration may be very deleterious (e.g., single-ventricle physiology, presence of surgical shunts, unrepaired tetralogy of Fallot). In these patients it is important that the patient stay orally hydrated up to 2 hours before the planned procedure, and if this is not possible, then intravenous fluids must be used. The anesthetic course will be dependent on the duration of the planned procedure, the patient's physiology (i.e., spontaneous versus controlled ventilation), airway management (natural versus laryngeal mask airway versus endotracheal tube airway), anesthetic maintenance, travel to and from the procedural area, and maintenance of the patient's temperature. Before leaving the induction area the anesthetic team must be prepared for airway misadventures and even a code situation; thus, the team must travel with auxiliary airway equipment and resuscitative drugs. The very number of these different venues may make it difficult to have an anesthesia machine present in each; however, an anesthetic cart with additional airway equipment, intravenous materials, and resuscitative drugs should be present. The anesthetic that is delivered may vary among practitioners and institutions, but the common details of importance are a thorough knowledge of the patient and the ability to treat expeditiously should any difficulty ensue in a remote venue.

84 Pediatric and Neonatal Intensive Care

Key Points

1. Critically ill children cared for in pediatric intensive care units have improved outcomes when compared with children treated in intensive care units that do not specialize in the treatment of children.
2. The autonomic nervous system has predominantly a parasympathetic vagal tone at birth and gradually shifts to a sympathetic tone in older children.
3. Because the Frank-Starling mechanism is less effective in the newborn, a greater but not exclusive dependence on heart rate is necessary for maintenance of cardiac output.
4. Improvements in ventilation strategies for children with acute lung injury have led to decreased mortality.
5. Microprocessor technology in ventilators has made volume-preset modes of ventilation possible in babies and small children.
6. A multidisciplinary task force has developed a set of guidelines for the acute medical management of severe traumatic brain injury in infants, children, and adolescents.
7. The leading causes of death in children 1 to 14 years of age are accidents and trauma.
8. Pediatric critical care transport systems not only provide a means of transferring a sick patient to a more appropriate facility but also initiate appropriate intensive care monitoring and treatment of the patient before leaving the referring hospital.
9. Mortality from sudden infant death syndrome dropped threefold with institution of the "Back to Sleep" campaign.
10. Pediatric cardiopulmonary arrest is usually manifested initially as respiratory compromise or arrest, followed by secondary cardiac arrest.

Pediatric intensive care requires surveillance, evaluation, and support of vital systems in infants and children who have acute, often reversible, life-threatening disease. In contrast to adults, fewer children who require pediatric intensive care suffer from chronic or degenerative organ system disorders. Most children have a potentially reversible life-threatening illness or injury that if successfully treated, will restore the child to a normal, productive life.[1]

The principles of intensive care for children are similar to those for adults. However, the spectrum of ages (infancy through adolescence) requires that the staff have special expertise in developmental physiology and psychology. All critically ill children, regardless of diagnosis or subspecialty category, should be treated in units dedicated to children. Specific guidelines describing minimum criteria for pediatric intensive care units (PICUs) and services have been published.[2]

When patients are cared for in PICUs, mortality is lower than it is when children are cared for in nonpediatric intensive care units (ICUs).[3] Hospitals without specialized facilities for pediatric intensive care should seriously consider transferring critically ill children to a regional PICU. Regional PICUs must have transport systems that facilitate the safe and timely transport of critically ill children to the referral center and must develop educational programs in emergency and critical care pediatrics for primary care and referring physicians and nurses.[4]

Organization of the Pediatric Intensive Care Unit

Medical and nursing directors, hospital administrators, and representatives from pediatric medicine, anesthesia, surgery, and the pediatric subspecialties should be responsible for policy and procedures pertaining to the PICU and should make recommendations regarding personnel staffing, equipment purchases, and structural and design changes within the unit.

The medical director oversees the quality of patient care, patient triage, implementation of policy and procedures, in-

service education, and coordination of consultants. Physician coverage should be full-time geographic at the resident, fellow, and attending staff level and should include in-house, full-time coverage at night.

The nursing director should have special skills in pediatric intensive care, education, and personnel management. The nursing staff must be trained in all aspects of pediatric critical care and resuscitation. Staffing should be flexible enough to provide one-on-one patient care when necessary. A multidisciplinary in-service program is essential for continuing education and orientation.

Other team members include respiratory therapists, physical therapists, nutritionists, social workers, laboratory technologists, pharmacists, and psychiatrists and psychologists for the patients and staff. All medical and support personnel should be encouraged to participate in rounds, educational endeavors, and team meetings whenever possible.

There must be adequate work space around each bed and enough storage space to keep life support equipment within reach. Space for reading, meeting, sleeping, and showering should be available for the staff. Space should be provided for parents to remain with their children during the day and for parents to sleep overnight. Parents should be encouraged to participate as much as possible in the care of their child.

Each bed space should be standardized so that it can be used to provide any level of care. Private rooms are ideal, but if shared rooms are necessary, the distance between beds must be adequate to ensure privacy and minimize nosocomial infection. Isolation rooms should be available within the confines of the unit.

Devices for diversion and entertainment should be available for conscious children. Television and computer games are often better than heavy sedation.[5,6] Adequate nurses and nursing involvement at the bedside will prevent potentially life-threatening events. Because sick children require close personal observation, centrally monitored nursing stations have little place in the PICU.

Cardiovascular System

Circulation

Infants and children continually undergo structural and functional maturational changes (see Chapter 82). Understanding these age-dependent processes is essential for the diagnosis and treatment of circulatory failure in young children.

Structural and Functional Development

The shape of the heart is complete by 6 weeks' gestation, but myofibrillar density and maturation increase through the first year of postnatal life. During this time, myocytes engage in rapid protein synthesis and rapid cell growth, which requires a high intracellular concentration of nuclei, mitochondria, and endoplasmic reticulum. The greater number of nonelastic and noncontractile elements makes the neonatal myocardium less compliant and it contracts less efficiently than the adult myocardium. In the fetus and newborn, the decreased ventricular compliance causes small changes in end-diastolic volume to induce large changes in end-diastolic pressure. In addition, augmentation of stroke volume by the Frank-Starling mechanism is less effective in young children. The newborn is more dependent on heart rate for maintenance of cardiac output.[7,8] Cardiac output increases only about 15% with volume loading; it increases much more by increasing the heart rate.[9]

Development of the Circulation

The adult and fetal circulation differs in many ways. The fetal circulation is distinguished by (1) the placenta as the organ of respiration, (2) high pulmonary vascular resistance (PVR), (3) low systemic vascular resistance (SVR), and (4) fetal ventricles that pump in parallel with right ventricular dominance. While the fetus lives in a low oxygen environment, the oxygen content of the blood of the fetus is similar to that of adults (20 mL of oxygen/100 mL of blood) because of a higher concentration of hemoglobin that has high affinity for oxygen. The neonatal circulation has several shunts—the ductus arteriosus, ductus venosus, and foramen ovale—that direct more oxygenated blood to the brain and heart and bypass the lungs. Changes then occur that allow the parallel circulation of the fetus to convert to the series circulation of the adult:

1. With the first breath, expansion of the lung, increased alveolar oxygen, an increase in pH, and neurohumoral mediators and nitric oxide (NO) relax the pulmonary vasoconstriction.[10,11]
2. When the placenta separates from the uterine wall, the placental blood vessels constrict, and SVR and left ventricular afterload increase. The decrease in PVR plus increase in SVR raises left atrial pressure above right atrial pressure and functionally closes the "flap valve" of the foramen ovale. The foramen ovale may not close anatomically for months to years, if ever. It is patent in at least 15% of adults.[12,13]
3. The decrease in PVR causes flow through the ductus arteriosus to reverse. This exposes the ductus to oxygenated systemic arterial blood, which along with the rapid decrease in prostaglandin E_2 (PGE_2) after birth, closes the ductus. Anatomic closure of the ductus requires several weeks.[14]
4. The ductus venosus closes passively with removal of the placental circulation and readjustment of portal pressure relative to inferior vena cava pressure.
5. There is a further gradual decline in PVR secondary to structural remodeling of the muscular layer of the pulmonary blood vessels. During fetal life, the central pulmonary vascular bed has a relatively thick muscle layer. After birth, the muscle coat thins and extends to the periphery of the lung, a process that takes months to years to complete.[15]

Development of Autonomic Control of the Circulation

The functional integrity of autonomic circulatory control during fetal and perinatal development is still a matter of considerable speculation. The fetal heart has reduced catecholamine stores and increased sensitivity to exogenously administered norepinephrine.

Adrenergic innervation of the human myocardium is complete between 18 and 28 weeks' gestation. Human newborns have low cardiac stores of norepinephrine and decreased numbers of sympathetic nerves after birth. Adrenergic responses are apparently present but diminished in newborn humans.

Table 84-1 Age-Related Circulatory Variables

Age	Heart Rate (Beats/min)	Systolic Blood Presssure (mm Hg)	Diastolic Blood Pressure (mm Hg)	Stroke Volume (mL/Beat)	Cardiac Index (L/min/m^2)	Oxygen Consumption (mL/kg/min)	Hemoglobin Concentration (g/dL)	P_{50} (mm Hg)
Term newborn	133 ± 18	80 ± 16	46 ± 16	4.5 ± 5.0	2.5 ± 0.6	6.0 ± 1.0	16.5 ± 1.5	18
6 mo	120 ± 20	89 ± 29	60 ± 10	7.4 ± 2.0	2.0 ± 0.5	5.0 ± 0.9	11.5 ± 1.0	24
12 mo	120 ± 20	96 ± 30	66 ± 25	11.5 ± 3.0	2.5 ± 0.6	5.2 ± 0.9	12.0 ± 0.75	—
2 yr	105 ± 25	99 ± 25	64 ± 25	16.9 ± 4.5	3.1 ± 0.7	6.4 ± 1.2	12.5 ± 0.5	27
5 yr	90 ± 10	94 ± 14	55 ± 9	27.8 ± 7.5	3.7 ± 0.9	6.0 ± 1.1	12.5 ± 0.5	—
12 yr	70 ± 17	113 ± 18	59 ± 10	53.5 ± 14.5	4.3 ± 1.1	3.3 ± 0.6	13.5 ± 1.0	—
Adult	75 ± 5	—	—	85.5 ± 6.0	3.7 ± 0.3	3.4 ± 0.6	14.0 ± 1.0	27

P_{50}, oxygen half-saturation pressure of hemoglobin.
From Crone RK: Pediatric Intensive Care. ASA Refresher Courses in Anesthesiology, vol 9. Philadelphia, JB Lippincott, 1981.

In human neonates, the cholinergic system is completely developed at birth, and the heart is sensitive to vagal stimulation. Bradycardia is the probable response to an increase in autonomic tone.

The baroreceptor reflex is present, but incompletely developed at term in humans. In preterm infants, postural changes elicit no change in heart rate, suggesting an incomplete or attenuated baroreceptor response.[16] The chemoreceptor response is well developed in utero. The fetal bradycardia that occurs in response to hypoxia is thought to be mediated through chemoreceptors and may be similar to the oxygen-conserving mechanisms of diving animals.[17]

Myocardial Metabolism

Fetal myocardial metabolism differs from that of adults. Relative "hypoxia" is normal in utero, and infant hearts tolerate hypoxia better than the hearts of adults do. This difference may be due in part to high concentrations of glycogen in fetal myocardial tissue and to the ability to more effectively use anaerobic metabolism.[18] Because of the high glycogen stores and the ability to use anaerobic metabolism efficiently, the fetal/newborn heart is relatively resistant to hypoxia and can be resuscitated more easily if oxygenation and perfusion are reestablished reasonably quickly.

Oxygen consumption increases precipitously after birth, presumably because neonates are required to maintain their own temperature. A full-term infant's oxygen consumption in a neutral thermal environment is approximately 6 mL/kg/min; it increases to 7 and 8 mL/kg/min at 10 days and 4 weeks, respectively.

Age-Related Circulatory Variables

Common Cardiovascular Disease States

Congenital Heart Disease

Congenital heart disease causes significant alterations in oxygenation, perfusion, and myocardial function after birth (Table 84-1; also see Chapter 83). These abnormalities can be divided into hypoxic and normoxic lesions. The latter include obstructive lesions of the left side of the heart (mitral valve stenosis, aortic valve stenosis, aortic stenosis, anomalous pulmonary venous return, ventricular septal defect, or patient ductus arteriosus with a right-to-left shunt), whereas hypoxic lesions include tricuspid valve stenosis, pulmonary valve stenosis, pulmonary artery stenosis or aplasia, and the tetralogy of Fallot. Right-sided lesions cause hypoxia if the left-to-right shunting of blood is sufficient to cause congestive heart failure (CHF) and pulmonary edema.

Newborns with significant congenital heart disease commonly have either cyanosis or CHF. The degree of dysfunction usually changes during the first few months of life as PVR decreases to adult levels. As PVR decreases, left-to-right shunting of blood usually increases, and the symptoms of CHF become more apparent. Many neonates with a significant ventricular septal defect have no left-to-right shunting for several weeks after birth; however, induction of alkalosis during surgery can increase shunting. In the newborn, the usual signs and symptoms of CHF include poor feeding, irritability, sweating, tachycardia, tachypnea, decreased peripheral pulses, poor cutaneous perfusion, and hepatomegaly. Many patients with pulmonary edema exhibit tachypnea without retractions. Cyanosis occurs with structural cardiac disease, but other causes such as respiratory disease, increased PVR (persistent pulmonary hypertension), and methemoglobinemia must also be considered (Box 84-1).

Box 84-1 Common Congenital Heart Lesions in the Newborn

Cyanotic congenital heart lesions
- Tetralogy of Fallot
- Transposition of the great arteries
- Hypoplastic left heart syndrome
- Pulmonary atresia with an intact ventricular septum
- Single ventricle
- Total anomalous pulmonary venous return
- Tricuspid atresia

Congenital heart lesions manifested as congestive heart failure
- Ventricular septal defect
- Patent ductus arteriosus
- Hypoplastic left heart syndrome
- Critical aortic stenosis
- Coarctation of the aorta

Congenital heart disease is diagnosed by physical examination, electrocardiogram (ECG), chest radiograph, and echocardiogram. Cardiac catheterization is occasionally performed as interventional therapy or as a diagnostic tool. Magnetic resonance imaging (MRI) is used to define the anatomy of congenital heart lesions before cardiac surgery.

Initial treatment of congenital heart disease is aimed at relieving CHF, improving systemic perfusion, and improving or maintaining pulmonary blood flow. The ductus arteriosus must be maintained open in instances of hypoplastic left heart syndrome, aortic stenosis or atresia, interrupted aortic arch, and symptomatic neonatal coarctation of the aorta. In many cases, infusion of PGE_1 sustains life until definitive surgical correction can be performed.[19]

Acute Circulatory Failure in Children

Acute circulatory failure is defined as insufficient systemic blood flow to meet the metabolic demands of the body.[20] The clinical syndrome of shock includes the signs and symptoms of both an inadequate circulation and an attempt by the patient to compensate for the circulatory failure. Children compensate for inadequate circulation by releasing endogenous catecholamine and increasing peripheral autonomic tone. The earliest signs of shock include anxiety or irritability, cool and pale extremities, and unexplained tachycardia. Tachypnea, moderate metabolic acidosis, oliguria, and somnolence are signs of inadequate tissue perfusion. Obtundation, periodic breathing, and apnea are signs of impending cardiopulmonary arrest. Arterial blood pressure is seldom a good indicator of the adequacy of perfusion in children because the pressure decreases late in the course of the disease. The child's ability to vasoconstrict is so effective that central blood pressure may remain normal despite impending circulatory collapse. Circulatory failure may be caused by pump failure, intravascular hypovolemia, hypoglycemia, and hypocalcemia. Hypovolemia is the result of either volume loss (blood, plasma, water) or an alteration in SVR (Table 84-2).

Hypovolemia is the most common cause of circulatory failure in children. These children have decreased ventricular preload, reduced stroke volume, and reduced cardiac output. Acute hypovolemia is caused by blood loss (trauma, gastrointestinal [GI] bleeding), plasma loss (capillary leak syndrome, hypoproteinemia, burns, peritonitis), and water loss (vomiting and diarrhea, glycosuric diuresis from diabetic ketoacidosis [DKA]). Children with acute hypovolemia have marked peripheral vasoconstriction and cool, poorly perfused extremities. Peripheral pulses may be thready, and the capillary refill time is prolonged unless the child has a fever.

Inadequate intravascular volume can also be caused by anaphylaxis, septic or endotoxic shock, spinal cord injury, or the ingestion of vasodilating drugs. In the case of vasodilation, peripheral perfusion is usually maintained (despite the presence of hypotension), and the extremities remain warm.[20,21]

Cardiogenic shock is relatively uncommon in pediatric patients. When it does occur, the usual causes are congenital heart disease with outflow obstruction or systemic-to-pulmonary shunting in neoates, although it might also occur as a result of viral or bacterial sepsis. In any child, extrinsic inflow or outflow obstruction (tension pneumothorax, hemopericardium, pneumopericardium, pericardial effusion) must be considered. Finally, viral or infiltrative cardiomyopathies, collagen vascular or Kawasaki's disease, and metabolic derangements such as hypoglycemia, sepsis, or uremia can produce circulatory failure and primary pump failure.[22-24] Arrhythmias, such as paroxysmal atrial tachycardia or atrioventricular (AV) block, can also precipitate circulatory failure in children.

Treatment The cause of shock can frequently be identified from the history and physical examination. Immediate therapy includes assessment of the airway, administration of oxygen, establishment of an airway (if necessary), and adequate ventilation. Vascular access must be obtained early and be of sufficient size to rapidly administer fluids if necessary. Percutaneous peripheral venous cannulation may be difficult because of peripheral vasoconstriction. The intraosseous (IO) route is used for fluid and drug administration if venous access cannot be obtained quickly.[25] A short-beveled trocar needle is used to place an IO line into the proximal third of the tibia (Fig. 84-1) or the distal end of the femur after approprialte sterilzation of the skin. IO needles, 18-gauge spinal needles, and bone marrow aspirate needles work well for this purpose. The needle must not be placed into the epiphysis. When the IO needle is properly positioned, its shaft is anchored in the bone cortex and the tip of the needle is in the marrow cavity. The cortex supports the needle. Blood and bone spicules can be aspirated, and infusion of fluid is easy. There is no distortion of the soft tissues of the leg with fluid injections. IO lines are effective for obtaining blood samples, delivering fluids, and administering the resuscitation medications traditionally

Table 84-2 Circulatory Failure: Hypotension

Low Central Venous Pressure: Intravascular Hypovolemia		
Vasoconstriction: Loss of Volume	**Vasodilation: Loss of Resistance**	**Normal or High Central Venous Pressure: Cardiogenic**
Blood loss	Anaphylaxis	Pump failure
Plasma loss	Sepsis	Shunting
Extracellular fluid loss	Drug intoxication	Outflow, inflow obstruction Arrhythmias

Modified from Crone RK: Acute circulatory failure in children. Pediatr Clin North Am 27:525, 1980.

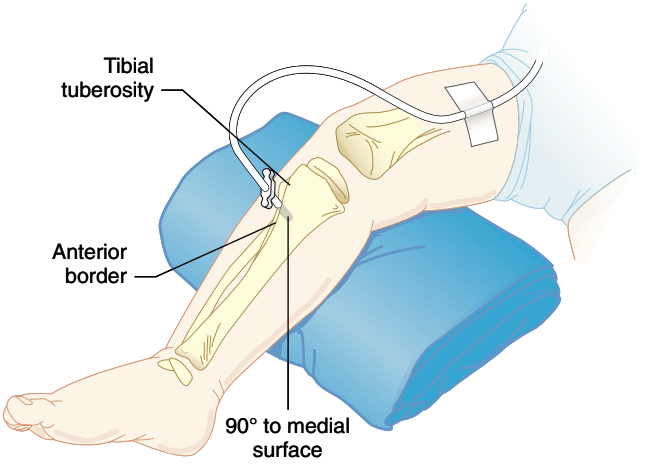

Figure 84-1 Intraosseous cannulation technique.

given intravenously. Standard intravenous access should be achieved as soon as possible because osteomyelitis can occur. Percutaneous cannulation of the jugular[26,27] and subclavian veins is relatively easy but carries a slight risk of carotid puncture, hemothorax, pneumothorax, or perforation of the superior vena cava or right atrium. The smaller size of the child increases the risk associated with cannulating any vessel.

Treatment of circulatory failure includes improving cardiac output and normalizing peripheral organ perfusion. Cardiac output is the result of heart rate and stroke volume, and an increase in either is usually beneficial. If tachycardia is not present, the heart rate may be increased by vagolysis or by α-adrenergic stimulation (positive chronotropy). Atropine (0.02 mg/kg—up to 1 mg), isoproterenol, and epinephrine are the most commonly used drugs for this purpose. In children, a 30% to 50% increase in heart rate above control is well tolerated and usually increases cardiac output substantially.[8] Stroke volume can be augmented by increasing preload, decreasing afterload, improving contractility, or a combination of these therapies.

Because most children in shock are hypovolemic, preload augmentation with an isotonic crystalloid or colloid solution is generally effective. A good starting point is 20 mL/kg given over a period of 2 to 10 minutes. The bolus should be repeated until perfusion improves or 60 mL/kg has been infused. If no improvement has occurred with this volume, other causes of shock should be sought, including ongoing losses, myocardial dysfunction, sepsis, anaphylaxis, and others.[20,21] Intravascular volume is assessed by physical examination, chest radiography, echocardiography, and the use of central venous pressure (CVP) and arterial catheters.

Echocardiography is rapid and noninvasive, but it requires the immediate availability of sophisticated equipment and personnel skilled in interpreting pediatric echocardiograms. Structural cardiac abnormalities can be ruled out and myocardial function may be qualitatively assessed.[28] Hypovolemia can also be diagnosed by echocardiography.[29] Most infants and children who need ongoing assessment and cardiovascular support require a central venous catheter for volume administration and measurement of CVP. Although a CVP of 5 cm H_2O is a reasonable estimate of adequate intravascular volume, there is no single optimal number for CVP. Several extracardiac factors, including lung compliance, the level of positive end-expiratory pressure (PEEP), peak inspiratory pressure, and increasing abdominal pressure, affect CVP or right ventricular filling pressure; thus, each patient's optimal CVP may differ considerably. If there is no improvement in blood pressure, cutaneous perfusion, or urine output with adequate CVP, cardiogenic causes of circulatory failure must be sought. Arterial blood gases (ABGs), hematocrit, serum electrolytes, glucose, and calcium concentrations should be determined. Correction of acidosis, hypoxemia, or other metabolic derangements is essential. Blood and other appropriate sites must be cultured and broad-spectrum parenteral antibiotics must be administered if sepsis is a possibility. Urine output in excess of 1 mL/kg/hr usually indicates adequate renal blood flow and cardiac output. Patients whose urine output is less than 0.5 mL/kg/hr should be evaluated for circulatory failure, renal failure, and obstruction to urine flow.

Myocardial contractility can be improved by correcting hypoxia, acidosis, and hypoglycemia and by administering positive inotropic agents, such as sympathomimetic amines (β-agonists), xanthines, and cardiac glycosides.

Pulmonary artery catheters are used less frequently in children than in adults because these catheters are often too large for the size of the pulmonary artery, especially in infants. Most conditions causing circulatory failure in children are associated with biventricular failure, not left ventricular failure, as occurs in adults. Consequently, left ventricular filling pressure reflects right atrial pressure, and CVP is an adequate indicator of left- and right-sided filling pressure. The pulmonary artery catheter, if used, allows the ICU team to continuously measure pulmonary artery pressure and intermittently measure cardiac output.[30,31]

Afterload reduction is often indicated when "pump failure" coexists with an elevated SVR.[32] The decrease in SVR permits the ventricle to pump more efficiently, increases stroke volume, and improves tissue perfusion. Afterload reduction is induced with a direct vasodilator (sodium nitroprusside), a β-agonist (isoproterenol), a phosphodiesterase III inhibitor (milrinone), or an α-antagonist (phentolamine or tolazoline). The effects of afterload reduction are often unpredictable. If the associated hypotension sufficently reduces coronary perfusion, cardiac efficiency may be reduced rather than improved. Vasoconstricting agents (phenylephrine or norepinephrine) must be available for immediate treatment of severe hypotension.

Vasoconstriction is instituted when anaphylaxis and warm septic shock cause inappropriate vasodilation.[20] Vasoconstricting drugs increase myocardial work and oxygen consumption and may worsen existing myocardial decompensation.

Cardiovascular Pharmacology in Children

Pharmacologic support of the circulation includes positive inotropic and chronotropic agents, vasoconstrictors and vasodilators (afterload reduction), and antiarrhythmics (see Chapters 12 and 82). Most currently used drugs have not been adequately tested in children, so dosage recommendations and anticipated effects must be extrapolated from adult doses and clinical experience.

Positive inotropic drugs are used to augment the cardiac output of patients with circulatory failure. Most inotropic agents also affect the heart rate and vasomotor tone. Tachycardia in a child is usually well tolerated and is frequently beneficial.[20] In a neonate whose ventricles are relatively noncompliant and whose stroke volume is less variable, tachycardia is an important means of augmenting cardiac output. Because drugs that increase the heart rate or contractility also increase myocardial oxygen consumption, adequate arterial oxygenation and sufficient metabolic substrates are required when these drugs are administered. The cardiovascular response to sympathomimetic amines is attenuated in the presence of severe acidosis and possibly sepsis; higher infusion rates of these drugs are required and need readjustment as the acidosis improves. Commonly used inotropes are listed in Table 84-3. Brief comments regarding their use in pediatric intensive care are provided in the following paragraphs.

Epinephrine

Epinephrine has become the first choice for the treatment of hypotension of many causes because of its cardiac stimulatory effects.

Dopamine

Dopamine is the most commonly infused inotrope in pediatric patients. Its effects are dose dependent, with dopaminergic activity at low doses, β-adrenergic activity with intermediate doses, and some α-adrenergic activity at higher doses. Young children

Table 84-3 Vasoactive and Inotropic Agents in Pediatrics

Drug	Effect	Dose*	Inotropy	Chronotropy	Vasodilation	Vasoconstriction
Epinephrine (Adrenalin)	α, β	0.05-2.0	++	++		++
Isoproterenol (Isuprel)	β_1, β_2	0.05-2.0	++	++	+	
Dopamine (Inotropin)	δ β > α β, α	1-3 5-15 >15	 + +	 + +	+Renal splanchnic	 +/– +
Milrinone		Bolus: 50 μg/kg over 10-min period Infusion: 0.375-0.75	+		+	
Norepinephrine	α >> β	0.05-1.0	sl+	+		++
Nitroprusside		0.5-10			++ Arterial > venous	
Nitroglycerin		1-20			++	

*All infusions are μg/kg/min.
sl, slight.

require higher doses of dopamine than adults do to produce the same effect. In one study, an infusion of 15 μg/kg/min was required to increase cardiac output above control levels after cardiac surgery.[33] This may reflect the decreased releasable myocardial stores of norepinephrine in immature ventricles.

Isoproterenol

Isoproterenol is a pure β-agonist with strong chronotropic effects and is usually well tolerated in children. However, high doses of isoproterenol can cause myocardia ischemia.[34] Isoproterenol also induces vasodilation that is responsive to acute volume administration.

Dobutamine

Dobutamine provides positive inotropy and afterload reduction. In children but not in adults it causes tachycardia.[35,36]

Norepinephrine

Norepinephrine, a drug with α- and β-agonist effects, has had a resurgence of use in infants and children.[37] Children with nearly normal cardiac function and marked peripheral vasodilation have good responses to this drug. It is expecially useful in instances of warm septic shock, anaphylaxis, liver failure, and sympathetic blockade with regional anesthesia.

Milrinone

Milrinone is a phosphodiesterase III inhibitor that increases cyclic adenosine monophosphate. Its has both inotropic and vasodilator effects. This drug has improved the outcome of children who have low cardiac output syndrome after cardiac surgery.[38] The loading dose of milrinone is 25 to 75 μg/kg administered over a period of 10 minutes; the maintenance infusion rate is 0.25 to 0.75 μg/kg/min. Hypotension and tachycardia occur primarily with the loading dose of the drug and generally respond to an infusion of fluid. Renal failure significantly increases the elimination half-life of this drug.[39-41]

Digitalis

Digitalis is useful for the long-term treatment of myocardial failure in children but may not be effective in neonates.[42] Because of its long half-life and unpredictability, digitalis should be administered cautiously to children who have changing levels of serum potassium, calcium, and pH. In these cases, it is more appropriate to use rapid-acting, titratable inotropic agents.

Calcium

When serum ionized calcium levels are below normal, administration of calcium produces a positive inotropic effect. If the patient's ionized calcium levels are normal, less marked inotropic effects occur. Low ionized calcium levels most commonly occur in patients with DiGeorge's syndrome, when large volumes of citrate-containing blood products are rapid administered, and in neonates with relatively unstable calcium metabolism. Calcium also has effects on the cardiac conduction system. Rapid administration of calcium can cause severe bradycardia or asystole. This effect may be exaggerated in hypokalemic children or in those receiving digitalis. The vasomotor effects of calcium are controversial, but most reports show an increase in both SVR and PVR when the drug is administered.[43]

Bicarbonate Therapy

Severe acidosis decreases myocardial function and tissue perfusion. Correction of acidosis with 1 to 2 mEq/kg of sodium bicarbonate is indicated for a pH below 7.20 if ventilation is adequate (P_{CO_2} <40 mm Hg if possible). Treatment is necessary because the circulatory system is refractory to sympathomimetic amines when the pH is less than 7.00. After initial correction of pH, persistence or reappearance of metabolic acidosis suggests a continuing underperfused state and the need for further therapy. Administration of sodium bicarbonate is only a stopgap measure to improve the response to drugs. Repeat infusions of sodium bicarbonate can cause hypernatremia and hyperosmolarity. Every 50 mEq of bicarbonate administered produces 1250 mL of CO_2 when the bicarbonate is fully reacted with acid. Consequently, adequate ventilation must be ensured while the drug is administered to avoid worsening the acidosis. Trishydroxymethylaminomethane (THAM) is an alternative to sodium bicarbonate, but larger volumes of THAM are required to produce the same amount of acid-base correction, which may be a problem in patients who have CHF. THAM does not increase P_{aCO_2}.

Vasodilators

Vasodilators are used to control systemic hypertension, increase cardiac output by decreasing afterload, control pulmonary hypertension, and control cardiac shunting. Vasodilators are effective treatment of systemic hypertension and increase cardiac output in children with CHF. Treatment of pulmonary hypertension and intracardiac shunting with vasodilators has met with limited success because they decrease both PVR and SVR, which may increase extrapulmonary right-to-right shunting and further reduce pulmonary blood flow.

Sodium Nitroprusside Sodium nitroprusside relaxes arteriolar and venous smooth muscle, which decreases afterload and preload. The half-life of sodium nitroprusside is only minutes, making it safe to titrate the drug to a desired effect. Nitroprusside is commonly used to control severe systemic hypertension, to provide controlled hypotension to reduce blood loss, and to increase cardiac output in children with low cardiac output syndromes (myocarditis, post–cardiac surgery status).[44] Sodium nitroprusside can generally be used for days without problems, although cyanide and thiocyanate poisoning develops in some children, especially those with renal failure or reduced renal perfusion. Serum thiocyanate levels of 10 mg/dL are associated with weakness, hypoxia, nausea, muscle spasms, and disorientation. When these symptoms occur, nitroprusside administraton should be discontinued immediately.

Nitroglycerin Intravenous nitroglycerin has effects similar to those of sodium nitroprusside, except that nitroglycerin has more effect on venous capacitance than on the arterial bed.

Hydralazine Hydralazine is used to control systemic hypertension because it relaxes arterial smooth muscle more than it relaxes veins. Administration of the drug can cause headache, nausea, dizziness, sweating, and tremors. The most important acute side effect is tachycardia, which may increase cardiac output; labetalol, a β-antagonist, can counteract this effect.[45]

Tolazoline and Phentolamine These competitive α-adrenergic blockers have had varied success in the treatment of pulmonary hypertension.[46] However, they are effective in treating the symptoms of pheochromocytoma preoperatively. Serious side effects of these drugs include tachycardia, ventricular arrhythmias, hypotension, and tissue edema.

Prostaglandin E_1 PGE_1 acts directly on vascular smooth muscle and has greatly improved the care of neonates with heart disease. At infusion rates of of 0.1 µg/kg/min, patency of the ductus arteriosus is maintained and a closed ductus reopens in some neonates. The drug is indispensable in the care of patients with ductus-dependent cardiac lesions, such as interrupted aortic arch, critical aortic stenosis, or hypoplastic left heart syndrome, where systemic blood flow is supplied through the ductus arteriosus. It is equally important for the care of patients who have pulmonary atresia or critical pulmonic stenosis.[19] PGE_1 has been used with varying degrees of success to treat pulmonary hypertension. Apnea, fever, and hypotension are common side effects of this drug.

Nitric Oxide NO is an endothelium-derived relaxing factor that selectively vasodilates the pulmonary vasculature.[47] When administered by inhalation to patients with pulmonary hypertension, NO reduces PVR. It improves the survival of neonates who have reactive pulmonary hypertension.[48-50] This compound is inactivated by hemoglobin before it reaches the systemic circulation. On rare occasion, NO causes systemic vasodilation or clinically significant methemoglobinemia when administered at 5 to 80 ppm.[49]

Sildenafil Sildenafil is a pulmonary vasodilator that increases intracellular cyclic guanosine monophosphate. The drug can be administered orally or intravenously to outpatients. Because it appears to treat pulmonary hypertension of several causes, it will potentially be a treatment of choice in the future.

Arrhythmias

Arrhythmias occur less commonly in children than in adults, probably because children do not have atherosclerosis. However, a few arrhythmias commonly occur in infants and children and must be considered.

Sinus bradycardia is the most common arrythmia in children and is frequently caused by hypoxemia. Hence, an open airway, oxygen, and ventilation are the treatments of choice. If such treatment does not increase the heart rate, atropine, 20 to 30 µg/kg (up to 1 mg), should be given. Heart block is a common form of bradycardia that occurs in children who have undergone surgical repair of congenital heart lesions. If heart block persists for more than 2 weeks after surgery, insertion of a pacemaker is indicated. Connective tissue disease, such as systemic lupus erythematosus, has induced heart block in utero.

Sick sinus syndrome is usually due to surgery, myocarditis, or myocardiopathy. Prolonged QT syndrome, an abnormality in ventricular repolarization, is a familial disorder that can cause sudden cardiac death. Supraventricular tachycardia (SVT), a narrow QRS complex with a regular R-R interval, is also a common arrhythmia of childhood. In infants and neonates, the heart rate may be 200 to 300 beats/min, and in older children it can be 150 to 250 beats/min. Older patients with SVT frequently complain of palpitations or a racing heart rate and seek medical care before CHF occurs. In contrast, younger nonverbal children are often initially seen with CHF. Treatment of SVT includes vagal maneuvers, adenosine by rapid intravenous bolus (0.1 to 0.2 mg/kg, with a maximum single dose of 12 mg), and direct-current cardioversion (0.25 to 1 J/kg).[51,52]

Hypertension

Essential hypertension is uncommon in children, but when it occurs, it is often associated with another disease process (Box 84-2) and is frequently difficult to control. The acute onset of severe systemic arterial hypertension is a medical emergency that has the potential of causing cardiovascular decompensation, encephalopathy, seizures, and intracranial hemorrhage. In older children, the neurologic manifestations of hypertension are more likely to precede cardiovascular decompensation. Neonates with severe hypertension are frequently initially found to have CHF. Treatment of hypertension is tailored to the disease process, the absolute degree of hypertension, and the presence of cardiovascular or neurologic symptoms.[53,54]

Classes of antihypertensive drugs are listed in Box 84-3. If malignant hypertension is the admitting diagnosis, close cardiac monitoring and insertion of an arterial line in an ICU are required. In emergency situations, diazoxide is often the drug of choice. This potent vasodilator rapidly reduces blood pressure, but its short half-life necessitates administering another drug with a longer duration of action. Nitroprusside infusions are also useful in the acute setting.

Box 84-2 Causes of Severe Hypertension in Children

Renal
Acute glomerulonephritis (e.g., poststreptococcal, Henoch-Schönlein purpura)
Hemolytic-uremic syndrome
Chronic glomerulonephritis (all types)
Acute and chronic pyelonephritis
Congenital malformations (dysplasia, hypoplasia, cystic diseases)
Tumors (e.g., Wilms', leukemic infiltrate)
Post–renal transplantation status; also rejection
Oliguric renal failure
Trauma
Obstructive uropathy
After genitourinary surgery
Blood transfusions in children with azotemia

Cardiovascular
Coarctation of the aorta
Renal artery abnormalities (e.g., stenosis, thrombosis)
Takayasu's disease

Endocrine
Pheochromocytoma
Neuroblastoma
Adrenogenital disease
Cushing's syndrome
Hyperaldosteronism
Hyperthyroidism
Hyperparathyroidism

Iatrogenic
Intravascular volume overload
Administration of sympathomimetic drugs (e.g., epinephrine, ephedrine)
Administration of corticosteroid
Rapid intravenous infusion of methyldopa

Miscellaneous
Immobilization (e.g., fractures, burns, Guillain-Barré syndrome)
Hypercalcemia (e.g., hypervitaminosis D, metastatic disease, sarcoidosis, some immobilized patients)
Hypernatremia
Stevens-Johnson syndrome
Increased intracranial pressure (any cause)
Dysautonomia
After resuscitation

Specific Pediatric Diseases

Kawasaki Disease

Kawasaki disease (mucocutaneous lymph node syndrome) occurs primarily in children 4 years of age or older. The disease is divided into three stages: an acute febrile stage (1 to 2 weeks), a subacute phase, and finally, the convalescent stage (typically 6 weeks after onset). The cause is uncertain, but it is presumed to be infectious.

Although the disease affects many organ systems, cardiovascular involvement is the usual cause of ICU admission. Forty percent of patients with this disease have myocarditis, pericardial effusions, arrhythmias, or any combination of these findings. Coronary aneurysms, with and without thrombosis, develop in 20% of cases. Acute myocardial infarction is responsible for the death of 3% to 4% of patients.

Laboratory tests reveal an elevated leukocyte count with a left shift, increased acute-phase reactants, and a platelet count that is often grossly elevated after the first few weeks of the disease. An echocardiogram is required for any child with this presumed diagnosis.

Treatment includes high-dose aspirin (20 to 25 mg/kg every 6 hours) and intravenous gamma globulin, 2 g/kg administered as a 10- to 12-hour infusion. Some patients require inotropic support. There is considerable controversy about whether children with thrombosed coronary arteries should receive anticoagulants. Survivors frequently resolve their aneurysms, although some require coronary artery bypass surgery to provide adequate myocardial blood flow.[55,56]

Box 84-3 Antihypertensive Medications

Converting enzyme inhibitors to decrease angiotensin II
  Caution in the face of renovascular disease
    Captopril
    Enalapril
Calcium channel blockers, usually type II blockers
  Caution: Myocardial decompensation
    Nifedipine
    Nimodipine
Diuretics, usually as an adjunct
β-Adrenergic blockers
  Caution: Reactive airway disease
    Propranolol
    Esmolol
α_2-Antagonist
  Prazosin
Central α-agonist
  Clonidine
α- and β-adrenergic blocker
  Labetalol
Dilators
  Hydralazine
  Diazoxide

Anomalous Origin of Coronary Arteries

Vascular causes of myocardial ischemia are uncommon in pediatric patients. An anomalous origin of the left coronary artery in which the coronary artery originates from the pulmonary artery occurs in 1 in 300,000 births. During the first weeks or months of life, coronary perfusion may be adequate because PVR is elevated. As PVR decreases, however, coronary perfusion may decrease. By 6 weeks of life, these infants usually have overwhelming myocardial failure. Patients with large collateral vessels can survive into adulthood. Treatment is surgical.[57]

Respiratory System

Age-Dependent Respiratory Variables: Structural and Functional Development

Airways and Alveoli

The lungs appear in the fourth to eighth weeks of gestation. At this time, the lung buds divide into the mainstem bronchi; by 6 weeks all subsegmental bronchi are present; and by 16 weeks, the number of airway generations is similar to that of adults. When airway development is complete, the terminal airways remodel and multiply to form a cluster of large saccules, or alveolar precursors, that can support gas exchange. True alveoli appear before and after birth, and the respiratory saccules are thin and septate during postnatal growth.

At birth, children have approximately 24 million alveoli; by 8 years of age, the number has increased to 300 million (Table 84-4). After that, further lung growth is primarily the result of increased alveolar size.

There is less elastic tissue in the neonatal lung than in the lungs of adults, and the elastin extends only to the alveolar duct. By 18 years of age, elastin extends to the alveolus and is at its maximum. It then slowly decreases over the next 5 decades. Lung compliance is integrally related to the amount of elastin; hence, compliance peaks in adolescence. It is lower in the very young and the very old. Airways close in the tidal volume range until about 5 years of age.

Pulmonary Circulation

The main axial arteries of the lungs are present at 14 weeks' gestation. By 20 weeks' gestation, the pattern of branching is similar to that of adults, and collateral supernumerary vessels are present. During fetal life, additional arteries develop to accompany the respiratory airways and saccules. Bronchial arteries appear between the 9th and 12th weeks of gestation. The arterial wall develops a fine elastic lamina by 12 weeks' gestation, and muscle cells are present as early as 14 weeks of gestation. By 19 weeks, the elastic tissue extends to the seventh generation of arterial branching, and muscularization extends distally. In the fetus, muscularization of the arteries ends at a more proximal level than in childen and adults. The muscularized arteries have thicker walls than arteries of similar size in adults. The pulmonary arteries are actively constricted until the latter part of gestation. In the fetal lamb, pulmonary blood flow is only 3.5% of the combined

Table 84-4 Age-Dependent Respiratory Variables: Normal Values*

	Newborn	6 mo	12 mo	3 yr	5 yr	12 yr	Adult
Respiratory rate (breaths/min)	50 ± 10	30 ± 5	24 ± 6	24 ± 6	23 ± 5	18 ± 5	12 ± 3
Tidal volume (mL)	21	45	78	112	270	480	575
Minute ventilation (L/min)	1.05	1.35	1.78	2.46	5.5	6.2	6.4
Alveolar ventilation (mL/min)	385	—	1245	1760	1800	3000	3100
Dead space–tidal volume ratio	0.3	0.3	0.3	0.3	0.3	0.3	0.3
Oxygen consumption (mL/kg/min)	6 ± 1.0	5 ± 0.9	5.2 ± 0.9	±	6.0 ± 1.1	3.3 ± 0.6	3.4 ± 0.6
Vital capacity (mL)	120	—	—	870	1160	3100	4000
Functional residual capacity (mL)	80	—	—	490	680	1970	3000
Total lung capacity (mL)	160	—	—	1100	1500	4000	6000
Closing volume as a percentage of vital capacity	—	—	—	—	20	8	4
Number of alveoli (saccules) × 10^6	30	112	129	257	280	—	300
Specific compliance: CL/FRC (mL/cm H_2O/L)	0.04	0.038	—	—	0.06	—	0.05
Specific conductance of small airways (mL/sec/cm H_2O/g)	0.02	—	3.1	1.7	0.12	8.2	13.4
Hematocrit	55 ± 7	37 ± 3	35 ± 2.5	40 ± 3	40 ± 2	42 ± 2	43-48
pH_a	7.30 ± 7.40	—	7.35-7.45	—	—	—	7.35-7.45

ventricular output at 0.4 to 0.7 of gestation and is just 7% near term. Immediately after birth, pulmonary blood flow increases to near adult levels. Development of the pulmonary venous system mirrors that of the arterial system.

The pulmonary arteries continue to develop after birth; new artery formation follows airway branching up to about 19 months of age, and supernumerary arteries continue to grow until 8 years of age. As alveolar size increases, the acinar branching pattern becomes more extensive and complex. The arterial structure also changes as preexisting arteries increase in size; the thickness of the muscular arteries decreases to adult levels during the first year of life.

Biochemical Development

By 24 weeks of gestation, the alveolar cuboidal epithelium flattens, and type I pneumocytes become the lining and supporting cells for the alveoli. The larger type II cells, which manufacture and store surfactant, also develop at this time. Surfactant initially appears at 23 to 24 weeks' gestation in humans and increases in concentration during the last 10 weeks of gestational life.[58] Surfactant is released into the alveoli at about 36 weeks' gestation, thus making normal extrauterine life possible.

Respiratory Transition: Placenta to Lung

By approximately 24 weeks' gestation, the lungs are capable of extrauterine gas exchange. However, several important circulatory and mechanical changes must occur immediately after birth for pulmonary gas exchange to be adequate.

Ventilation begins to match perfusion within the first hours of life. Initially, there is right-to-left intrapulmonary shunting through atelectatic areas of the lung, as well as left-to-right shunting through the ductus arteriosus and some right-to-left shunting through the foramen ovale. The resultant Pao_2 of 50 to 70 mm Hg indicates a right-to-left shunt that is three times that of normal adults.

Transition from fetal to neonatal respiration and circulation is dynamic. Postnatally, the pulmonary vascular bed remains constricted if it is exposed to acidosis, cold, or hypoxia. If pulmonary artery constriction occurs, right-to-left shunting of desaturated blood through the foramen ovale and ductus arteriosus increases and consequently reduces pulmonary blood flow. Maintenance of this active pulmonary vasoconstriction is called persistent pulmonary hypertension of the newborn or persistent fetal circulation. It also occurs in patients who have congenital diaphragmatic hernia, meconium aspiration, and sepsis.[59]

Mechanics of Breathing

For ventilation of the lungs, the respiratory muscles must overcome the lung's static-elastic and dynamic-resistive forces. Changes in these opposing forces during postnatal development affect lung volume, the pattern of respiration, and the work of breathing.

Lung Compliance Versus Age

Lung compliance changes with age because of the changing alveolar structure, amount of elastin, and amount of surfactant. At birth, compliance is low because alveolar precursors have thick walls and decreased amounts of elastin. A deficiency of surfactant (e.g., hyaline membrane disease) further decreases lung compliance. The improved lung compliance occurring over the first years of life is the result of continued development of alveoli and elastin.

Chest Wall

The chest wall of infants is very compliant because their ribs are cartilaginous. Because of the box-like configuration of an infant thorax, there is less elastic recoil than there is with the dorsoventrally flattened thoracic cage of adults. Adults have a high proportion of slow-twitch, high-oxidative, fatigue-resistant fibers in their diaphragm and intercostal muscles. Whereas adults have 65% of these fibers in the intercostal muscles and 60% in the diaphragmatic muscles, neonates have only 19% to 46% of these fibers in their intercostal muscles and 10% to 25% in the diaphragm.[60] Consequently, infants are more vulnerable to muscle fatigue and decreased stability of the chest wall. The net effect of the compliant chest wall and the poorly compliant lungs is alveolar collapse and lower resting lung volume (functional residual capacity [FRC]). Despite this tendency for lung collapse, a child maintains a large dynamic FRC via rapid respiratory rates, laryngeal breaking, and stabilization of the chest wall with increased intercostal tone during exhalation.[61]

Upper Airway

The upper airways of children and adults have several anatomic differences that affect their ability to maintain a patent airway. The more anterior and cephalad position of the larynx in children makes the "sniffing position" ideal for mask ventilation and endotracheal intubation. Extreme neck extension can actually obstruct the airway. The narrowest part of the adult airway is the vocal cords. Up to the age of 5 years, the narrowest portion of a child's airway is at the cricoid cartilage because the posterior larynx is positioned more cephalad than the anterior larynx, which causes the cricoid ring to be an ellipse rather than a circle. By 5 years of age, the posterior larynx has descended to the adult level.[62,63] An endotracheal tube (ETT) that passes easily through the vocal cords of a young child may cause ischemic damage to the distal airway. The cricoid narrowing and very pliant tracheal cartilage provide an adequate seal around an uncuffed ETT. Children younger than 5 years rarely require a cuffed ETT, although some practitioners use cuffed tubes regularly in these patients.[64,65]

Closing Capacity

The elastic properties of the lung closely correlate with closing capacity. Closing volume is the lung volume at which the terminal airways close and gas is trapped behind the closed airways.[66] Large closing volumes increase dead space ventilation, which leads to atelectasis and right-to-left shunting of blood. Elastic tissues help keep the airways open, so the greater the elastic stroma in the small airways, the lower the lung volume required to close small, noncartilaginous airways. Closing volume is small in late adolescence and relatively large in the elderly and the very young. Children overcome the complications of large closing volumes and secondary atelectasis by breathing rapidly, by constant activity, and by crying. Closing volume becomes a significant problem in infants who are inactive, sedated, or anesthetized.

Resistive Forces

Neonates have small airways with high resistance or low conductance (conductance = 1/resistance). The diameter of the small

airways does not significantly increase until about 5 years of age; hence, young children have elevated airway resistance at baseline and are particularly vulnerable to diseases that cause further narrowing of the airways (i.e., smooth muscle constriction, airway edema/inflammation). The normal high airway resistance of neonates and young children helps maintain FRC.

Control of Breathing

The newborn's respiratory control is unique. Hypoxia initially increases ventilation for a short time. This increase is followed by a sustained decrease in ventilation.[67] The response is more exaggerated in preterm neonates. In full-term infants, it disappears after several weeks. Periodic breathing is also more common in infants, particularly preterm infants, and is probably due to inadequate development of the medullary respiratory centers.

Oxygen Transport: Oxygen Loading and Unloading

Fetal hemoglobin has low levels of 2,3-diphosphoglycerate and an oxygen half-saturation pressure of hemoglobin (P_{50}) of 18 mm Hg, which is much lower than the 27 mm Hg in adults. This lower P_{50} allows the fetus to load more oxygen at low placental oxygen tension, but it makes unloading oxygen in tissues more difficult. Three to 6 months after birth, fetal hemoglobin has been replaced with adult hemoglobin. The increased oxygen content of fetal hemoglobin and the increased fetal hemoglobin concentration are advantageous to the fetus because it allows an oxygen content of 20 mL of oxygen/100 mL of blood to be delivered to the brain and heart. This is the same oxygen content that adults have when breathing room air. The oxygen concentration of neonates at birth is 6 to 8 mL/kg/min. It decreases to 5 to 6 mL/kg/min over the first year of life. The decreased ventilation-perfusion ratio, the decreased P_{50} of fetal hemoglobin, and the progressive anemia characteristic of infants can make it difficult to deliver adequate oxygen during the first few months of life. Infants compensate by having a cardiac output of approximately 250 mL/kg/min for the first 4 to 5 months of life.

Respiratory Failure

Respiratory failure is the inability of the lungs to adequately oxygenate and remove CO_2 from pulmonary arterial blood. There are many causes of respiratory failure, including a low environmental oxygen concentration, parenchymal lung desease, and pulmonary vascular disease.

A complete history of the severity and chronicity of the respiratory problem helps formulate a differential diagnosis and an approach to treatment. Specific data should include a history of prematurity, previous airway instrumentation, previous mechanical ventilation, nonpulmonary organ dysfunction, and a family history of respiratory disease. A detailed feeding history and up-to-date growth chart may provide valuable information because growth failure may increase the need for oxygen. Usually, 1% to 2% of the total oxygen consumed is used for breathing. During respiratory illneses, as much as 50% of the total oxygen consumption may be used for breathing.

Infants and children with respiratory failure often have intercostal and suprasternal retractions, signs that the work of breathing and oxygen consumption are increased. Patients grunt during expiration in an attempt to maintain FRC. Most infants and children have tachypnea, which also helps maintain FRC by decreasing the time for exhalation. Less energy is required to breath rapidly and shallowly than to take deep breaths. Infants with respiratory failure often have cyanotic lips, skin, and mucous membranes. However, it is often difficult to recognize skin color changes unless the Pao_2 is below 70 mm Hg. Symmetry of chest movement should be noted. Differences in movement may indicate pneumothorax or blockage of a bronchus. The small thoracic volume allows easy transmission of breath sounds from one side to the other. Breath sound may be normal, even when pneumothorax is present. Abdominal distention can dramatically impede breathing in infants and young children.

Radiologic evaluation of the nasopharynx, neck, and thorax can provide meaningful information regarding the cause and severity of the respiratory dysfunction. Fluoroscopy can be used to evaluate the airways and movement of the diaphragm in an uncooperative child. If a child must leave the ICU for these examinations, someone capable of providing ventilatory support should accompany the patient.

Pulmonary function tests help assess respiratory function, but because of lack of cooperation, these tests are difficult to perform in children younger than 5 years without sedation, which may be dangerous for an unintubated child with respiratory failure. Most pulmonary function testing requires the use of a tight-fitting mask, and this in and of itself can be problematic.[68] If the trachea is intubated, lung volumes, expiratory flow rates, compliance, and inspiratory forces can be measured easily; in fact, most mechanical ventilators are now equipped with monitors that allow these variables to be measured routinely.

Analysis of ABGs is used to determine the effectiveness of gas exchange. Pao_2 measurements allow calculation of the alveolar/arterial oxygen gradient and right-to-left shunting of blood across the lung.

Elimination of CO_2 from arterial blood is another indicator of lung function. Failure to remove CO_2 from pulmonary arterial blood indicates maldistribution of blood flow in the lungs; specifically, there is increased dead space.

Umbilical artery cannulation is common in neonates, so those caring for such children can obtain arterial blood and continuously measure arterial blood pressure. These catheters are relatively simple to insert and reasonably easy to maintain.[69] The tip of the catheter ideally should be at or just above the level of the aortic bifurcation and below the level of the renal arteries (L2). Once the child's condition is stable, a peripheral artery catheter should be inserted and the umbilical artery catheter should be removed. All intra-arterial catheters have the potential to cause distal thromboembolic disease. Care must be taken to flush arterial catheters gently to prevent cerebral or cardiac emboli. With proper insertion and maintenance, serious complications of arterial lines are rare. Although arteries that are cannulated for a long time may occlude, they recanalize within a short period.[70]

Less invasive techniques for monitoring gas exchange have been developed. Transcutaneous electrodes accurately measure oxygen and CO_2 in infants and young children, but they lose accuracy during hypoperfusion. The electrodes require some warm-up time, which makes "spot checks" difficult. These monitors are best used as trend monitors in older children and adults.[71,72] Pulse oximeters are routinely used to care for critically ill infants and children because they are accurate, require no warm-up time, and need little skill to apply. The probe is easily wrapped around an infant's or young child's entire hand or foot.[73] End-tidal CO_2 monitoring allows CO_2 elimination to be meas-

ured continuously. However, this technology has limited application in small children because of the increased dead space and the weight of the sampling device on the end of the ETT, which can kink the ETT and cause accidental extubation. The volume of gas withdrawn for sampling (about 75 mL/min) can alter the tidal volume of an extremely small child.[74]

Causes of Respiratory Failure

The cause of respiratory failure depends to some degree on the age of the patient. Newborn respiratory failure is often the result of congenital anomalies and immaturity of the lungs and their blood vessels. Congenital anomalies can include airway malformations, dysgenesis or malfunction of the lung or nonpulmonary organs, and abnormalities of the pulmonary vessels. Lesions of immaturity include apnea of prematurity, hyaline membrane disease, and abnormalites of surfactant production and secretion. During the perinatal period neonates are subject to infections and stress. Persistent pulmonary hypertension can complicate neonatal pulmonary and nonpulmonary problems. These and other important causes of respiratory failure in the newborn are listed in Table 84-5. A wide variety of disorders cause respiratory failure in older children (Box 84-4). Regardless of the specific cause, respiratory failure can be categorized as hypoventilation syndromes in patients with normal lungs, intrinsic alveolar and interstitial disease, and obstructive airway disease.

Hypoventilation Syndromes in Children with Normal Lungs

Causes of hypoventilation include neuromuscular disease, central hypoventilation, and structural/anatomic impairment of lung expansion (i.e., upper airway obstruction, massive abdominal distention). These clinical conditions are characterized by inadequate lung expansion, secondary atelectasis, intrapulmonary right-to-left shunting, and systemic hypoxia. Atelectasis and the secondary reduction in FRC increase the work of breathing. The child's response to the increased work of breathing and lower lung volumes is to breathe faster with a smaller tidal volume. This pattern of breathing eventually increases the amount of atelectasis and shunting. As a result, children with intrinsically normal lungs and hypoventilation syndromes exhibit tachypnea, small tidal volumes, increased work of breathing, and cyanosis. Chest radiographs reveal small lung volumes and miliary or lobar atelectasis. Positive-pressure ventilation and PEEP quickly reverse the pathologic processes.

Primary Pulmonary Alveolar or Interstitial Disorders

Intrinsic lung disease involving the alveoli or pulmonary interstitium decreases lung compliance and increases airway closure, both of which cause atelectesis and increase the work of breathing. Edema or inflammation of the alveoli or fibrosis of the interstitium decreases lung compliance. The stiffer lung requires a greater negative intrapleural pressure for air movement, thereby increasing the work of breathing and the risk for pneumothorax.

Obstructive Airway Disease

Airway obstruction can be extrinsic or intrinsic. Intrinsic small airway obstruction commonly occurs with bronchiolitis, bronchopneumonia, asthma, and bronchopulmonary dysplasia (BPD).

Table 84-5 Classification of Causes of Neonatal Respiratory Failure

	Congenital Abnormalities	Developmental Immaturity	Specific Neonatal "Stress"
Impaired control of ventilation	Central nervous system dysgenesis Ondine's curse	Apnea of prematurity Intracranial hemorrhage	Drug intoxication (note maternal drugs) Sepsis Central nervous system infections Seizures
Neuromuscular disorders	Congenital myopathies		High cervical cord injuries
Structural impairment	Thoracic deformities Lung hypoplasia Diaphragmatic hernia Potter's syndrome Abdominal malfunction Gastroschisis Omphalocele		Severe abdominal distention Pneumothorax or other air leak
Airway obstruction	Choanal atresia		Massive meconium aspiration
Upper airway	Pierre Robin syndrome Laryngeal web/cleft Congenital tracheal/laryngeal stenosis Recurrent laryngeal palsy Hemangioma Lymphangioma		Vocal cord paralysis secondary to myelodysplasia
Lower airway	Tracheoesophageal fistula Lobar emphysema		Meconium/blood aspiration
Alveolar disorders		Respiratory distress syndrome	Bronchopulmonary dysplasia
Cardiovascular disorders	Congenital cardiac malformations Congestive heart failure (critical coarctation or aortic stenosis) Total anomalous pulmonary venous return		Persistent pulmonary hypertension

Box 84-4 Causes of Respiratory Failure in Children

- Impaired control of ventilation
  - Head trauma
  - Intracranial hemorrhage
  - Increased intracranial pressure secondary to tumor, edema, hydrocephalus, Reye's syndrome, etc.
  - Central nervous system infections
  - Ondine's curse
  - Drug intoxication
  - Status epilepticus
- Neuromuscular disorders
  - High cervical cord injury
  - Poliomyelitis
  - Guillain-Barré syndrome
  - Neurodegenerative diseases (e.g., Werdnig-Hoffmann syndrome)
  - Muscular dystrophies and myopathies
  - Myasthenia gravis
  - Botulism
  - Tetanus
  - Phrenic nerve injury
- Structural impairment
  - Severe kyphoscoliosis
  - Flail chest
  - Large intrathoracic tumor
  - Pneumothorax or pneumomediastinum
  - Large pleural effusion, hemothorax, empyema
  - Severe abdominal distention
  - Severe obesity (pickwickian syndrome)
- Airway obstruction
  - Upper airway
    - Congenital anomalies
    - Tumor—intrinsic or extrinsic
    - Epiglottitis
    - Croup (laryngotracheobronchitis)
    - Foreign body
    - Postintubation edema, granulation tissue, or scarring
    - Vocal cord paralysis
    - Burns
    - Vascular ring
  - Lower airway
    - Asthma
    - Bronchiolitis
    - Foreign body
    - Lobar emphysema
    - Cystic fibrosis
- Alveolar disorders
  - Pneumonia
    - Infectious—bacterial, viral, fungal, *Pneumocystis*
    - Chemical—aspiration, hydrocarbon, smoke inhalation
  - Pulmonary edema—cardiogenic, near-drowning, capillary leak syndrome
- Massive atelectasis
- Oxygen toxicity
- Pulmonary contusion
- Pulmonary hemorrhage

Airway obstruction decreases conductance and increases airway resistance and the work of breathing. Partial obstruction impedes expiration more than inspiration and causes gas trapping or regional emphysema. Complete airway obstruction results in atelectasis and right-to-left shunting of blood within the lung. Patients with disease of the small airways usually have a mixture of total and partial airway obstruction and inhomogeneous collapse and overdistention of the lung. The areas of collapse cause intrapulmonary right-to-left shunting of blood, and the overdistended areas increase the amount of dead space. If the entire lung is overdistended, compliance is decreased and the work of breathing is increased. The clinical and radiographic picture varies with the different degrees of collapse and overdistention of the lung.

In summary, all causes of respiratory failure share similar pathophysiology: atelectasis and decreased FRC with intrapulmonary right-to-left shunting of blood or alveolar overdistention with increased dead space and decreased CO_2 elimination, or both. The increased work of breathing associated with all forms of respiratory dysfunction can cause fatigue and a breathing pattern that further complicates the initial process. It may also lead to apnea, hypoxia, and cardiac arrest in young childeren if the increased work of breathing is not quickly detected and treated.

Treatment of Respiratory Failure

Treatment of respiratory failure includes ensuring an open airway, increasing the inspired oxygen concentration, relieving airway obstruction, treating infection, correcting fluid overload, correcting abnormalities of all nonpulmonary systems, and instituting mechanical ventilation. Exogenous surfactant, high-frequency ventilation, lung-protective mechanical ventilation strategies,[75] inhalation of NO, prone positioning, liquid ventilation,[76] and extracorporeal membrane oxygenation (ECMO) may be effective in particular clinical situations.

Infants and young children often require help to maintain airway patency. Specific maneuvers include keeping the child in a semiupright position to avoid aspiration or gastroesophageal reflux and to minimize the effects of abdominal distention. It is usually appropriate to keep the head in a midline position and to minimize excessive neck flexion.

The inspired oxygen concentration can be increased by a tight-fitting anesthesia mask. Nasal prong oxygen often helps but may agitate some children and negate any beneficial effects of the increased F_{IO_2}. Blow-by oxygen, space masks, croup tents, and head boxes are less invasive and generally are better tolerated by children.

Upper airway obstruction can be relieved by inserting a laryngeal mask, an ETT, a tracheostomy, or an oropharyngeal or nasopharyngeal tube. Inhaled racemic epinephrine and intravenous steroids often decrease subglottic edema,[77,78] antibiotics decrease infectious swelling, and β-agonists and inhaled anticholinergic medications relax bronchial smooth muscle.[79] Patients with pneumonitis should have cultures for bacterial, viral, or fungal pathogens and be treated with appropriate antibiotics. Pulmonary edema is treated by limiting fluid intake and administering diuretics and cardiotonic or vasoactive drugs. Good oral or

intravenous nutrition, fluid and electrolyte balance, and adequate cardiovascular and renal function are part of pulmonary support.

Mechanical ventilation is the main treatment of respiratory failure. The following are several nonpulmonary reasons for mechanical ventilation:

1. Resuscitation from circulatory collapse. In situations in which the cardiovascular system is unstable, it is safest to mechanically ventilate the lungs. During cardiac arrest, respiratory support is mandatory, although bag-and-mask ventilation may initially be effective. *Patients seldom die of lack of an ETT. They usually die of lack of oxygen, which is sometimes forgetten in our haste to place an ETT.* Mechanical ventilation is used after cardiac surgery to ensure adequate gas exchange until the circulation is stable. Mechanical ventilation also reduces the risk of untoward cardiovascular decompensation.
2. Respiratory assistance. Intentional hyperoxia is occasionally used to dilate the pulmonary vascular bed of some newborns while initiating other therapies.[46] Mechanical ventilation is also used to reduce intracranial pressure (ICP) by inducing mild respiratory alkalosis and decreasing cerebral blood volume.[80] When this is done, mean arterial pressure must be kept at pre-hyperventilation levels or higher to prevent further cereberal ischemia. Children with underlying conditions that predispose them to respiratory failure (morbid obesity, sepsis, nutritional debilitation, and kyphoscoliosis) may also require mechanical ventilation.
3. Reduced work of breathing. Reducing the oxygen cost of breathing by mechanically ventilating patients may improve some patients' ability to survive a major physiologic insult. Childern with BPD may require long-term mechanical ventilation to conserve the energy expended for breathing and use this energy for growth.[81]

Ventilatory Therapy

Respiratory assistance is provided by continuous positive airway pressure (CPAP), intermittent positive-pressure ventilation, and negative-pressure ventilation. Positive-pressure ventilation is usually applied through an ETT or a tracheostomy. Some infants and children can be supported with mask CPAP, noninvasive ventilation, or nasal prongs with high flow. Oral intubation is easier than nasal intubation is, especially in emergency situations.

The size of ETT required should be selected carefully. One formula that estimates the appropriately sized tube for children older than 2 years is (age + 16)/4.

This formula provides the internal diameter of the appropriately sized ETT. The correct size should have a slight air leak when a positive pressure of 20 to 30 cm H_2O is applied.[82] Serious lifelong laryngeal and subglottic damage can result from using inappropriately large ETTs, particularly in children with inflammatory lesions of the upper airway such as laryngotracheobronchitis. Because of the more flexible tracheal cartilage and the relative subglottic narrowing of children, uncuffed ETTs generally provide an adequate seal in those younger than 5 years. However, if the patient has lung disease that requires high ventilation pressure, a cuffed tube is more appropriate. Small cuffed ETTs are frequently used in the ICU in younger patients,[65] but care should be taken to ensure that there is a small leak of air at 25 to 30 cm H_2O. Cuffed tubes will usually eliminate the air leak around an ETT, but overinflation of the cuff may occlude venous flow and injure the airway. There are presently no data on the long-term safety of using cuffed ETTs in young children.

With endotracheal intubation, it is important to correctly position the ETT. If correctly positioned, chest movements should be symmetric, and breath sounds should be equal when auscultated in the axillae. An electronic or colorimetric CO_2 detection system helps confirm whether the ETT is in the trachea or the esophagus.[83] If the double lines on the ETT are at the level of the vocal cords, the ETT is usually in the correct position. Another way to correctly position the ETT is to advance it into the right mainstem bronchus and listen for breath sounds in the left axilla. Breath sounds will be diminished. Withdraw the ETT slowly. When breath sounds are heard on the left, pull the tube out an additional 1 to 2 cm, depending on the size of the child. If the breath sounds are equal, fix the tube in place. The tip of the ETT should be midway between the vocal cords and the carina on the chest radiograph. In small infants, the distance between the carina and the vocal cords is very short. Consequently, it is easy to inadvertently place the ETT in a mainstem bronchus. Flexion of the head moves the ETT into the airway. Extension moves it toward the vocal cords. Turning the head to the side may obstruct the tip of the ETT if it comes in contact with the tracheal wall, which may cause CO_2 retention or hypoxemia, or both (unpublished data).

It is common to leave a child's trachea intubated for more than 2 weeks before performing a tracheostomy. This is possible with proper humidification of the inspired gases, improved endotracheal suctioning and monitoring (Sao_2), and excellent nursing care.

Everyone caring for the child must be constantly alert to the possiblity that the ETT will become obstructed by secretions or that accidental extubation or mainstem bronchus intubation will occur. In neonates, ETTs with a "Murphy" eye become obstructed more often with secretions than those without a Murphy eye do (unpublished data). The Murphy eye is very near the end of the ETT. Once the ETT enters the mainstem bronchus, it is impossible for the infant to effectively breath through the "eye." Because the ETT is almost the same size as the trachea, it is nearly impossible for the infant to breath around the tube. Thus, ETTs with Murphy eyes are dangerous and probably should not be used in young infants. Tracheostomy is indicated when children require a long-term artificial airway for mechanical ventilation, for endotracheal suctioning, or to bypass an upper airway obstruction. Accidental dislodgement of the tracheostomy tube before the tract is well healed can be life threatening. Reinsertion of a tracheostomy tube during the first 72 hours after insertion can be very difficult and can create false passages that can make it impossible to ventilate the lungs or can cause pneumothorax.

Continuous Positive Airway Pressure and Positive End-Expiratory Pressure With CPAP, the child breathes spontaneously through a system that maintains constant PEEP during exhalation. With PEEP, the lungs are mechanically ventilated while a constant end-expiratory pressure is maintained.

CPAP is applied by ETT, nasal cannula, or facemask. Because most newborns are obligate nose breathers, nasal CPAP is often effective, even for small premature infants. Successful application of CPAP depends on the size and condition of the infant and on whether the infant is mouth breathing. Crying and mouth breathing reduce the efficiency of nasal CPAP because

both reduce pharyngeal pressure. Gaseous distention of the abdomen occurs with nasal or mask CPAP. An orogastric tube is required to vent the stomach.[84] Facemask CPAP is effective for short periods in children and adults. Use of mask CPAP for prolonged periods may cause pressure necrosis of the face or eyes (or both). Low to moderate levels of PEEP can be maintained in children with an uncuffed ETT, but large gas leaks around the ETT make the PEEP level unstable. Using a larger ETT or a cuffed ETT solves this problem.

The optimum level of CPAP or PEEP is difficult to determine but is usually thought to be the lowest level of pressure that maintains a normal Pao_2 without elevating $Paco_2$ excessively. Too little pressure does not effectively increase Pao_2, whereas too much pressure overdistends the lungs and increases dead space ventilation. Low levels of CPAP or PEEP (2 to 5 cm H_2O) are advocated for any child with an artificial airway.[85]

The goal is to use the lowest level of CPAP or PEEP that adequately improves oxygenation while minimizing the effects on ventilation. One approach is to use the level of CPAP or PEEP that improves oxygenation and allows Fio_2 to be reduced to 0.6 or less. A second approach is to increase end-expiratory pressure until maximal improvement in compliance occurs.[86]

Suter and colleagues[87] proposed that the best PEEP (or CPAP) is the level of end-expiratory pressure required to produce maximal oxygen transport, which is the product of cardiac output and arterial oxygen content. This requires repeated cardiac output measurements and a Swan-Ganz thermodilution catheter, which is seldom done in young children. Most clinicians approximate the best CPAP or PEEP by using the CPAP or PEEP that gives an adequate Pao_2 and $Paco_2$ and allows Fio_2 to be reduced.

Positive-Pressure Ventilation Positive-pressure mechanical ventilators are classified according to their method of control as (1) volume preset, (2) pressure preset, and (3) time-flow preset.[88] As a general rule, time-flow or pressure-preset ventilators are more convenient to use in infants and young children (<10 kg), whereas volume-preset ventilators are commonly used in older children (>10 kg) and adults. Time-flow and pressure-preset ventilators have several advantages in infants and young children. Most of these patients are intubated with an uncuffed ETT, which causes a variable leak around the ETT. This leak, along with the relatively large compression volume of the circuit relative to the tidal volume of infants, makes volume-preset ventilation unreliable. The main problem with pressure-preset or time-flow–preset ventilators is that the volume delivered depends on the child's thoracic and lung compliance and on airway resistance. Improved lung and chest wall compliance may overdistend the alveoli and cause alveolar rupture. Alternatively, decreased compliance may cause atelectasis and hypoventilation.

Intermittent mandatory ventilation (IMV) allows the child to breathe spontaneously from a fresh gas source at low resistance while intermittently receiving a tidal volume from the mechanical ventilator at preset intervals.[89] Between ventilator breaths, children can breathe with the same Fio_2 and PEEP that they receive from the ventilator. IMV is produced either by a continuous-flow circuit or by a series of demand valves. Continuous-flow IMV circuits are simpler and require no additional patient effort during spontaneous breathing. Demand-valve systems may be ineffective in children who have relatively high respiratory rates because the sensitivity of the valve and the valve's response time may not allow the ventilator to function in synchrony with the patient's breaths. During pressure-support ventilation, each spontaneous breath is augmented by delivery of gas at a preset pressure. The patient determines the respiratory rate and the inspiratory time, and the machine determines the inspiratory pressure. Pressure-support ventilation increases tidal volume, may decrease the work of breathing, and may improve patient comfort. This mode of ventilation is commonly used to wean patients from mechanical ventilation. Pressure support will not work if patients have an abnormal respiratory drive.[90-92]

Box 84-5 outlines the salient features of the pathophysiology of acute respiratory distress syndrome (ARDS). Better understanding of the pathology of this disease has led to ventilator strategies that use relatively long inspiratory times, high end-expiratory pressures, and low tidal volumes. This lung-protective ventilator strategy results in lower minute ventilation and elevated $Paco_2$. It also decreases the shear forces acting on the terminal airways and recruits lung units that are below closing volume.[93] Acid-base status can be kept relatively normal by inducing a metabolic alkalosis by retaining bicarbonate in the kidney and administering sodium bicarbonate or THAM.

The optimal ventilation pattern for patients with obstructive airway disease is a faster inspiratory flow rate, a shorter inspiratory time, and a longer expiratory time to better ventilate relatively normal lung and to allow gas to escape from obstructed portions of the lung. Pharmacologic dilation of the bronchi is the principal treatment of disease of the small airways. Barotrauma and alveolar rupture occur commonly during mechanical ventilation of these patients.

Initiation of Mechanical Ventilation An inspiratory-to expiratory ratio of 1.5 : 1 or 1 : 1 and a relatively slow ventilation rate (<24 cycles/min in infants and <16 cycles/min in children) are useful starting points for many patients. Based on blood gases, pH, and oxygen saturation, the ventilator settings are changed.

Chest expansion, auscultation of the chest, and the adequacy of alveolar ventilation (as determined by $Paco_2$) are important criteria when determining the adequacy of ventilation. Peak airway pressure should be measured frequently and as near to the ETT as possible.

PEEP is begun at 3 to 4 cm H_2O and increased in 2–cm H_2O increments until the Sao_2 is appropriate. Few pediatric patients require end-expiratory pressure greater than 20 cm H_2O.

Initiation of positive-pressure ventilation may cause systemic arterial hypotension, which usually improves with the infusion of 10 to 20 mL/kg of crystalloid, colloid, or blood. CVP should be measured when a PEEP of 10 cm H_2O or greater is required. Measurement of intravascular arterial pressure and

Box 84-5 Pathophysiology of Acute Respiratory Distress Syndrome

- Disruption of endothelial barriers with leakage of protein-containing fluid and inflammatory cells into alveoli
- Inactivation of surfactant resulting in increased surface tension of the alveolar lining layer
- Atelectasis and loss of lung volume
- Shunting of blood through nonventilated areas of the lung resulting in hypoxemia and tissue hypoxia
- Decreased pulmonary compliance

CVP helps detect detrimental effects of mechanical ventilation and positive airway pressure on the cardiovascular system.

Adjunctive Pharmacologic Therapy: Sedatives and Analgesics Sedation is often required to help conscious children cooperate with mechanical ventilation. The amount of sedation required depends on the child's age, size, underlying disease, and amount of respiratory support needed. Some infants are sufficiently depressed and require no sedation. Sedation allows patients to breathe "in phase" with the ventilator, which reduces the peak airway pressure and eliminates coughing and straining, all of which can cause pulmonary gas leaks. A continuous infusion of fentanyl (1 to 2 µg/kg/hr) provides pain relief and sedation. However, it may be necessary to increase the infusion rate of fentanyl on subsequent days to maintain the same level of sedation.[94] Other drugs, such as lorazepam (0.1 to 0.2 mg/kg administered intravenously every 4 to 6 hours) or an infusion of midazolam (0.05 to 0.2 mg/kg/hr), can be useful adjuncts to opioid administration. These drugs usually have minimal cardiovascular effects if intravascular volume is adequate.[95] However, administering lorazepam to premature neonates for several days may cause steroid-responsive hypotension as a result of buildup of drug in the body. The half-life of lorazepam is approximately 72 hours in premature infants. Giving the drug every 4 to 6 hours causes accumulation of the drug in blood and tissues.

Neuromuscular blocking agents increase chest wall compliance, reduce oxygen consumption,[96] and facilitate mechanical ventilation. If neuromuscular blocking drugs are used, they should be administered in conjunction with medications that cause amnesia and anxiolysis and control pain.

Pancuronium and vecuronium are the most commonly administered muscle relaxants used in the PICU (also see Chapter 29). The usual dose of pancuronium is 0.1 mg/kg administered intravenously every 1 to 1½ hours or 40 to 100 µg/kg/hr as an infusion. The tachycardia associated with pancuronium is an undesired side effect in adults, but it is generally desirable in infants and children because it helps maintain cardiac output. Vecuronium (0.08 to 0.2 mg/kg, followed by an infusion of 60 to 150 µg/kg/hr) produces less tachycardia than pancuronium does; cisatracurium (0.1 to 0.2 mg/kg followed by an infusion of 60 to 120 µg/kg/hr) is often useful because its elimination is not dependent on renal or hepatic function. If these drugs are given for more than a day, provision of regular drug holidays should be considered to avoid serum buildup of the drug and prolonged paralysis.

Weaning from Mechanical Ventilation The criteria for weaning are ill defined. In general, weaning from respiratory support begins when the child's cardiovascular system is stable and the child is awake and alert. Mechanical ventilation should not be withdrawn if there is still significant risk for acute cardiac decompensation. It is also best to correct severe anemia, hypoglycemia or hyperglycemia, hypernatremia, hypochloremia, or malnutrition before initiating weaning because these metabolic disorders impair the child's ability to be weaned from mechanical ventilation. The child should be able to generate at least −20 cm H_2O pressure at the airway (inspiratory force) and inhale at least 10 mL/kg of gas with maximal effort (vital capacity) before weaning is considered.

When pressure-limited or time-flow–limited ventilators are used, the peak inspiratory pressure must be reduced when lung compliance improves because failure to do so may cause pneumothorax or pneumomediastinum (or both).

Ventilator rates are not usually decreased before ABGs are stable, the inspired oxygen concentration is less than 0.6, PEEP is less than 10 cm H_2O, and peak airway pressure is below 30 to 35 cm H_2O.

There should not be any residual effects of neuromuscular blocking drugs, and the level of sedation should be minimal. Neuromuscular blockade can be reversed with intravenous neostigmine (0.05 to 0.07 µg/kg) and glycopyrrolate (0.01 mg/kg); acceptable neuromuscular function should be confirmed with a peripheral nerve stimulator. When all these factors are in place, the ventilator rate is gradually decreased over a period of hours to days.

Weaning should continue as long as ABGs remain within an acceptable range and the child's clinical condition is stable. As spontaneous ventilation increases, the increased work of breathing may worsen the child's condition. Tachycardia, hypertension or hypotension, tachypnea, increased work of breathing, and anxiety are danger signs. If these signs occur, weaning should be discontinued and ventilatory support should be increased. Frequent assessment of ABGs and the child's clinical condition is essential throughout the weaning process. If a child has residual lung disease and decreased lung compliance, a further decrease in FRC and increased hypoxemia may delay weaning. These potential problems can be minimized by using moderate levels of CPAP or PEEP (5 to 10 cm H_2O) during weaning. FRC is similar in mechanically ventilated infants with a PEEP of 2 cm H_2O as it is after tracheal extubation.[97]

Tracheal extubation should be performed by an individual skilled in tracheal intubation because reintubation of the trachea may be necessary. Once tracheal extubation has occurred, it is usual to increase F_{IO_2} by 20%. Patients old enough should be encouraged to deep-breathe, cough, and clear secretions as often as possible. Incentive spirometry, early mobilization, and chest physical therapy are important adjunts when recovering from respiratory failure.[98]

Before tracheal extubation, the quality and volume of tracheal secretions should be assessed. Large volumes of thick secretions may make it difficult for the patient to clear the secretions after extubation. It is usually best to extubate the trachea while a full staff is available so that the child can be observed closely and a chest radiograph can easily be obtained. If weaning and tracheal extubation have been carefully planned and executed, reintubation is relatively uncommon.

High-Frequency Ventilation High-frequency ventilation provides smaller than anatomic dead space tidal volumes at high respiratory rates (150 to 3000 breaths/min). Several different types of ventilators, including high-frequency jet ventilators, high-frequency oscillating ventilators (HFOVs), and flow interrupters, are effective.[99] Each of these machines differs in technical design and clinical application and may differ in the mechanism of gas exchange.[100]

HFOVs are commonly used for neonates and children with severe lung disease and respiratory failure. Use of HFOVs has reduced the number of infants requiring ECMO.[101,102] HFOV is also successful in the treatment of children with acute homogeneous interstitial and alveolar disease.[103] This form of ventilation has been less successful in the treatment of large children and adults because of physical limitations of the equipment. Jet ventilation is used to treat respiratory failure of many causes, although the main indication for its use is to treat barotrauma or bronchopleural fistula.

Exogenous Surfactant

Administration of exogenous surfactant is now routine therapy for surfactant deficiencies of premature infants and has improved the survival of these children and decreased their need for aggressive mechanical ventilation and ECMO.[104] Exogenous surfactant has not been as effective in older children and adults, primarily because the type of lung disease is different. Older patients more often have abnormal surfactant function than they have an absolute decrease in the amount of surfactant.

Extracorporeal Membrane Oxygenation

ECMO is the standard of care for infants older than 34 weeks' gestation who have acute respiratory failure (ARF) that is unresponsive to standard therapy. More than 24,000 infants with a predicted mortality of 80% to 85% with conventional management have been treated by ECMO, and more than 80% of these patients survived.[105] Approximately 30% of infants with cardiac lesions, especially stunned myocardium, are saved by ECMO. The majority of ECMO has been venoarterial (VA), where blood is drained from the venous system and returned to the ascending aorta. VA ECMO supports respiratory and cardiac function. Venovenous (VV) ECMO is less efficient than VA ECMO, but it preserves pulmonary flow and avoids cannulation of a major artery. VV ECMO is less effective in patients with myocardial dysfunction. However, VV ECMO is rapidly gaining in popularity and is being used as commonly or more commonly than VA ECMO.[106] Target neonatal ECMO populations are also changing. Exogenous surfactant, inhaled NO, and HFOV have significantly reduced the need for ECMO greater preponderance of sepsis and multiorgan system failure. Today's ECMO candidates are sicker and have a greater preponderance of sepsis and multiorgan system failure.

ECMO support for older children and adults with ARF continues to be investigated. Approximately 7000 pediatric ECMO patients have been reported worldwide. All were patients who had a presumed 80% predicted mortality. About 50% of ECMO-treated patients survived. The reason for this difference in outcome in the two age groups is related to the marked heterogeneity in age, diagnoses, conventional management, and criteria for ECMO. In addition, neonates have only a few causes of ARF, and most are reversible. Older patients have multiple causes of ARF that are not always reversible.[107,108]

Common Respiratory Disorders

Laryngotracheobronchitis (Croup)

Croup is the most common cause of acute upper airway obstruction in otherwise healthy children (see Chapter 82). It occurs most frequently in the 3-month-old to 3-year-old age group. Croup is a viral infection (parainfluenza, influenza, adenovirus) that causes edema of the tissues in the upper airway, particularly in the immediate subglottic region. There is usually a history of a few days of upper respiratory tract infection symptoms followed by hoarseness, a croupy cough, and possibly stridor. The degree of respiratory distress and the child's ability to compensate for the increased work of breathing are best assessed clinically.

These patients are initially treated with mist and aerosolized racemic epinephrine to reduce swelling of upper airway mucosa.[109] Steroid administration is common yet controversial.[77] Tracheal intubation is required when the child can no longer sustain the increased work of breathing and CO_2 increases. When the trachea is intubated, the ETT should be 0.5 to 1.0 mm smaller than usual for age. The ETT must be of sufficient size that the patient can breathe easily during spontaneous ventilation and the nurses can effectively suction secretions from the airways. Croup usually resolves spontaneously in 3 to 7 days. The average duration of tracheal intubation is approximately 5 days. Laryngotracheobronchitis is less common in children older than 4 years.

Epiglottitis

Epiglottitis is an inflammation of the mucosa of the supraglottic structures that was previously caused by *Haemophilus influenzae* type B but is now commonly caused by *Staphylococcus aureus* and streptococcal organisms because immunizatiion against the *Haemophilus* organism has been so effective. In the past, epiglottitis was a disease of 4- to 6-year-old children. Now, it occurs more commonly at older ages (even in adults).[110] In young children, epiglottitis is a true airway emergency because it may rapidly progress to complete and fatal airway obstruction. Providing a secure airway is the first priority. Children with epiglottitis appear toxic and have a fulminant onset of fever and respiratory distress. Tracheal intubation during anesthesia is commonly required until antibiotic therapy (ampicillin and chloramphenicol or ceftriaxone) is initiated and the signs of systemic toxicity subside. Introduction of the *H. influenzae* vaccine has dramatically decreased the incidence of *H. influenzae* infection, as well as that of other *H. influenzae* processes.[111]

Bronchiolitis

Bronchiolitis is an acute viral infection of the lower respiratory tract that occurs primarily during the first 2 years of life. The signs and symptoms of this malady are air trapping, wheezing, mild to moderate systemic hypoxemia, increased work of breathing, and increased airway resistance. The cause is usually an infection with respiratory syncytial virus (RSV).[112]

Patients at high risk for respiratory failure from this disease include infants and young children with a history of prematurity, chronic lung disease, or congenital heart disease. Apnea is frequently the first sign of decompensation in neonates, which often occurs before significant hypercapnia appears. Fatigue is a common indication for mechanical ventilation. Treatment is primarily supportive and includes endotracheal intubation and mechanical ventilation for respiratory failure.[113]

RSV immune globulin (RespiGam) is a prophylactic intravenous drug that is administered to patients at risk for seasonal RSV disease (ex-premature infants, infants with congenital heart disease, immunosuppressed patients, or those with multiple congenital anomalies); it has dramatically decreased the incidence of illness in this population. Ribavirin is a virostatic drug available for the treatment of children with RSV and congenital heart disease, immunosuppressive disease, or multiple congenital anomalies.

Status Asthmaticus

Asthma, a disease of airway hyperreactivity, is the most common chronic respiratory disorder of childhood and is a frequent cause of admission to emergency rooms and hospitals. Acute attacks are generally associated with intercurrent viral infections, exposure to allergen, stress, or noncompliance with therapy.[114]

A stepwise approach to the treatment of asthma includes inhaled aerosolized β-agonists, cromolyn/nedocromil, leuko-

triene pathway modifiers, and inhaled glucocorticoids.[115] The number of asthmatic patients and the mortality rate associated with asthma are increasing. This increase is associated with a number of risk factors, including teenage years, black race, history of previous life-threatening episodes, hospitalization within the last year, poor long-term medical care, and psychological and psychosocial problems.

Most episodes of status asthmaticus respond to emergency department management with oxygen, nebulized/inhaled β-agonists, anticholinergic agents, and intravenous steroids.[116]

Even with this therapy, some children fail to improve or their condition worsens. Signs of respiratory failure include tachypnea and tachycardia; prolonged expiration; marked intercostal, supracostal, and infracostal retractions; nasal flaring; pulsus paradoxus; and anxiety or depression. Despite the increased minute ventilation, $Paco_2$ is normal or elevated, and moderate to severe hypoxemia is present. Treatment of impending respiratory failure requires maximizing conservative therapy, starting an infusion of intravenous terbutaline at 0.1 μg/kg/min, and increasing the dose until clinical improvement occurs or significant tachycardia develops. When aminophylline is used, blood levels should be monitored closely. Both phosphodiesterase inhibitors and adrenergic agonists increase myocardial oxygen consumption and may cause myocardial ischemia and ventricular arrhythmias; hence, hypoxia must be prevented and the ECG must be closely monitored. Children tolerate drugs used to treat asthma better than adults do, probably because children have relatively normal coronary arteries and better myocardial reserve. Heliox (a 70:30 helium-oxygen mixture) is about one third as dense as room air and decreases the work of breathing of some asthmatics. Heliox cannot be used if high oxygen concentrations are required. Intravenous magnesium sulfate is a smooth muscle relaxant that has been used to treat asthma. When 25 to 40 mg/kg (maximum of 2 g) is infused over a period of 20 minutes, pulmonary function frequently improves. Hypotension, decreased reflexes, and drowsiness may occur.[117,118]

Most clinicians tolerate $Paco_2$ values of 70 or 80 mm Hg as long as there is no evidence of cardiovascular or neurologic problems.[119] Tracheal intubation is seldom required in pediatric patients with asthma and is avoided when possible because the ETT may further irritate the airway and increase bronchoconstriction. It may also be difficult to remove the ETT later. Mechanical ventilation is frequently ineffective in patients with disease of the small airways and may cause barotrauma. Halothane and isoflurane have been used in mechanically ventilated asthma patients who have respiratory failure and are unresponsive to conventional therapy.[120] Usually, the severe bronchospastic state returns when the inhaled anesthetic is discontinued. ECMO has been used in some asmatic patients when gas exchange could not be achieved with conventional ventilators.[121]

Cystic Fibrosis

Cystic fibrosis is a fatal autosomal recessive disease carried on chromosome 7. Although it affects the pancreatic, hepatic, pulmonary, GI, and reproductive systems, 90% of the reported morbidity and mortality is pulmonary.[122] The pulmonary pathology consists of severe airway obstruction, bronchiectasis, emphysema, and terminal respiratory failure.

Survival of patients with cystic fibrosis has improved dramatically over the past 30 years. More than one third of patients survive to greater than 30 years of age.[123] This change is the result of improved antibiotic therapy, nutritional support, and aggressive treatment of complications. Lung transplantation has been performed in patients with chronic respiratory failure with varied success.[124,125]

Bronchopulmonary Dysplasia

BPD is a form of chronic lung disease that occurs in patients who have survived severe neonatal lung disease. The cause of this disease is uncertain, but usually patients were premature, had hyaline membrane disease, and required prolonged and aggressive respiratory support with high inflating and distending pressure and high oxygen concentrations. Inflammation appears to be an important component of this disease.[126] Children with BPD have decreased dynamic compliance, increased airway resistance, increased physiologic dead space, and markedly increased work of breathing. The lungs are hyperinflated, and there are intercostal retractions, nasal flaring, and wheezing. Chest radiographs demonstrate large lung volumes and fibrosis as well as cystic and atelectatic areas. Hypercapnia and hypoxia are present to varying degrees.[127,128]

Therapy for BPD includes providing enough calories to meet the higher energy expenditure required for the increased work of breathing. Respiratory support (mechanical ventilation, CPAP) is required for some patients. Diuretics and bronchodilators are frequently used and may be associated with electrolyte abnormalities. Most long-term survivors have subjectively normal pulmonary function. However, some survivors have severe chronic physiologic changes.[129,130] During the first years of life, viral or bacterial pulmonary infections often increase the need for respiratory support; these infections may prove to be fatal.

Great effort is being made to prevent BPD. Because the trauma of mechanical ventilation on an immature lung is thought to be the major cause of BPD, alternative modes of ventilatory support are being evaluated, including exogenous surfactant, high-frequency ventilation (especially HFOV),[101] ECMO, and liquid ventilation.[127,131]

Sleep Apnea

Normal ventilation during sleep requires normal upper airway anatomy and normal intact reflexes. The latter include central responses to hypercapnia and hypoxia, response to airway irritation, and dynamic phasic contraction of the pharyngeal and hypopharyngeal muscles. Sleep apnea usually occurs when one or more of these protective responses is abnormal.

In infancy, sleep apnea is relatively common. Numerous causes have been postulated, the most attractive of which is immaturity of the medullary chemoreceptors. Patients with Ondine's curse, the most severe form of central apnea, have complete apnea when asleep. Lesser breathing disorders may be present during sleep in patients with sudden infant death syndrome (SIDS). Treatment of sleep apnea consists of respiratory stimulants (theophylline), cardiorespiratory monitoring during sleep, and in some severe cases, tracheotomy and nighttime mechanical ventilation.[132]

Obstructive sleep apnea occurs in all pediatric age groups. It may be associated with an identifiable anatomic disorder, such as enlarged tonsils and adenoids, the Pierre Robin syndrome, and tracheal and laryngeal malacia. Signs and symptoms of obstructive sleep apnea include loud snoring, obstructive episodes with frequent arousal, behavior disorders caused by sleep deprivation, and cor pulmonale. The diagnosis is made by the history, ECG,

and formal sleep studies. Bronchoscopy may also be helpful in defining the problem. In young children, an enlarged liver may suggest that the child has pulmonary hypertension.

Treatment of sleep apnea includes removal or bypass of an obstruction. Although tonsillectomy and adenoidectomy may improve the airway, there may still be significant airway obstruction for the first few days after surgery. Rarely does such a child require a tracheostomy.

Foreign Body Aspiration

Foreign body aspiration is a relatively common and often catastrophic event in children. Although it can occur at any age, the peak incidence of foreign body aspiration occurs at 6 months to 3 years of age. Vegetable matter (peanuts) and other foodstuff (hot dogs) or coins and small pieces of toys are the most commonly aspirated material. Many of these objects are radiolucent. The symptoms of aspiration are related to the location of the foreign body within the airway and the time since the object was aspirated. Acute symptoms may include total airway obstruction, stridor, wheezing, or acute onset of coughing, whereas more chronic symptoms include bloody sputum, chronic coughing, or wheezing. The diagnosis of a foreign body in the airway is made from the history and physical examination and, in some cases, by radiologic imaging.

The efficacy and safety of abdominal thrusts have been questioned. Heimlich's maneuver and back slaps are reserved for acute upper airway obstruction with no air movement. Treatment of less acute or lower airway foreign body aspiration includes bronchoscopy, postural drainage, chest physical therapy, bronchodilators, and surgical removal of the object.[133]

Upper Airway Obstruction and Meningomyelocele

Vocal cord paralysis is a common result of several disorders, including brainstem abnormalities and myelodysplasia. Children with meningomyelocele usually have an Arnold-Chiari malformation and may have stridor. This lesion allows caudal displacement of the medulla, stretching of the cranial nerve tracts, and abnormal arterial architecture of the brainstem.

Vocal cord paralysis may result from pressure on the brainstem (i.e., with hydrocephalus) or from focal infarcts of the brainstem. Treatment of these brainstem abnormalities includes relief of the hydrocephalus and, if the paralysis persists, cervical decompression of the Arnold-Chiari lesion. Despite these surgical procedures, some children require a tracheotomy and long-term mechanical ventilation.

Central Nervous System

Systemic illness is a common cause of central nervous system (CNS) dysfunction in infants and children. Seizures, head trauma, CNS infections, and hypoxic or metabolic encephalopathy commonly cause acute neurologic dysfunction in the PICU. Assessment of neurologic function depends on an understanding of the age-dependent progression of motor and cognitive skills. Table 84-6 lists the developmental milestones.

Functional Postnatal Neurologic Development

Motor function in the newborn depends on gestational rather than postnatal age.[134] That is, an infant born at 28 weeks' gestation exhibits motor responses similar to those of a full-term newborn when the former is 3 months old. Although potentially modifiable by cortical influence, most neonatal motor behavior is subcortically controlled, which permits normal motor behavior in newborns who have severe cortical damage.

Table 84-6 Normal Ages for Major Developmental Milestones

Age	Motor Function	Language	Adaptive Behavior
4-6 wk	Lifts head from prone position and turns from side to side	Cries	Smiles
4 mo	Shows no head lag when pulled to sitting from supine position; tries to grasp large objects	Utters sounds of pleasure	Smiles, laughs aloud, and shows pleasure to familiar objects or persons
5 mo	Grasps voluntarily with both hands; plays with toes	Makes primitive sounds	Smiles at self in mirror (ah, goo)
6 mo	Grasps with one hand; rolls prone to supine; sits with support	Has increased range of sounds	Expresses displeasure and food preferences
8 mo	Sits without support; transfers objects from hand to hand; rolls supine to prone	Combines syllables (baba, dada, mama)	Responds to "No"
10 mo	Sits well; crawls; stands holding; finger-thumb apposition in picking up small objects		Waves bye-bye; plays patty-cake and peek-a-boo
12 mo	Stands holding; walks with support	Says two or three words with meaning	Understands names of objects; shows interest in pictures
15 mo	Walks alone	Utters several intelligible words	Requests by pointing; imitates
18 mo	Walks up and down stairs holding; removes clothes	Says many intelligible words	Carries out simple commands
2 y	Walks up and down stairs by self; runs	Makes two- or three-word phrases	Engages in organized play; points to some parts of the body

Modified from Crone RK: Pediatric critical care: Supporting the developing organ system. *In* Shoemaker WC (ed): Critical Care: State of the Art, vol 5. Fullerton, CA, Society of Critical Care Medicine, 1984, p D1.

Assessment of intellectual development is difficult in a newborn; initially, it is based on the absence of reflexes and the acquisition of new motor skills. Adaptive or interactive behavior is first seen with accommodation to repeated stimuli and eye contact. The infant's intellectual development depends on the presence of external stimulation and social interaction, preferably from one or a few individuals. This is why infants and children who require long-term intensive care must have parental input and exposure to a limited number of caregivers.

Monitoring of Neurologic Function

Clinical examination is the most important tool we have for assessing neurologic function in children. In an awake child, interactions with the examiner and caretakers are sensitive indicators of high or integrative cortical function. When the child's cognitive function is depressed from disease or drugs, examination of the general level of activity and peripheral and brainstem reflexes becomes an important, albeit crude measure of CNS function. The Glasgow Coma Scale (GCS) is a tool to evaluate the level of function of neurologically impaired patients (Table 84-7).[135] Table 84-8 presents the pediatric GCS for children without language skills.

Laboratory Assessment of Neurologic Function

The electroencephalogram (EEG) is used to diagnose seizures and isoelectric brain death and to monitor the effects of barbiturates administered to induce coma. Otherwise, the EEG is so nonspecific that it is not very helpful. Brainstem evoked potentials (auditory, visual, and somatosensory) allow neurologic assessment of comatose or anesthetized patients. Evoked potentials define marginally functioning neurons that are undetectable clinically. Asymmetry, abnormality, or absence of conduction of auditory, visual, or tactile stimuli through the brainstem to the cortex provides useful information regarding the progress or recovery from neurologic injury. Although evoked potentials are only mildly affected by barbiturates, a flat EEG during barbiturate coma cannot be regarded as diagnostic of brain death.

Table 84-7 Glasgow Coma Scale Score*

Sign	Evaluation	Score
Eye opening	Spontaneous	4
	To speech	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate	3
	Incomprehensible	2
	None	1
Best motor response	Obeys commands	6
	Localizes pain	5
	Withdrawal to pain	4
	Flexion to pain	3
	Extension to pain	2
	None	1

From Ramondi AJ: Head injury in the infant and toddler. Childs Brain 11:12, 1984.

Computed tomography (CT) allows rapid detection of CNS lesions, the extent of structural injury, and noninvasive assessment of ICP. Cranial ultrasound is a bedside technique used to assess ventricular size and intracranial anatomy in infants with nonfused cranial sutures. MRI permits intraorbital and ocular injuries and brainstem and spinal cord lesions to be examined; it is also good for defining soft tissue abnormalities.[136] MRI's major drawback is the length of time required for each examination and the relative inaccessibility of the patient while in the scanner. Maintaining body temperature can also be a problem in small children during MRI scanning because the room must be cold. It may be difficult to safely perform MRI in patients who have significant cardiorespiratory compromise because many of the pumps and ventilators cannot enter the scanner.

Doppler ultrasound allows bedside assessment of cerebral blood flow (CBF) velocity in the ICU. Although it does not directly measure CBF, Doppler ultrasound is a useful bedside guide to therapy. CBF scans are the "gold standard" and are usually required to diagnose brain death during barbiturate coma.

ICP can be monitored by inserting a catheter into a lateral ventricle or by inserting a subarachnoid screw or transducer into the epidural space or cerebral parenchyma. The ventricular catheter provides an accurate waveform and permits withdrawal of cerebrospinal fluid (CSF) to reduce ICP. The other devices used to measure ICP provide less consistent pressure waves and do not permit removal of CSF.

Pathophysiology of Neurologic Disease

The pathophysiology of critical neurologic disease includes increased ICP, abnormal electrical discharge (status epilepticus), and focal loss of functioning neurons (see Chapter 63).

Increased Intracranial Pressure

With severe neurologic diseases, increased ICP increases morbidity and mortality. Such diseases include head trauma, Reye's

syndrome, hypoxic-ischemic encephalopathy, metabolic encephalopathies, intracranial space-occupying lesions, and hydrocephalus. ICP increases when the intracranial volume of one of the four compartments (CSF, blood, brain, and supporting tissues) within the cranial vault increases. An increase in one compartment can occur without raising ICP if an equal volume is displaced from another compartment. When displacement is no longer possible, ICP rises in proportion to the added volume.[137] In older children and adults who have a rigid calvaria, the cranial cavity is a closed container, and the contents are noncompressible.

Intracranial Compliance Curve

Intracranial hypertension causes neurologic injury by two mechanisms: (1) a sufficiently high ICP that reduces cerebral perfusion pressure and causes brain ischemia and (2) a sufficiently elevated ICP that compresses and herniates the brainstem or other vital structures. Monitoring of ICP and anticipatory treatment of intracranial hypertension may improve outcome, particularly in patients with head trauma.[138]

It is often difficult to determine who is at risk for intracranial hypertension. A normal cranial CT scan does not always rule out the development of intracranial hypertension, and open fontanelle/sutures do not preclude it from occurring. One study found an ICP higher than 20 mm Hg in 86% of children with a GCS score of 3 to 8.[139] Although certainly not a substitute for careful neurologic assessment, ICP monitoring may suggest that further intervention is necessary. In head-injured patients, intracranial hypertension can occur with or without a surgical lesion, or it may occur after a hematoma is evacuated. Although the outcome of children is better than that of adults with similar head injuries, children may still have significant long-term CNS injury.[140] Prompt recognition and treatment of increased ICP increase survival and improve neurologic outcomes.[141]

Hypoxic-Ischemic Encephalopathy

There is little evidence that increased ICP or correction of ICP alters the outcome of patients with hypoxic-ischemic encephalopathy. The clinical impression is that the outcome is less favorable in patients who have trauma or metabolic encephalopathy and that aggressive management of ICP, at best, prevents further CNS damage, which is important. The GCS score provides a reasonable assessment of neurologic function in these patients.

Hydrocephalus

Another cause of increased ICP is an increase in CSF volume (i.e., hydrocephalus). Common causes of hydrocephalus include obstructed ventricular shunts, aqueductal stenosis/compression as a result of congenital malformations, infection, posterior fossa tumors, or intracranial bleeding. Inserting an external or internal shunt to reduce the volume of CSF can be lifesaving.

Tumors

Brain tumors are common in children and many occur in the posterior fossa. The initial symptoms may include focal deficits, ataxia, or symptoms of increased ICP.

Guidelines for Monitoring Intracranial Pressure

Patients with head trauma, Reye's syndrome, or metabolic encephalopathy are candidates for ICP monitoring if they have a GCS score of 8 or less, clinical signs of increased ICP, or evidence of increased ICP on CT. Coagulopathies must be corrected before inserting an ICP monitor.

Treatment of Increased Intracranial Pressure

When intracranial hypertension is present, therapy should be initiated promptly. Although removing CSF acutely decreases ICP, the underlying cause of the elevated ICP must be sought and treated (i.e., hematomas should be evacuated, antibiotics should be administered when appropriate, and plans should be made to remove tumors or other masses). Treatment of increased ICP includes positioning, oxygenation, and administration of hypertonic solutions.

Positioning Elevating the head of the bed 15 to 30 degrees while keeping it in the midline position enhances cerebral venous outflow. Even slight movement of the head to a few degrees off midline may double the ICP.

Adequate Oxygenation Children with increased ICP should undergo tracheal intubation after being given appropriate premedication to mitigate further increases in ICP. Pao_2 should be kept at or above 100 mm Hg and $Paco_2$ between 30 and 35 mm Hg (when possible) by mechanical ventilation. The lowest airway pressures possible should be used to achieve these goals to avoid interfering with venous drainage from the head. Mean arterial pressure should be kept at the preintubation level.

Mannitol and Hypertonic Saline Mannitol reduces ICP by decreasing blood viscosity and transiently increasing CBF and oxygen transport. The adenosine concentration decreases and CBF is maintained in areas that have intact autoregulation.[142] CBF remains constant despite a decrease in cerebral blood volume and ICP. Mannitol also reduces ICP by withdrawing water from the brain parenchyma and excreting the water as urine.[143] It takes 20 to 30 minutes for this osmotic effect of the drug to develop. Intermittent boluses of 0.25 to 1 g/kg of mannitol are administered intravenously to control ICP. The drug eventually enters the CSF and can increase ICP.

Use of 3% saline to treat increased ICP is gaining in popularity[144] because the sodium does not cross the blood-brain barrier quickly and it has an osmolar gradient similar to that of mannitol. Three percent saline has additional theoretical beneficial effects, including enhancement of cardiac output, reduction of inflammation, restoration of normal cellular resting membrane potential and cell volume, and stimulation of the release of atrial natriuretic peptide.

Muscle Relaxants

Paralysis of striated muscles may decrease ICP by reducing the increased intrathoracic and venous pressure caused by coughing, straining, or "bucking against the ventilator."

Sedation

Fear, anxiety, and the response to painful stimuli may increase CBF and ICP. Sedation of unconscious patients can obscure the neurologic examination, but the reduction in ICP may outweigh this risk in many cases. Most intravenous sedatives, including benzodiazepines, butyrophenones, and barbiturates, decrease CBF and ICP. Ketamine increases CBF and should be avoided in most cases. Opioids can be used if the patient's respiration is controlled.

Steroids

Steroids decrease vasogenic edema around brain tumors and reduce eighth nerve swelling and associated hearing loss caused by bacterial meningitis.[145] Steroids play no role in the treatment of traumatic brain injury or global cerebral edema.[146] If steroids are administered, care should be taken to prevent the development of gastric ulcers.

Temperature Control

Hyperthermia may be detremental to patients with brain injury. Even an increase of a few degrees in body temperature significanlty increases CNS injury in patients with head injuries and other causes of cerebral injury. The cerebral metabolic rate increases 5% to 7%°C. Antipyretic agents (acetaminophen) and cooling devices are used to decrease the brain temperature. Hypothermia reduces the cerebral metabolic rate. For example, at 30°C, the cerebral metabolic rate is about 50% below control values.[147] Inducing hypothermia before a cerebral ischemic insult takes place allows longer periods of inadequate CBF before CNS injury occurs, but there is some evidence that inducing hypothermia after an insult improves neurologic outcomes.[148] Decreasing the body temperature to 35°C reduces long-term CNS injury.[149] Temperatures below 33°C are associated with increased morbidity and mortality related to an increased metabolic rate, increased bleeding, and increased rates of infection. Hypothermia should be used only if the patient is paralyzed and anesthetized to prevent shivering.

Glucose Control

Hyperglycemia can worsen neurologic outcome after head injury in adults and children.[150,151] In animals, hyperglycemia increases CNS injury, possibly by causing lactic acidosis.[152-154] Giving sufficient insulin to maintain the glucose concentration near normal was associated with fewer neurologic deficits than in hyperglycemic animals.[155] Hypoglycemia should also be avoided. Dextrose-containing solutions should be administered to patients with head injury only if there is clear evidence of hypoglycemia and just in sufficient quantities to maintain normoglycemia.

Seizure Control

Seizures increase the metabolic requirements of the brain and increase CBF, cerebral blood volume, and ICP.[156] Paralyzed patients should have an EEG to determine the presence or absence of seizures. Aggressive treatment of seizures with anticonvulsants is mandatory.

Barbiturates

Barbiturates reduce CBF and cerebral metabolism. Thiopental, 1 to 5 mg/kg by intravenous bolus, reduces ICP for 5 to 10 minutes. A bolus of pentobarbital (Nembutal), 3 mg/kg or more intravenously, plus a continuous infusion of 1 to 2 mg/kg/hr, effectively reduces ICP. Blood levels of 20 to 40 mg/L are generally required to produce a significant reduction in ICP. Higher concentrations may be necessary to achieve burst suppression. In these doses, barbiturate metabolism and excretion may be altered, so blood levels must be monitored closely. Myocardial depression and hypotension are common complications of barbiturate administration. Consequently, cardiovascular function should be monitored closely, and steps must be taken to improve cardiac function and arterial blood pressure.[157] Although barbiturate administration decreases ICP, it may not improve survival or neurologic outcome.[158-160]

Lidocaine

A bolus of intravenous lidocaine, 1 mg/kg, may minimize increases in ICP associated with noxious airway stimulation (i.e., endotracheal suctioning).

Status Epilepticus in Children

Status epilepticus is a continuous motor seizure that lasts for more than 20 minutes or a series of seizures without intercurrent awakening. Although it is common for physicians to never find a cause of the seizures, the most commonly diagnosed causes are infections (meningitis or encephalitis) and metabolic abnormalities (toxins, head trauma, and hypoxic and ischemic injury). Because seizure activity increases with status epilepticus, brain and skeletal muscle metabolism and oxygen consumption increase and place the child at risk for cellular hypoxia. During a seizure, airway obstruction and ineffective chest wall and diaphragmatic excursion can limit ventilation and worsen arterial hypoxemia and hypercapnia.

Treatment of a seizure begins with establishing a patent airway, administering oxygen, and ensuring adequate ventilation. Intravenous anticonvulsant drugs are given to stop the seizure. Commonly used anticonvulsants include lorazepam, phenobarbital, paraldehyde, and phenytoin.

Lorazepam is a rapid and reliable drug used to stop seizures. Boluses of 0.1 mg/kg are given intravenously or rectally when there is no intravenous access. Phenobarbital, 5- to 10- mg/kg boluses (maximal dose of 20 mg/kg), also stops seizures. The main complication of lorazepam is respiratory depression when administered in high doses. Giving both phenobarbital and lorazepam together exaggerates the respiratory depression. Fosphenytoin is also given intravenously in doses of up to 20 mg/kg and should be administered slowly to avoid cardiovascular depression. Paraldehyde, 0.3 mL/kg, can be given rectally. Finally, an intravenous injection of 1 to 4 mg/kg of sodium thiopental stops most intractable seizures; higher does of the drug may cause apnea, and the risk of vomiting and aspiration of gastric contents is real. Once the seizures are under control, the cause of the seizures must be determined.

Brain Death

Irreversible cessation of cardiorespiratory function is the most common definition of death (also see Chapter 98). However, the advent of organ transplantation and the need for organs have made the definition of death less clear. The problem is that it is possible to maintain cardiopulmonary function indefinitely, even after brain function has ceased. Consequently, brain death is the clinical and legal definition of death, "a permanent cessation of brain function."

Criteria for brain death include irreversibly absent cerebral and brainstem functions. Absent cerebral function is defined as lack of cortically mediated responses to external stimuli.[161] Absent brainstem function is defined as absent brainstem reflexes, including absent pupillary response to light and absent corneal,

oculocephalic, oculovestibular, oropharyngeal, and respiratory reflexes.

Irreversible brain death occurs when the cause of coma is sufficient to account for the loss of brain function and when the possibility of recovery is excluded by clinical observation, laboratory studies, or both. Laboratory studies include analysis of blood and urine for toxic substances, EEG, radionuclide brain scans, cerebral angiography, and brainstem evoked potentials. These tests are supplementary to the clinical history and physical examination. Factors that can simulate the clinical or laboratory criteria for absent brain function (a core temperature <30°C and high blood barbiturate concentrations) must be ruled out. Both hypothermia and barbiturates can significantly depress electrical activity in the brain and render an EEG meaningless. In such cases, a technetium 99m radionuclide angiogram will demonstrate the presence or absence of CBF. Brain-dead patients have no arterial blood flow in the anterior and middle cerebral arteries and no venous flow in the sagittal sinus; blood flow in extracranial tissues is usually preserved. This study is independent of the patient's core temperature or barbiturate level. Two or more physicians should concur on the clinical or laboratory diagnosis of brain death (or both) before care is discontinued. All evidence of brain death and all related discussions must be clearly documented in the patient's record.

Whenever a patient is declared brain-dead, the family should be approached for organ donation. Tissue donation (e.g., eyes and heart valves) is also possible after death. Regional procurement agencies can provide protocols and support to the ICU staff and families.

Renal System

Structural and Functional Development of the Excretory System

Embryologic development of the renal system begins in the middle of the third week of gestation with development of the pronephric tubules. By 10 weeks' gestation, a functioning kidney and collection system exist, and fetal urine is discharged into the bladder. At 32 to 36 weeks' gestation, each kidney has a full complement of nephrons. Table 84-9 presents normal values for pediatric renal function.

Table 84-9 Normal Values for Pediatric Renal Function

	Age	Value
Creatinine (mg/dL)	1 yr 10 yr 18 yr	0.41 ± 0.1 0.61 ± 0.22 0.91 ± 0.17
Glomerular filtration rate (mL/min/1.72 m^2)	2-8 days 6-12 mo 2-12 yr	39 (range, 17-60) 103 (range, 49-157) 127 (range, 89-165)
Urine concentration (mOsm/L)	1 mo 2-16 yr	600-1100 1089 (range, 870-1309)

Modified from Goldsmith DI: Clinical and laboratory evaluation of renal function. *In* Edelman CM Jr (ed): Pediatric Kidney Disease. Boston, Little, Brown, 1978, p 213.

Functional Development of the Kidney

Because the placenta is the major excretory organ of the fetus, renal growth is not governed by functional requirements. Renal growth increases linearly with body weight and body surface area during the third trimester of pregnancy. The glomerular filtration rate (GFR) increases rapidly from 28 to 35 weeks of gestation. At term, the GFR is 10 mL/min/m^2 and increases to 20 mL/min/m^2 by 2 weeks of age. Although the GFR of premature infants is lower, the rate of increase is the same as that in a term infant.[162] Tubular function is not fully mature in full-term newborns. The newborn kidney is sensitive to antidiuretic hormone (ADH) and vasopressin, and urine osmolarity can vary from only 50 up to 780 mOsm/L.[163] The tubular function of premature infants is less mature.

The newborn's renal threshold for bicarbonate is about 20 mEq/L, which means that standard acid-base nomograms do not apply to infants because their serum bicarbonate concentration of 20 mEq/L is not indicative of metabolic acidosis. The renal tubular glucose threshold of term infants is similar to that of adults, but it is only 125 to 150 mg/dL in premature infants. A full-term infant has 1% or less fractional excretion of sodium by the third day of life. Fractional excretion of sodium can be much higher (5%) in premature infants.[164] Renin, angiotensin, and aldosterone concentrations are high in newborns and decrease over the first few weeks of life. Normal values for pediatric renal function are presented in Table 84-9.[165]

Renal Failure

Acute renal failure is defined as an abrupt, often temporary loss of renal function (see Chapters 65 and 67). Oliguria is the rule, polyuria is the exception, and anuria is uncommon. Urine volume and composition are altered, and fluid, electrolyte, and acid-base disorders are common. Therapy is directed at maintaining normal metabolic and fluid homeostasis, supporting nutrition, and exhibiting patience. Acute renal failure is caused by prerenal, postrenal (obstructive), or intrinsic renal disorders. Prerenal causes are due to reduced renal blood flow. Reduced cardiac output or renal blood flow is a common cause of reduced urine output and results in azotemia and ischemic renal damage. The adequacy of circulating blood volume is assessed by CVP and cardiac output measurements and by estimating renal blood flow with Doppler flow studies or nuclear imaging techniques. These studies help differentiate prerenal from renal causes of azotemia, but they may be difficult to obtain in sick neonates.

Postrenal obstruction of urine flow can occur anywhere within the collecting system but it occurs most commonly as partial obstruction of the bladder neck or the ureterovesical or ureteropelvic junction. All these malformations cause obstructive nephropathy and renal injury or renal failure. Signs of obstruction may be subtle and require radiologic, ultrasonic, or endoscopic evaluation to detect. Recurrent urinary tract infections are frequent clinical manifestations of obstructive lesions.[166]

Intrinsic renal failure is caused by disorders of the renal glomeruli, tubules, or blood vessels. Glomerular diseases include hemolytic-uremic syndrome (HUS), poststreptococcal glomerulonephritis, Henoch-Schönlein purpura, and other inflammatory and immune complex diseases. Acute tubular injury is most commonly caused by hypoxia and ischemia; other causes are rhabdomyolysis, sepsis, hyperthermia, hemolysis, and a myriad of

nephrotoxins, including mercury, carbon tetrachloride, and ethylene glycol. Vascular diseases, including arterial embolism, venous thrombosis, and congenital malformations, are also causes of acute renal failure.

Hemolytic-Uremic Syndrome

HUS is one of the most common causes of acute renal failure in children. This syndrome is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal injury. In North America, HUS is most often associated with infection by cytotoxin-producing *Escherichia coli* O157, but other serotypes and other Shiga-like toxin–producing bacteria have been implicated.[167]

E. coli O157 resides in the intestinal tract of cattle and may contaminate beef during processing.[168] The organism is killed by cooking. Infections can be spread by person-to-person contact in daycare centers, institutions, and the military. There is also a familial form of the disease that accounts for a small percentage of the total cases.[169]

HUS is seen predominately in 0.5- to 4-year-old children but it can occur in all age groups.[170] It shares many laboratory and clinical features with the adult disease, thrombotic thrombocytopenic purpura. In fact, some investigators consider the two disorders a continuum of the same disease. The abnormalities that develop in HUS are believed to be caused by cytotoxins and lipopolysaccharide, a bacterial endotoxin. Toxin-induced damage to renal endothelial cells, the vasculature, and other organs is directly or indirectly associated with the activation of leukocytes.[171] Cytokines such as interleukin-1 and tumor necrosis factor, prostaglandin I_2, thromboxane A_2, and von Willebrand factor (vWF) multimeres probably play a role in the pathogenesis of this disease.[172]

The time from exposure to the organism to initial evaluation of the patient varies from 3 to 12 days. Symptoms last for about a week. Patients usually have abdominal cramping, bloody diarrhea, tenesmus, and vomiting.[173] On average, about 10% of children with *E. coli* O157–induced bloody diarrhea progress to HUS. Mildly affected patients exhibit anemia, thrombocytopenia, azotemia, and decreased urine output and have an uncomplicated course. In severely affected patients, anuria is common, hypertension and seizures may occur, and the duration of illness is prolonged. A small number of children exhibit progressive and permanent renal insufficiency, severe and recurrent hemolysis, thrombocytopenia, and neurologic impairment.

Hematologic abnormalities include hemolysis and thrombocytopenia. Hemolysis often causes hyperbilirubinemia and, despite reticulocytosis, severe anemia with hemoglobin concentrations of 4 to 5 g/dL. Thrombocytopenia is the result of platelet destruction and sequestration in the liver and spleen.[174] The remaining platelets show evidence of impaired aggregation.[175] Disseminated intravascular coagulation (DIC) is relatively common. Glomerular capillary endothelial injury is the most consistent renal finding in HUS. Acute renal failure with oliguria or anuria usually lasts less than a week but may linger for more than 10 weeks.[176] Glomerular or arterial injury, or both, may predominate, depending on the presence and extent of renal insufficiency (glomerular injury) and hemolysis and hypertension (arterial injury). CNS abnormalities are manifested as decreased levels of consciousness, seizures, irritability, ataxia, hypotonia, hemiparesis, hyperreflexia, and hallucinations; these problems may be caused by severe hypertension, electrolyte disturbances, microthrombi, or cerebral edema and increased ICP.[177] Abdominal cramping is common and may be difficult to distinguish from intussusception, intestinal stricture or bowel perforation, colonic gangrene, or other surgical emergencies.[178] Pancreatitis is common in patients with HUS. CHF may occur if there is fluid overload, hypertension, anemia, or myocardial depression caused by circulating endotoxins.

Treatment of HUS is primarily supportive. Meticulous attention should be paid to volume status, electrolyte and acid-base balance, nutrition, antisepsis, and treatment of hypertension and coagulopathies. Enteric isolation is mandatory to prevent secondary spread of the disease. Accurate fluid intake and output measurements and frequent assessment of weight and volume status are important for management of these patients. A central venous catheter is useful for CVP measurements, blood sampling, and administration of intravenous medications and nutrition. Nephrotoxic drugs should be avoided if possible. If nephrotoxic drugs must be given, the drug dose should be adjusted and serum concentrations monitored closely. Daily fluids should be restricted to the amounts required to replace insensible losses, urine output, and other ongoing losses. Fluids administered should reflect the electrolyte content of the fluid losses. Caloric support is essential. Enteral feedings are preferred, but parenteral feeding may be necessary if ileus develops. Antidiarrheal medications prolong the duration of colitis, and antibiotics may increase the risk for HUS.[179,180] No specific treatment has been effective to date. Heparin, fibrinolytic agents, aspirin, dipyridamole, corticosteroids, vitamin E, and furosemide have not affected the outcome of HUS.[181] Immunoglobulin therapy, plasmapheresis, and infusions of fresh frozen plasma have had mixed results, but no long-term therapeutic benefit has been demonstrated.

Dialysis, improved nutrition, and supportive care have decreased the mortality rate from 100% in the original report to less than 10% in the last 30 years. Mortality rates remain high in developing countries and in children with a genetic predisposition for HUS.

Peritoneal dialysis requires the insertion of a soft, multiholed catheter into the peritoneal cavity. When patency of the catheter is confirmed, a dialysate solution is infused that equilibrates with plasma and extracellular fluids. The parietal and visceral surfaces function as semipermeable dialysis membranes. The composition of the dialysis fluid is similar to that of plasma and consist of approximately 130 mEq/L of sodium, 100 mEq/L of chloride, 35 mEq/L of acetate or lactate as a buffer, 3.5 mEq/L of calcium, and 1.5 mEq/L of magnesium. The glucose concentration of the solution can be either isosmotic or hyperosmotic. Hyperosmotic solutions remove fluid and electrolytes. Respiratory compromise may occur with peritoneal dialysis because the increased abdominal pressure caused by the dialysate in the abdomen may prevent effective spontaneous ventilation. Mechanical ventilation will be required if this occurs. Bacterial or fungal peritonitis is common. Severe dehydration, circulatory collapse, and metabolic derangements are other complications of peritoneal dialysis. The principles of hemodialysis are essentially the same as those of peritoneal dialysis, but the blood interfaces with a semipermeable membrane rather than with the peritoneum. Hemodialysis is more efficient than peritoneal dialysis and is more appropriate in the acute setting. Hemofiltration and ultrafiltration are processes in which blood is cleansed by convective

solute transport. During this procedure, an ultrafiltrate of plasma is created by hydrostatic pressure exerted across a highly permeable membrane. Simultaneous blood volume replacement with modified lactated Ringer's solution is required.[182]

Outcome

The prognosis with acute renal failure depends on the patient's age, underlying disease, and the extent of the precipitating insult (also see Chapter 18). In general, children do better than adults; in fact, children usually recover completely from a renal insult if the hypoxia or ischemia lasted only a short time and other organ systems are not involved.[183] Children with chronic renal failure require long-term outpatient peritoneal dialysis or hemodialysis until they can undergo renal transplantation.[184]

Endocrine System

It is beyond the scope of this chapter to discuss chronic endocrine diseases in detail, but the acute disorders most commonly encountered in the PICU are discussed in the following sections.

Adrenal

Abnormalities of the adrenal axis result in deficient or excessive production of glucocorticoids, mineralocorticoids, or both. Many of these disorders are diagnosed and treated as they are in adults. Congenital adrenal hyperplasia, pheochromocytoma, and iatrogenic chronic adrenal insufficiency will be discussed briefly.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is an autosomal recessive disorder that is associated with deficiencies in either 21-, 11-, or 17-hydroxylase. 21-Hydroxylase deficiency in children can be partial (simple virilizing form) or more complete (salt-losing form); at birth, affected children demonstrate masculinization of the external genitalia, and those with the more complete deficiency show a progressive salt-losing state (i.e., loss of sodium and elevation of potassium). This condition is usually manifested in the first few weeks of life as feeding difficulty, vomiting, and failure to thrive. The clinical and historical course is suggestive of pyloric stenosis. If the deficiency is not diagnosed and treated early in life, affected children may suffer severe cardiovascular collapse. A blood sample should be obtained for electrolytes, glucose, and if the diagnosis has not been established, adrenocorticotropic hormone (ACTH), cortisol, aldosterone, and plasma renin activity.

Treatment requires aggressive support of intravascular volume and myocardial function, glucose, and replacement of the deficient hormones. Cortisol can be replaced by oral administration of hydrocortisone at a dose of 25 mg/m^2/day divided into three doses; if the child cannot tolerate oral medication, cortisone acetate can be administered intramuscularly at a dose of 37.5 mg/m^2/day once every 3 days. For emergency therapy, when the oral route is not possible and perfusion of the muscle is poor, hydrocortisone acetate is used intravenously at a bolus dose of 1.5 to 2.0 mg/kg and then 25 to 250 mg/day in divided doses. Mineralocorticoid is replaced with cortisone acetate, 0.05 to 0.2 mg/day orally; these patients usually require the addition of salt to their diet. Deficiencies of 11- and 17-hydroxylase do not result in salt wasting; masculinization and hypertension are the common initial signs.[185]

Pheochromocytoma

Less than 5% of pheochromocytomas are diagnosed in childhood. As a rule, these tumors are confined to the adrenal medulla, but they can occur anywhere throughout the sympathetic chain. The clinical signs and symptoms of excessive catecholamines are the same as those in adults.

Iatrogenic Chronic Adrenal Insufficiency

Long-term daily use of steroids for the treatment of asthma, nephrotic syndrome, and malignancies is common. Such use may cause a hypoadrenal state and increase the risk for cardiovascular collapse during a severe illness or stress. In children, topical steroids can also depress the production of ACTH. Replacement of stress-level steroids (three times the daily replacement dose) is required.

Anterior Pituitary

Panhypopituitarism is usually secondary to a tumor or to aggressive dissection of a tumor.[186] Acute ICU problems related to this lesion include support of the adrenal axis and abnormalities of ADH.

Diabetes Insipidus

Diabetes insipidus can be of central, renal, or psychogenic origin. The central mechanism is the most common form in ICU patients. Absence of ADH results in polyuria and polydipsia; patients with a severe form of this disease may not be able to drink sufficiently to meet their requirement, and severe hypovolemia may develop. Diabetes insipidus is precipitated by brain tumors, head trauma, neurosurgery, and clinical brain death.[187,188] Treatment, in the setting of the ICU, is fluid replacement or, if unwieldy, hormone replacement with aqueous vasopressin (Pitressin), 0.1 to 1.0 mL intramuscularly (duration, 4 to 6 hours); Pitressin tannate in oil, 0.25 to 1.0 mL intramuscularly (duration, 24 to 72 hours); or desmopressin acetate intranasal, 2.5 to 10 µg twice daily (duration, 10 to 11 hours). The clinical syndrome may be transient or chronic. In either case, close supervision of fluid intake and output is essential.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

The syndrome of inappropriate ADH secretion is associated with hyponatremia and hypo-osmolality caused by inappropriate urinary loss of sodium and free water in patients with normal kidneys. Urine osmolality is greater than serum osmolality. This syndrome is precipitated by a number of mechanisms, including head trauma, neurosurgery, meningitis, hypoxia, and any major surgical procedure in which there is large-volume fluid shifts and fluid replacement.[189,190]

This disease is usually self-limited, and the only real problem occurs if the diagnosis is not considered and the level of hyponatremia is low enough to cause CNS dysfunction. Seizures are rare unless serum sodium is less than 120 mEq/dL. Care should be taken to raise the serum concentration of sodium

slowly. This syndrome is treated by fluid restriction and, in severe cases, by the infusion of hypertonic or isotonic saline.

Pancreas/Insulin

Hypoglycemia

Hypoglycemia is a common problem in ICU patients. What constitutes hypoglycemia in children has been disputed. However, it is uncommon to find a blood glucose level below 40 mg/dL in normal, nourished premature or term neonates.

The usual symptoms of hypoglycemia include tachycardia, diaphoresis, weakness, mental clouding, seizures, and coma. The causes of hypoglycemia can be subdivided into disorders of increased utilization and disorders of decreased production. Transient hypoglycemia of the newborn is caused by decreased or immature hepatic gluconeogenesis and it self-corrects within hours to days. If the hypoglycemia persists, hepatic enzyme deficiencies, endocrine problems, or hyperinsulinism (i.e., pancreatic cell abnormalities, infants of diabetic mothers) must be considered. Other causes of hypoglycemia in the neonatal period include sepsis, hypothermia, hypoxia, and transplacental exposure to maternal hypoglycemic drugs.

In older children, hypoglycemia is associated with ketotic hypoglycemia,[191] hepatic enzyme abnormalities, hyperinsulinism, hepatic failure, and Reye's syndrome, and it is a side effect of certain drugs. Regardless of cause, the initial treatment of hypoglycemia is glucose administration. The initial dose is 0.5 g/kg given as 50% dextrose in water ($D_{50}W$). This dose should be followed by an infusion of dextrose that is sufficient to meet the metabolic requirements of the child (see the later section on the gastrointestinal system).

Diabetic Ketoacidosis

The most serious acute complication of diabetes mellitus is DKA, a syndrome of glucose and ketone overproduction and underutilization that causes hyperglycemic ketoacidosis. The clinical syndrome includes dehydration and hypovolemic shock from hyperglycemic osmotic diuresis, compensatory hyperventilation (Kussmaul pattern), life-threatening electrolyte depletion, and in cases of severe metabolic imbalance, neurologic obtundation and coma.[192] Laboratory evaluation demonstrates elevated blood glucose concentrations, severe metabolic acidosis and compensatory hypocapnia, increased osmolality, hyperlipidemia, and a normal or low sodium level (usually fictitiously low because of the hyperlipidemia). Total-body depletion of potassium and possibly phosphate occurs. Levels of both may be falsely normal because of the metabolic acidosis.

Treatment of DKA requires careful correction of the metabolic derangements with meticulous monitoring of the multisystem complications of DKA, as well as the complications of therapy. Adequate intravascular volume is restored with an isotonic glucose-free solution. Regular insulin is given as an intravenous infusion of 0.1 U/kg/hr. The goal is to decrease blood glucose by 75 to 100 mg/dL/hr. This infusion is continued until the blood glucose reaches 250 to 300 mg/dL, at which time 5% dextrose in normal saline (D_5NS) is added to the infusate. This regimen of simultaneous glucose and insulin infusion can be continued until the patient can tolerate oral feedings and routine subcutaneous insulin administration. Most clinicians continue the insulin infusion until the acidosis is nearly corrected. Potassium concentrations should be monitored closely. These children have total-body potassium depletion, but potassium should not be added to any infusion until there is urine output. The need for phosphate may be more theoretical than real, but in most situations, half the potassium is given as a phosphate salt. The severe metabolic acidosis is usually corrected with volume and insulin administration.

The use of bicarbonate to correct acidosis is generally avoided because bicarbonate may precipitate or worsen the child's neurologic dysfunction. In severe DKA, the intracellular volume of brain cells is reduced by hyperosmolar dehydration. In an attempt to maintain their normal size, brain cells generate osmotically active idiogenic osmoles (e.g., inositol) that attract more water into the intracellular compartment. As systemic rehydration and correction of the hyperosmolar state begin, the brain cells may swell until the idiogenic osmoles are metabolized or cleared. Consequently, rapid correction of osmolarity can cause significant brain edema[193] and may also worsen the neurologic dysfunction. The pH of the brain is determined by the CSF bicarbonate level and by the CO_2 content; the CSF CO_2 content equilibrates much more rapidly with the vascular space than bicarbonate does. Therefore, correcting the systemic acidosis decreases the level of hyperventilation and causes a rise in $PaCO_2$; if this rise is precipitous, the CSF acidosis could worsen before the bicarbonate equilibrates with CSF. Because rapid correction of pH is problematic, bicarbonate administration is not advocated in DKA unless cardiovascular instability is present. Even then, the doses administered are small. Unfortunately, despite very careful and slow correction of the hyperosmolar and acidotic state, hyperosmolar coma and fulminant brain edema can occur.[194] The pathophysiology of brain swelling in DKA is poorly understood. Subclinical brain swelling may be relatively common in children with DKA.[195] If the swelling is significant, mannitol should be administered immediately and therapy for intracranial hypertension begun. The goal is to prevent secondary injury to the brain.

Gastrointestinal System

GI problems in the ICU include organ dysfunction and failure from acquired disease and from congenital anatomic malformations and dysfunction. Delivery of adequate nutrition to critically ill patients is necessary.

Structural and Functional Development of the Intestine

Knowledge of fetal midgut development makes it easier to understand a number of severe congenital anomalies. Although the intestine begins as a hollow tube, it is occluded by 7 to 10 weeks' gestation by rapidly growing epithelial cells. The lumen is later reconstituted when vacuoles within the epithelial cells coalesce. Some of the neonatal intestinal atresias are the result of abnormalities of this recanalization process. At 3 to 10 weeks' gestation, the midgut lies outside the abdominal cavity, with only the hindgut fixed in the left side of the abdomen. The gut rotates 270 degrees counterclockwise and re-enters the abdominal cavity at 10 weeks' gestation. If the midgut fails to migrate back into the

abdominal cavity, an omphalocele occurs. Abnormalities in midgut rotation result in abnormal intra-abdominal relationships, the most important being malrotation and volvulus of the intestine.

Development of the Liver

The liver begins as an outgrowth of the foregut at approximately 3 weeks' gestation. During fetal life it is relatively large in comparison to the adult liver. Although the fetus relies on the maternal liver and placenta for detoxification and excretory function in utero, the fetal liver is necessary for both prenatal and postnatal survival. As early as 10 to 12 weeks' gestation, the fetal liver is involved in glucose regulation, protein synthesis, and lipid synthesis and is capable of some drug metabolism.

The fetal liver contains approximately three times the amount of glycogen as the adult liver, but the glycogen is nearly completely released within hours of birth to compensate for interruption of the placental supply of nutrients.[196] It takes several weeks for the newborn to reestablish the store of liver glycogen, putting the infant at risk for hypoglycemia during this vulnerable period.

Congenital Malformations

Gross anatomic malformations are usually diagnosed during the first few days of life. Some, such as omphalocele, gastroschisis, diaphragmatic hernia, and imperforate anus, are apparent on the initial physical examination. Others manifest themselves in the first few days of life as failure to feed enterally, intestinal atresia, microcolon, tracheoesophageal fistula, and meconium ileus. Other malformations present difficult diagnostic and therapeutic dilemmas after the neonatal period. Specific clinical problems are discussed in the following sections.

Intestinal Malrotation and Midgut Volvulus

Malrotation of the intestine is caused by incomplete rotation of the fetal midgut when the gut migrates into the abdominal cavity. This abnormal rotation can cause partial or complete duodenal obstruction by peritoneal (Ladd) bands or, more importantly, midgut volvulus. The midgut (duodenum to transverse colon) and its vascular supply hang on a single pedicle; if the pedicle twists, the entire midgut may infarct. Infants with omphalocele almost invariably have associated malrotation of the gut. Symptomatic infants and children have signs of high intestinal obstruction (bilious vomiting) or signs of an acute abdomen, intestinal perforation, and sepsis. Treatment is surgical reduction and fixation of the volvulus and resection of nonviable bowel. Postoperative respiratory support and total parenteral nutrition are often necessary in infants who were severely compromised before surgery.

Meckel's Diverticulum

Meckel's diverticulum represents persistence of the omphalomesenteric or vitelline duct and is brought to the attention of the physician because of painless lower GI bleeding. The bleeding site is due to ulceration of the bowel mucosa caused by secretion of gastric acid. Although usually self-limited, massive and life-threatening hemorrhage has been reported.[197] The diagnosis can be difficult to make because it is often one of exclusion. The technetium pertechnetate isotope scan demonstrates gastric mucosa in the diverticulum. Therapy is supportive, but particular attention must be paid to blood replacement. Definitive therapy is surgical resection.

Hirschsprung's Disease

Hirschsprung's disease (congenital aganglionic megacolon) is characterized by the absence of parasympathetic ganglion cells in the rectum and colon and occasionally in the small bowel.[198] Lack of ganglia cause narrowing of the distal bowel and distention of the normal proximal bowel. The clinical symptoms can be relatively minor, with abdominal distention and stool retention, or severe, with toxic megacolon, peritonitis, and intestinal perforation. Toxic megacolon is usually manifested in younger children; reported mortality rates are as high as 75% with toxic megacolon.

The diagnosis of Hirschsprung's disease is occasionally made by the history and physical examination. A barium enema reveals a narrowed segment with ballooning of the proximal part of the bowel. The definitive diagnosis is made by finding no ganglion cells on rectal or colon biopsy (or both). Treatment of toxic megacolon is both supportive (volume re-expansion and antibiotic administration) and definitive (surgical decompression via colostomy).

Other Intestinal Disorders

Intestinal disorders can cause bleeding, obstruction, or inflammation, and there can be secondary problems such as malabsorption and bowel perforation. GI bleeding in children is caused by inflammatory diseases (gastritis), ulcers, varices, or vascular malformations. Although ulcer disease is an uncommon initial complaint in pediatric patients, stress gastritis or stress ulcers occur in critically ill children. Prophylactic antacids or an H_2 antagonist should be considered. Bowel obstruction can be caused by intussusception, twisting of the bowel around congenital or postsurgical bands, and twisting of the bowel on itself (volvulus). Intussusception is relatively common in the pediatric age group and usually occurs in the distal part of the ileum. In only a few cases can a leading point, such as a polyp or localized edema (as seen in Henoch-Schönlein purpura) be identified. Treatment of intussusception can be surgical or, in patients with no evidence of necrotic bowel, with barium, air, or saline enema.[199] Inflammatory bowel diseases include Crohn's disease and regional enteritis.[200] Infectious agents to be considered include *Salmonella*, *Shigella*, and *Yersinia*. These patients often have diarrhea, malabsorption (especially lactose intolerance), and bloody diarrhea. They also can have a toxic acute abdomen.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is an often fulminant neonatal disease characterized by ulceration and necrosis of the small bowel and colon. Its cause is unknown but is probably multifactorial. Prematurity is the greatest risk factor for NEC. It is probably due to a combination of intestinal ischemia, oral feeding, and pathogenic organisms. Umbilical artery catheters, perinatal asphyxia, respiratory distress syndrome, and persistent patent ductus arteriosus have all been implicated.[201] The incidence of NEC is on the rise, with 1% to 5% of infants in neonatal ICUs affected. The most common initial signs are feeding intolerance, abdominal distention, and bloody stools. Intestinal obstruction, bowel perforation, and sepsis may follow. Treatment consists of withholding enteral feeding, nasogastric decompression, intrave-

nous fluids, hemodynamic support, administration of appropriate antibiotics, and surgical exploration if there is evidence of an acute abdomen with free air. Peritoneal drainage may be helpful for very-low-birth-weight babies and for those in extremis.[202] Total parenteral nutrition is frequently required for several weeks, and intestinal obstruction may occur weeks to months after a relatively benign course.[203]

Hepatic Failure

Hepatic failure occurs with chronic or acute liver disease. Chronic liver failure can be caused by biliary atresia, inborn errors of metabolism (tyrosinosis, Wilson's disease, galactosemia, cystic fibrosis), or chronic inflammatory hepatitis. Children with chronic disease often have signs and symptoms of synthetic dysfunction (malnutrition, hypoalbuminemia, abnormal coagulation), degradation dysfunction (icterus and hyperammonemia), and portal hypertension (hypersplenism and varices). Acute liver failure is most commonly caused by infectious hepatitis A and B.

Evidence of bleeding, edema, and other organ dysfunction, including identification of liver and spleen size, is sought on physical examination. Laboratory evaluation should include screening for synthetic function (albumin, prothrombin time [PT], partial thromboplastin time [PTT]), degradation products (bilirubin, ammonia), and liver enzyme concentrations. Hepatic ultrasound, radiographic contrast studies, and liver biopsy are indicated on an individual basis.

Life-threatening complications of liver failure include acute bleeding and cardiovascular compromise (from massive intravascular hypovolemia as a result of fluid shifts) and intracranial hypertension from toxic encephalopathy. Treatment is expectant and supportive. A 10% dextrose infusion will provide adequate carbohydrate intake. Low-protein diets minimize ammonia production. Coagulation is supported with vitamin K, fresh frozen plasma, and platelets as required. Plasmapheresis with fresh frozen plasma and platelets improves coagulation and maintains normovolemia. Oral lactulose and neomycin enemas decrease the enterohepatic cycle of ammonia production and absorption.[204] Cardiovascular and respiratory function should be monitored closely and supported as required.

The development of intracranial hypertension must be anticipated. Serum ammonia levels are used to monitor neurologic dysfunction,[204] but it is unknown whether ammonia is the primary CNS toxin or whether it is just one of many chemical markers. Steroids have been used for some forms of inflammatory hepatitis. Exchange transfusions and plasmapheresis have been used to decrease the toxin load,[205] but there is no strong evidence that such measures reduce morbidity and mortality.[206] Patients with certain forms of acute hepatic failure, including those resulting from toxic and infectious causes, may be considered candidates for liver transplantation.[207,208]

Extrahepatic Biliary Atresia

Extrahepatic biliary atresia occurs once in every 8000 to 10,000 live births.[209] The extent of atresia differs from patient to patient and involves variable degrees of obstruction or discontinuity of the biliary tree between the duodenum and the proximal branches of the hepatic ducts. Treatment is surgical (jejunal Roux-en-Y and portoenterostomy) and is tailored to the amount of extrahepatic bile duct present. The Kasai procedure is most successful in patients operated on before they are 6 to 9 months of age. However, this procedure is associated with many acute and chronic complications, including hepatic failure, ascending cholangitis, and cirrhosis with portal hypertension and varices. Despite these complications, the Kasai procedure persists because there are not enough suitable donor organs.[210]

Liver Transplants

Improved immunosuppressive drugs and surgical techniques have increased the success of liver transplantation (see Chapter 67). For transplantation to be successful, the perioperative and postoperative periods require a coordinated approach among surgery, gastroenterology, anesthesia, immunology, and the ICU staff. Most of the clinical issues that arise can be anticipated. Large blood losses occur and massive replacement therapy is required in the operating room. Accordingly, intravascular volume status, renal status, and hematology/coagulation profiles must be closely monitored. The immunosuppression required puts the patient at risk for infection with both "normal" and opportunistic organisms. Surveillance cultures and early aggressive antibiotic therapy are indicated. Systemic hypertension, which appears to be unrelated to elevated CVP or pulmonary capillary wedge pressure, is due to the antirejection drugs. Many patients require aggressive antihypertensive therapy (hydralazine, diazoxide, captopril).[211,212]

Nutritional Support in Critically Ill Children

Adequate nutritional support of a critically ill child is of paramount importance to decrease morbidity and mortality (see Chapter 95). The caloric and mineral requirements of these patients must be met when possible. The nutritional requirements of healthy children have been defined, but the requirements of critically ill children are not well understood; measurements of oxygen consumption and nitrogen balance are not easly done at the bedside.

It may be difficult to deliver adequate nutrition because of bowel compromise, severe fluid restriction for renal or CNS disease, or glucose intolerance. All avenues of nutrition (enteral and parenteral) must be followed to prevent a catabolic state from developing.

Using the GI tract for alimentation when possible is the safest and most efficient approach. Numerous commercial formulas with variable sources and quantities of protein, fat, and carbohydrate are available. Protein requirements can be met with whole protein, protein hydrolysates, or individual amino acids. Whole protein, which has the least osmotic effect, has greater nutrient density. However, it can be used only in children with normal pancreatic function and no allergy. Children with protein allergy, pancreatic deficiency, or severe intestinal mucosal disease may benefit from a protein hydrolysate. However, these formulas have high osmolarity. Free amino acid formulas are used in chemically defined diets restricted by specific requirements or intolerances.

The high caloric density of fat makes it an important component in nutritional support. Long-chain triglycerides (LCTs) yield approximately 9 kcal/g, and medium-chain triglycerides (MCTs) yield 8.3 kcal/g. Although of greater caloric density, LCTs are less readily absorbed. MCTs are hydrolyzed more rapidly and are converted almost exclusively to free fatty acids and glycerol. MCTs are absorbed, even in the absence of lipase, because of their relative water solubility and emulsification properties. However,

MCTs contain no essential fatty acids. Consequently, linoleic acid is required to supplement the diet.[213]

Parenteral Alimentation

Parenteral nutrition is used for children who cannot tolerate enteral feedings because they have acute respiratory or GI disease; it is also used as primary treatment of chronic short-bowel syndrome, Crohn's disease, and renal failure.

Procedure for Implementation of Parenteral Nutrition in Children

When intravenous alimentation is considered, $D_{10}W$ is administered at 1 to 1.5 times maintenance for 24 hours (also see Chapter 95). The patient is closely monitored for glycosuria, hyperglycemia, and edema. If the glucose load is tolerated, a $D_{10}W$ solution with amino acids (PN-10) can then be initiated. Administration of $D_{10}W$ with or without amino acids is done through a central or peripheral catheter. Because concentrated solutions sclerose peripheral veins, they must be given through a central line. If a central line is in place and the patient is tolerating 1.5 times maintenance with PN-10 or $D_{10}W$, the dose of glucose can be increased to 20% and the fluid rate can be reduced to maintenance. The patient should gain little weight until 1.5 times maintenance with PN-20 is achieved. In general, if a patient is malnourished (<0.80 weight for height), fluid rates must be adjusted downward to roughly 80% of those for normal children of the same weight. After 1 week of nutritional rehabilitation, regular maintenance fluids may be used (Table 84-10).

Intravenous Lipid Alimentation

Lipid in Central Intravenous Alimentation

With central intravenous alimentation, lipid is required to prevent essential fatty acid deficiency and should be given as 5% to 10% of the total calories (see Chapter 95). The following fluid rate permits rough determination of the lipid rate necessary to prevent essential fatty acid deficiency during central intravenous alimentation: 5 to 10 mL/kg for the first 10 kg, 2.5 to 5 mL/kg for the second 10 kg, and 1.25 to 2.5 mL/kg for weight greater than 20 kg. Lipids are usually introduced several days after parenteral nutrition is begun. Tolerance of lipids is improved if the patient has had a period of adequate caloric intake. Fatty acids may impair the patient's ability to tolerate large doses of dextrose. Serum lipid concentrations should be checked whenever lipids are infused.

Lipid in Peripheral Intravenous Alimentation

With peripheral intravenous alimentation (10% concentration), lipid often constitutes a major portion of the caloric intake because it is the only isomolar product with sufficient caloric density to provide significant caloric intake by peripheral vein.

Table 84-10 Maintenance Fluid Rates in Pediatric Patients Receiving Parenteral Nutrition

Regular Maintenance Weight	Malnourished Body (mL/kg/day)	Maintenance (mL/kg)
1st 10 kg	100	80-90
2nd 10 kg	50	40
Weight >20 kg	20	20

Table 84-11 Calculated Caloric Density of Lipid Products Used in Pediatric Peripheral Intravenous Alimentation

Lipid Product	Caloric Density
Amino acids	3.33 cal/g
10% dextrose	0.34 cal/mL
20% dextrose	0.68 cal/mL
PN-10	0.39 cal/mL
PN-20	0.73 cal/mL
Lipid 10%	1.1 cal/mL
Lipid 20%	2.0 cal/mL

Thus, once a patient who is receiving peripheral alimentation has reached a maximum rate of PN-10, Intralipid is added at 10 mL/kg/day and advanced by 10 mL/kg/day to a maximum of 40 mL/kg/day. Lipid calories should not exceed 60% of the total calorie intake.[214] Lipid clearance is facilitated by administering lipid continuously over a 24-hour period. For calculations, the caloric densities shown in Table 84-11 may be used.

Peripheral versus Central Alimentation: Energy Considerations

Peripheral intravenous alimentation is a stopgap measure that rarely allows caloric intake to exceed maintenance requirements. Therefore, few extra calories will be available for growth. Peripheral intravenous alimentation should be limited to 2 weeks' duration. Central alimentation, on the other hand, can provide caloric and nitrogen requirements for growth and maintenance. However, central indwelling catheters carry a risk of infection.

Caloric requirements represent the energy intake necessary for maintenance, growth, and activity. Whatever net energy is left after allowing for maintenance and activity is available for growth. The caloric cost of growth is at least 5 cal/g weight. Normal growth is approximately 25 to 30 g/day for the first 6 months of life, 10 to 15 g/day for the next 6 months, and roughly 7 to 10 g/day thereafter. Representative maintenance energy requirements for the nonstressed state are listed in Table 84-12. By using these data, intravenous alimentation can be adjusted to produce normal or moderate catch-up growth rates. Weight gain, in the face of inadequate caloric intake (less than maintenance), inevitably means that the child is edematous. If the goal of nutritional therapy is merely supportive over a period of 1 to 2 weeks, there is less concern about growth; peripheral alimentation will be adequate. If significant catch-up growth or long-term support is required, growth and activity requirements should be met.

Table 84-12 Maintenance Energy Requirements for Nonstressed Patients

Age (yr)	Maintenance Energy (kcal/kg/day)
<2	75-80
2-5	70-75
5-10	55-70
10-17	40-55
Adult	40

Monitoring of Children Receiving Total Parenteral Nutrition

Intake, output, and body weight should be assessed daily. The site of alimentation, either peripheral or central, should be evaluated regularly for signs of obstruction, extravasation, or occlusion. The skin and mucous membranes are evaluated for evidence of trace metal deficiency. Liver size and function must be monitored; intrahepatic cholestasis, excessive fat and glycogen deposition, and elevated liver function have been documented in patients receiving parenteral nutrition. Other metabolic studies should include routine screening of electrolytes, glucose, blood urea nitrogen, and creatinine, as well as ammonia. Total protein, albumin, hemoglobin, and triglycerides should be checked regularly, but less frequently.[214]

Outcome

Survival of children depends on adequate nutritional intake. Infants with a nonfunctioning GI tract can survive on total parenteral nutrition for years, but this is clearly a stopgap measure.[215] The risk of complications from central venous cannulation increases over time, and vascular access becomes increasingly limited as sites are used up.

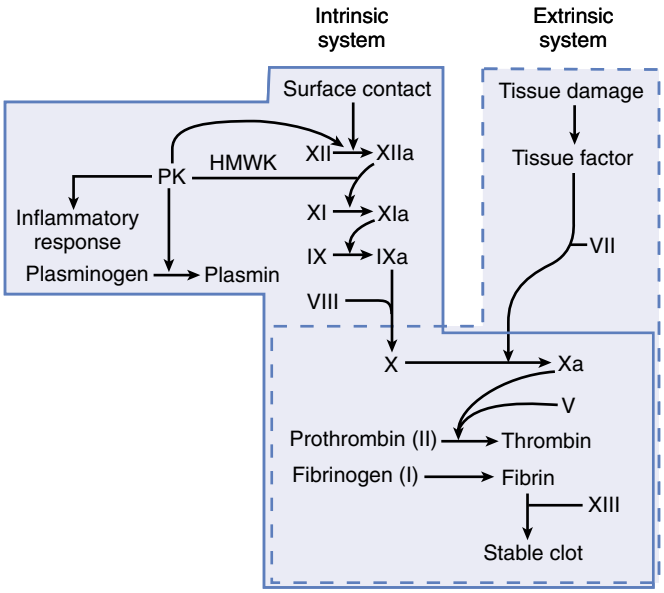

Figure 84-2 Scheme of blood coagulation. The suffix "a" denotes the activated factor with enzyme activity. HMWK, high-molecular-weight kininogen; PK, prekallikrein. *(Redrawn from Hathaway WE: Hemostasis.* In *Rudolph AM [ed]: Pediatrics, 17th ed. East Norwalk, CT, Appleton-Century-Crofts, 1982, p 1110.)*

Hematology

Hematologic emergencies in the ICU include abnormalities in coagulation, immunity, and red blood cell (RBC) mass. They can be primary isolated defects, or they can be caused by multiorgan system failure. The immune system is discussed in the section on infectious disease.

Coagulation System

Normal clotting includes initial platelet hemostatic plug formation and fibrin production (intrinsic or extrinsic pathways) (Fig. 84-2). For both to occur, platelets, coagulation factors, and an intact blood vessel are essential.[216,217] Neonates have a number of measurable coagulation abnormalities that rarely have clinical manifestations. Full-term and most preterm infants have normal platelet-vessel interaction, but platelet aggregation is transiently impaired. In addition, many coagulation factors show decreased activity or concentration in the fetus and newborn. Of greatest importance are the vitamin K–dependent factors: factors II, VII, IX, and X. These factors are low at birth and decrease to even lower levels during the first week of life unless vitamin K is administered. The amounts of factor V and VIII are close to adult levels in all but the most premature of infants. Although routine screening tests for coagulation activity are prolonged in infants, the newborn's blood clots more rapidly in vitro because neonates lack sufficient naturally occurring protease inhibitors, principally antithrombin III.[216]

Diagnosis of Hemostatic Disorders

Coagulation disorders are diagnosed by the history, physical examination, and laboratory data. It is important to elicit a history of easy bleeding, bruising, drug ingestion, and associated illnesses or a family history of bleeding. The patient should be examined closely for evidence of petechiae or bruising, bleeding gums, or hepatosplenomegaly. Bleeding or venipuncture sites should be observed for fresh clot or oozing. Laboratory evaluation of the PTT, PT, thrombin time, platelet count, and bleeding time gives valuable information on the nature of the hemostatic defect.

Specific Coagulation Disorders

Congenital Disorders

Hereditary deficiencies of most coagulation factors have been described, but classic hemophilia (factor VIII) and Christmas disease (factor IX) account for most deficiencies (see Chapter 35). Since the advent of modern factor replacement therapy, these disorders seldom cause life-threatening hemorrhage requiring ICU management.[218]

Factor VIII Deficiency or Hemophilia A Factor VIII deficiency, or hemophilia A, is transmitted by sex-linked recessive inheritance and occurs in 1 in 10,000 male infants.[219] The severity of the clinical disease is determined by the amount of circulating factor: severe disease is associated with less than 1% of normal levels, moderately severe disease with 1% to 5%, and very mild disease with 5% to 30% of normal levels. The most common sites of bleeding are the joint spaces, but hemorrhage may also occur in the peritoneal cavity, GI tract, muscle, skin, or CNS. Severe trauma or surgery can cause extensive bleeding. The diagnosis of hemophilia is made by demonstrating an elevated PTT and decreased levels of factor VIII. Treatment with plasma-derived factor VIII or recombinant proteins is necessary.

von Willebrand's Disease von Willebrand's disease occurs nearly as commonly as hemophilia A and is transmitted to both sexes by autosomal dominant inheritance. vWF is a multimeric glycoprotein that is produced by megakaryocytes and endothelial cells. vWF adheres to the subendothelial matrix after vascular injury. Changes in its conformation cause platelets to adhere and activate. von Willebrand's disease is classified into

three types. Type I has a quantitatively reduced amount of normal vWF and accounts for 85% of cases. Type II has qualitatively abnormal vWF, and type III has no vWF. Skin and mucous membrane bleeding, particularly nosebleeds and menorrhagia, are the most frequent clinical problems. The PTT and bleeding time are prolonged, as are some tests of platelet function. Desmopressin increases plasma vWF in patients with type I and some patients with type II disease. Cryoprecipitate or other plasma derivatives of vWF can be used when patients are unresponsive to desmopressin and if there is severe bleeding.[220]

Hereditary Thrombocytopenia Hereditary thrombocytopenia is an uncommon congenital defect. Most cases are associated with familial sex-linked immunodeficiency diseases, such as Wiskott-Aldrich syndrome.[221] Platelet transfusions help control bleeding. Splenectomy often corrects the thrombocytopenia, and successful bone marrow transplantation cures Wiskott-Aldrich syndrome.

Acquired Disorders

A variety of circumstances can impair the production of coagulation factors. The vitamin K–dependent factors are most commonly affected. These factors are decreased with liver disease, warfarin therapy, and malabsorption syndromes secondary to either bowel disease or altered bowel flora caused by long-term antibiotic therapy. In addition, untreated neonatal vitamin K deficiency results in hemorrhagic disease of the newborn. In these disorders, the PT is prolonged and there are low levels of factors II, VII, IX, and X. Administration of vitamin K usually reverses these deficiencies unless the synthetic function of the liver is markedly compromised.

Acquired platelet abnormalities include decreased production, increased destruction, and decreased function. Decreased production or hypoproliferative states include marrow diseases, such as leukemia and aplastic anemia, and the side effects of chemotherapeutic agents. Increased destruction can be immune mediated (i.e., idiopathic thrombocytopenic purpura[222]) or the result of consumption (i.e., microangiopathic states, HUS, or thrombotic thrombocytopenic purpura[223]). Finally, platelet dysfunction has been found with uremia and chronic polycythemia in patients with cyanotic heart disease.[224]

Treatment of acquired thrombocytopenia includes platelet transfusions and, if possible, correction of the underlying disorder. Therapeutic splenectomy will increase platelet survival in some patients with severe immune-mediated diseases.

DIC is characterized as a consumptive coagulopathy with decreased platelets and fibrinogen; increased PT, PTT, and thrombin time; and elevated fibrin degradation products. DIC complicates a number of nonspecific conditions: sepsis, anaphylaxis, shock, acidosis, massive tissue trauma, sickle cell disease, and certain malignancies, particularly acute myelogenous leukemia (AML) in childhood.[225] Purpura fulminans is a particularly severe form of DIC that is associated with ecchymosis and thrombosis of the skin, subcutaneous tissue, and distal ends of the extremities. This condition is seen with acute meningococcemia and with other bacterial, viral, and fungal septicemias. Purpura fulminans is associated with high morbidity and mortality; the main morbidity is ischemic loss of the distal ends of the extremities.

Treatment of DIC requires removal of the triggering event as soon as possible. Support of vascular volume and oxygen transport is essential. When active bleeding is present, transfusion of platelets (0.2 U/kg) and fresh frozen plasma (10 mL/kg) every 4 to 6 hours replenishes platelet and clotting factors. Coagulation antagonists, such as antithrombin III, may also be required. Heparin administration has been advocated by some clinicians; however, it has not improved outcome and may enhance bleeding. Transfusion with factor concentrates is helpful when the volume of fresh frozen plasma that can be administered is limited by intravascular hypervolemia. Occasionally, exchange transfusion with fresh whole blood or plasma exchange/plasmapheresis with fresh frozen plasma and platelets may be necessary to effectively treat severe DIC.[226]

Red Blood Cell Abnormalities

RBC abnormalities include either a decrease in RBC mass or RBCs that do not function normally. RBC mass is reduced by either decreased production or increased loss. Decreased RBC production is associated with factor deficiencies (iron, folate, vitamin B_{12}), bone marrow disease (aplastic anemia, leukemia), chronic diseases (infection, neoplasm, renal disease), and rarely, a congenital deficiency of RBC precursors (Diamond-Blackfan syndrome). RBC loss is caused by extracorporeal blood loss (hemorrhage) or cell destruction (hemolysis). Hemolysis can be caused by intrinsic RBC abnormalities or by extrinsic factors. Intrinsic anomalies include membrane defects (spherocytosis, elliptocytosis), enzyme defects (glucose-6-phosphate dehydrogenase, pyruvate kinase deficiencies), and hemoglobinopathies (hemoglobin S, C, D, and E and thalassemia). Extrinsic abnormalities can be immune mediated or infection and toxin mediated, or they may occur secondary to microangiopathic destruction.[227]

Regardless of what causes the decrease in RBC mass, the signs, symptoms, and therapy depend on the acuity and severity of the blood loss. Acute loss of large amounts of blood (hemorrhage) may cause hypovolemic shock. Treatment consists of oxygen, intravascular volume re-expansion, and replacement of RBCs. In the absence of hypovolemia, acute and chronic RBC loss is tolerated until the loss of oxygen-carrying capacity is critical and results in high-output cardiac failure. Treatment of these severe anemias includes oxygen and replacement of the RBC mass, which should be done cautiously and slowly to avoid the complications of fluid overload. Partial exchange transfusions are sometimes necessary to replace RBCs without causing volume overload.

Patients with hemoglobinopathies have RBCs that cannot carry oxygen appropriately; sulfhemoglobinemia and methemoglobinemia are the most common of these abnormalities. These disorders can be congenital or acquired. The congenital forms are usually asymptomatic and require no therapy; the acquired or toxic forms may be fatal. Treatment includes oxygen, intravenous administration of methylene blue, and occasionally, exchange transfusion.

Complications of Transfusion Therapy

Although the administration of blood products can be lifesaving, a number of potential complications should be anticipated (also see Chapter 55). Whenever massive transfusion therapy is used, the risks of citrate toxicity, transfusion reactions, and leukocyte

and platelet sensitization must be kept in mind, especially when large volumes of blood and products must be given rapidly to small children. In addition, depending on the age and type of the administered blood component, electrolyte disturbances such as hypocalcemia, hyperkalemia, and hypernatremia can occur. Whenever in doubt, a sample of the infusate should be sent for electrolyte analysis. Serum electrolytes and ionized calcium should be monitored during therapy. Transfusion-acquired infections, including hepatitis, cytomegalovirus, and acquired immunodeficiency syndrome, have decreased with improved screening of blood donors and extensive testing of units of blood.[228]

Finally, hemochromatosis complicates the care of patients who require long-term transfusion therapy to treat an RBC abnormality. Efforts to decrease this often lethal complication include aggressive iron chelation therapy and transfusion of young RBCs to increase the time interval between transfusions.[229]

In addition to RBC loss and abnormal oxygen binding, grossly deformed RBCs can cause vaso-occlusive disease. Sickle cell anemia is the best example of this pathology. Sickle cell anemia is a hemoglobinopathy. The major ICU complication is vaso-occlusive disease, which can be manifested as a painful crisis; if vaso-occlusion occurs in the cerebral vessels or in other vital organs, it is usually manifested as stroke or infarction.[230] Vaso-occlusive disease of the lung is referred to as acute chest syndrome and is clinically manifested as ARDS. Treatment consists of hydration, oxygen, and when severe, exchange transfusion and mechanical ventilation.[231] The other potentially fatal crisis of sickle cell disease is splenic sequestration, which occurs in infants and young children who have not undergone autosplenectomy. Splenic sequestration is manifested as severe anemia and hypovolemic shock. Treatment consists of aggressive supportive therapy with emergency surgical splenectomy. Other children with sickle cell disease have had a functional autosplenectomy as a result of multiple splenic infarcts. These "splenectomized" children are at risk for severe infection from encapsulated organisms. Pneumococcal vaccine is given to these children.

Oncology

Neoplastic disease in children usually involves the hematopoietic system, CNS, sympathetic nervous system, soft tissue, bone, and kidney. Much of oncologic care is performed on an outpatient basis, but some patients still require hospitalization and intensive care.

Blast Crisis in Leukemia

Children with an initial white blood cell (WBC) count of greater than 100,000 are at high risk for leukostasis and metabolic crisis (tumor lysis syndrome [TLS]).

Leukostasis

Leukostasis (vascular obstruction) results from high viscosity caused by elevated cell counts or by the WBCs themselves. This syndrome is anticipated in patients with acute lymphoblastic leukemia when the WBC count exceeds 500,000 and in AML patients with WBC counts greater than 200,000/mm^3. In AML, leukemic cells are less deformable than lymphoblasts, so a lower WBC count produces the same syndrome.

The brain and lungs are the two major target organs for leukostasis; vascular plugging and organ infarction are the usual manifestations. Initial symptoms include tachypnea, cyanosis, increased work of breathing, altered mental status, and focal neurologic deficits. Besides supportive therapy, reducing the circulating tumor load and viscosity are the primary goals of therapy. Leukapheresis and exchange transfusion transiently accompish these goals. Cranial irradiation may reduce the CNS tumor load, and chemotherapy will interrupt cell production and possibly destroy circulating cells. The initial goal of chemotherapy is to stop cell production without producing massive cell lysis; this halts the increase in tumor load without causing a severe metabolic crisis before adequate perfusion is reestablished.[232,233]

Tumor Lysis Syndrome

TLS is a metabolic crisis precipitated by acute lysis of a large number of tumor cells. Serum uric acid, potassium, and phosphate concentrations are elevated; the elevated phosphate concentrations cause hypocalcemia. The hyperkalemia and hypocalcemia can be life threatening; increased uric acid may cause acute renal failure.[234]

Therapy for TLS consists of alkalinization of urine, fluid administration, and diuresis. Before any chemotherapy is administered, the patient's renal function should be assessed. If renal function is normal, allopurinol or rasburicase therapy is begun. In most cases, this conservative approach of forced diuresis and allopurinol or rasburicase will prevent renal failure, but occasionally dialysis must be instituted. Indications for the initiation of dialysis include

1. Potassium >6 mEq/L and rising despite resin exchange
2. Uric acid >19 mg/L
3. Creatinine >10 mg/L
4. Phosphorus >10 mg/L or rapidly rising
5. Volume overload
6. Symptomatic hypocalcemia

If dialysis is necessary, it is usually required for only a few days.

Respiratory Distress and Mediastinal Mass

Children with a mediastinal mass and respiratory distress often complain of coughing, difficulty breathing, stridor, and shortness of breath. They prefer to sit upright and cannot lie supine. The chest radiograph usually shows a large mediastinal mass, often with obliteration or obscuring of the tracheal air column. These masses can also cause positional obstruction of vascular structures such as the superior vena cava or a pulmonary artery. These tumors can be malignant (87% Hodgkin's and non-Hodgkin's lymphoma) or benign; the prognosis and therapy rely on adequate diagnosis, which is best made by obtaining a tissue sample before treatment is begun.[235] However, obtaining a sample of the mediastinal mass may require anesthesia and surgery, and the airway must be manipulated and instrumented. All these manuevers may cause the patient to die. Local anesthesia with fine-needle biopsy under radiographic guidance allows tissue sampling without anesthesia in some patients. Irradiation of the

tumor before obtaining a tissue sample may reduce the size of the tumor and make biopsy easier and safer under anesthesia.

Obstruction of the intrathoracic trachea is a major anesthetic risk for these patients; it is often impossible to maintain a patent airway when the patient lies supine, is deeply anesthetized, or is paralyzed with muscle relaxants.[236,237] Care of these patients clearly requires individualized and creative approaches. Pulmonary function tests with flow-volume loops help identify patients at increased risk and guide response to treatment before anesthetic care. However, the patient must cooperate sufficiently to perform the test, which is often difficult for them because of respiratory distress. Induction of anesthesia and tracheal intubation are usually done with the patient in the sitting position and breathing spontaneously. If the airway compromise is severe, the tumor should be irradiated and the child given steroids before a tissue diagnosis is made. Sometimes, a peripheral node or mass can be biopsied under local anesthesia, or if the tumor mass is very large, some of the tumor can remain outside the field of radiation. In summary, although diagnosis is the key to treatment of neoplastic disease, the risk associated with biopsy may far outweigh the benefit of tissue diagnosis.

Fever and Neutropenia

The most common admitting diagnoses for children with neoplastic disease are fever and neutropenia. Neutropenia increases the child's risk for life-threatening infections.

Infectious Disease: Life-Threatening Infections in Infants and Children

Infections in the Newborn

Neonates with developmental immunologic deficiencies have increased susceptibility to infection. Depressed cell-mediated immunity makes the fetus and infant more susceptible to viral and fungal infection. In addition, infants have depressed B-cell function and diminished production of immunoglobulins. The latter is partially offset by increased maternal immunoglobulin G (IgG). By 2 to 3 months of age, which is before infants can adequately produce their own antibodies in sufficient quantity, the level of maternal antibodies reaches a nadir.[238] The time during which the circulating antibody concentration is low is a time when the risk for infections is increased.

Perinatal infections are either congenitally or postnatally acquired. Congenital infections occur with prenatal exposure to viral, protozoal, or rarely, bacterial pathogens. Common diseases include the TORCH infections: *Toxoplasma gondii* (T); "other" (O), including human immunodeficiency virus (HIV), syphilis, and tuberculosis; rubella (R); cytomegalovirus (C); and herpes simplex virus type 2 (H). Only rarely do these infections cause overwhelming sepsis, but they can be confused with bacterial infection when profound CNS depression, circulatory collapse, or thrombocytopenia occurs. When a TORCH infection develops in the first trimester of pregnancy, it causes fetal wastage or major organ malformation.[239]

Premature infants have a high incidence of acute infections in the newborn period. Regardless of gestational age, the signs and symptoms of infection are often subtle. Therefore, a very high index of suspicion and low threshold for diagnosing and treating infection are required.[240] Box 84-6 lists the common signs and symptoms of neonatal sepsis.

Box 84-6 Common Signs and Symptoms of Neonatal Sepsis

- Temperature instability (hypothermia and hyperthermia)
- Lethargy and poor feeding
- Respiratory distress and apnea
- Hypoglycemia and metabolic acidosis
- Poor cutaneous perfusion, hypotension
- Rashes or petechiae
- Seizures

The most common acquired pathogens are those that colonize the mother's genital tract: group B streptococci, *E. coli*, *Listeria monocytogenes*, and herpesvirus. Herpes is such a fulminant infection in neonates that the presence of active herpes lesions in the birth canal is an indication for cesarean section, although this may not prevent herpes in all children. Group B *Streptococcus* is the most common bacterial pathogen that causes neonatal sepsis. Infection with group B streptococci is manifested as severe cardiorespiratory instability and meningitis in 30% of cases. By 2 to 3 weeks of age, this organism is more commonly associated with meningitis and less commonly with pulmonary disease.

Whenever sepsis is suspected, cultures of blood, urine, and CSF should be obtained. Because it is difficult for the physician to localize the infection in an infant, repeated complete sepsis workups are often required. When appropriate cultures are obtained, treatment with ampicillin and an aminoglycoside, such as gentamicin, is usually begun until specific bacteriologic information becomes available. Only about 50% of neonates thought to be septic have positive cultures.

The Older Child: Sepsis and Septic Shock

Infectious diseases that require intensive care include sepsis with organ dysfunction and septic shock. In a previously well child, sepsis is frequently associated with an obvious primary site or source of infection. Although older children generally localize an infection as well as adults do, younger children do not. CNS infections may be difficult to diagnose in children younger than 2 years because they cannot give an adequate history of headache and because meningismus or other signs of meningeal irritation are unreliable.

Common clinical manifestations of sepsis in neonates include fever or hypothermia, tachypnea and tachycardia, poor cutaneous perfusion, altered level of neurologic function (agitation and irritability followed by apnea or coma), petechiae, purpura or other rashes, DIC, and the metabolic abnormalities associated with metabolic acidosis, hypoglycemia, and hypocalcemia. Sepsis can also cause septic shock. In septic shock, endotoxin, exotoxin, or other endogenously liberated vasoactive substances produce an endothelial lesion that causes increased vascular permeability, ARDS, increased use of metabolic substrate, depressed myocardial function, and profound DIC.[241]

The primary goal of therapy for any infection is eradication of the organism. Rationally chosen parenteral broad-spectrum antibiotic coverage should be initiated immediately and any septic focus or abscess should be drained surgically. Treatment of septic shock often requires early cardiorespiratory support. Endotracheal intubation and positive-pressure ventilation with PEEP may be required to treat the ARDS that often accompanies septic shock. Inotropic drugs may be used to maintain adequate cardiac output and tissue perfusion. Cardiovascular assessment with echocardiography, CVP monitoring, and sometimes a pulmonary artery catheter provide useful information that guides therapy. Because coagulopathies, including thrombocytopenia and generalized clotting factor deficiencies, are common in septic shock, fresh frozen plasma and platelet transfusions are frequently required. Steroids have few positive and possibly deleterious effects in septic shock.[242] Use of these drugs is therefore not advocated, except as steroid replacement in purpura fulminans and Waterhouse-Friderichsen syndrome.

Immunocompromised children may not have a specific primary focus of infection and may have repeated infections with different pathogens. Immunocompromised children may also have polymicrobial sepsis that is the result of bacterial seeding from the GI tract. There are few if any premonitory signs or symptoms before shock develops. Fever is the most common and often the earliest sign of opportunistic infection in immunocompromised children. Bacterial, fungal, and viral cultures should be obtained and broad-spectrum antimicrobial therapy should be initiated immediately. Antifungal drugs should also be considered. Granulocyte transfusions may benefit septic, neutropenic patients.[243] Table 84-13 lists the most common predisposing

Table 84-13 Opportunistic Infection in Inherited and Acquired Disorders

Predisposing Causes: Inherited and Acquired Disorders of Inflammation or Immunity	Opportunistic Organism Isolated Most Frequently	Suggested Mechanisms
Chronic granulomatous disease	*Staphylococcus*, gram-negative enteric organisms, *Serratia*, *Nocardia*	Impaired production of H_2O_2 with defective bactericidal function
Job's syndrome	*Staphylococcus aureus*	Unknown
Myeloperoxidase deficiency	*Candida*	Failure to kill *Candida*
Glucose-6-phosphate dehydrogenase deficiency	*Staphylococcus*, *Serratia*	Deficient cellular NADH and NADPH, deficient HMPS activity, decreased H_2O_2 production, defect in bacterial killing
Chédiak-Higashi syndrome	Pyogenic infection	Defective bactericidal activity, impaired chemotaxis, neutropenia
Congenital neutropenia	*Herellea*, *Serratia*, *Pseudomonas*, *Staphylococcus epidermidis*	Insufficient number of neutrophils
Complement deficiencies (C3, C3 inactivator)	Pathogens (e.g., *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Neisseria meningitidis*)	Defective chemotaxis, impaired opsonization
Splenic insufficiency	*Streptococcus pneumoniae*, *Salmonella*	Defective opsonization, defective clearing of organisms
Sickle cell disease and other hemoglobinopathies	*Streptococcus pneumoniae*, *Salmonella*, *Edwardsiella*	Reticuloendothelial blockade, defective opsonization
Humoral immunodeficiency syndrome (predominantly B-cell defects)	Bacterial pathogens, *Pseudomonas*	Reduced phagocytic efficiency, failure of lysis and agglutination of bacteria, inadequate neutralization of bacterial toxins
Cellular immunodeficiency syndromes (predominantly T-cell defects)	*Mycobacterium*, *Listeria*, *Nocardia*, cytomegalovirus, varicella, *Cryptococcus*, *Candida*, *Pneumocystis*	Absence of or impaired delayed hypersensitivity response, absent T-cell cooperation for B-cell synthesis of antibodies to T-cell–specific antigens
Severe combined immunodeficiency syndrome	Many bacteria, fungi, viruses, and *Pneumocystis*	Absence of T- and B-cell responses
Cancer	*Pseudomonas*, *Klebsiella*, *Escherichia coli*, *Listeria*, *Cryptococcus*, varicella-zoster, herpes simplex, *Pneumocystis*, *Mycobacterium*; incidence of infection with gram-negative organism increases in the presence of neutropenia	Granulocytopenia, decreased neutrophil chemotaxis, decreased bactericidal activity of neutrophils, lymphopenia, defective cell-mediated immunity, impaired antigenic response to challenge
Immunosuppression	*Pseudomonas*, *Klebsiella*, *Escherichia coli*, *Herellea*, *Serratia*, herpes simplex, varicella-zoster, cytomegalovirus, Epstein-Barr virus, papovavirus, hepatitis virus, *Candida*, *Aspergillus*, *Mucor*, *Cryptococcus*	Dependent on the agent used

Table 84-13 Opportunistic Infection in Inherited and Acquired Disorders—cont'd

Predisposing Causes: Inherited and Acquired Disorders of Inflammation or Immunity	Opportunistic Organism Isolated Most Frequently	Suggested Mechanisms
Transplantation	*Staphylococcus*, *Pseudomonas*, *Klebsiella*, *Candida*, *Aspergillus*, *Nocardia*, *Pneumocystis*, cytomegalovirus, hepatitis viruses, herpes simplex, varicella-zoster	Probably related to the use of immunosuppressive agents
Malnutrition	Measles, herpes simplex, varicella-zoster, *Mycobacterium*	Impaired T-cell function, reduction in complement activity, impaired migration of phagocytes, reduced bacterial activity
Cystic fibrosis	*Staphylococcus*, *Pseudomonas*	Presence of ciliary dyskinesia factor, impaired phagocytosis of *Pseudomonas*
Diabetes mellitus	*Staphylococcus*, *Escherichia coli*, *Proteus*, *Clostridium*, *Actinomyces*, *Candida*, *Mucor*, *Torulopsis*	Impaired phagocytic activity, decreased serum opsonizing capacity, decreased chemotaxis of neutrophils
Polyendocrinopathy	*Candida*	Unknown
Nephrotic syndrome	*Streptococcus pneumoniae*, enteric bacteria	Unknown
Uremia	*Bacteroides*, *Serratia*, *Enterobacter*, *Staphylococcus*, *Candida*, *Mucor*, herpes, varicella-zoster	Defects in early phases of the inflammatory response, lymphopenia, impaired T-cell function
Exudative enteropathy	*Streptococcus pneumoniae*, enteric bacteria, *Giardia lamblia*	Low levels of IgG, depressed T-cell function in intestinal lymphangiectasia
Inflammatory bowel disease	*Candida*, *Mucor*, herpes, varicella-zoster	Probably not related to basic disease but rather to the use of corticosteroids
Collagen diseases	*Candida*, *Mucor*, *Aspergillus*, *Pneumocystis*, diphtheroids, *Listeria*, *Pseudomonas*, *Serratia*, *Staphylococcus*, *Nocardia*, *Aspergillus*, cytomegalovirus, herpes, varicella-zoster	Probably related to the use of immunosuppressive agents; may relate to involvement of the reticuloendothelial system

HMPS, hexose monophosphate shunt; H_2O_2, hydrogen peroxide; NADH, reduced nicotinamide-adenine dinucleotide; NADPH, reduced NADH phosphate.
From Feigin RD, Matson DO: Opportunistic infections: The compromised host. *In* Feigin RD, Cherry JD (eds): Textbook of Pediatric Infectious Diseases, vol 1, 2nd ed. Philadelphia, WB Saunders, 1987, p 1013.

causes of immunosuppression, along with the most frequently associated opportunistic organisms.[244]

Human Immunodeficiency Virus

Major improvements in the treatment and management of HIV disease have decreased the incidence of new infections in children in North America and Western Europe. In young chidren, HIV infection is the result of vertical transmission from a seropositive mother. HIV-infected adolescents are affected in much the same way as adults; therefore, this discussion is limited to HIV in younger children.

A mother who has an untreated HIV infection has a 12% to 30% chance of infecting her child. Perinatal treatment of infected mothers with antiretroviral drugs dramatically decreases these rates. Vertical transmission of HIV can occur in utero (30% to 40%), in the intrapartum setting by exposure to infected blood or cervicovaginal secretions (60% to 70%), or in the postpartum setting by breastfeeding. Diagnosis of perinatal infection may be difficult because most infants have passively acquired maternal IgG antibodies, which prevents serodiagnosis. In developed countries, nucleic acid–based detection methods are the preferred virologic assay. Testing is performed during the first 2 days of life, and antiretroviral therapy is initiated when needed. False negatives can occur, and repeat testing through 4 to 6 months of age is recommended. The usual clinical manifestation of HIV infection in the very young includes failure to thrive, hepatosplenomegaly, and chronic interstitial pneumonitis. Toddlers have a higher incidence of lymphadenopathy, recurrent bacterial infections, delay in neurologic development, and progressive encephalopathy. Some children may remain asymptomatic for years.

Pneumocystis carinii pneumonia (PCP) is seen in all age groups, but it occurs more commonly and is associated with a higher mortality rate in children younger than 1 year. The mainstay of treatment remains trimethoprim-sulfamethoxazole and supportive care.

Lymphocytic interstitial pneumonitis is a slowly progressive disease characterized by chronic cough and slight to moderate hypoxemia. It is more common in children younger than 1 year. Radiographic findings include small nodules and fine reticular densities. Treatment is supportive. The efficacy of steroids is uncertain.

Children with HIV infection are most commonly admitted to an ICU because they have pulmonary disease, usually PCP. Aggressive care is provided. Antibiotic prophylaxis and prevention have drastically decreased the incidence of disease and improved survival after respiratory failure from PCP.[245]

Pediatric Trauma

Prenatal and Perinatal Injuries

Perinatal trauma occurs before or immediately after birth (also see Chapter 72). The most common prenatal injuries are due to maternal gunshot wounds and blunt trauma. Fetal mortality in both cases is at least twice that of the mother,[246] with fetal death being attributable to maternal shock and fetal oxygen deprivation rather than direct injury. Birth injuries occur more commonly in large full-term infants and in infants born by breech presentation. Injuries to the head include linear or depressed skull fractures, cephalohematomas, subdural or subarachnoid hematomas, and intraparenchymal or intraventricular hemorrhage. Intracranial injuries can increase ICP and cause cerebral ischemia, neurologic injury, and death. Injury to the sternocleidomastoid muscle may cause torticollis; traction on the neck may transect the cervical spinal cord. Less devastating nerve injuries caused by cervical traction are phrenic nerve paralysis and Erb's or Klumpke's palsy, which is caused by brachial plexus stretching or tearing (or both).

Shoulder dystocia is commonly associated with clavicular and humoral fractures; femoral shaft fractures occur with breech deliveries. Injuries to the liver, spleen, adrenal glands, and kidneys can cause life-threatening hemorrhage or thrombosis. Vaso-occlusion causes tissue loss in the cerebral, coronary, or renal vascular beds. Emergency instrumentation of the airway in the delivery room on rare occasion leads to tracheal and esophageal perforation, particularly in a premature infant.

Trauma in Children

Accidents and trauma are the leading causes of death in children 1 to 14 years of age.[247] Children are frequently victims of falling or being dropped, drowning, near-drowning, motor vehicle accidents (pedestrian), ingestions, and burns. Head injuries are common, especially in younger children, who have disproportionately large heads and relatively poor neck muscle support.[248] Young children are less likely to be victims of gunshot or knife attacks; blunt injuries are more usual. Blunt trauma to the abdomen can cause solid organ injury (liver and spleen) rather than a perforated viscus. Hypothermia is a frequent complication of trauma; children lose heat rapidly because they have a relatively large surface-to-volume ratio. Drowning and near-drowning are the prototypical hypothermic injuries.

Management of trauma patients of all ages requires an organized approach that permits rapid diagnosis and treatment. Most preventable deaths in pediatric trauma patients are caused by airway obstruction, pneumothorax, and shock; shock is often the result of inadequate treatment of bleeding or secondary brain injury from an expanding intracranial hematoma.[249] The American College of Surgeons recommends a four-step approach to pediatric trauma patients: (1) primary survey, (2) resuscitation, (3) secondary survey, and (4) definitive care.[250] The primary survey requires rapid assessment of the airway, breathing, and circulation (ABCs). A disproportionately large tongue, in relation to a narrow oropharynx, easily obstructs the airway in an unconscious child. Proper jaw positioning enables bag-and-mask ventilation until the trachea is intubated. Ventilation through an inadequate airway may lead to gaseous distention of the stomach, vomiting, and aspiration of gastric contents. Cervical spine injuries are less common in children than in adults, but the child's neck should be immobilized until spinal injury is excluded. After establishing an airway, adequacy of respiration should be verified by observation of symmetric chest movement, auscultation of normal and equal breath sounds, and an early chest radiograph. Tension hemopneumothorax can be diagnosed clinically and treated by needle aspiration. Aspiration will alleviate the tension and stabilize the patient's condition until a chest tube can be inserted. Circulation can be quickly assessed by looking for tachycardia, poor peripheral perfusion, weak peripheral pulses, and hypotension (which may not occur until blood loss exceeds 25% of the circulating blood volume).[251] A severely hypovolemic child requires rapid insertion of a central venous catheter. If a peripheral venous catheter cannot be inserted expeditiously, an IO cannula should be placed.[252] The amount of volume resuscitation is dictated by the clinical condition of the child and the estimated volume of blood or plasma lost.

During the secondary survey, a thorough head-to-toe examination is performed, and a plan of definitive treatment is developed. Diagnostic measures in a pediatric trauma patient are similar to those in adult patients, but there should be consideration of special problems that occur in children. Most intra-abdominal injuries requiring laparotomy are recognized clinically because they produce peritonitis or cause increasing abdominal girth.[253] Diagnostic peritoneal lavage may be of help in children who are hemodynamically unstable despite administering more than 40 mL/kg of blood. Peritoneal lavage may locate the site of occult bleeding in a child too unstable to undergo CT, or it can be used to evaluate abdominal injury in a child about to undergo emergency nonabdominal surgery. Many practitioners forego this procedure if surgery is imminent. Indications for surgical intervention for abdominal trauma include free peritoneal air, evidence of a ruptured viscus, and acute uncontrolled bleeding. A ruptured spleen or a liver laceration is not an indication for surgery in and of itself; the preferred treatment is supportive, blood volume replacement, and re-evaluation.[254]

A careful head and neurologic examination is done to quickly detect intracranial trauma. The most important indicator of intracranial trauma is a decrease in the level of consciousness. Rapid diagnosis and treatment of intracranial mass lesions will reduce ICP and may prevent secondary brain injury.

Child Abuse

The diagnosis of child abuse is made by finding an acute injury that may have a plausible explanation and signs of past trauma, including healing bruises, contusions, and fractures. Child abuse may also take the form of psychological or sexual abuse and failure to meet a child's need for food, clothing, shelter, hygiene, medical care, education, or supervision.

Suspicion of child abuse begins with an inappropriate or inadequate explanation for the child's injuries or when the degree of trauma exceeds the stated cause. Multiple hospital admissions, emergency department visits, doctor or hospital "shopping," and a history of previous trauma should be of concern. Frequently, the story regarding the injury changes over time. Certain clinical features are common to child abuse, but they are by no means pathognomonic. Most abused children are older than 3 years and may have poor hygiene and delayed somatic or psychological development. The injuries most commonly include bruises, welts,

lacerations, scalds, and burns from cigarettes, stoves, heating grates, or irons. Long-bone fractures, often of varying age, abdominal injuries, signs of smothering, and multiple soft tissue or genital bruises are also common. Head injuries can occur. Shaking an infant can cause neck injuries, intracranial hemorrhage, and contra-coup injuries without necessarily producing external manifestations of trauma. The approach to a suspected victim of child abuse includes a meticulous and nonjudgmental history, written in detail in the chart. All allegations are recorded and changes in the reported history are documented. The physical examination includes growth parameters, descriptions of soft tissue bruising or burns, and diagrams or preferably photographs of all injuries. The color, shape, placement, and estimated age of all injuries should be catalogued. Laboratory studies should include the following: a skeletal survey of all long bones, ribs, and the skull; a coagulation profile, including hematocrit, platelet count, PT, and PTT; and genital and throat cultures for venereal disease if sexual abuse is suspected. If child abuse is suspected, it must be reported to the authorities.

Ingestion Injury

Despite the success of various preventive public health programs, poisoning continues to occur commonly in pediatric patients. Fortunately, the vast majority of presumed poisonings in young children can be managed by telephone consultation with a regional poison control center. In one study, acute poisoning accounted for approximately 5% of all medical admissions to a PICU.[255] Approximately half of these admissions were accidental ingestions and half were attempted suicides. The median age for the accidental poisoning group was 2 years. For the suicide group it was 15 years. Although many different toxic substances are ingested by children and adolescents, management of poisoning has three main goals: (1) identifying, decontaminating, and eliminating the toxic agents[256]; (2) minimizing the toxic effects on the child; and (3) providing close observation and organ system support until detoxification is complete. Procedures for drug elimination include emesis, gastric lavage, activated charcoal, and magnesium citrate. Toxic effects can be minimized with specific antidotes when available, by hemodialysis, or by charcoal hemoperfusion. Examples of specific antidotes are deferoxamine for iron ingestion, ethanol infusion for methanol ingestion, naloxone for narcotic overdose, and *N*-acetylcysteine for acetaminophen ingestion. Because many ingestions, particularly those for attempted suicide, include multiple drugs, specific antidote therapy is only occasionally successful. Organ system support usually includes airway protection and mechanical ventilation, intravenous fluids, cardiovascular monitoring for arrhythmias and myocardial depression, and anticonvulsive therapy for patients who are seizing. Consultation with clinical pharmacologists or with the regional poison control center and contacting a social worker or psychiatrist are essential aspects of the care of an acutely toxic child. Common complications of ingestions and their therapy include aspiration pneumonia with hydrocarbon ingestion or loss of glottic function, sepsis, respiratory depression, myocardial depression, arrhythmias, seizures, and coma. The psychosocial environment that allowed or precipitated the ingestion must also be considered. Families should be counseled about proper supervision and "child-proofing" their home. Psychiatric intervention should be introduced early; unsuccessful suicide attempts are often repeated.

Transporting Critically Ill Infants or Children

With regionalization of neonatal pediatric intensive care, emergency interhospital transport systems were developed to provide rapid, safe, and effective transfer of critically ill children from community hospitals to regional intensive care facilities. Transport systems not only transfer sick patients to a facility where a patient can receive needed care but also initiate appropriate monitoring and treatment of the patient before leaving the referring hospital. Care of the patient begins as soon as the referring physician telephones the referral hospital. The ICU physician offers advice regarding immediate treatment and then mobilizes the transport team and alerts the appropriate consultants and hospital resources required for the incoming patient. The transport team usually consists of a physician and nurse specially trained in neonatal or pediatric intensive care. Other personnel may include respiratory therapists, anesthesiologists (particularly in the case of a pediatric upper airway problem), emergency medical technicians, or additional nursing or physician trainees. Portable intensive care equipment must include cardiovascular monitoring devices, an infant transport device to maintain a neutral thermal environment during transport, resuscitation equipment (including airway and breathing devices and a defibrillator), and additional equipment to institute intensive care on arrival at the referral hospital.

Problems that may arise during transport must be anticipated and treated before the patient is transported, which usually requires a careful assessment of the airway, breathing, and the adequacy of gas exchange, plus monitoring the adequacy and stability of the circulation. Because procedures are so difficult to perform in transit, tracheal intubation and placement of venous or arterial catheters are completed at the referring hospital if the transport team believes that these procedures may be required during transport. Medications required during transport should be anticipated and should be available. Transport can be carried out by ambulance, helicopter, or fixed-wing aircraft, depending on local circumstances. The environment during helicopter transport is difficult inasmuch as it is hard to provide surveillance and treatment because of poor temperature and noise control and limited operating space. Communication between the transport team and regional center is essential. Consultation with senior staff members helps the ICU anticipate the nature and degree of the illness. The most serious flaws in the transport system are usually the response time of the transport team after a referral call is made and the availability of adequately trained on-call transport team members. An institutional commitment of funds, personnel, and equipment, along with excellent organization, can ensure that neonatal and pediatric transport systems have a significant impact on patient care, community physician education, and regional hospital referrals.[257,258]

Sudden Infant Death Syndrome

SIDS is defined as the unexplained, sudden death of an infant younger than 1 year. It is the third leading cause of infant mortality in the United States, and the incidence was stable at 2 to 3 deaths per 1000 live births per year until advent of the "Back to Sleep" campaign in 1994. The rate is now 0.7 death per 1000 live births. The incidence peaks at 3 to 4 months of age and can be

temporally, but not causally associated with an upper respiratory tract infection, recent immunization, and rarely, anesthesia and surgery. Potential causes of SIDS include abnormalities in the cardiac conduction system, such as prolonged QT interval syndrome and Wolff-Parkinson-White syndrome, and abnormalities in the respiratory system, such as central or peripheral chemoreceptor abnormalities, upper airway obstruction, and the central hypoventilation associated with sleep.[259] In most cases, SIDS appears to be a "quiet" death in that breathing appears to stop without evidence of arousal or struggle. Occasionally, an infant is observed to be apneic and cyanotic and responds to tactile stimulation or to more vigorous resuscitative efforts. These infants are often admitted to the PICU for intensive monitoring and observation and may require treatment of hypoxic-ischemic injury to multiple organ systems.

Future treatment and monitoring of survivors of unexplained, apparent life-threatening events remain controversial; home cardiorespiratory monitoring does not decrease the incidence of SIDS. Caretakers should be thoroughly instructed in infant cardiopulmonary resuscitation (CPR) techniques. Parent groups and the National Foundation for Sudden Infant Death are helpful to some families.

The Asphyxiated Child

An asphyxiated patient, whether an older child or an infant with aborted SIDS or birth asphyxia, poses an important challenge for the intensivist. Asphyxia injures a number of target end organs.

Asphyxial Injury to Organ Systems

Cardiovascular System

The hypoxia and mixed metabolic and respiratory acidosis associated with asphyxia decreases cardiac output by depressing the medullary cardiac regulation center and by causing bradycardia and decreased myocardial contractility. As compensation for the decreased cardiac output, blood flow is preferentially redistributed to the cerebral and coronary circulations at the expense of the kidneys and GI tract. Asphyxiated children are cold and mottled and have evidence of a low-output shock state. Specific therapy for asphyxia-induced cardiovascular dysfunction consists of correcting the respiratory abnormality, correcting the acidosis, and administering chronotropic and inotropic agents as needed. (Appropriate monitoring and general treatment of circulatory failure are discussed in the section on acute circulatory failure in children.)

Respiratory System

Asphyxia-induced respiratory decompensation is commonly manifested as pulmonary edema, increased microvascular pressure, hypoxic myocardial failure, capillary endothelial damage, and capillary leak. Treatment of both conditions includes cardiovascular support, positive-pressure ventilation, and PEEP.

Central Nervous System

CNS complications of asphyxia include intraventricular hemorrhage, cortical infarction, and cerebral edema. Intraventricular hemorrhage in premature infants is a consequence of hypoxic-ischemic necrosis of the paraventricular germinal matrix, which undergoes liquefaction. The vessels rupture into the ventricular system hours to days after the initial asphyxic injury.[260]

Cortical infarction occurs in children of all ages. This condition usually develops in a watershed area and affects the motor cortex controlling the upper extremities and the visual cortex.

Cerebral edema is a relatively late consequence of asphyxia that occurs 8 to 72 hours after injury. Because the ultimate neurologic outcome depends principally on the degree of cortical injury that occurs with asphyxia, aggressive management of cerebral edema may prevent or reduce secondary damage. Measures that ensure adequate oxygenation and hemodynamic stability should be instituted. Patients who have purposeful movements and a normal brainstem examination 24 hours after their hypoxic insult generally have a good neurologic recovery. Children without these findings 24 hours after injury are more likely to have severe neurologic deficits or die.[261] (Treatment of cerebral edema is discussed in the CNS section.)

Renal and Metabolic Effects

Asphyxia may cause renal ischemia, tubular or glomerular necrosis, and renal vein or glomerular capillary thrombosis. Metabolic complications of asphyxiated infants and children may also include hypoglycemia, hypocalcemia, hypomagnesemia, and metabolic acidosis. These complications of asphyxia often produce profound myocardial depression and systemic hypotension. Hypervolemia and hypo-osmolality and the syndrome of inappropriate ADH secretion can occur with fluid resuscitation. Free water overload should be avoided if at all possible.

Hematologic System

The major hematologic complication of asphyxia is DIC. In the newborn, as well as in older children, levels of vitamin K–dependent factors (II, VII, IX, X) may be low because of asphyxia-induced hepatic dysfunction; these conditions may respond to vitamin K.

Gastrointestinal System

Splanchnic ischemia may cause necrosis, ulceration, or perforation of the GI tract.[262] Monitoring includes testing nasogastric secretions and stool for blood, measuring abdominal girth, and evaluating abdominal radiographs for intraluminal, intramural, intraportal, or extraluminal air. NEC is a common problem after asphyxia in premature infants. In severe cases, bowel perforation, peritonitis, and sepsis can lead to death. Management of NEC consists mainly of treatment with appropriate antibiotics, maintenance of intravascular volume, and minimizing the osmotic load of feedings until the GI tract has fully recovered. Oral or gastric alimentation is avoided for several days to several weeks after injury. When feedings are initiated, low-osmolality solutions should be used. While the bowel is recovering, intravenous alimentation should be provided through a central venous catheter. Gastric pH should be monitored and abnormalities should be treated with antacids or an H_2 blocker. Hypoxia and hypoperfusion of the liver may cause hepatocellular damage. The extent of the injury is directly related to the duration and severity of the insult. Elevated transaminase levels, abnormal coagulation, elevated bilirubin, and unstable carbohydrate metabolism are common; all functional and laboratory abnormalities should be corrected if possible.[263]

Approach to Death from Asphyxia

Because the CNS is very sensitive to asphyxia, it is relatively common to have full cardiovascular recovery and profound CNS damage or brain death. In situations in which meaningful neurologic recovery is hopeless or when brain death has occurred, life support can be terminated. The parents and siblings of children who die require support, counseling, and understanding. They often react with guilt, denial, or hostility for not having been more vigilant. These issues must be addressed directly by trained professionals.

Cardiopulmonary Resuscitation

Resuscitation of the Newborn

Profound changes occur in the cardiovascular and respiratory systems at birth. Failure to successfully make these changes may result in death or CNS injury (also see Chapter 97). Consequently, someone capable of performing neonatal resuscitation must be present at every delivery. Wasting time finding someone to resuscitate the neonate may be disastrous for the infant. This section discusses the causes and effects of cardiorespiratory insufficiency at birth and the techniques of resuscitation. When possible, the recommendations of the American Academy of Pediatrics have been followed.

Guidelines for neonatal resuscitation have been issued by many orgaizations, including the American Heart Association and the American Academy of Pediatrics. Guidelines are helpful for remembering the sequence for resuscitation. Failure to follow the guidelines has resulted in bad outcomes.[264] However, slavish adherence to guidelines without thinking may also result in bad outcomes. Understanding the physiology of delivery and birth is the keystone to success.

Resuscitation of the newborn requires education and practical experience. Unfortunately, there is little opportunity to learn and refresh the neonatal resuscitation skills of most anesthesiologists because few of their patients require resuscitation. Simulators solve this problem. In the near future, those who resuscitate babies will be required to train with a neonatal simulator and to repeat this training several times a year to maintain board certification.[265]

Detecting potential problems and preparing to treat them before birth increase the likelihood of successfully resuscitating patients. Fetal heart rate monitoring is a moderately reliable and widely used means of detecting early, serious fetal problems. Analysis of fetal blood gases and pH can be used to detect asphyxia and may help decide whether early, rapid delivery of the fetus is required.

Asphyxia (i.e., decreased Pa_{O_2} and pHa and increased Pa_{CO_2}) occurs when gas exchange by the placenta (fetus) and by the lung (neonate) is inadequate or when there is right-to-left shunting of blood in the heart or lungs after birth. It also occurs with myocardial dysfunction.

During fetal asphyxia, Pa_{O_2} decreases from its normal of 25 to 40 mm Hg to less than 5 mm Hg in about 2 minutes (Fig. 84-3) and is followed by anaerobic metabolism. Five minutes of asphyxia reduces the pH to 6.90 or less, increases Pa_{CO_2} to greater than 100 mm Hg, and reduces Pa_{O_2} to unmeasurable levels.[266,267] Blood flow to the liver, kidney, gut, skin, and muscle is reduced, and flow

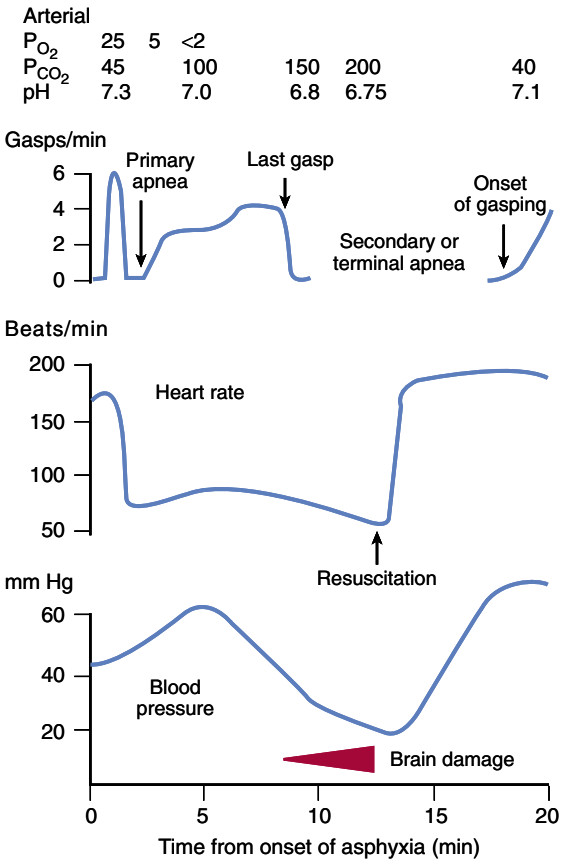

Figure 84-3 The response of newborn monkeys to asphyxia. *(From Dawes GS: Foetal and Neonatal Physiology. Chicago, Year Book Medical Publishers, 1968.)*

to the heart, brain, adrenal glands, and placenta is constant or increased. Oxygen extraction from blood is greatly increased.[268] Myocardial function is maintained by myocardial glycogen and lactic acid metabolism.[269] A heart rate of less than 100 beats/min significantly decreases cardiac output. Catecholamines are also important for survival from asphyxia. Intrapartum asphyxia may result in hypervolemia or hypovolemia.

Assessment of the Fetus at Birth

The Apgar score, if done properly, is a simple, useful guide to neonatal well-being and resuscitation (Table 84-14), but it is only a guide. The 1-minute score correlates well with acidosis and survival. The 5-minute score may or may not be predictive of neurologic outcome.[270,271] To be of value, each variable must be evaluated at 1 and 5 minutes. However, some very acidotic neonates have relatively normal Apgar scores at 1 and 5 minutes and are peripherally vasoconstricted, exhibit pallor, and have a relatively normal heart rate and arterial blood pressure.

Heart Rate

The heart rate of normal fetuses and neonates ranges from 120 to 160 beats/min. When the heart rate is less than 100 beats/min, cardiac output and tissue perfusion are reduced.

Respiratory Effort

Breathing usually begins by 30 seconds after birth and is sustained by 90 seconds of age. A few minutes after birth, the respira-

Table 84-14 The Apgar Scoring System

	Score*		
Sign	**0**	**1**	**2**
Heart rate	Absent	Less than 100/min	More than 100/min
Respiratory effort	Absent	Slow, irregular	Good, crying
Color	Blue, pale	Body pink, extremities blue (acrocyanosis)	Completely pink
Reflex irritability (response to insertion of a nasal catheter)	Absent	Grimace	Cough, sneeze
Muscle tone	Limp	Some flexion of extremities	Active motion

*Each variable is evaluated individually and scored from 0 to 2 in an infant at 1 and 5 minutes of age. The total score at each time is the sum of the scores of the individual variables. A total score of 10 is perfect.

tory rate of normal neonates is between 30 and 60 breaths/min. The absence of a pause between inspiration and expiration helps develop and maintain FRC. Apnea and bradypnea prolong exhalation, reduce FRC, and cause hypoxia. Causes of apnea and bradypnea include severe acidosis, asphyxia, maternal drugs, infections, and CNS damage. Tachypnea (>60 breaths/min) occurs with hypoxemia, hypovolemia, metabolic and respiratory acidosis, CNS hemorrhage, pulmonary gas leaks, pulmonary disease (e.g., hyaline membrane disease, aspiration syndromes, infections), pulmonary edema, and maternal drugs (e.g., narcotics, alcohol, magnesium, barbiturates).

Resuscitation with 100% oxygen can be detrimental.[272] Neonates resuscitated with room air do equally well as those resuscitated with added oxygen.[273] Animals resuscitated with air had less cerebral hydrogen peroxide than did those resuscitated with oxygen.[274] Polymorphonuclear cells were less activated with room air.[275] Oxygen administration in excess of room air increases the likelihood of an inflammatory response. When possible, room air rather than oxygen should be used to resuscitate neonates.

Muscle Tone

Most neonates, including those born preterm, are active at birth and move all extremities in response to stimuli. Asphyxia, maternal drugs, CNS damage, amyotonia congenita, and myasthenia gravis decrease muscle tone. Flexion contractures and absent joint creases are signs of in utero CNS damage.

Reflex Irritability

Normal neonates move with stimulation and grimace or cry when a catheter is inserted into a nostril. Neonates who have hypoxia, acidosis, CNS injury, and congenital muscle disease or are sedated by maternal drugs may not move.

Color

Essentially all neonates have a blue-tinged cast to their skin at birth. By 60 seconds of age most of them are entirely pink, except for their hands and feet, which remain blue. If central cyanosis persists beyond 90 seconds of age, asphyxia, low cardiac output, pulmonary edema, methemoglobinemia, polycythemia, congenital heart disease, arrhythmias, and pulmonary disorders (e.g., respiratory distress, airway obstruction, hypoplastic lungs, diaphragmatic hernia) should be considered, especially if the infant remains cyanotic despite oxygen and controlled ventilation.

Neonates who are pale at birth are often asphyxiated, hypovolemic, acidotic, or anemic, or they have congenital heart disease. A neonate whose skin is entirely pink within 2 minutes of birth may be intoxicated with alcohol or magnesium or may be alkalotic (pH >7.50). Rubrous neonates are usually polycythemic.

Resuscitation Equipment

Resuscitation beds should allow positioning of the neonate's head below the level of the lungs to promote drainage of lung fluid and reduce the likelihood of aspirating gastric contents. A servocontrolled infrared heater should be used to maintain the neonate's temperature between 36°C and 37°C unless there is evidence of asphyxia. If asphyxia is noted, body temperature should be reduced to 34°C to 35°C for brain protection. A suction device should be available and should allow the suction pressure to be varied; pressures below −100 mm Hg should not be used.

Equipment required for tracheal intubation includes 0 and 00 straight laryngoscope blades; a pencil-type laryngoscope handle; 2.5-, 3.0-, and 3.5-mm ETTs; and a suction catheter that easily fits through each size tube.

The ventilation system must permit ventilatory rates of at least 150 breaths/min and make it possible to maintain PEEP. One-way valves can stick in the closed position, especially when high gas flow and high respiratory rates are used. The modified Jackson-Rees or Ayres system works well when appropriately trained people use it. Overexpansion of the lungs with large tidal volumes injures the lungs and activates inflammatory processes that may cause chronic lung disease.[276] Gentle inflation of the lung is less injurious to the lung. Airway inflation pressures should be measured continuously during assisted or controlled ventilation in the delivery room, and excessive pressures and tidal volumes should be avoided.

As in any critical care situation, patient care should be guided by information. Consequently, blood gas and pH measurements are mandatory, and the results of these tests must be available within 10 minutes of drawing the blood sample. Umbilical arterial catheters are useful for measuring arterial blood pressure and withdrawing blood for blood gas analysis and pHa. They can also be used to infuse emergency fluids.

Arterial oxygen saturation (Sao_2) can be measured immediately after birth by attaching a pulse oximeter to a hand or foot.[277] Pulse oximeters permit rapid detection of changes in oxygenation and rapid reduction of Fio_2. The normal Sao_2 of neonates is usually 87% to 95%, which is associated with a Pao_2 of 55 to 70 mm Hg.[278]

Pulmonary Resuscitation

If the heart rate is below 80 beats/min and Sao_2 is less than 85%, tracheal intubation should be considered and positive-pres-

sure ventilation should be initiated at 30 to 60 breaths/min. For the first several minutes every fifth breath should be held for 2 seconds to expand the atelectatic lung and remove lung fluid. PEEP at 3 to 5 cm H_2O should be maintained. Excessive airway pressure is to be avoided. As few as six large breaths at birth markedly increased lung injury in premature lambs and prevented a response to surfactant.[279] Excessive inspiratory volumes are also associated with inflammation and chronic lung disease.[276] Measuring airway pressure helps prevent us from using excessive pressure and volumes.

Tracheal Intubation

The head should be placed in a neutral or "sniffing" position during bag-and-mask ventilation and tracheal intubation. An appropriately sized ETT is inserted and its tip is placed 1 to 2 cm below the vocal cords, depending on the size of the neonate. Usually, this means that the distance from the tip of the tube to the gums is 7, 8, 9, or 10 cm in 1-, 2-, 3-, and 4-kg infants. A small gas leak should be present between the ETT and trachea when the ventilation pressure is 15 to 25 cm H_2O. This usually entails the use of a 2.5-mm (internal diameter) tube for neonates weighing less than 1.5 kg, a 3.0-mm tube for those between 1.5 and 2.5 kg, and a 3.5-mm tube for those weighing more than 2.5 kg. Successful tracheal intubation is confirmed by observing the ETT pass through the vocal cords, by observing bilateral chest movement with each mechanical inspiration, and by observing condensation in the ETT during exhalation. Breath sounds should be much louder over the chest than over the abdomen, and the skin color, heart rate, and Sao_2 should improve with positive-pressure ventilation. Carbon dioxide should be present during exhalation.

However, the small tidal volumes and low pulmonary blood flow of some infants at birth may make it difficult to use capnography effectively.

Adequacy of Ventilation

Both sides of the chest should rise equally and simultaneously with inspiration, but the amount of rise should not exceed that associated with the neonate's normal spontaneous breathing. The presence of breath sounds may be misleading because they are well transmitted within the neonate's small chest. A difference in breath sounds between the two sides of the chest should raise suspicion of endobronchial intubation, pneumothorax, atelectasis, or a congenital anomaly of the lung. The presence of loud breath sounds over the stomach suggests esophageal intubation or a tracheoesophageal fistula. If ventilation is adequate, the neonate will become pink, initiate rhythmic breathing, and have a normal heart rate.

Because most asphyxiated neonates have no lung disease, they can be effectively ventilated with peak airway pressures lower than 25 cm H_2O, even for the first few breaths. Those with stiff lungs (e.g., erythroblastosis fetalis, congenital anomalies of the lung, pulmonary edema, severe meconium aspiration, diaphragmatic hernia) may require higher inspiratory pressure to ventilate their lungs and are more likely to have pulmonary gas leaks. To reduce this likelihood, the lungs should first be ventilated with an inspiratory pressure of 15 to 20 cm H_2O and inspiratory rate of 150 to 200 breaths/min. If low-pressure (low-volume), high-rate ventilation does not improve the oxygenation, higher pressure and volume may be required. Failure to adequately ventilate the lungs at birth may worsen hypoxemia and lead to CNS damage or even death. If Pao_2 exceeds 70 to 80 mm Hg or Sao_2 exceeds 94%, the inspired oxygen concentration should be reduced (if increased concentrations of oxygen are used) until Sao_2 and Pao_2 are normal for age. Oxygenation is maintained at the low range of normal in neonates 34 weeks' or less gestation to avoid the retinopathy of prematurity.[280,281] The neonate's heart rate should be monitored continuously during endotracheal intubation because the process of tracheal intubation may cause arrhythmias in hypoxic neonates.

Routine Tracheal Suctioning

The trachea should be suctioned before the lungs are ventilated if there is thick meconium in the amniotic fluid or major vaginal bleeding has occurred. Meconium aspiration has been reviewed elsewhere.[282-285]

Particulate meconium should be removed from the lung before breathing is established. The mouth and pharynx are suctioned as soon as the head is delivered. An ETT is inserted, a suction device especially designed for this purpose is applied to the ETT, and suction is applied to the ETT as it is withdrawn from the trachea.[286] The laryngoscope is left in place as the ETT is removed. If meconium is retrieved from the airway, the ETT should be quickly reinserted and the airway suctioned again. The lungs are then gently ventilated. The heart rate should be continuously monitored during laryngoscopy and suctioning and 100% oxygen blown over the neonate's face. The stomach should be suctioned to remove meconium that can be regurgitated and aspirated later. Neonates with Apgar scores of 9 or 10 do not require tracheal suctioning. Removing thin watery meconium at birth has no beneficial effect, whereas removing thick meconium is effective.[287]

Other Causes of Respiratory Failure

Pneumothorax

Pneumothorax occurs in 1% of all vaginal deliveries, in 10% of meconium-stained neonates, and in 2% to 3% of neonates who require mechanical ventilation in the delivery room. The hemithorax containing free air is usually hyperexpanded and moves poorly with ventilation. The point of maximum cardiac impulse is shifted toward the side without the pneumothorax. Heart tones may be muffled.

If a small, high-intensity cold light is placed directly on the skin of the neonate's chest, the involved side of the chest will glow if a pneumothorax is present.[288] Pneumothoraces are relieved by needle or chest tube drainage.

Administration of Surfactant

Surfactant administration has significantly reduced the incidence of pulmonary gas leaks, hyaline membrane disease, deaths, BPD, and interstitial emphysema.[289-292] Surfactant is administered as 5 mL of solution per kilogram into the trachea at or shortly after birth, which briefly reduces oxygen saturation. Sao_2 then increases rapidly in most instances, as does compliance of the lung. The improved lung compliance will result in overinflation of the lung and lung injury or a pulmonary gas leak if the ventilation pressure is not reduced.

Premature infants are often supported with nasal CPAP shortly after birth to reduce the need for tracheal intubation and mechanical ventilation.[265] However, this does not reduce the incidence of CNS hemorrhage or chronic lung disease.[293] The

duration of oxygen administration and chronic lung disease is unchanged.

Vascular Resuscitation

Vascular resuscitation is a neglected aspect of neonatal resuscitation. If the neonate's condition does not improve with ventilation, oxygen (if needed), and tactile stimulation, an umbilical artery catheter should be inserted so that blood gases and pH and arterial blood pressure can be measured and blood volume can be expanded if necessary.

Correction of Acidosis

Respiratory acidosis is corrected by mechanical ventilation. Metabolic acidosis is corrected by administering sodium bicarbonate. Sodium bicarbonate solutions consist of about 1800 mOsm/L. Rapid administration of this solution (>1 mEq/kg/min) may possibly cause intracranial hemorrhage in premature infants. The complete reaction of hydrogen ions with 50 mEq of bicarbonate generates approximately 1250 mL of CO_2. If ventilation is adequate, there is no increase in $Paco_2$; if ventilation is inadequate, $Paco_2$ increases significantly and may cause cardiac arrest or intracranial hemorrhage, or both. *Sodium bicarbonate should be infused only to correct metabolic acidosis if ventilation is adequate.* Administration of bicarbonate may also induce hypotension in hypovolemic infants (Fig. 84-4) by relaxing acidosis-induced intense peripheral vasoconstriction. THAM is an alternative to sodium bicarbonate. It reduces $Paco_2$ rather than increases it.

If the Apgar score is 2 or less at 2 minutes or is 5 or less at 5 minutes despite tactile stimulation and controlled ventilation, consider giving 2 mEq/kg of sodium bicarbonate while the lungs are being ventilated. If the pH is below 7.00, $Paco_2$ is below 35 mm Hg, and blood volume is adequate, correct a fourth of the base deficit. If the pH is above 7.10, administration of base should

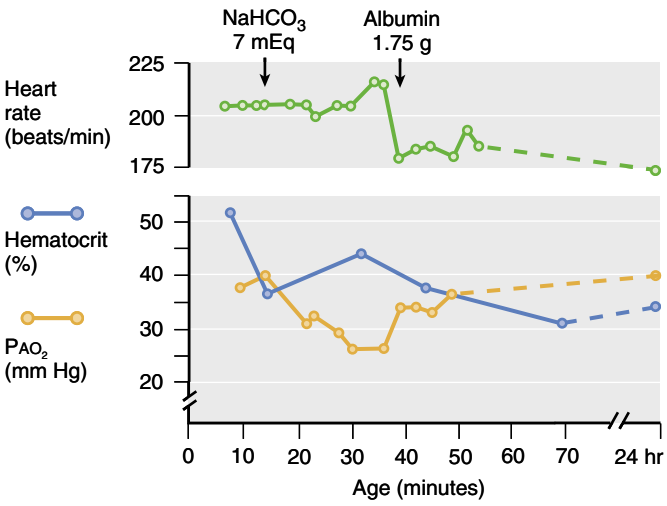

Figure 84-4 Effects of sodium bicarbonate on aortic blood pressure (PAO), heart rate, and hematocrit level. Notice that hypotension occurred after the administration of sodium bicarbonate. The hematocrit level decreased as fluid was "pulled" into the intravascular space to compensate for the hypovolemia that was present since birth. Raising the pH decreased the peripheral vasoconstriction produced by the preexisting acidosis. Giving albumin increased the aortic pressure to normal. On the basis of the final hematocrit level, the initial blood volume was approximately 30% less than predicted. *(Adapted from Phibbs RH: Problems of neonatal intensive care units.* In *Lucey JF [ed]: Report on the 59th Ross Conference on Pediatric Research. Columbus, OH, Ross Laboratories, 1969.)*

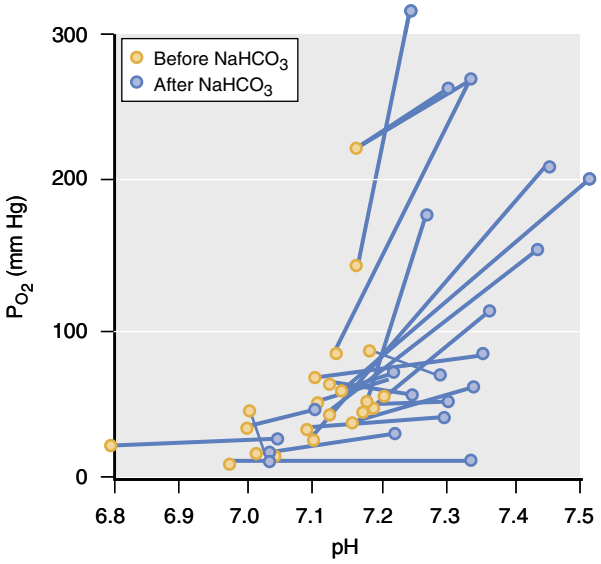

Figure 84-5 Effects of rapid infusion of sodium bicarbonate on Pao_2 and pH when ventilation was held constant. Pao_2 increased when the pH increased above 7.10 to 7.20. *(Adapted from Gregory GA: Resuscitation of the newborn. Anesthesiology 43:225, 1975.)*

be delayed and lung ventilation should be continued. Five minutes later, arterial pH and blood gas analysis should be repeated. If the pH is 7.15 or higher, ventilate the lungs and again delay bicarbonate therapy. If the pH has decreased or is unchanged, correct a fourth of the base deficit with bicarbonate or THAM while continuing artificial ventilation. Figure 84-5 shows the effects of sodium bicarbonate on the Pao_2 of a group of asphyxiated neonates whose ventilation was held constant. No significant increase in Pao_2 occurred until the pH exceeded 7.10 to 7.20, the point at which Rudolph and Yuen[294] found the most significant decrease in PVR.

Metabolic acidosis is usually caused by poor tissue perfusion that is the result of hypovolemia or heart failure. Acidosis-induced heart failure generally occurs when the pH is 7.00 or less. When the pH is above 7.15, cardiac output improves. Congenital bradycardia-induced heart failure is usually treated with isoproterenol (starting with 0.05 µg/kg/min and increasing the dose as necessary) or insertion of a transvenous pacemaker. Hypoglycemia may also cause heart failure. Thus, the glucose concentration should be measured during resuscitation of the child.

Expansion of Intravascular Volume

If the umbilical cord is clamped early or if it is wound tightly around the neck of the fetus and the umbilical cord must be cut for delivery, the baby may be hypovolemic. The baby may also be hypovolemic with intrauterine asphyxia, placental abruption, or transection of the placenta.

Detection of Hypovolemia

Hypovolemia is detected by measuring arterial blood pressure and by physical examination (i.e., skin color, perfusion, capillary refill time, pulse volume, and extremity temperature) (Table 84-15). Table 84-16 shows the systolic, diastolic, and mean arterial pressure during the first 12 hours after birth.

CVP measurements are useful in detecting hypovolemia and in determining the adequacy of fluid replacement. The venous

Table 84-15 Relationships of Skin Color, Capillary Refill Time, Pulse Volume, and Extremity Temperature to Hypovolemia

Amount of Volume Depletion (%)	Skin Color	Capillary Refill Time (sec)	Posterior Tibial Pulse Volume	Skin Temperature
None	Pink	<2	Full	Warm
5	Pale	3-4	Moderately full	Cold from the midcalf and midforearm out
10	Gray	4-5	Markedly diminished or absent	Cold from the midthigh and upper arm out
15	Mottled	>5	Markedly diminished or absent	Entire extremity cold

pressure of normal neonates is 2 to 8 cm H_2O. If CVP is less than 2 cm H_2O, hypovolemia should be suspected.

Treatment of Hypovolemia

Treatment of hypovolemia requires expansion of intravascular volume with blood and crystalloid. Albumin may also be used, but evidence of its effectiveness is limited. If it is suspected that the neonate will be hypovolemic at birth, Rh-negative type O packed RBCs should be available in the delivery room before the the neonate is born.

Occasionally, enormous volumes of blood and fluid are required to raise arterial blood pressure to normal. At times, more than 50% of the blood volume (85 mL/kg in term neonates and 100 mL/kg in preterm neonates) must be replaced (Fig. 84-6), especially when the placenta is transected or abrupted during birth. In most cases, less than 10 to 20 mL/kg of volume restores mean arterial pressure to normal.

Overexpansion of intravascular volume should be avoided because sudden systemic hypertension may disrupt the intracerebral vessels and cause intracranial hemorrhage, particularly in premature infants.[295]

Other Causes of Hypotension

Hypoglycemia, hypocalcemia, and hypermagnesemia also cause hypotension in neonates. Hypotension induced by alcohol or magnesium intoxication usually responds to blood volume expansion or dopamine, or to both. Hypermagnesemic neonates generally respond to 100 to 200 mg/kg of calcium gluconate administered over a 5-minute period.

Cardiac Massage

If the heart rate at 1 minute or less of age is less than 80 beats/min despite stimulation and ventilation, the trachea should be intubated, the lungs ventilated with oxygen, and closed chest massage begun. Place both thumbs on the sternum and allow the fingers to support the back (Fig. 84-7). Compress the sternum about 2 to 2.5 cm at a rate of 100 to 120 times per minute. It is not necessary to interrupt ventilation of the lungs during cardiac massage. The effectiveness of cardiac massage is determined by measuring blood gases and pH, by the arterial pressure generated, and by examining the pupils, which should be in the midposition or constricted. If the pupils are dilated and no atropine has been given, CBF and oxygenation are inadequate.

Resuscitation Drugs

Table 84-17 lists the drugs and their usual starting doses used during resuscitation of the newborn. Severe acidosis (pH < 7.0) may decrease the effectiveness of these drugs. Thus, the pH must be raised above 7.20 as soon as possible. All drugs should be infused in the smallest volume of fluid possible to reduce the risk of inducing hypervolemia.

Table 84-16 Average Systolic, Diastolic, and Mean Arterial Blood Pressure during the First 12 Hours of Life in Normal Infants

Blood Pressure Measures by Birth Weight	Blood Pressure (mm Hg) during the First 12 Hours of Life											
	1	2	3	4	5	6	7	8	9	10	11	12
Birth Weight 1001-2000 g												
Systolic	49	49	51	52	53	52	52	52	51	51	49	50
Diastolic	26	27	28	29	31	31	31	31	31	30	29	30
Mean	35	36	37	39	40	40	39	39	38	37	37	38
Birth Weight 2001-3000 g												
Systolic	59	57	60	60	61	58	64	60	63	61	60	59

Mean	43	41	43	43	44	43	45	43	44	44	43	42
Birth Weight >3000 g												
Systolic	70	67	65	65	66	66	67	67	68	70	66	66
Diastolic	44	41	39	41	40	41	41	41	44	43	41	41
Mean	53	51	50	50	51	50	50	51	53	54	51	50

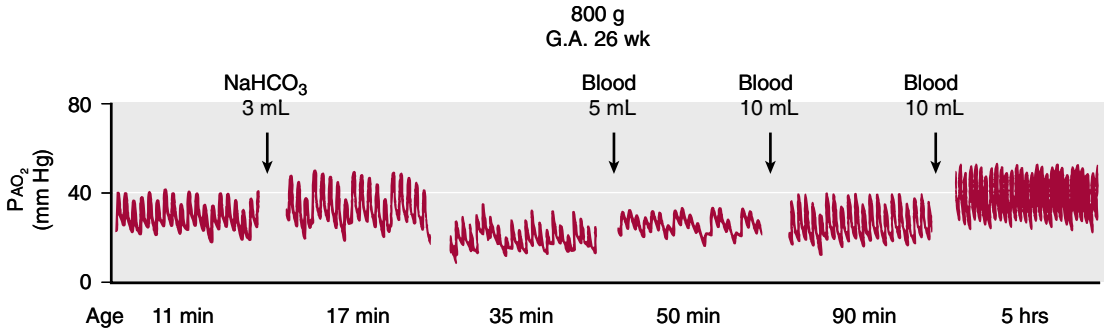

Figure 84-6 Aortic blood pressure (PAO) during the first 5 hours of life of a premature infant with hypovolemia. PAO values equal mean aortic pressure. G. A., gestational age. *(From Gregory GA: Resuscitation of the newborn. Anesthesiology 43:225, 1975.)*

When to Discontinue Resuscitation

The decision to stop resuscitation is usually based on the physician's experience, the condition of the patient, and the desires of the parents. If the chances of a productive, useful life are very poor, discontinuing all resuscitative efforts should be considered. Whether to resuscitate micropremies is questionable[296,297] because the outcome of neonates born before 26 weeks' gestation is abysmally poor.[298,299] Frank discussions should be undertaken with the family before the baby is born when possible. If this cannot be done, it may be necessary to initiate resuscitation and then discontinue it after talking with the parents.

Resuscitation of Children

Pediatric cardiopulmonary arrest differs in a number of ways from arrest in adults. Cardiac arrest in adults is usually caused by severe cardiac ischemia and malignant arrhythmias. Children seldom have primary malignant arrhythmias. The more commom cause of cardiac arrest in children is respiratory compromise or respiratory arrest. Another difference is the character of the arrhythmia observed. Adults generally display ventricular arrhythmias, whereas children are more likely to have a bradyarrhythmia that degenerates into asystole.

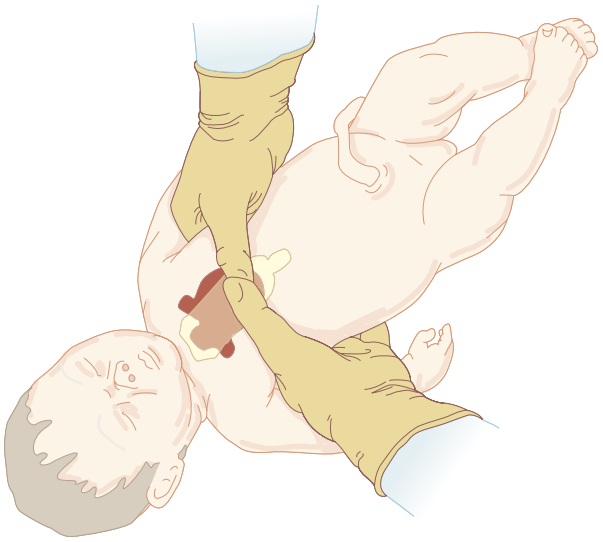

Figure 84-7 Closed chest massage. For simplification, ventilation is not shown. *(From Gregory GA: Resuscitation of the newborn. Anesthesiology 43:225, 1975.)*

Identifying patients at risk for cardiopulmonary arrest is just as important as providing good CPR. This requires constant clinical evaluation and identification of risk factors. Critically ill patients are often at increased risk for cardiac arrest during airway manipulation, any change in therapy, or manipulation of the patient or bed and when doctors and nurses change shifts.

The basic ABCs of resuscitation must be sufficiently familiar that no thought is required to begin the initial resuscitative efforts. Despite the evolving literature regarding new CPR, the standard American Heart Association CPR is still advocated as the appropriate method.[300] If despite ventilation there is no evidence of a pulse, external cardiac compressions are initiated immediately and the lungs are ventilated. The rate of compression should be 80 to 100/min in children and adults. One hand can be placed behind the back for support while the child's sternum is compressed with two fingers of the other hand. The adult-style two-handed massage is preferable in older children. Pressure should always be completely released between forceful compressions to permit filling of the cadiac chambers, and a pulse should be sought to assess the adequacy of compressions.

Vascular access is attained as soon as possible. Although a number of medications (atropine, epinephrine, lidocaine) have been given through the ETT, bicarbonate, calcium, fluid, and pressors require vascular access. The evidence that endotracheal administration of drugs is better is inconclusive. Common drugs used for CPR include the following:

1. Atropine (0.02 to 30 mg/kg with a minimum dose of 0.1 mg and a maximum dose of 1.0 mg) is used to treat bradycardia.
2. Sodium bicarbonate corrects the metabolic component of the acidosis. The recommended initial dose is 1 mEq/kg in association with adequate ventilation. Because the acidosis is primarily respiratory, inadequate ventilation during bicarbonate administration will only increase $Paco_2$ and decrease the pH. Overzealous use of bicarbonate lowers the threshold for ventricular fibrillation and causes a left shift of the oxygen dissociation curve. Present guidelines suggest that bicarbonate administration be guided by ABG results.
3. Calcium is a positive inotrope and peripheral vasoconstrictor; it may decrease the threshold for ventricular

Table 84-17 Drugs Used during Resuscitation

Drug	Indication	Dose*	Route	Response	Complications
Atropine	Bradycardia	0.03 mg/kg	IV	Increased heart rate	Marked tachycardia, diminished cardiac output
Calcium gluconate	Low cardiac output	100 mg/kg over 5-10 minutes (ECG monitoring)	IV	Improved cardiac arrhythmias	Bradycardia
Epinephrine	Flat-line ECG	0.1 mL of a 1 : 10,000 solution per kg	IV	Flat-line ECG converted to some rhythmic response	Hypertension, ventricular fibrillation
Isoproterenol	Bradycardia, hypotension, low cardiac output	4 mg/250 mL of 5% dextrose; start at 0.01 μg/kg/min and increase until the heart rate increases	IV	Increased heart rate, improved cardiac output	Arrhythmias, low cardiac output if the heart rate is greater than 180-220/min
Dopamine	Hypotension	40 mg/100 mL; start at 5 μg/kg/min and increase until the desired effect is achieved	IV	Increased arterial pressure; improved cardiac output, perfusion, and urine output	Arrhythmias (uncommon)

*In general, doses given are starting doses and may have to be increased. Most drugs tend to be more effective when the pH is higher than 7.15.
ECG, electrocardiogram.

arrhythmias. In pediatric patients, ventricular arrhythmias seldom cause cardiac arrest. Thus, administration of calcium may be safer. Ten to 20 mg of elemental calcium per kilogram of body weight is appropriate in patients who have hypocalcemia, hyperkalemia, or an overdose of calcium channel blockers.

4. Dextrose (0.5 to 1.0 g/kg) is given to correct hypoglycemia, which may be a precipitating cause of the arrest. It is available as $D_{50}W$ (1 to 2 mL/kg) and $D_{25}W$ (2 to 4 mL/kg). $D_{50}W$ and $D_{25}W$ are also osmotic diuretics. Dextrose (0.5 g/kg) in combination with insulin (0.1 U/kg) is administered to treat hyperkalemia. Hyperglycemia should be avoided during resuscitation for fear of increasing CNS damage.
5. Epinephrine is usually given intravenously or intraosseously, but it can also be administered through the ETT (0.1 mL/kg of a 1 : 1000 solution). Epinephrine is supplied as a 1 : 10,000 solution (0.1 mg/mL); the dose is 0.1 mL/kg and is repeated every 3 to 5 minutes as needed. The maximum recommended dose is 1 mg intravenously/intraosseously or 10 mg by ETT.
6. Lidocaine is used to decrease ventricular irritability and to help maintain a normal rhythm after defibrillation. It decreases myocardial contractility and should therefore be given only when absolutely necessary, such as when a stable rhythm cannot otherwise be maintained. The dose is 1 mg/kg as a single dose; this dose can be repeated several times or the drug can be given as an infusion of 20 to 50 μg/kg/min.
7. Amiodarone, 5 mg/kg intravenously/intraosseously, is used to treat ventricular tachydysrhythmias by slowing AV conduction, prolonging the AV refractory period and QT interval, and slowing ventricular conduction. The drug can be administerd rapidly to patients in cardiac arrest, but it should be administered more slowly to patients with a pulse—blood pressure should be monitored. The ECG should be monitored for evidence of bradycardia.
8. Adenosine is administered rapidly for diagnosis and treatment of narrow-complex tachycardias in doses of 0.1 mg/kg (maximum dose of 6 mg), which can be repeated as 0.2 mg/kg (maximum of 12 mg). ECG recording during adenosine administration is very useful to determine whether the drug is effective or if more drug is needed.
9. Vasopressin is used frequently in resuscitation of adults, but there is limited experience with the use of vasopressin in pediatric patients (dosing is not well established, but the drug has been administered in doses of 1 U/kg intravenously/intraosseously).[301] The American Heart Association believes that there is insufficient evidence to make a recommendation for or against the routine use of vasopressin during cardiac arrest.
10. It is common to infuse an inotrope or chronotrope during resuscitation. Cardioversion is indicated if ventricular fibrillation or ventricular tachycardia is present or if either one develops. The pediatric dose is 1 to 3 W-sec/kg or 10 to 15 W-sec/yr of life. The synchronized mode is used for ventricular tachycardia, and the nonsynchronized mode is used for fibrillation. If small paddles are not immediately available for use with small children, adult paddles can be placed in an anteroposterior position. If resuscitation efforts are unsuccessful, the primary event that precipitated the arrest should be re-evaluated to determine whether there are correctable mechanical or metabolic problems (or both). Possible reasons for unsuccessful resuscitation include tension pneumothorax/hemothorax, disruption of a major vessel, cardiac tamponade, profound hypovolemia, profound metabolic imbalance, toxin ingestion, and hypothermia. A patient with a core temperature lower than 30°C may appear dead and be unresponsive to pharmacologic management. The patient must be warmed as part of the resuscitation. It may be necessary to open the chest and bathe the heart in warm water to increase its temperature sufficiently so that it will be responsive to drugs. A hypothermic patient can be pronounced dead only if there is no electrical activity on the ECG and the core temperature is at least 30°C or if it is impossible to warm the patient to 30°C with aggressive methods, including peritoneal dialysis.

Iatrogenic complications, including traumatic pneumothorax from attempted vascular cannulation, pericardial tamponade

from intracardiac injections, splenic or hepatic rupture from closed-chest compressions, pneumothorax from overzealous positive-pressure ventilation, and placement of the ETT into the esophagus, may also make resuscitation unsuccessful. Because patients in cardiorespiratory distress or arrest have an excellent chance of full recovery with adequate resuscitation, speedy, orderly direction, cooperation of all personnel, and continuous assessment of the effectiveness of resuscitation are key. Keeping the brain alive is the objective of every resuscitative effort, and rapid institution and maintenance of ventilation and cardiac massage increases the chance of this occurring.

Parent/Family Support

Numerous unavoidable stresses occur in any intensive care setting. In a PICU, the difficulty of dealing with the illness or death of a child often magnifies the amount of stress. To adequately support the ICU staff, children, and families, potential problems should be discussed and understood. ICU staff members are exposed to extremes of frustration and success, and this has an emotional and psychological impact on everyone. Support systems for patients, parents, and staff are a necessity.

Pediatric patients range from premature infants to adults, and each patient must be approached in an age-appropriate manner. Diseases, procedures, and treatments should be discussed with the patient when appropriate; children should participate in their own care to the degree that age, sedation, and disability permit. Parents of a child with a critical illness often progress through the stages of grief reaction described by Kübler-Ross.[302] Their interaction with the ICU staff and with their child is dramatically influenced by the character of their grief reaction. In addition, the ICU may be very confusing. The hectic pace and the numbers of physicians and nurses often leave parents feeling that they lack control and direction. ICUs are also very intimidating and isolating. They are frequently geographically isolated and have a separate dedicated staff, a level of technology not seen in other parts of the hospital, and a terminology of numbers and abbreviations that can render conversations uninterpretable. All these factors make it difficult for parents to maintain a parenting role. Too often, parents assume the role of an absent or passive parent, an angry critical parent, or a parent who wants to assume the role of physician. Some parents can never be directed into a more productive role, but frequently, careful explanations of ICU operational procedures and generous use of social and clerical services can help parents maintain their parenting roles. Other members of the family, especially the patient's siblings, should also be considered. Many parents need help and encouragement before they can involve their children at home in the events taking place at the hospital. Sibling visits should be encouraged and supported by the ICU staff.

Acknowledgment

Dorre Nicholau

85 The Postanesthesia Care Unit

Key Points

1. Emergence from general anesthesia and surgery may be accompanied by a number of physiologic disturbances that affect multiple organ systems. Most common are PONV, hypoxia, hypothermia and shivering, and cardiovascular instability.
2. In a prospective study of more than 18,000 consecutive admissions to the PACU, the complication rate was found to be as high as 24%. Nausea and vomiting (9.8%), the need for upper airway support (6.8%), and hypotension (2.7%) were the most common problems.
3. The most frequent cause of airway obstruction in the immediate postoperative period is the loss of pharyngeal muscle tone in a sedated or obtunded patient. The persistent effects of inhaled and intravenous anesthetics, neuromuscular blocking drugs, and opioids all contribute to the loss of pharyngeal tone in the PACU patient.
4. Pharyngeal function is not normalized until an adductor pollicis train-of-four ratio is greater than 0.90.
5. The ability to strongly oppose the incisor teeth against a tongue depressor is a reliable indicator of pharyngeal muscle tone. This maneuver correlates with an average train-of-four ratio of 0.85 as opposed to 0.60 for the sustained head lift.
6. An estimated 8% to 10% of patients who undergo abdominal surgery subsequently require intubation and mechanical ventilation in the PACU. Respiratory failure in the immediate postoperative period is often due to transient and rapidly reversible conditions such as splinting from pain, diaphragmatic dysfunction, muscular weakness, and pharmacologically depressed respiratory drive.
7. Although a combination of leads II and V_5 will reflect 80% of the ischemic events detected on a 12-lead ECG, visual interpretation of the cardiac monitor is often inaccurate. Because of human error, the American College of Cardiology guidelines recommend that computerized ST-segment analysis be used (if available) to monitor high-risk patients in the immediate postoperative period.
8. In one study, urinary retention was defined as bladder volume greater than 600 mL in conjunction with inability to void within 30 minutes and the incidence of postoperative urinary retention in the PACU was 16%. The most significant predictive factors were age older than 50 years, intraoperative fluid greater than 750 mL, and bladder volume on entry to PACU greater than 270 mL.
9. Perioperative attention to adequate hydration is indicated in any patient who has received an intravenous contrast agent. Aggressive hydration with normal saline provides the single most effective protection against contrast nephropathy.
10. Rhabdomyolysis has been reported to occur in 22.7% of 66 consecutive patients undergoing laparoscopic bariatric surgery. Risk factors include increased body mass index and duration of operation.
11. The incidence of postoperative shivering may be as high as 65% (range, 5% to 65%) after general anesthesia and 33% after epidural anesthesia. Identified risk factors include male gender and the choice of induction agent; propofol is more commonly associated with shivering than pentothal is.
12. Approximately 10% of adult patients older than age 50 who undergo elective surgery will experience some degree of postoperative delirium within the first 5 postoperative days. The incidence is much higher for certain procedures, such as repair of hip fracture (>35%) and bilateral knee replacement (41%).
13. PACU Standards of Care require that a physician accept responsibility for the discharge of patients from the unit (Standard V). This is the case even when the decision to discharge the patient is made at the bedside by the PACU nurse in accordance with hospital-sanctioned discharge criteria or scoring systems.

The postanesthesia care unit (PACU) is designed and staffed to monitor and care for patients who are recovering from the immediate physiologic effects of anesthesia and surgery. PACU care spans the transition from one-on-one monitoring in the operating room to the less acute monitoring on the hospital ward or, in some cases, independent function of the patient at home. To serve this unique transition period, the PACU is equipped to resuscitate unstable patients while providing a tranquil environment for the "recovery" and comfort of stable patients. Its location in close proximity to the operating rooms facilitates rapid access to physician consultation and assistance.

Admission to the PACU

The PACU is staffed by specially trained nurses skilled in the prompt recognition of postoperative complications. On arrival to the PACU, the anesthesiologist provides the PACU nurse with pertinent details of the patient's history, medical condition, anesthesia, and surgery. Particular attention is directed to monitoring oxygenation (pulse oximetry), ventilation (breathing frequency, airway patency, capnography), and circulation (systemic blood pressure, heart rate, electrocardiogram [ECG]). Vital signs are recorded as often as necessary but at least every 15 minutes while the patient is in the unit. Vital signs and other pertinent information are recorded as part of the patient's medical record. Specific requirements and recommendations for patient monitoring and therapeutic intervention can be found in the Practice Standards and Guidelines drafted by the American Society of Anesthesiologists.[1,2]

The Standards for Postanesthesia Care

Practice Standards delineate the required *obligation* of *minimal* care in the clinical setting. As such, they serve as a threshold that can be exceeded when indicated by the clinical judgment of the practitioner. The Standards for Postanesthesia Care are updated on a regular basis to keep up with changing practice parameters and technologic advances. The most recent revision published in 2004 is summarized here.

I. All patients who have received general anesthesia, regional anesthesia or monitored anesthesia care shall receive appropriate post anesthesia management.
II. A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.
III. Upon arrival in the PACU, the patient shall be re-evaluated and a verbal report provided to the responsible PACU nurse by the anesthesia care team who accompanies the patient.
IV. The patient's condition shall be evaluated continually in the PACU. *The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, level of consciousness and temperature.*
V. A physician is responsible for the discharge of the patient from the postanesthesia care unit.

PACU, postanesthesia care unit.
From Practice Guidelines for Post Anesthetic Care. Anesthesiology 96:742, 2002.

Unlike Practice Standards, Practice Guidelines are not requirements. They are recommendations designed to assist the health care provider in clinical decision-making. The ASA Practice Guidelines for Post Anesthetic Care are the result of a multiple-step process that incorporates input from three groups: (1) an ASA-appointed task force consisting of private practice and academic anesthesiologists and epidemiologists, (2) PACU consultants, and (3) ASA members at large. The guidelines are based upon literature review, expert opinion, open forum commentary, and clinical feasability. They recommend the appropriate assessment, monitoring, and treatment of the major organ system functions during recovery from anesthesia and surgery (Table 85-1).[2]

Early Postoperative Physiologic Changes

Emergence from general anesthesia and surgery may be accompanied by a number of physiologic disturbances that effect multiple organ systems. Most common are postoperative nausea and

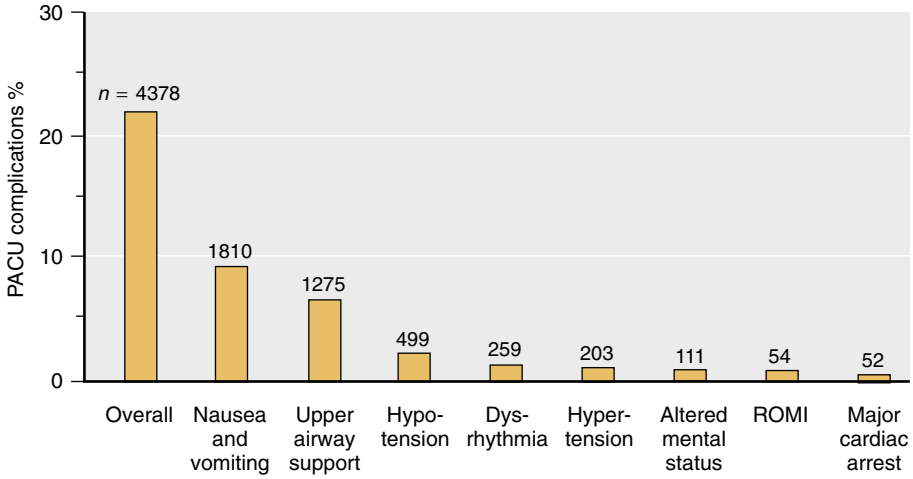

Figure 85-1 The overall complication rate in 18,473 consecutive patients entering a postanesthesia care unit (PACU) was 23.7%. Nausea and vomiting, the need for upper airway support, and hypotension were the most frequent individual complications. (*From Hines HR, Barash PG, Watrous G, et al: Complications occurring in the postanesthesia care unit: A survey. Anesth Analg 74:503-509, 1992, with permission.*)

vomiting (PONV), hypoxia, hypothermia and shivering, and cardiovascular instability. In a prospective study of more than 18,000 consecutive admissions to the PACU, the complication rate was found to be as high as 24%. Nausea and vomiting (9.8%), the need for upper airway support (6.8%), and hypotension (2.7%) were the most common (Fig. 85-1).[3]

Over a 4-year period ending in 1989, 7.1% of the 1175 anesthesia-related malpractice claims in the United States were attributed to recovery room incidents.[4] Despite the significant incidence of nausea and vomiting in the PACU, serious adverse outcomes correlate more closely with airway/respiratory and cardiovascular compromise. In 2002, airway/respiratory problems (183 [43%]) and cardiovascular events (99 [24%]) accounted for the majority of 419 recovery room incidents reported to the Australian Incident Monitoring Study (AIMS) database (Table 85-2).[5] Similar data were obtained from the U.S. closed claims database in 1989, in which critical respiratory incidents accounted for more than one half of the recovery room malpractice claims.[4]

Transport to the PACU

Upper airway patency and the effectiveness of the patient's respiratory efforts must be monitored when transporting the patient from the operating room to the PACU. Adequate ventilation can be confirmed by watching for the appropriate rise and fall of the chest wall with inspiration, listening for breath sounds, or simply feeling for exhaled breath with the palm of one's hand over the patient's nose and mouth.

With rare exception, patients who undergo general anesthesia should receive supplemental oxygen during their transport to the PACU. In an observational study of 502 patients admitted to the PACU, breathing room air during transport was the single most significant factor to correlate with hypoxemia (O_2 sat < 90%) on arrival. Other significant factors included elevated body mass index (BMI), sedation score, and respiratory rate.[6]

Although the majority of otherwise healthy patients undergoing ambulatory surgery can be transported safely breathing room air, the decision to do so must be made on a case-by-case basis. In the ambulatory setting, advanced age (>60 years) and weight (>100 kg) identifies adults who are at increased risk for oxygen desaturation when breathing room air on transport to the PACU.[7] Hypoventilation alone may cause hypoxemia even in healthy patients who undergo minor procedures.

Table 85-2 Primary Presenting Problem in 419 Recovery Room Incidents Reported to AIMS

Primary Presenting Problem	No. (%)

Upper Airway Obstruction

Loss of Pharyngeal Muscle Tone

The most frequent cause of airway obstruction in the immediate postoperative period is the loss of pharyngeal muscle tone in a sedated or obtunded patient. The persistent effects of inhaled and intravenous anesthetics, neuromuscular blocking drugs, and opioids all contribute to the loss of pharyngeal tone in the PACU patient.

In an awake patient, opening of the upper airway is facilitated by the contraction of the pharyngeal muscles at the same time that negative inspiratory pressure is generated by the diaphragm. As a result, the tongue and soft palate are pulled forward, tenting the airway open during inspiration. This pharyngeal muscle activity is depressed during sleep, and the resulting decrease in tone can promote airway obstruction. A vicious cycle then ensues wherein the collapse of compliant pharyngeal tissue during inspiration produces a reflex compensatory increase in respiratory effort and negative inspiratory pressure that promotes further airway obstruction.[8]

The effort to breathe against an obstructed airway is characterized by a paradoxical breathing pattern consisting of retraction of the sternal notch and exaggerated abdominal muscle activity. Collapse of the chest wall and protrusion of the abdomen with inspiratory effort produces a rocking motion that becomes more prominent with increasing airway obstruction. Obstruction secondary to loss of pharyngeal tone can be relieved by simply opening the airway with the "jaw thrust maneuver" or continuous positive airway pressure (CPAP) applied via a facemask (or both). Support of the airway is needed until the patient has adequately recovered from the effects of drugs administered during anesthesia. In selected patients, placement of an oral or nasal airway, laryngeal mask airway, or endotracheal tube may be required.

Table 85-3 Factors Contributing to Prolonged Nondepolarizing Neuromuscular Blockade

Drugs
Inhaled anesthetic drugs
Local anesthetics (lidocaine)
Cardiac antidysrhythmics (procainamide)
Antibiotics (polymyxins, aminoglycosides, lincosamines [clindamycin], metronidazole [Flagyl], tetracyclines)
Corticosteroids
Calcium channel blockers
Dantrolene
Metabolic and Physiologic States
Hypermagnesemia
Hypocalcemia
Hypothermia
Respiratory acidosis
Hepatic/renal failure
Myasthenia syndromes
Factors Contributing to Prolonged Depolarizing Blockade
Excessive dose of succinylcholine
Reduced plasma cholinesterase activity
Decreased levels
Extremes of age (newborn, old age)
Disease states (hepatic disease, uremia, malnutrition, plasmapheresis)
Hormonal changes
Pregnancy
Contraceptives
Glucocorticoids
Inhibited activity
Irreversible (echothiophate)
Reversible (edrophonium, neostigmine, pyridostigmine)
Genetic variant (atypical plasma cholinesterase)

Residual Neuromuscular Blockade

When evaluating upper airway obstruction in the PACU, the possibility of residual neuromuscular blockade should be considered in any patient who received neuromuscular blocking drugs during anesthesia (Table 85-3) (see Chapter 29). Residual neuromuscular blockade may not be evident on arrival in the PACU because the diaphragm recovers from neuromuscular blockade before the pharyngeal muscles do. With an endotracheal tube in place, end-tidal carbon dioxide concentrations and tidal volumes may indicate adequate ventilation while the ability to maintain a patent upper airway and clear upper airway secretions remains compromised. The stimulation associated with tracheal extubation, followed by the activity of patient transfer to the gurney and subsequent mask airway support, may keep the airway open during transport to the PACU. Only after the patient is calmly resting in the PACU does upper airway obstruction become evident. Even patients treated with intermediate- and short-acting neuromuscular blocking drugs may manifest residual paralysis in the PACU despite what was deemed clinically adequate pharmacologic reversal in the operating room.

Measurement of the train-of-four ratio is a subjective assessment that is often misleading. A decline in this ratio may not be appreciated until it reaches a value less than 0.4 to 0.5, whereas significant signs and symptoms of clinical weakness persist to a ratio of 0.7.[9] Pharyngeal function is not restored to normal until an adductor pollicis train-of-four ratio is greater than 0.90.[10]

In the anesthetized patient, 5 seconds of sustained tetanus to 100-Hz stimulation is the most reliable indicator of adequate reversal of drug-induced neuromuscular blockade.[9,11] In an awake patient, clinical assessment of reversal of neuromuscular blockade is preferred to the application of painful train-of-four or tetanic stimulation. Clinical evaluation includes grip strength, tongue protrusion, the ability to lift the legs off the bed, and the ability to lift the head off the bed for a full 5 seconds. Of these maneuvers, the 5-second sustained head lift has been considered to be the standard, reflecting not only generalized motor strength but, more importantly, the patient's ability to maintain and protect the airway. However, the ability to strongly oppose the incisor teeth against a tongue depressor is a more reliable indicator of pharyngeal muscle tone. This maneuver correlates with an average train-of-four ratio of 0.85 as opposed to 0.60 for the sustained head lift.[9]

Weakness in the PACU patient may manifest as respiratory distress and/or agitation. If one suspects the persistence or return of neuromuscular weakness in the PACU, prompt review of pos-

sible etiologic factors is indicated (see Table 85-3). Common etiologic factors include respiratory acidosis and hypothermia, alone or in combination. Upper airway obstruction as a result of the residual depressant effects of volatile anesthetics or opioids (or both) may result in progressive respiratory acidosis after the patient is admitted to the PACU and external stimulation is minimized. Simple measures such as warming the patient, airway support, and correction of electrolyte abnormalities can facilitate recovery from neuromuscular blockade. It is hoped that the use of sugammadex, instead of neostigmine, will lead to a reduced incidence of residual neuromuscular blockade.

Laryngospasm

Laryngospasm refers to a sudden spasm of the vocal cords that completely occludes the laryngeal opening. It typically occurs in the transitional period when the extubated patient is emerging from general anesthesia. Although it is most likely to occur in the operating room at the time of tracheal extubation, patients who arrive in the PACU asleep after general anesthesia are also at risk for laryngospasm on awakening.

Jaw thrust with CPAP (up to 40 cm H_2O) is often sufficient stimulation to "break" the laryngospasm. If jaw thrust and CPAP maneuvers fail, immediate skeletal muscle relaxation can be achieved with succinylcholine (0.1 to 1.0 mg/kg IV or 4 mg/kg IM). It is not acceptable to attempt to forcibly pass a tracheal tube through a glottis that is closed because of laryngospasm.

Edema or Hematoma

Airway edema is a possible operative complication in patients undergoing prolonged procedures in the prone or Trendelenburg position. It can be particularly significant in procedures that involve a large blood loss and require aggressive fluid resuscitation. Although facial and scleral edema is an important physical sign that can alert the clinician to the presence of airway edema, significant edema of pharyngeal tissue may not be accompanied by visible external signs. In addition to the generalized edema just described, surgical procedures on the tongue, pharynx, and neck, including thyroidectomy,[12,13] carotid endarterectomy,[14] and cervical spine procedures,[15] can produce more localized tissue edema or hematoma. If tracheal extubation is to be attempted in these patients in the PACU, evaluation of airway patency must precede removal of the endotracheal tube. The patient's ability to breathe around the endotracheal tube can be evaluated by suctioning the oral pharynx and deflating the endotracheal tube cuff. With occlusion of the proximal end of the endotracheal tube, the patient is then asked to breathe around the tube. Good air movement suggests that the patient's airway will remain patent after tracheal extubation.[16] An alternative method involves measuring the intrathoracic pressure required to produce a "leak" around the endotracheal tube with the cuff deflated. This method was originally used to evaluate pediatric patients with croup before extubation.[17] When used in patients with general oropharyngeal edema, the "safe" pressure threshold can be difficult to identify. Lastly, when ventilating patients in the volume control mode, one can measure the exhaled tidal volume before and after cuff deflation. Patients who require reintubation generally have a smaller leak (less percentage difference between exhaled volume before and after cuff deflation) than those who do not. A difference greater than 15.5% is the advocated cutoff value for extubation of the trachea.[18] The presence of a cuff leak demonstrates the likelihood of successful extubation, not a guarantee, just as a failed cuff leak does not rule out a successful extubation. The cuff leak test does not take the place of sound clinical judgment.

It may not be possible to mask-ventilate a patient with severe upper airway obstruction resulting from edema or hematoma. In the case of hematoma after thyroid or carotid surgery, an attempt can be made to decompress the airway by releasing the clips or sutures on the wound and evacuating the hematoma. This maneuver is recommended as a temporizing measure, but it will not effectively decompress the airway if a significant amount of fluid or blood (or both) has infiltrated the tissue planes of the pharyngeal wall. If emergency tracheal intubation is required, it is important to have ready access to difficult airway equipment and, if possible, surgical backup for performance of an emergency tracheostomy. If the patient is able to move air by spontaneous ventilation, an awake technique is preferred because visualization of the cords by direct laryngoscopy may not be possible.

Obstructive Sleep Apnea

Because most patients with obstructive sleep apnea (OSA) are not obese and a vast majority are undiagnosed at the time of surgery, obstructive sleep apnea syndrome is often an overlooked cause of airway obstruction in the PACU (see Chapter 64).[19,20]

Patients with OSA are particularly prone to airway obstruction and should not be extubated until they are fully awake and following commands.[8,21] Any redundant compliant pharyngeal tissue in these patients not only increases the incidence of airway obstruction but also often makes intubation by direct laryngoscopy difficult or impossible.[22,23] Once in the PACU, a patient with OSA whose trachea has been extubated is exquisitely sensitive to opioids and, when possible, continuous regional anesthesia techniques should be used to provide postoperative analgesia.[24,25] Interestingly, benzodiazepines can have a greater effect on pharyngeal muscle tone than opioids, and the use of benzodiazepines in the perioperative setting can contribute significantly to airway obstruction in the PACU.[8,26]

When caring for a patient with OSA, plans should be made preoperatively to provide CPAP in the immediate postoperative period. Patients should be asked to bring their CPAP machines with them on the day of surgery so that the equipment can be set up before the patient's arrival in the PACU. Patients who do not routinely use CPAP at home or who do not have their machines with them may require additional attention from the respiratory therapist to ensure proper fit of the CPAP delivery device (mask or nasal airways) and to determine the amount of positive pressure needed to prevent upper airway obstruction.[27,28]

Management of Upper Airway Obstruction

An obstructed upper airway requires immediate attention. Efforts to open the airway by noninvasive measures should be attempted

before reintubation of the trachea. Jaw thrust with CPAP (5 to 15 cm H_2O) is often enough to tent the upper airway open in patients with decreased pharyngeal muscle tone. If CPAP is not effective, an oral, nasal, or laryngeal mask airway can be inserted rapidly. After successfully opening the upper airway and ensuring adequate ventilation, the cause of the upper airway obstruction should be identified and treated. In adults the sedating effects of opioids and benzodiazepines can be reversed with persistent stimulation or small titrated doses of naloxone (0.3 to 0.5 μg/kg IV) or flumazenil (0.2 mg IV to maximum dose of 1 mg), respectively. Residual effects of neuromuscular blocking drugs can be reversed pharmacologically or by correcting contributing factors such as hypothermia.

$$P_{A}O_2 = Fi_{O_2}(PB - PH_2O) - \frac{P_{CO_2}}{RQ}$$

$$P_{aCO_2} = 40 \text{ mm Hg}$$
$$P_{AO_2} = 21(760 - 47) - \frac{40}{0.8} = 150 - 50 = 100 \text{ mm Hg}$$

$$P_{aCO_2} = 80 \text{ mm Hg}$$
$$P_{AO_2} = 21(760 - 47) - \frac{40}{0.8} = 150 - 100 = 50 \text{ mm Hg}$$

P_{AO_2} = alveolar oxygen pressure
Fi_{O_2} = fraction of inspired oxygen concentration
PB = barometric pressure
PH_2O = vapor pressure of water
RQ = respiratory quotient

Figure 85-2 Hypoventilation as a cause of arterial hypoxemia. (*From Nicholau D: Postanesthesia recovery. In Stoelting RK, Miller RD [eds]: Basics of Anesthesia, 5th ed. Philadelphia, Elsevier, 2002.*)

Differential Diagnosis of Arterial Hypoxemia in the PACU

Atelectasis and alveolar hypoventilation are the most common causes of transient postoperative arterial hypoxemia in the immediate postoperative period.[29] Clinical correlation should guide the workup of a postoperative patient who remains persistently hypoxic.[30] Review of the patient's history, operative course, and clinical signs and symptoms will direct the workup to rule in possible causes (Table 85-4).

Alveolar Hypoventilation

Review of the alveolar gas equation demonstrates that hypoventilation alone is sufficient to cause arterial hypoxemia in a patient breathing room air (see also Chapter 15) (Fig. 85-2). At sea level, a normocapnic patient breathing room air will have an alveolar oxygen pressure (P_{AO_2}) of 100 mm Hg. Thus, a healthy patient without a significant alveolar-arterial gradient will have a Pa_{O_2} near 100 mm Hg. In the same patient, an increase in Pa_{CO_2} from 40 to 80 mm Hg (alveolar hypoventilation) results in a P_{AO_2} of 50 mm Hg. Hence, even a patient with normal lungs will become hypoxic if allowed to significantly hypoventilate while breathing room air.

Normally, minute ventilation increases linearly by approximately 2 L/min for every 1-mm Hg increase in Pa_{CO_2}. In the immediate postoperative period, the residual effects of inhaled anesthetics, opioids, and sedative-hypnotics can significantly depress this ventilatory response to carbon dioxide. In addition to depressed respiratory drive, the differential diagnosis of postoperative hypoventilation includes generalized weakness due to residual neuromuscular blockade or underlying neuromuscular disease. The presence of restrictive pulmonary conditions, such as preexisting chest wall deformity, postoperative abdominal binding, or abdominal distention, can also contribute to inadequate ventilation.

Arterial hypoxemia secondary to hypercapnia can be reversed by the administration of supplemental oxygen (Fig. 85-3)[31] or by normalizing the patient's Pa_{CO_2} by external stimulation of the patient to wakefulness, pharmacologic reversal of opioid or benzodiazepine effect, or controlled mechanical ventilation of the patient's lungs.

Table 85-4 Factors Contributing to Postoperative Arterial Hypoxemia

Right-to-left intrapulmonary shunt (atelectasis)
Mismatching of ventilation to perfusion (decreased functional residual capacity)
Congestive heart failure
Pulmonary edema (fluid overload, postobstructive)
Alveolar hypoventilation (residual effects of anesthetics and/or neuromuscular blocking drugs)
Diffusion hypoxia (unlikely if receiving supplemental oxygen)
Inhalation of gastric contents (aspiration)
Pulmonary embolus
Pneumothorax
Increased oxygen consumption (shivering)
Sepsis
Transfusion-related lung injury
Adult respiratory distress syndrome
Advanced age
Obesity

Decreased P_{AO_2}

Diffusion hypoxia refers to the rapid diffusion of nitrous oxide into alveoli at the end of a nitrous oxide anesthetic. Nitrous oxide dilutes the alveolar gas and produces a transient decrease in P_{AO_2} and Pa_{CO_2}. In a patient breathing room air, the resulting decrease in P_{AO_2} can produce arterial hypoxemia while decreased Pa_{CO_2} can depress the respiratory drive. In the absence of supplemental oxygen administration, diffusion hypoxia can persist for 5 to 10 minutes after discontinuation of a nitrous oxide anesthetic; therefore, it may contribute to arterial hypoxemia in the initial moments in the PACU.

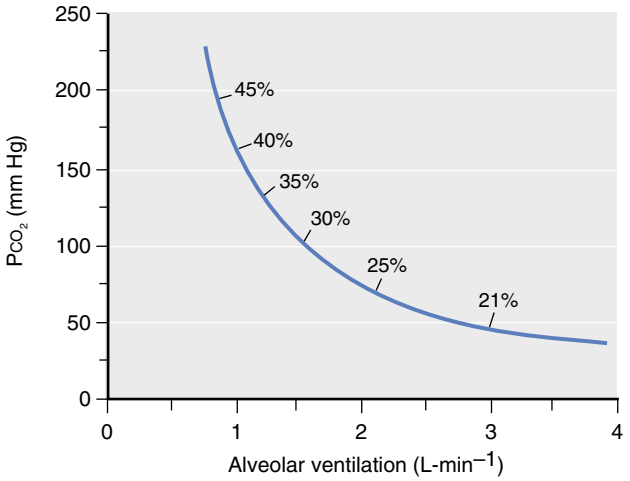

Figure 85-3 Alveolar P_{CO_2} as a function of alveolar ventilation at rest. The percentages indicate the inspired oxygen concentration required to restore alveolar P_{O_2} to normal. (*Adapted from Nunn JF: Nunn's Applied Respiratory Physiology, 6th ed. Philadelphia, Butterworth-Heinemann, 2005, with permission.*)

Ventilation-Perfusion Mismatch and Shunt

Hypoxic pulmonary vasoconstriction refers to the attempt of normal lungs to optimally match ventilation and perfusion (see also Chapters 15 and 44). This response constricts vessels in poorly ventilated regions of the lung and directs pulmonary blood flow to well-ventilated alveoli. In the PACU, the residual effects of inhaled anesthetics and vasodilators such as nitroprusside and dobutamine used to treat systemic hypertension or improve hemodynamics will blunt hypoxic pulmonary vasoconstriction and contribute to arterial hypoxemia.

Unlike a $\dot{V}/\dot{Q}$ mismatch, a true shunt will not respond to supplemental oxygen. Causes of postoperative pulmonary shunt include atelectasis, pulmonary edema, gastric aspiration, pulmonary emboli, and pneumonia. Of these, atelectasis is probably the most common cause of pulmonary shunting in the immediate postoperative period. Mobilization of the patient to the sitting position, incentive spirometry, and positive airway pressure by facemask can be effective in treating atelectasis.

Increased Venous Admixture

Increased venous admixture typically refers to low cardiac output states. It is due to the mixing of desaturated venous blood with oxygenated arterial blood. Normally, only 2% to 5% of cardiac output is shunted through the lungs, and this shunted blood with a normal mixed venous saturation has a minimal effect on P_{AO_2}. In low cardiac output states, blood returns to the heart severely desaturated. Additionally, the shunt fraction increases significantly in conditions that impede alveolar oxygenation, such as pulmonary edema and atelectasis. Under these conditions, mixing of desaturated shunted blood with saturated arterialized blood decreases P_{aO_2}.

Decreased Diffusion Capacity

A decreased diffusion capacity may reflect the presence of underlying lung disease such as emphysema, interstitial lung disease, pulmonary fibrosis, or primary pulmonary hypertension. In this regard, the differential diagnosis of arterial hypoxemia in the PACU must include the contribution of any preexisting pulmonary condition.

Finally, keep in mind that inadequate oxygen delivery may result from an unrecognized disconnection of the oxygen source or empty oxygen tank.

Pulmonary Edema

Pulmonary edema in the immediate postoperative period is often cardiogenic in nature secondary to intravascular volume overload or congestive heart failure. Less frequently, pulmonary edema may result from airway obstruction (postobstructive pulmonary edema), sepsis, or transfusion (transfusion-related lung acute lung injury [TRALI]).

Postobstructive Pulmonary Edema

Postobstructive pulmonary edema and the resulting arterial hypoxemia are rare, but significant consequences of upper airway obstruction that may follow tracheal extubation at the conclusion of anesthesia and surgery. Postobstructive pulmonary edema is a transudative edema produced by the exaggerated negative intrathoracic pressure generated by an inspiratory effort against a closed glottis. The resulting negative intrathoracic pressure and increased venous return increase the hydrostatic pressure gradient across the pulmonary vascular bed, promoting the transudation of fluid. Muscular healthy patients are at increased risk of postobstructive pulmonary edema because of their ability to generate significant inspiratory force.

Laryngospasm is likely the most common cause of postobstructive pulmonary edema in the PACU, but postobstructive pulmonary edema may result from any condition that occludes the upper airway.[32,33] The resultant arterial hypoxemia is usually manifested within 90 minutes of the upper airway obstruction and is accompanied by bilateral fluffy infiltrates on the chest radiograph. Treatment is supportive and includes supplemental oxygen, diuresis, and, in severe cases, positive-pressure ventilation of the patient's lungs.

Transfusion-Related Lung Injury

The differential diagnosis of pulmonary edema in the PACU should include transfusion-related lung injury in any patient who received blood products intraoperatively (see Chapter 55).[34,35] Transfusion-related lung injury is typically manifested within 1 to 2 hours after the transfusion of plasma-containing blood products, including packed red blood cells, whole blood, fresh frozen plasma, or platelets. Because reactions can occur up to 6 hours after transfusion, the syndrome may develop during the patient's stay in the PACU after a transfusion in the operating room. The

Table 85-5 Criteria for the Diagnosis of Transfusion-Related Acute Lung Injury: The American-European Consensus Conference Recommendations

1. Acute lung injury evidenced by:
   a. Acute onset of signs and symptoms
   b. Hypoxemia:
      i. $Pao_2/Fio_2 < 300$ or
      ii. Room air $Spo_2 < 90\%$, or
      iii. Other clinical evidence of hypoxemia
   c. Bilateral infiltrates on chest radiography without cardiomegaly
   d. No clinical evidence of left atrial hypertension
2. No preexisting acute lung injury before transfusion
3. Onset of lung dysfunction within 6 hours of transfusion
4. No temporal association of onset to alternative causes of acute lung injury

Adapted from Swanson K, Dwyre DM, Krochmal J, Raife TJ: Transfusion-related acute lung injury (TRALI): Current clinical and pathophysiologic considerations. Lung 184:177-185, 2006.

resulting noncardiogenic pulmonary edema is often associated with fever and systemic hypotension. If a complete blood cell count is obtained with the onset of symptoms, it is possible to document an acute drop in the white blood cell count (leukopenia), reflecting the sequestration of granulocytes within the lung and exudative fluid.[36,37] Treatment is supportive and includes supplemental oxygen and drug-induced diuresis. Mechanical ventilation may be needed to support hypoxemia and respiratory failure. Vasopressors may be required to treat refractory hypotension.[38]

In past years, the lack of specific diagnostic criteria has resulted in the underdiagnosis and underreporting of the syndrome. Recently, implementation of diagnostic criteria developed by the American-European Consensus Conference, a group of transfusion experts, has raised the awareness of the syndrome (Table 85-5).[39,40]

Monitoring and Treatment of Hypoxemia

Oxygen Supplementation

In the era of cost containment, it has been suggested that the routine delivery of supplemental oxygen to all patients recovering from general anesthesia is a costly and unnecessary practice.[41] The argument against the use of routine oxygen supplementation relies on the fact that continuous pulse oximetry, now a PACU standard, readily identifies those patients who will require oxygen therapy.[42] Supporting this argument is the observation that a majority of patients after general anesthesia do not become hypoxic (63% at threshold of $Sao_2 < 90\%$—and 83% at threshold of $Sao_2 < 94\%$) when breathing room air in the PACU.[42] Although the authors of this observational study predict that the elimination of routine oxygen supplementation in the PACU would result in significant cost savings, others assert that the economic benefit of limited oxygen therapy is likely to be offset by the cost of complications.[43,44]

Although the practice of prophylactic oxygen therapy to all patients after general anesthesia is controversial, most would argue that the benefits outweigh the risks. Even with oxygen supplementation, a significant percentage of patients will become hypoxic at some point during their PACU stay.[45,46] Russell and associates studied 100 patients who were transferred to the PACU breathing room air before receiving at least 40% oxygen by aerosol face tent in the unit. All patients had an Sao_2 greater than 97% before the 2-minute transport to the PACU. Fifteen percent of patients experienced transient desaturation on arrival in the PACU (<92% saturation for >30 sec). This immediate desaturation correlated positively with patient age, body weight, ASA classification, general anesthesia, and increased volume of intravenous fluid greater than 1500 mL. An even larger percentage of patients (25%) desaturated 30 to 50 minutes later in their PACU stay despite prophylactic oxygen administration. These later desaturations were more severe (71%-91%) and lasted longer (5.8 ± 12.6 min) than those that occurred on admission. Additional correlating factors included duration of anesthesia and female gender.

The safe practice of postanesthesia care without oxygen supplementation requires ideal conditions at all times, that is, functioning oxygen delivery apparatus at every bedside as well as sufficient manpower for observation and immediate intervention. Gravenstein argues that this degree of vigilance is likely unrealistic and the risk of adverse outcome to even a small number of patients is unwarranted.[47]

Limitations of Pulse Oximetry

The ASA Standards for Post Anesthesia Care require that patients be observed and monitored with "particular attention given to" both oxygenation and ventilation. The pulse oximeter is a standard monitor in the PACU for the detection of hypoxemia, but it does not reflect the adequacy of ventilation.[69] Although several studies have demonstrated oximetry's limited ability to detect hypoventilation in patients breathing room air,[70,71] they confirm that it does not reliably detect hypoventilation in patients breathing oxygen.[71] When monitoring ventilation in the PACU, pulse oximetry is not a substitute for close observation by trained personnel.

Optimal Perioperative Oxygenation

Postoperative Nausea and Vomiting

A number of studies have asked whether perioperative supplemental oxygen administration can reduce the incidence of PONV (see also Chapter 86). In the first such study, Grief and colleagues randomized 231 patients undergoing elective colon resection to receive either 30% or 80% oxygen (balanced with nitrogen). In this study, the administration of 80% supplemental oxygen intraoperatively and 2 hours postoperatively reduced the incidence of PONV nearly twofold (30% to 17%).[48] In a subsequent study of 240 patients undergoing laparoscopic gynecologic surgery, the same group found that perioperative supplemental oxygen (80%) was as effective as ondansetron (with 30% oxygen) in preventing

PONV. When compared with 30% oxygen alone, both oxygen and ondansetron decreased the incidence of PONV by 50% in the first 24 hours postoperatively (44% to 22%).[49]

Increased oxygen supplementation did not reduce the incidence of PONV in children undergoing elective dental surgery,[50] adults undergoing thyroid surgery,[51] or patients undergoing strabismus surgery.[52] In 210 patients (aged 4-79 years) undergoing strabismus surgery, the incidence of PONV was the same among three groups: those who received 30% oxygen/air (+ ondansetron on induction), 80% oxygen/air, or 30% oxygen/air. Finally, in patients undergoing laparoscopic cholecystectomy, the elimination of nitrous oxide, not increased oxygen fraction, was found to correlate with decreased PONV. In this study, increasing the oxygen concentration from 40% in air to 80% in air offered no further benefit.[53]

The mechanism by which the elimination of nitrous oxide and increased oxygen fraction may contribute to a reduction in PONV is unknown. Whereas there is evidence that perioperative oxygen administration may reduce PONV in patients undergoing colorectal procedures, the data do not support its use for surgical procedures that do not directly involve the bowel.[55] This lack of efficacy of supplemental oxygen in patients undergoing peripheral procedures argues for a local effect on the gastrointestinal tract where the elimination of nitrous oxide and nitrogen together with hyperoxia work to decrease bowel distention and reduce gastrointestinal ischemia.

Studying elderly patients transported by ambulance after minor trauma, Kober and colleagues found that hyperoxia reduced the incidence of nausea and vomiting fourfold over patients breathing air. In this double-blind study, patients were randomized to receive room air or 100% facemask O_2 delivered at 10 L/min. Here the authors propose a central mechanism for the effect of oxygen on motion sickness.[54]

Wound Infections

Supplemental oxygen appears to reduce the incidence of surgical wound infections in patients undergoing colorectal surgery. Grief and colleagues randomized 500 patients undergoing colon resection to receive either 30% or 80% oxygen (in air). In this study the higher concentration of oxygen reduced the incidence of surgical site infection by 6% (11.2% to 5.2%).[56] More recently, a randomized controlled multicenter study of 300 patients in 14 Spanish hospitals found that patients who received supplemental oxygen had a 30% reduction in surgical site infections.[57] This study compared 30% to 80% oxygen administration intraoperatively and 6 hours postoperatively. The perioperative care was standardized, and surgical site infections were identified by criteria delineated by the Centers for Disease Control.

These results were not consistent with a study of patients undergoing major intra-abdominal surgical procedures where patients who received 80% oxygen had a significantly higher infection rate (25%) than those who received 35% oxygen. It is notable that this study has been widely criticized for failure of randomization because the patients receiving 80% oxygen were more obese, underwent a longer duration of surgery, and had a larger blood loss than those receiving 35% oxygen. Unlike the Spanish study, the diagnosis of surgical site infection was made by chart review rather than standardized criteria.[58]

Nitrous Oxide

The role of nitrous oxide in the risk of wound infection remains controversial. When controlling for oxygen concentration (35%) in patients undergoing colon resection, the Outcomes Research Group found that the elimination of nitrous oxide did not decrease the incidence of surgical site infection.[59]

The largest multicenter trial to date comparing nitrous oxide–based anesthesia with nitrous oxide–free general anesthesia included 2050 patients who underwent major surgery. Exclusion criteria included cardiac and thoracic surgery. The exclusion of patients undergoing colon surgery or those who had a history of PONV was left to the discretion of the anesthesiologist. Patients were randomized to receive 30% oxygen and 70% nitrous oxide or 80% oxygen with 20% nitrogen. In this study, the elimination of nitrous oxide significantly decreased the incidence of PONV and major complications within 30 days of surgery. Major complications included pneumonia, pneumothorax, pulmonary embolism, wound infection, myocardial infarction, venous thromboembolism, stroke, and awareness. It did not decrease the length of hospital stay, the study's primary endpoint.[60] Significantly, this study did not control for inspired oxygen concentration; therefore, it is not clear whether the beneficial effects were the result of the elimination of nitrous oxide or the increase in F_{IO_2}.[61]

Oxygen Delivery Systems

Supplemental Oxygen

The choice of oxygen delivery system in the PACU is determined by the degree of hypoxemia, the surgical procedure, and patient compliance. Patients who are status post head and neck surgery may not be candidates for facemask oxygen owing to the risk of pressure necrosis on incision sites and microvascular muscle flaps, whereas nasal packing prohibits the use of nasal cannulas in others. Face tent oxygen or blow-by setups are viable alternatives in cases in which tight-fitting masks and straps are contraindicated.

The delivery of oxygen through a traditional nasal cannula with bubble humidifier is usually limited to a maximum flow of 6 L/min to minimize the discomfort and complications that result from inadequate humidification. As a general rule, each liter per minute of oxygen flow through nasal cannula increases the F_{IO_2} by 0.04, with 6 L/min delivering an F_{IO_2} of approximately 0.44. Until recently, maximum oxygen delivery to extubated patients required delivery by facemask through a nonrebreather system or high flow nebulizer. These systems can be inefficient, however, because of inadequate mask fit and/or high minute ventilation requirements that result in significant entrainment of room air. The newer high-flow nasal cannula devices can comfortably deliver oxygen at 40 L/min, 37°C, and 99.9% relative humidity.[62] The delivery of high flow oxygen directly to the nasopharynx produces an F_{IO_2} equal to that delivered by traditional mask devices. In fact, the Vapotherm system has been shown to deliver a higher F_{IO_2} than a nonrebreather mask at similar flow ranges (10-40 L/min). Unlike the nonrebreather mask, these devices

deliver high flow oxygen directly to the nasopharynx throughout the respiratory cycle. The efficacy of these devices may be enhanced by a CPAP effect resulting from the high gas flow.[63]

Continuous Positive Airway Pressure

An estimated 8% to 10% of patients who undergo abdominal surgery subsequently require intubation and mechanical ventilation in the PACU. As discussed elsewhere in this chapter, respiratory failure in the immediate postoperative period is often due to transient and rapidly reversible conditions such as splinting from pain, diaphragmatic dysfunction, muscular weakness, and pharmacologically depressed respiratory drive. Readily reversible hypoxemia may be due to hypoventilation, atelectasis, or volume overload. The application of CPAP in this setting can potentially decrease hypoxemia due to atelectasis by recruiting alveoli. The resulting increase in functional reserve capacity may also improve pulmonary compliance and decrease the work of breathing. In a recent randomized controlled trial, 209 consecutive patients undergoing major elective abdominal surgery were randomized to receive supplemental oxygen alone or in conjunction with CPAP (at 7.5 cm H_2O pressure) in the PACU. In this study, the application of CPAP in the PACU significantly reduced the incidence of intubation, pneumonia, infection, and sepsis. The study was halted due to efficacy after the enrollment of 209 patients (Table 85-6).[64]

A large percentage of obese patients undergoing Roux-en-Y gastric bypass surgery have OSA and stand to benefit significantly from postoperative CPAP therapy (see Chapter 64). Yet surgeons were initially hesitant to embrace this modality for fear that application of positive pressure to the airway would inflate the stomach and proximal intestine and result in anastomotic disruption. In a single center study of 1067 patients undergoing gastrojejunostomy bypass, 420 with diagnosed OSA, CPAP did not increase the risk of postoperative anastomotic leaks.[65]

Noninvasive Positive-Pressure Ventilation

Even with the application of CPAP in the PACU there will be a number of patients who will require additional ventilatory support. Noninvasive positive-pressure ventilation (NIPPV) (see Chapter 93) has been shown to be an effective alternative to endotracheal intubation in the ICU setting. Although the use of NIPPV in both chronic and acute respiratory failure is well established, there is a limited experience in its application in the PACU.

In the past, the use of NIPPV was avoided in the immediate postoperative period because of the potential for gastric distention, aspiration, and wound dehiscence. This is especially true in patients who have undergone esophageal or gastric surgery. The decision to use noninvasive modes of ventilation in the PACU must be guided by careful consideration of both patient and surgical factors. Relative contraindications include hemodynamic instability or life-threatening arrhythmias, altered mental status, high risk of aspiration, inability to use nasal or facial mask (head and neck procedures), and refractory hypoxemia.[66] Several case reports describe the successful application of NIPPV in lieu of endotracheal intubation in both adults and children in the PACU. In 2000, Tobias reported the successful application of NIPPV in two patients, one after gastrostomy tube placement and another after cholecystectomy.[67] A larger case series (8 patients) reported by Albala and Ferrigno did not include intra-abdominal procedures.[68] The authors of both studies agree that the successful application of NIPPV is dependent on appropriate patient selection and careful instruction.

NIPPV can be delivered by facemask using the pressure support mode of a mechanical ventilator. Alternatively, the use of a BiPap machine allows the delivery of positive pressure by either nasal cannula or facemask. An example protocol for instituting NIPPV in patients with acute respiratory failure is shown in Table 85-7.

Hemodynamic Instability

Hemodynamic compromise in the PACU patient manifests in a number of ways (systemic hypertension, hypotension, tachycardia, or bradycardia) alone or in combination. Hemodynamic instability in the PACU has a negative impact on long-term outcome. Interestingly, postoperative systemic hypertension and tachycardia are associated with an increased risk of unplanned critical care admission and a higher mortality than hypotension and bradycardia.[72]

Table 85-6 CPAP for Postoperative Hypoxemia: Secondary Outcomes

	Control (*n* = 104)	CPAP (*n* = 105)	Difference of Means (95% CI) Relative Risk (95% CI)	*P* Value*

Systemic Hypertension

Patients with a history of essential hypertension are at greatest risk for significant systemic hypertension in the PACU.[73] Additional factors include pain, nausea and vomiting, hypoventilation and associated hypercapnia, emergence excitement, advanced age, urinary retention, and preexisting renal disease (Table 85-8). The surgical procedures most commonly associated with postoperative hypertension are carotid endarterectomy and intracranial operations. A significant number of patients, especially those with a known history of hypertension, will require pharmacologic blood pressure control in the PACU.

Table 85-8 Factors Leading to Postoperative Hypertension

Preoperative hypertension
Arterial hypoxemia
Hypervolemia
Emergence excitement
Shivering
Drug rebound
Increased intracranial pressure
Increased sympathetic nervous system activity
Hypercapnia
Pain
Agitation
Bowel distention
Urinary retention

Systemic Hypotension

Postoperative systemic hypotension may be characterized as (1) hypovolemic (decreased preload), (2) distributive (decreased afterload) (see Table 85-7), or (3) cardiogenic (intrinsic pump failure) (Table 85-9).

Hypovolemic (Decreased Preload)

Systemic hypotension in the PACU is often due to decreased intravascular fluid volume and preload, and as such, it responds favorably to intravenous fluid administration. Common causes of decreased intravascular fluid volume in the immediate postoperative period include ongoing third-space translocation of fluid, inadequate intraoperative fluid replacement (especially in patients who undergo major intra-abdominal procedures or preoperative bowel preparation), and loss of sympathetic nervous system tone as a result of neuraxial (spinal or epidural) blockade.

Table 85-7 Example Protocol for Instituting Noninvasive Positive-Pressure Ventilation in Patients with Acute Respiratory Failure*

1. Choose the appropriate patient based on the surgical procedure and the patient's risk of aspiration, ability to protect their airway, and ability to comply with the mask fit.
2. Position the head of the bed at ≥45-degree angle.
3. Choose the correct size mask and connect mask to ventilator.
4. Explain the modality to the patient and provide reassurance.
5. Set initial ventilatory settings (CPAP, 0 cm H_2O; pressure support, 10 cm H_2O).
6. Hold mask gently on face until patient is comfortable and synchronous with ventilation.
7. Apply wound care dressing on nasal bridge and other pressure points.
8. Secure mask with head straps.
9. Slowly increase CPAP.
10. Adjust pressure support to achieve adequate tidal volumes and maximal patient comfort.
11. In hypoxic patients, increase CPAP in increments of 2 to 3 cm H_2O until $F_{IO_2} \leq 0.6$.
12. Avoid peak mask pressures > 30 cm H_2O.
13. Set ventilator alarms and apnea backup parameters.
14. Ask the patient and nurse to call for needs (repositioning mask, pain, or discomfort) or if complications occur (respiratory difficulties, abdominal distention, nausea, vomiting).
15. Monitor with oximetry and adjust ventilator settings after blood gas results.

Ongoing bleeding should be ruled out in hypotensive patients who have undergone a surgical procedure in which significant blood loss is possible. This is true regardless of the estimated intraoperative blood loss because the measured blood loss may be inaccurate. If the patient is unstable, hemoglobin can be measured at the bedside to eliminate laboratory turnover time. It is also important to remember that tachycardia may not be a reliable indicator of hypovolemia or anemia (or both) if the patient is taking β-blockers or calcium channel blockers.

Table 85-9 Differential Diagnosis of Hypotension in the PACU

Intravascular volume depletion
Persistent fluid losses
Ongoing third spacing of fluid
Bowel preparation
Gastrointestinal losses
Surgical bleeding
Increased capillary permeability
Sepsis
Burns
Transfusion-related acute lung injury
Decreased cardiac output
Myocardial ischemia/infarction
Cardiomyopathy
Valvular disease
Pericardial disease
Cardiac tamponade
Cardiac dysrhythmias
Pulmonary embolus
Tension pneumothorax
Drug induced (β-blockers, calcium channel blockers)
Decreased vascular tone
Sepsis
Allergic reactions (anaphylactic, anaphylactoid)
Spinal shock (cord injury, iatrogenic high spinal)
Adrenal insufficiency

PACU, postanesthesia care unit.

Distributive (Decreased Afterload)

Distributive shock in the PACU may be the result of a number of physiologic derangements, including iatrogenic sympathectomy, critical illness, allergic reactions, and sepsis. Iatrogenic sympathectomy secondary to regional anesthetic techniques is an important cause of hypotension in the perioperative period. A high sympathetic block (to T4) will decrease vascular tone and block the cardioaccelerator fibers. If not treated promptly, the resulting bradycardia in the presence of severe hypotension can lead to cardiac arrest even in young healthy patients.[74] Vasopressors, including phenylephrine and ephedrine, are pharmacologic treatments of hypotension caused by residual sympathetic nervous system blockade.

Critically ill patients may rely on exaggerated sympathetic nervous system tone to maintain systemic blood pressure and heart rate. In these patients, even minimal doses of inhaled anesthetics, opioids, or sedative-hypnotics can decrease sympathetic nervous system tone and produce marked systemic hypotension.

Allergic (anaphylactic or anaphylactoid) reactions may be the cause of hypotension in the PACU. Epinephrine is the drug of choice to treat hypotension secondary to an allergic reaction. Increased serum tryptase concentrations confirm the occurrence of an allergic reaction, but this change does not differentiate anaphylactic from anaphylactoid reactions. The blood specimen for tryptase determination must be obtained within 30 to 120 minutes after the allergic reaction, but the results may not be available for several days. Neuromuscular blocking drugs are the most common cause of anaphylactic reactions in the operative setting (Table 85-10).[75,76]

If sepsis is suspected as the cause of hypotension in PACU, blood should be obtained for culture and empirical antibiotic therapy should be initiated before transfer of the patient to the ward. Urinary tract manipulation and biliary tract procedures are examples of interventions that can result in a sudden onset of severe systemic hypotension secondary to sepsis. Although fluid resuscitation is the most important immediate intervention, pressor support is often required—at least transiently. Vasopressin deficiency has been shown to contribute to vasodilation in septic shock[77] and low dose vasopressin (0.01-0.05 unit/min) improves mean arterial pressure, decreases catecholamine vasopressor requirement, and may spare renal function in severe septic shock.[78]

Table 85-10 Drugs Involved in Perioperative Anaphylaxis

Substance	Incidence of Perioperative Anaphylaxis (%)	Most Commonly Associated with Perioperative Anaphylaxis
Muscle relaxants	69.2	Succinylcholine, rocuronium, atracurium
Natural rubber latex	12.1	Latex gloves, tourniquets, Foley catheters
Antibiotics	8	Penicillin and other β-lactams
Hypnotics	3.7	Propofol, thiopental
Colloids	2.7	Dextran, gelatin
Opioids	1.4	Morphine, meperidine
Other substances	2.9	Propacetamol, aprotinin, chymopapain, protamine, bupivacaine

Cardiogenic (Intrinsic Pump Failure)

Significant cardiogenic causes of postoperative hypotension include myocardial ischemia and infarction, cardiomyopathy, cardiac tamponade, and cardiac dysrhythmias. The differential diagnosis depends on the surgical procedure and patient's preoperative cardiac risk and medical condition. To determine the cause of the hypotension, central venous pressure monitoring, echocardiography, and, rarely, pulmonary artery catheter monitoring may be required.

Myocardial Ischemia: Evaluation and Treatment

Low-Risk Patients

Interpretation of changes on the electrocardiogram in the PACU is influenced by the patient's cardiac history and risk index. In low-risk patients (<45 years of age, no known cardiac disease, only one risk factor), postoperative ST-segment changes on the ECG do not usually indicate myocardial ischemia. Relatively benign causes of ST changes in these low-risk patients include anxiety, esophageal reflux, hyperventilation, and hypokalemia. In general, low-risk patients require only routine PACU observation unless associated signs and symptoms warrant further clinical evaluation. A more aggressive evaluation is indicated if the changes are accompanied by cardiac rhythm disturbances, hemodynamic instability, or both.

High-Risk Patients

In contrast to low-risk patients, ST-segment and T-wave changes on the ECG in high-risk patients can be significant even in the absence of typical signs or symptoms. In this patient population, any ST or T-wave changes that are compatible with myocardial ischemia should prompt further evaluation to rule out myocardial ischemia. Determination of serum troponin levels is indicated when myocardial ischemia or infarction is suspected in the PACU. Once blood samples for measurement of troponin are obtained and a 12-lead ECG is completed, arrangements must be made for the appropriate cardiac monitoring and cardiology follow-up.

Cardiac Monitoring

In the immediate postoperative period, myocardial ischemia is rarely accompanied by chest pain, and confirming myocardial ischemia in a PACU patient is dependent on the sensitivity of the cardiac monitoring (see Chapters 40, 41, and 42). Although a combination of leads II and V_5 will reflect 80% of the ischemic events detected on a 12-lead ECG, visual interpretation of the cardiac monitor is often inaccurate. Because of human error, the American College of Cardiology guidelines recommend that

computerized ST-segment analysis be used (if available) to monitor high-risk patients in the immediate postoperative period.[79,80] A recent small scale single-center study by Goldman and associates suggests that a postoperative 12-lead ECG obtained in the PACU may be a valuable tool to adjust risk stratification in low-risk patients older than 50 years.[81] However, at this time a routine postoperative 12-lead ECG is recommended only for patients with known or suspected coronary artery disease who have undergone high- or intermediate-risk surgery.

Cardiac Dysrhythmias

Perioperative cardiac dysrhythmias are frequently transient and multifactorial (see Table 85-8). Reversible causes of cardiac dysrhythmias in the perioperative period include hypoxemia, hypoventilation and associated hypercapnia, endogenous or exogenous catecholamines, electrolyte abnormalities, acidemia, fluid overload, anemia, and substance withdrawal.[82]

Tachycardia

Common causes of sinus tachycardia in the PACU include pain, agitation, hypoventilation with associated hypercapnia, hypovolemia, and shivering. Less common but serious causes include bleeding, cardiogenic or septic shock, pulmonary embolism, thyroid storm, and malignant hyperthermia.

Atrial Dysrhythmias

The incidence of new postoperative atrial dysrhythmias may be as high as 10% after major noncardiothoracic surgery. The incidence is even higher after cardiac and thoracic procedures when the cardiac dysrhythmia is often attributed to atrial irritation.[83] The risk of postoperative atrial fibrillation is increased by preexisting cardiac risk factors, positive fluid balance, electrolyte abnormalities, and oxygen desaturation.[84] These new-onset atrial dysrhythmias are not benign because they are associated with a longer hospital stay and increased mortality.[85]

Ventricular Dysrhythmias

Premature ventricular contractions (PVCs) and ventricular bigeminy occur commonly in the PACU. PVCs most often reflect increased sympathetic nervous system stimulation that may accompany tracheal intubation, pain, and transient hypercapnia. True ventricular tachycardia is rare and is indicative of underlying cardiac pathology. In the case of torsades de pointes, QT prolongation on the electrocardiogram may be intrinsic or drug related (amiodarone, procainamide, or droperidol).

Bradydysrhythmias

Bradycardia in the PACU is often iatrogenic. Drug-related causes include β-blocker therapy, anticholinesterase reversal of neuromuscular blockade, opioid administration, and treatment with dexmedetomidine. Procedure- and patient-related causes include bowel distention, increased intracranial or intraocular pressure, and spinal anesthesia. A high spinal block that blocks the cardioaccelerator fibers originating from T1 through T4 can produce severe bradycardia. The resulting sympathectomy, bradycardia, and possible intravascular fluid volume depletion and associated decreased venous return can produce sudden bradycardia and cardiac arrest, even in young healthy patients.

Atrial Fibrillation

Control of the ventricular response rate is the immediate goal in the treatment of new-onset atrial fibrillation. Hemodynamically unstable patients may require prompt electrical cardioversion, but most patients can be treated pharmacologically with an intravenous β-adrenergic blocker or calcium channel blocker.[87] Diltiazem is the calcium channel blocker of choice for patients in whom β-blockers are contraindicated. If hemodynamic instability is a concern, the short-acting β-blocker esmolol is an option. Rate control with these agents is often enough to chemically cardiovert the postoperative patient whose arrhythmia may be catecholamine driven. If the goal of therapy is chemical cardioversion, an amiodarone load can be initiated in the PACU with the knowledge that QT prolongation, bradycardia, and hypotension may accompany the intravenous infusion of this drug.

Treatment

The urgency of treatment of a cardiac dysrhythmia depends on the physiologic consequences of the dysrhythmia, principally hypotension or cardiac ischemia or both. Tachydysrhythmias decrease coronary perfusion time and increase myocardial oxygen consumption. Their impact depends on the patient's underlying cardiac function, and they are most harmful in patients with coronary artery disease. Bradycardia has a more deleterious effect in patients with a fixed stroke volume, such as infants and patients with restrictive pericardial disease or cardiac tamponade. For the most part, treatment relies on identifying and correcting the underlying cause (i.e., hypoxemia or electrolyte abnormalities).[86] The possible role of myocardial ischemia or the occurrence of pulmonary embolism must be considered when contemplating treatment options.

Renal Dysfunction

The differential diagnosis of postoperative renal dysfunction includes prerenal, intrarenal, and postrenal causes (Table 85-11). Frequently, the cause is multifactorial, with a preexisting renal insufficiency that is exacerbated by an intraoperative insult. In the PACU, diagnostic efforts should focus on identification and treatment of the readily reversible causes of oliguria (urine output < 0.5 mL/kg/hr). For example, urinary catheter obstruction or dislodgment is easily remedied and often overlooked (see Table 85-10). When appropriate, one should confer with the surgical team regarding the details of the surgical procedure (urologic or gynecologic) to rule out anatomic obstruction or disruption of the ureters, bladder, or urethra.

Table 85-11 Postoperative Oliguria

Prerenal
Hypovolemia (bleeding, sepsis, third-space fluid loss, inadequate volume resuscitation)
Hepatorenal syndrome
Low cardiac output
Renal vascular obstruction or disruption
Intra-abdominal hypertension
Renal
Ischemia (acute tubular necrosis)
Radiographic contrast dyes
Rhabdomyolysis
Tumor lysis
Hemolysis
Postrenal
Surgical injury to the ureters
Obstruction of the ureters with clots or stones
Mechanical (urinary catheter obstruction or malposition)

Oliguria

Intravascular Volume Depletion

The most common cause of oliguria in the immediate postoperative period is depletion of intravascular fluid volume. In this regard, a fluid challenge (500 to 1000 mL of crystalloid) is usually effective in restoring urine output. A hematocrit measurement is indicated when surgical blood loss is suspected and repeated volume boluses are required to maintain urine output. Volume resuscitation to maximize renal perfusion is particularly important to prevent ongoing ischemic injury and the development of acute tubular necrosis.

Renal perfusion may be altered by a number of perioperative events. Preoperative or intraoperative angiography can result in ischemic injury secondary to renal vasoconstriction and direct renal tubular injury. Perioperative volume depletion can exacerbate hepatorenal syndrome or acute tubular necrosis caused by sepsis. The surgical procedure itself can alter renal vascular patency decreasing renal perfusion. Finally, increased intra-abdominal pressure can impair renal perfusion.

If a fluid challenge is contraindicated or oliguria persists, assessment of intravascular fluid volume status and cardiac function is indicated to differentiate hypovolemia from sepsis and low cardiac output states. Fractional excretion of sodium can be useful in determining the adequacy of renal perfusion (assuming that diuretics have not been given), but the diagnosis of prerenal azotemia will not differentiate between hypovolemia, congestive heart failure, or hepatorenal syndrome. Further evaluation with central venous monitoring or echocardiography, or both, may facilitate the differential diagnosis.

Postoperative Urinary Retention

Postoperative urinary retention can cause bladder overdistention and permanent detrusor damage. Ultrasonography can measure bladder volume and identify urinary retention in the PACU.[88] Using this technique, Keita and associates attempted to identify high-risk patients by measuring bladder volume in 313 adult inpatients on admission to and before discharge from the PACU. They collected data on age, sex, history of urinary retention, intraoperative administration of anticholinergics, amount of intraoperative fluid administration, and intravenous use of morphine. Urinary retention was defined as bladder volume greater than 600 mL in conjunction with inability to void within 30 minutes. In this study, the incidence of postoperative urinary retention in the PACU was 16%. The most significant predictive factors were age older than 50 years, intraoperative fluid more than 750 mL, and bladder volume on entry to PACU greater than 270 mL.[89] This study argues for the use of ultrasound in high-risk patients to identify possible urinary retention.

Contrast Nephropathy

Angiography with intravascular stent placement is replacing open surgical procedures to treat carotid stenosis, aortic aneurysm, and peripheral vascular disease. As a result, contrast nephropathy will be more frequently included in the differential diagnosis of postoperative renal dysfunction. Perioperative attention to adequate hydration is indicated in any patient who has received an intravenous contrast agent. Aggressive hydration with normal saline provides the single most effective protection against contrast nephropathy. Alkalinization of the urine with sodium bicarbonate has been shown to provide additional protection.[90] If bicarbonate is used for renal protection, 154 mEq/L should be infused at a rate of 3 mL/kg/hr for 1 hour before injection of a contrast agent followed by 1 mL/kg/hr for 6 hours.[90] Mucomyst is a relatively inexpensive and easily administered medication (single oral dose before and after procedure) that may also provide protection.[91] Although a number of studies support the efficacy of Mucomyst, meta-analysis does not consistently confirm its usefulness.[92,93]

Intra-abdominal Hypertension

Intra-abdominal hypertension should be considered in any oliguric patient with a tense abdomen on examination after abdominal surgery. An intra-abdominal pressure greater than 30 cm H_2O can impede renal perfusion and lead to renal ischemia and postoperative renal dysfunction. In a prospective study of patients undergoing major abdominal surgery, intra-abdominal hypertension accounted for 40% of new-onset renal insufficiency. In this study, postoperative renal impairment was independently associated with four factors: hypotension, sepsis, older age, and increased abdominal pressure.[94] Bladder pressure should be measured in patients in whom intra-abdominal hypertension is suspected so that prompt intervention can be initiated to relieve intra-abdominal pressure and restore renal perfusion.

Rhabdomyolysis

Rhabdomyolysis may complicate the postoperative course of patients who have suffered major crush or thermal injury. The incidence is also significantly increased in morbidly obese patients who undergo bariatric surgery. It has been reported to occur in 22.7% of 66 consecutive patients undergoing laparoscopic bariatric surgery.[95-97] Risk factors include increased BMI and length of operation. Patient history and the operative course should guide your decision to measure creatine phosphokinase in the PACU.[95] Early aggressive hydration to maintain urine output is the main-

stay of treatment. Loop diuretics can be used to flush the renal tubules and avoid fluid overload.[98] The infusion of mannitol to enhance the elimination of myoglobin casts from the renal tubules and bicarbonate to protect against myoglobin toxicity is commonly practiced but may not provide further benefit. In a study of more than 2000 trauma patients with rhabdomyolysis, the infusion of bicarbonate and mannitol did not further decrease the incidence of acute renal failure.[99] There is no evidence that renal dose dopamine affords renal protection in this setting.[100]

Body Temperature and Shivering

Postoperative shivering often occurs after general and epidural anesthesia (see Chapter 48). The incidence of postoperative shivering may be as high as 65% (range, 5% to 65%) after general anesthesia and 33% after epidural anesthesia. Identified risk factors include male gender and the choice of induction agent; propofol is more commonly associated with shivering than pentothal is.[101]

Mechanism

Postoperative shivering is usually, but not always, associated with hypothermia. Although thermoregulatory mechanisms can explain shivering in the hypothermic patient, a number of different mechanisms have been proposed to explain shivering in normothermic patients. One proposed mechanism is based on the observation that the brain and spinal cord do not recover simultaneously from general anesthesia. The more rapid recovery of spinal cord function is thought to result in uninhibited spinal reflexes manifested as clonic activity. This theory is supported by the fact that doxapram, a central nervous system stimulant, is somewhat effective in abolishing postoperative shivering. Other proposed mechanisms include the action of kappa opioid, *N*-methyl-D-aspartate (NMDA), and 5-hydroxytryptamine receptors.

Treatment

Intervention includes the identification and treatment of hypothermia if present. Accurate core body temperatures can be most easily obtained at the tympanic membrane. Axillary, rectal, and nasopharyngeal temperature measurements are less accurate and may underestimate core temperature. Forced air warmers are used to actively warm the hypothermic patient. A number of opioids, ondansetron,[102] and clonidine[103] have been shown to be effective in abolishing shivering once it starts, but in adults meperidine, 0.35 to 0.4 mg/kg (12.5 to 25 mg IV), is most commonly used. The infusion of low-dose ketamine (0.5 mg/kg IV) before general[104] and regional anesthesia[105] has been shown to be an effective prophylactic measure.

Clinical Effects

In addition to significant patient discomfort, postoperative shivering increases oxygen consumption, CO_2 production, and sympathetic tone. It is associated with increased cardiac output, heart rate, systemic blood pressure, and intraocular pressure. Patients who are hypothermic on arrival in the PACU should be actively warmed to avoid these immediate complications as well as delayed consequences of hypothermia. Mild to moderate hypothermia (33°C to 35°C) inhibits platelet function, coagulation factor activity, and drug metabolism. It exacerbates postoperative bleeding, prolongs neuromuscular blockade, and may delay awakening. Whereas these immediate consequences are associated with a prolonged PACU stay,[106] long-term deleterious effects include an increased incidence of myocardial ischemia and myocardial infarction, delayed wound healing, and increased perioperative mortality.

Postoperative Nausea and Vomiting

Without prophylactic intervention, roughly one third of patients who undergo inhalational anesthesia will develop PONV (range: 10% to 80%) (see also Chapter 86).[107] The consequences of PONV include delayed discharge from the PACU, unanticipated hospital admission, increased incidence of pulmonary aspiration, and significant postoperative discomfort. The ability to identify high-risk patients for prophylactic intervention can significantly improve the quality of patient care and satisfaction in the PACU. From a patient's perspective, PONV may be more uncomfortable than postoperative pain.

Prevention and Treatment

Prophylactic measures to prevent PONV include modification of anesthetic technique and pharmacologic intervention. In a randomized controlled multicenter multifactorial trial, Apfel and associates studied the efficacy of six prophylactic interventions in high-risk patients (PONV risk > 40%).[107] Interventions were both pharmacologic and technique related. Pharmacologic intervention included droperidol, 1.25 mg; dexamethasone, 4 mg; or ondansetron, 4 mg. Anesthetic intervention included propofol in lieu of volatile anesthetic, nitrogen in lieu of nitrous oxide, or remifentanil in lieu of fentanyl. More than 4000 patients were assigned to one of 64 possible combinations. The study found that each of the three antiemetics reduced the relative risk of PONV to the same degree (26%). Together, propofol (19% decrease) and nitrogen (12% decrease) reduced the relative risk of PONV to a similar degree.

Although prophylactic measures to prevent PONV are more effective than rescue, a subset of patients will require treatment in the PACU even after appropriate prophylactic treatment. There is no convincing evidence that any of the serotonin receptor antagonists commonly prescribed at this time are more effective than any others. Table 85-12 lists the different classes of antiemetic medications commonly prescribed in the PACU. If an adequate dose of antiemetic given at the appropriate time is ineffective, simply giving more of the same class of drug in the PACU is unlikely to be of significant benefit.

Delirium

Approximately 10% of adult patients over the age of 50 who undergo elective surgery will experience some degree of post-

Table 85-12 Commonly Used Antiemetics (Adult Doses)

Anticholinergics
Scopolamine (0.3-0.65 mg IV)
Scopolamine (1.5 mg) transdermal patch to a hairless area behind the ear before surgery (remove 24 hours postoperatively)
Antihistamines
Hydroxyzine (12.5-25 mg IM)
Phenothiazines
Promethazine (12.5-25 mg IM)
Butyrophenones
Droperidol (0.625-1.25 mg IV); monitor the ECG for prolongation of the QT interval for 2-3 hours after administration; preoperative 12-lead ECG recommended
Prokinetic
Metoclopramide (10-20 mg IV; avoid if any possibility of gastrointestinal obstruction)
Serotonin Receptor Antagonists
Ondansetron (4 mg IV 30 minutes before the conclusion of surgery)
Anzemet (12.5 mg IV 15-30 minutes before the end of surgery)
Vasopressors
Ephedrine (25 mg IM with hydroxyzine, 25 mg)
Corticosteroids
Dexamethasone (4-8 mg IV with induction of anesthesia)

operative delirium within the first 5 postoperative days (see Chapters 70 and 71).[108] The incidence is much higher for certain procedures, such as repair of hip fracture (>35%)[109] and bilateral knee replacement (41%).[110] Although the majority of these are elderly patients who develop delirium within the first several postoperative days, the percentage who become delirious while they are recovering in the PACU is not well known. This is because many studies of postoperative delirium and postoperative cognitive dysfunction (POCD) do not evaluate the PACU stay.[111] The American Psychiatric Association defines *delirium* as an acute change in cognition or disturbance of consciousness that cannot be attributed to a preexisting medical condition, substance intoxication, or medication[112]; however, the risk of immediate postoperative delirium is influenced by preexisting conditions such as age, functional status, and substance abuse.

Risk Factors

Persistent postoperative delirium is generally a condition of elderly patients.[113] It is a costly complication in both human and monetary terms because it increases the length of hospital stay, pharmacy costs, and mortality. In adults, patients at risk for postoperative delirium can be identified before surgery. The most significant preoperative risk factors include (1) advancing age (>70 years), (2) preoperative cognitive impairment, (3) decreased functional status, (4) alcohol abuse, and (5) a previous history of delirium. Intraoperative factors that are predictive of postoperative delirium include surgical blood loss, hematocrit less than 30%, and the number of intraoperative blood transfusions.[108,113] In adults, intraoperative hemodynamic derangements (hypotension),[114] the administration of nitrous oxide,[115] and the anesthetic technique (general versus regional)[116] have not been shown to increase the risk of postoperative delirium or longer-term POCD.

Clinical evaluation of a delirious patient in the PACU includes a thorough evaluation of any underlying disease or metabolic derangement, such as hepatic and/or renal encephalopathy. The workup for postoperative delirium must exclude or treat iatrogenic factors, including inadequate hydration, perioperative medications, arterial hypoxemia, hypercapnia, pain, sepsis, and electrolyte abnormalities.

Management

It is useful to identify the high-risk patient before admission to the PACU.[113,117] Severely agitated patients may require restraints and/or additional personnel to control their behavior and avoid self-inflicted injury. Early identification of high-risk patients can also guide pharmacologic therapy postoperatively. Elderly patients older than 60 years who are to undergo minor surgery should be scheduled in an outpatient center whenever possible to minimize the incidence of POCD.[118]

Emergence Excitement

Persistent postoperative delirium should not be confused with emergence "excitement," a transient confusional state that is associated with emergence from general anesthesia. Emergence excitement is common in children, with more than 30% experiencing agitation or delirium at some period during their PACU stay.[119] It usually occurs within the first 10 minutes of recovery but can have onset later in children who are brought to the recovery room asleep. The peak age of emergence excitement in children is between 2 and 4 years. Unlike delirium, emergence excitement typically resolves quickly and is followed by uneventful recovery.[120]

In children, emergence excitement is most frequently associated with rapid "wake up" from inhalational anesthesia. Although it has also been reported after isoflurane[121] and, to a lesser extent, halothane[122] anesthesia, it is most often associated with the less-soluble vapors sevoflurane[123] and desflurane. Several studies suggest that the incidence of emergence excitement is more a reflection of the anesthetic agent used rather than the rapidity of emergence.[124] In studies comparing sevoflurane and propofol, propofol resulted in a much smoother awakening than sevoflurane despite rapid emergence. Furthermore, delaying emergence by a slow reduction in the inhaled concentration of sevoflurane did not reduce the incidence of emergence excitement.[125]

In addition to rapid emergence, the literature supports a number of possible etiologic factors, including intrinsic characteristics of the anesthetic, postoperative pain, type of surgery, age, preoperative anxiety, underlying temperament, and adjunct medications. Awareness of these contributors allows one to identify and treat children who are at increased risk.[120]

Simple preventative measures should be taken to treat children at risk. These include reducing preoperative anxiety, treating postoperative pain, and providing a stress-free environment for recovery. Medications that have been used to prevent and treat emergence agitation/delirium in children include midazolam,[126]

clonidine,[127-129] dexmedetomidine,[130,131] fentanyl,[132,133] ketorolac,[134] and physostigmine.[135] In children, the most common preoperative anxiolytic, midazolam, has produced conflicting data. Although midazolam is generally associated with a decrease in the incidence and duration of postoperative delirium, not all studies are in agreement. In studies in which it has not been shown to be beneficial, it is unclear whether midazolam is an independent factor or merely a reflection of other preoperative variables.[136]

The incidence of emergence excitement in adults is significantly less than in children. It is estimated to be between 3% and 4.7%.[137] One study found that significant surgical- and anesthesia-related risk factors included preoperative medication with midazolam (OR 1.9), breast surgery (OR 5.190), abdominal surgery (OR 3.206), and, to a much lesser extent, length of surgery.[137]

Delayed Awakening

Even after prolonged surgery and anesthesia, a response to stimulation in 60 to 90 minutes should occur.[138] When delayed awakening occurs, it is important to evaluate the vital signs (systemic arterial blood pressure, arterial oxygenation, ECG, body temperature) and perform a neurologic examination (patients may be hyperreflexic in the early postoperative period). Monitoring with pulse oximetry and analysis of arterial blood gases and pH can detect problems of oxygenation and ventilation. Additional blood studies may be indicated to evaluate possible electrolyte derangements and metabolic disturbances (blood glucose concentration).

Residual sedation from drugs used during anesthesia is the most frequent cause of delayed awakening in the PACU. If residual effects of opioids are a possible cause of delayed awakening, it is appropriate to administer carefully titrated intravenous doses of naloxone (20- to 40-μg increments in adults) while keeping in mind that this treatment will also antagonize opioid-induced analgesia. Physostigmine may be effective in reversing the central nervous system sedative effects of anticholinergic drugs (especially scopolamine). Flumazenil is a specific antagonist for the residual depressant effects of benzodiazepines. In the absence of pharmacologic effects to explain delayed awakening, it is important to consider other causes, such as hypothermia (especially <33°C), hypoglycemia, and increased intracranial pressure. Computed tomography may be indicated in patients in whom a central nervous system cause of delayed awakening is a consideration. A stat measurement of serum glucose is indicated if hypoglycemia is a possibility, as in patients with known insulin-dependent diabetes mellitus. Residual neuromuscular block may appear to be delayed awakening. Confirmation with peripheral nerve stimulation and sugammadex administration should correct this situation.

Discharge Criteria

Although specific PACU discharge criteria may vary, certain general principles are universally applicable (Table 85-13).[2] To summarize, a mandatory minimum stay in the PACU is not required. Patients must be observed until they are no longer at risk for ventilatory depression and their mental status is clear or has returned to baseline. Hemodynamic criteria are based on the patient's baseline hemodynamics without specific systemic blood pressure and heart rate requirements. An assessment and written documentation of the patient's peripheral nerve function on discharge from the PACU may become useful information should a new peripheral neuropathy develop in the later postoperative period.

Table 85-13 Summary of Recommendations for Discharge

1. Patients should be alert and oriented or mental status returned to baseline.
2. A minimum mandatory stay is not required.
3. Vital signs should be stable and within acceptable limits.
4. Discharge should occur after patients have met specified criteria.
5. Use of scoring systems may assist in documentation of fitness for discharge.
6. The requirement to urinate before discharge and drink and retain clear liquids should *not* be part of a routine discharge protocol although they may be appropriate for selected patients.
7. Outpatients should be discharged to a responsible adult who will accompany them home.
8. Outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a phone number to call in case of emergency.

Postanesthesia Scoring Systems

In 1970, Aldrete and Kroulik developed a postanesthesia scoring system to monitor recovery from anesthesia. The original Aldrete score assigned a number of 0, 1, or 2 to five variables: activity, respiration, circulation, consciousness, and color. A score of 9 out of 10 was considered adequate for discharge from the PACU.[139] Over the years, this system has been modified to keep up with advances in technology and anesthesia practice, including the expansion of ambulatory surgery. In 1995, pulse oximetry replaced visual assessment of oxygenation and additional assessments were added to accommodate patients undergoing ambulatory surgery (Tables 85-14 and 85-15).[140]

With the increase in number and complexity of outpatient surgeries, discharge criteria have been amended by various authors to include assessment of home readiness. The resulting PADSS, or postanesthesia discharge scoring system, continues to evolve. It was initially based on five criteria: vital signs, ambulation and mental status, pain and nausea/vomiting, surgical bleeding, and fluid intake/output. The current version has been modified to separate pain and nausea/vomiting and to eliminate the need to urinate before discharge.[141-145] In the ambulatory surgery setting, postoperative pain is the most significant cause of delayed discharge and unplanned hospital admission (see Chapter 78). In an effort to improve patient satisfaction and timely discharge, Chung and associates identified a subset of high-risk patients who are likely to benefit from intense prophylactic analgesic therapy. This study of 10,008 consecutive ambulatory surgical patients found that the incidence and intensity of postoperative pain increased with increasing BMI and duration of anesthesia. Orthopedic and urologic procedures were the most significant surgical factors.[146]

Table 85-14 Criteria for Determination of Discharge Score for Release from the Postanesthesia Care Unit

Variable Evaluated	Score
Activity	
Able to move four extremities on command	2
Able to move two extremities on command	1
Able to move no extremities on command	0
Breathing	
Able to breathe deeply and cough freely	2
Dyspnea	1
Apnea	0
Circulation	
Systemic blood pressure ≠ 20% of the preanesthetic level	2
Systemic blood pressure is 20% to 49% of the preanesthetic level	1
Systemic blood pressure ≠ 50% of the preanesthetic level	0
Consciousness	
Fully awake	2
Arousable	1
Not responding	0
Oxygen Saturation (Pulse Oximetry)	
>92% while breathing room air	2
Needs supplemental oxygen to maintain saturation >90%	1
<90% even with supplemental oxygen	0

Adapted from Aldrete JA: The post anaesthesia recovery score revisited. J Clin Anesth 7:89-91, 1995.

PACU Standards of Care require that a physician accept responsibility for the discharge of patients from the unit (Standard V).[1] This is the case even when the decision to discharge the patient is made at the bedside by the PACU nurse in accordance with hospital-sanctioned discharge criteria or scoring systems. If discharge criteria are to be used, they must first be approved by the department of anesthesia and the hospital medical staff. A responsible physician's name must be noted on the record.

Infection Control

Limitations in space,[147] staffing,[148,149] and time contribute to the transmission of infectious organisms in the PACU. The PACU is typically an open unit without physical barriers between bed stations. Nurses and respiratory therapists care for more than one patient simultaneously, and admissions to the unit are transient with a length of stay measured in hours rather than days. Complicating infection control monitoring is the fact that an infection resulting from a lapse in infection control in the PACU will not be identified by routine monitoring until days later on the surgical ward. In 1999, serial hand washing audits in a large metropolitan hospital cited the physical design of the PACU (open patient bays) as a significant barrier to improvement in hand washing compliance.[147]

With these limitations in mind, it is not surprising that the PACU has been described as the "weakest link" in the chain of care that bridges the sterile technique practiced in the operating room with infection control protocols practiced on the surgical unit. Despite awareness of the factors that increase the risk of infection in the PACU, until recently there have been no studies addressing the problem. A recent study of hand cleansing during postanesthesia care documents the poor compliance of PACU nurses with this standard infection control procedure.[150,151] In this observational study of 3143 patient care activities, the average compliance with hand cleansing was only 19.6% on patient admission to the unit and 12.5% in patients already admitted to the unit. In this study, the intensity of patient care activities was an independent predictor of noncompliance, that is, the greater the work load the less likely the nursing staff would comply with infection control measures. Additional independent factors included patients of advanced age and (>65 years) and those recovering from clean (surgical sites where the respiratory, alimentary, and urinary tracts are not entered) and clean-contaminated (surgical sites in which respiratory, alimentary, genital or urinary tracts are entered under controlled conditions without unusual contamination) surgery. As expected, compliance was best in patients with contaminated or known infected wounds.

The installation of bedside alcohol-based cleansers increases compliance of hand hygiene among heath care workers in the intensive care unit (ICU).[152-155] While no equivalent study has been done in the PACU, the unit is similar to the ICU in work load and intensity of patient care. The Centers for Disease Control

Table 85-15 Criteria for Determination of Discharge Score for Release Home to a Responsible Adult

Variable Evaluated	Score*
Vital Signs (stable and consistent with age and preanesthetic baseline)	
Systemic blood pressure and heart rate within 20% of the preanesthetic level	2
Systemic blood pressure and heart rate 20% to 40% of the preanesthetic level	1
Systemic blood pressure and heart rate >40% of the preanesthetic level	0
Activity Level	
Steady gait without dizziness or meets the preanesthetic level	2
Requires assistance	1
Unable to ambulate	0
Nausea and Vomiting	
None to minimal	2
Moderate	1
Severe (continues after repeated treatment)	0
Pain (minimal to no pain, controllable with oral analgesics)	
Yes	2
No	1
Surgical Bleeding (consistent with that expected for the surgical procedure)	
Minimal (does not require dressing change)	2
Moderate (up to two dressing changes required)	1
Severe (more than three dressing changes required)	0

*Patients achieving a score of at least 9 are acceptable for discharge.
Modified from Marshall SI, Chang F: Discharge criteria and complications after ambulatory surgery. Anesth Analg 88:508-517, 1999.

and Prevention *Guideline for Hand Hygiene in Health-Care Settings* recommends that an "alcohol based hand rub [be made] available at the entrance to the patient's room or at the bedside, in other convenient locations, and in individual pocket-sized containers to be carried by HCWs."[156] Although the convenience of appropriately placed alcohol based cleansers is expected to improve hand cleansing compliance, no followup studies in the PACU have been published.

Future Considerations

Intensive Care

In recent years, the demand for ICU beds has increased significantly within the United States and Europe. Because the PACU possesses the equipment and expertise to monitor, ventilate, and resuscitate patients recovering from general anesthesia, it has become the logical choice to provide care for critically ill patients for whom ICU beds are not available.[157] Although it is now common to care for critically ill patients in the PACU, the maintenance of quality patient care continues to challenge hospital administrators and staff.[158]

One obstacle to efficient ICU care in the PACU is the diversity of physician coverage required. Whereas the proximity of the operating room and the patient population recovering from anesthesia dictate that an anesthesiologist be the responsible physician for the majority of patients in the unit, nonsurgical ICU patients often require physician coverage by specialists who are unfamiliar with the unit and whose practices are located in distant areas of the hospital. As a result, PACU nurses must identify and contact physicians with whom they rarely interact.

Physician coverage (who will be primarily responsible for patient care—internist, anesthesiologist, or surgeon), privacy for family visitation (lack of space in a traditionally open unit), infection control (the proximity of patient beds and rapid turnover of patients), and nursing competencies (ongoing ICU training of staff) are some of the challenges facing the PACU today.[159] In a study of 400 ICU overflow patients admitted to the PACU in the United Kingdom, Ziser and colleagues identified insufficient medical and nursing coverage, inadequate communications, and visiting facilities for patient's families as the most significant problems facing the unit. The ICU patients in this study were on average 53 years of age with a mean length of stay of 12.9 hours. Seventy percent were mechanically ventilated, 77.8% required invasive monitoring, and 4.5% died in the PACU while awaiting placement in the ICU. The busiest hours of admission were 1 AM to 11 AM.[160]

In an effort to ensure the quality of patient care in the PACU, the professional societies responsible for the delivery of care in the unit have collaborated to develop standards for the care of ICU overflow patients. The "Joint Position Statement on ICU Overflow Patients" issued in 2000 is the result of this collaboration. It specifically requires that PACU staffing meet the nursing staffing ratios and competencies required in the critical care units.[161]

The Joint Position Statement reproduced here recommends that the following criteria be met:

- It must be recognized that the primary responsibility for Phase 1 PACU is to provide the optimal standard of care to the postanesthesia patient and to effectively maintain the surgery schedule.
- Appropriate staffing requirements should be met to maintain safe, competent nursing care of the postanesthesia patient as well as the ICU patient. Staffing criteria for the ICU patient should be consistent with ICU guidelines and based on individual acuity and needs.
- Phase 1 PACUs are by their nature critical care units and as such should meet the competencies required for the care of the critically ill patient. These competencies should include, but are not limited to, ventilator management, hemodynamic monitoring, and medication administration, as appropriate to their patient population.
- Management should develop and implement a comprehensive resource utilization plan with ongoing assessment that supports the staffing needs for both the PACU and ICU patients when the need for overflow admission arises.
- Management should have a multidisciplinary plan to address appropriate utilization of ICU beds. Admission and discharge criteria should be utilized to evaluate the necessity for critical care and to determine the priority of admission.

In addition to increasing the acuity of patient care in the PACU, the shortage of ICU beds has encouraged the de-escalation of care in selected patient populations. Postoperative patients who were historically admitted directly to the ICU from the operating room for intensive or specialized monitoring have had successful recovery by routine postoperative care in the PACU. Examples include postoperative craniotomy,[162] liver transplantation,[163,164] and cardiac surgery patients. The neurosurgical group at the University of Florida has shown that uncomplicated craniotomy patients can be safely cared for in the PACU at a significant savings of hospital-days and cost without increased morbidity or mortality.[162] Likewise, the trend to early extubation of liver transplant patients in the operating room has lead to the successful uncomplicated recovery of these patients in the PACU. Finally, in an effort to protect ICU bed availability and reduce the number of cardiac surgery cancellations, a group in Melbourne established a cardiac surgery recovery unit within the PACU.[165] Each of these examples requires adequate space and specialized nursing skills to be successful.

Outpatient Procedures

Finally, the PACU has responded to the economic restrictions that currently limit hospital resources by accommodating the performance of simple outpatient procedures (see Chapter 78).[166] The PACU is uniquely equipped to care for patients who are undergoing noninvasive and minimally invasive procedures such as electroconvulsive therapy,[167,168] cardioversion,[169] epidural blood patch,[166] and liver biopsy.[166] Ambulatory patients undergoing such procedures can be admitted directly to the PACU for the procedure and discharged to home after a brief recovery period. In order to do so, the PACU must be appropriately staffed and scheduled so as to not interfere with routine operating

room scheduling and postoperative recovery. Electroconvulsive therapy is somewhat unique in that it requires general anesthesia that is delivered by an anesthesia care practitioner. Typically these are short procedures that can be scheduled before the routine operating room cases. One successful electroconvulsive therapy program schedules the procedure at 5:30 AM with nurse-to-patient ratio of 2:1 and estimated PACU length of stay of 2 hours.[168]

Summary

The PACU is more than a postanesthesia observation unit. It is unique in its ability to support the care of patients of all ages and in every stage of illness. Since its inception more than 50 years ago, the PACU has proved to be an exceptionally adaptable unit that is equipped to meet the demands of an evolving health care system.

86 Postoperative Nausea and Vomiting

Key Points

1. Postoperative nausea and vomiting (PONV) may be triggered by various pathways through peripheral and/or centrally located receptors; however, the exact etiology is unknown.
2. Numerous patient-, anesthesia-, and surgery-related risk factors are associated with a high incidence of PONV, but this association may not be causal. For example, the high incidence of PONV after gynecologic surgery is likely observed because the surgery is conducted in women, who are more susceptible to PONV, and not because of the surgery itself.
3. Instead of assessing a wide range of associated risk factors, a patient's risk for PONV is best predicted by a simplified risk score using independent predictors (statistically corrected for confounders).
4. In adult inpatients undergoing a general inhaled anesthesia, Apfel's simplified risk score includes female gender, nonsmoking status, history of PONV/motion sickness, and the use of postoperative intravenous opioids as the main independent predictors. When 0, 1, 2, 3, or 4 of these factors are present, the risk for PONV is about 10%, 20%, 40%, 60%, or 80%, respectively.
5. In children, a similar simplified risk score exists for postoperative vomiting (POV) with duration of surgery greater than or equal to 30 minutes, age older than or equal to 3 years, strabismus surgery, and a positive patient history of POV or POV/PONV in relatives as the main predictors.
6. Because main triggers for PONV appear to be inhaled anesthetics and opioids, strategies to avoid or reduce exposure (e.g., regional or total intravenous anesthesia) are effective means to reduce the risk for PONV.
7. A PONV prophylaxis strategy should be tailored based on a patient's baseline risk, which can be determined using a simplified risk score. Patients at greatest risk will experience the greatest absolute risk reduction from interventions (absolute risk reduction = baseline risk x relative risk reduction).
8. Effective antiemetics to reduce PONV are cyclizine, dimenhydrinate, droperidol, dexamethasone, metoclopramide, ondansetron, dolasetron, tropisetron, and granisetron. The relative risks (RR) of these antiemetics versus placebo for nausea and for vomiting vary between approximately 0.60 and 0.80.
9. Neurokinin (NK1) antagonists are similarly effective against nausea compared with other antiemetics but are considerably more effective against postoperative vomiting.
10. While the minimally effective dose for prophylaxis with ondansetron is 4 mg, the minimally effective dose for rescue treatment with ondansetron is only 1 mg. Based on this observation, it has been generalized that about a quarter of the prophylactic dose is needed for rescue treatment.
11. Patient who suffer from PONV in spite of intraoperative prophylaxis with ondansetron do not respond to rescue treatment with a second dose of ondansetron or granisetron in the postanesthesia care unit. It is therefore concluded that rescue treatment targeting an already blocked receptor is ineffective so that an antiemetic strategy using a different mechanism should be used instead.

Nausea and vomiting in the postoperative period occurs in 20% to 30% of patients[1] and together are the second most common complaints reported (pain is the most common).[2-8] After the landmark 1992 review from Watcha and White,[9] *postoperative nausea and vomiting (PONV)* became the more commonly used clinical term; and in 1999, PONV became a medical subject heading in the National Library of Medicine. The term *PONV* will be used throughout this chapter to reflect its current widespread usage to describe the composite postoperative symptoms of nausea and/or vomiting and/or retching. However, the description of these symptoms as "postoperative" should not be construed to suggest that surgery is their most important direct cause, although this is a widely held belief. Several large prospective cohort studies now suggest that the varying incidences of PONV observed after dif-

ferent types of surgeries are largely a reflection of important patient-specific and anesthesia-related risk factors rather than surgery itself.[4,5,8]

PONV can be such an unpleasant experience that patients often rate it worse than postoperative pain.[10] Patients' "willingness to pay" out of pocket for effective antiemetic treatment of PONV, as measured by well-designed studies, is $56 in the United States[11] and €65 in Europe.[12] Prevention of PONV in high-risk patients significantly improves postoperative ratings of well-being and satisfaction.[13] While the experience of PONV is generally self-limited, postoperative vomiting/retching (POV) can lead to rare but serious medical complications, such as aspiration of gastric contents, suture dehiscence, esophageal rupture, subcutaneous emphysema, or pneumothorax (the actual incidence due to PONV has not been quantified).[14,15] PONV may delay patient discharge from postanesthesia care units (PACUs) and can be the leading cause of unexpected hospital admission after ambulatory anesthesia.[16] Annual PONV-related health care costs approach several hundred million dollars in the United States alone.[17,18]

The ongoing need to improve understanding, prevention, and treatment of PONV is reflected in the literature: over 2000 randomized controlled PONV trials have been published in peer-reviewed journals, and almost 200 new studies are published each year. This is in part due to the interest of the pharmaceutical industry in developing new and more effective treatments for this condition. The purpose of this chapter is to provide an up-to-date review of PONV by a deepened methodological understanding that allows resolution of discrepancies between traditional beliefs and the best available evidence. This more current understanding and knowledge shall then enable the reader to better manage PONV in daily clinical practice.

Etiology: Pathways for Nausea and Vomiting

Nausea and vomiting may be induced through various pathways (Fig. 86-1).[19,20]

Toxic Materials in the Gastrointestinal Lumen

Ingestion of toxic substances (e.g., hypertonic saline or copper sulfate) results in the release of serotonin (5-hydroxytryptamine [5-HT]) from enterochromaffin cells in the gut wall.[21] These enterochromaffin cells hold over 90% of the body's serotonin and appear to release it under various chemical and mechanical stimuli. Serotonin may also be released indirectly via M_3-receptors, β-adrenoceptors, and H_3-receptors; conversely, the stimulation of $GABA_B$-receptors, 5-HT_4-receptors, and α_2-adrenoceptors and the presence of vasoactive intestinal polypeptide and somatostatin have been proposed to reduce the release of serotonin.[19] Serotonin is secreted in close proximity to afferent vagal nerve endings of the gut wall that travel to the dorsal brainstem via the nucleus tractus solitarius, as demonstrated in animal models in which vagotomy blocks cisplatin-induced emesis.[22] However, large amounts of serotonin released by neuroendocrine carcinoid tumors lead to flushing, diarrhea, wheezing, and abdominal cramps but typically not to nausea and vomiting. This finding suggests that serotonergic emetogenic stimuli are primarily mediated through the autonomic nervous system rather than the bloodstream. Therefore, even though renal secretion of 5-hydroxyacetic acid (a metabolite of serotonin, with a much longer half-life) is associated with PONV after abdominal surgery,[23] a causal relationship to PONV remains unclear.

Absorbed Toxins and Drugs

Absorbed toxins or drugs circulating in the blood can cause nausea and vomiting via stimulation of the chemoreceptor trigger zone (CRTZ).[24] The CRTZ is located in the area postrema, a circumventricular organ at the bottom of the fourth ventricle. Even though the CRTZ resides anatomically in the central nervous system, its uniquely permeable endothelium (i.e., lack of a blood-brain barrier) allows it to detect emetogenic substances in the bloodstream as if it were a peripheral organ.[25] Based on a series

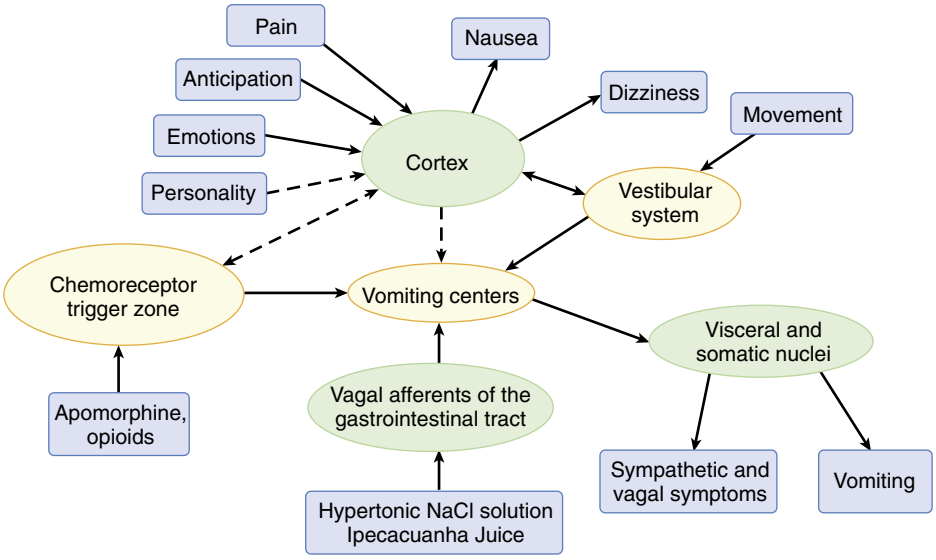

Figure 86-1 Pathways for nausea and vomiting. Dotted lines are hypothetical pathways with only indirect evidence. (*Created by Christian Apfel, MD, PhD.*)

of papers, Borison and Wang were able to demonstrate in the early 1950s that the CRTZ has an abundance of receptors and that its stimulation can send emetogenic triggers to the brainstem's vomiting center to activate the vomiting reflex (Fig. 86-2).[26-30] Although this mechanism explains how apomorphine (a fairly selective dopamine [D_2] agonist) provokes emesis, and why droperidol (a D_2 antagonist) will reverse apomorphine's emetogeneic effect, it remains unclear how the CRTZ senses or transduces emetic stimuli and why nausea and vomiting are not typical side effects of dopamine infusions. Again, it remains unclear why certain receptor agonists circulating in the blood fail to trigger nausea and vomiting while corresponding receptor antagonists prevent or reduce nausea and vomiting.

Stimulation of the Vestibular System

The vestibular system is another source of emetogenic stimuli, as observed in motion sickness or Ménière's disease.[31-33] Motion sickness is a risk factor for PONV.[2-8] Whether vestibular

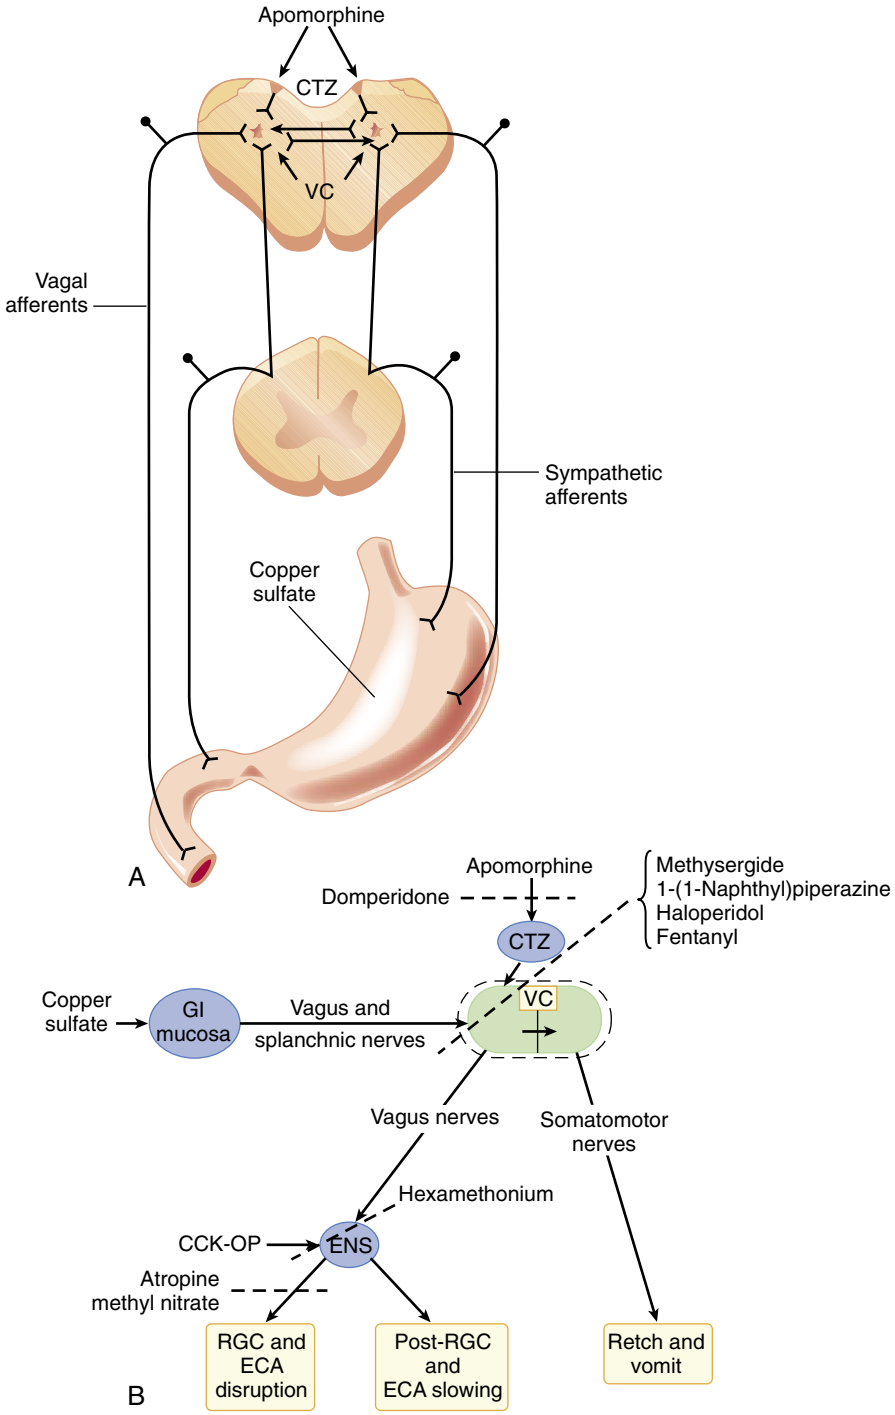

Figure 86-2 Different types of schematic representation of the organization of the emetic reflex from the original Wang and Borison (**A**) 1952 model and Lang and Marvig (**B**) in 1989, Borison and McCarthy (**C**) in 1981, and Andrews, Rapeport, and Sanger (**D**) in 1988. Note that all the models contain essentially the same key elements. GI, gastrointestinal; CTZ, chemoreceptor trigger zone; VC, vomiting center; CCK-OP, cholecystokinin octapeptide; ENS, enteric nervous system; RGC, retrograde giant contraction; ECA, electrical control activity; NTS, nucleus tractus solitarius; PCRF, parvicellular reticular formation; 5-HT, 5-hydroxytryptamine; SP, substance P.

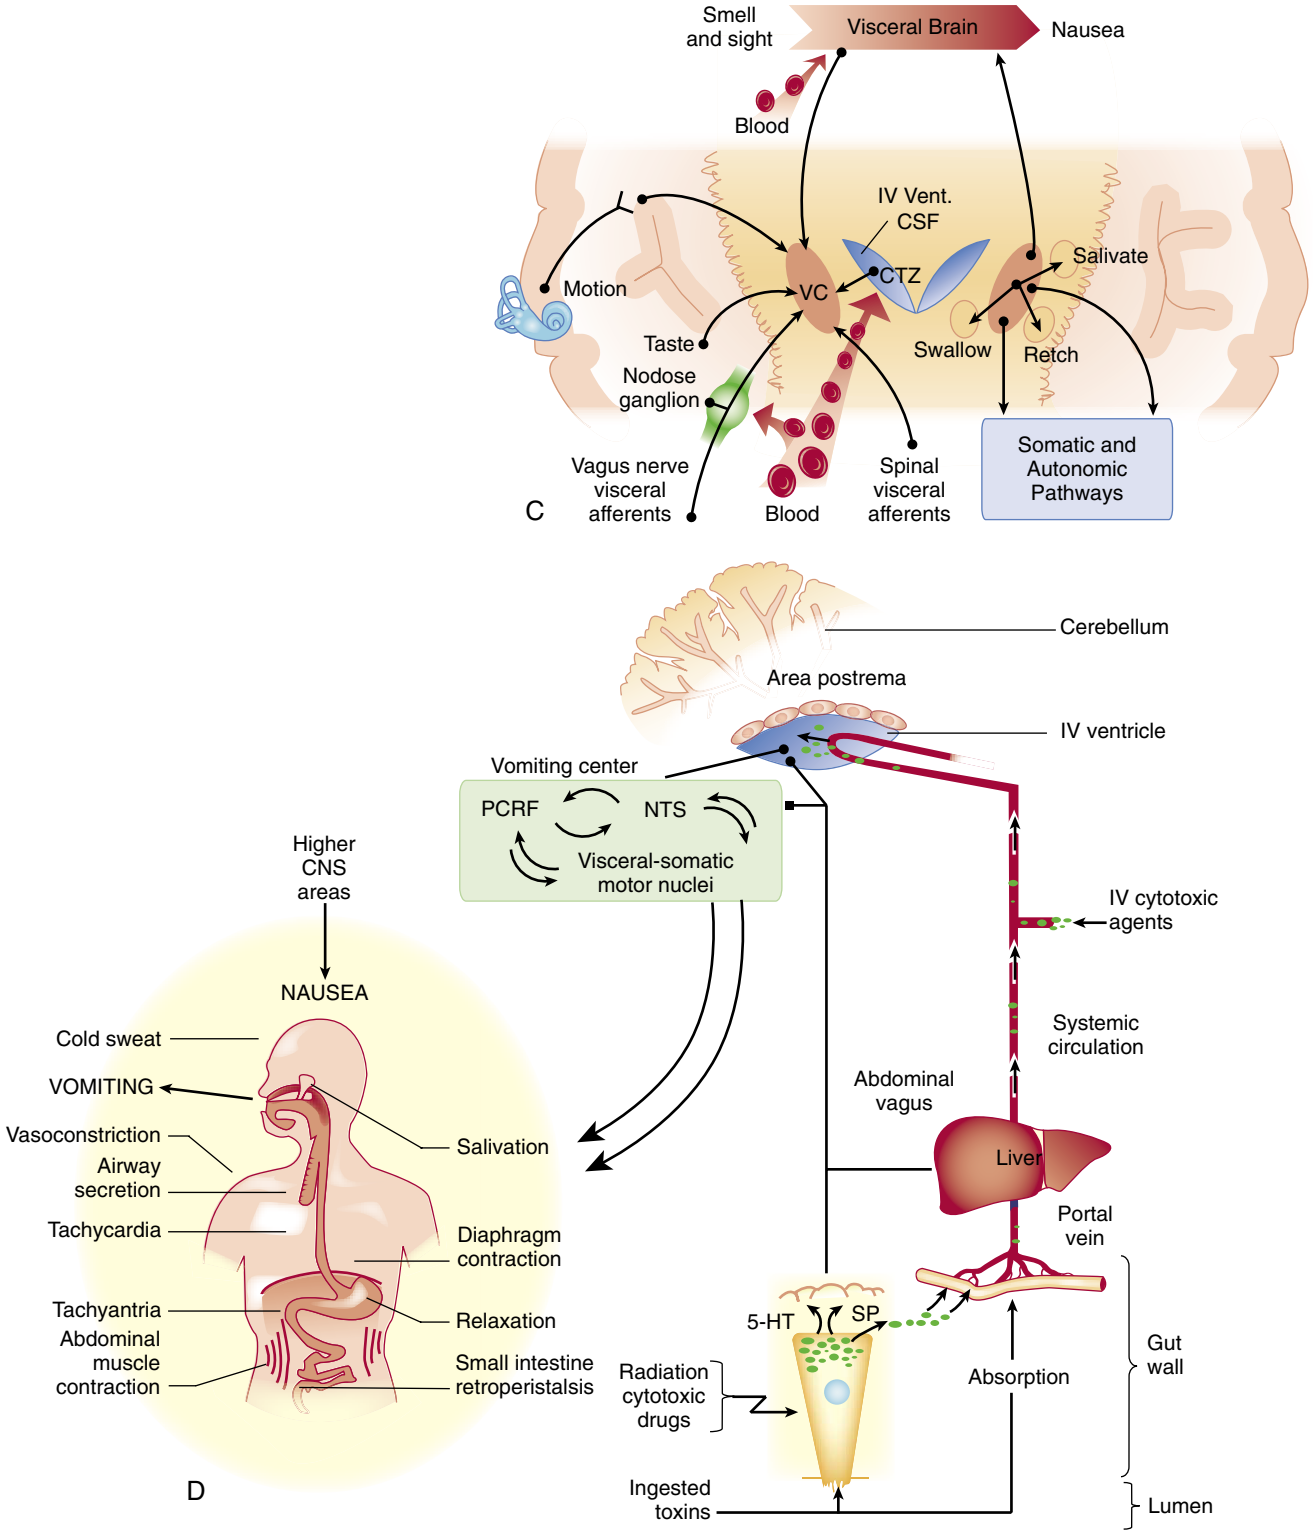

Figure 86-2, cont'd

input contributes to the emetogenic state in the vomiting center or whether anesthetics or opioid analgesics contribute to the susceptibility of the vestibular organ or signal processing is not clear.

Risk Factors and Independent Predictors

Distinguishing Association from Causality

The recognition of risk factors plays a critical role in making diagnostic and therapeutic decisions in medicine. The term *risk factor* was likely first coined in the Framingham study, where risk of heart disease was associated with specific conditions such as hypertension, high cholesterol, and smoking. To know which of the risk factors is most likely *causal* or merely *correlational* can be critical for the development of valid risk assessment tools to be used for clinical decisions. For example, women are more susceptible than men to certain emetogenic stimuli (motion, chemotherapy, inhaled anesthetics, and opioids).[34,35] If we consider that the average incidence of PONV is about 30% overall and females are about three times more likely to develop PONV,[3,5] the average incidence in male and female patients should be in the range of 15% and 45% (assuming the same number of men and women are anesthetized).[36] It is therefore not surprising that approximately one in two women undergoing gynecologic surgery suffers from PONV. From this perspective, the type of surgery can be considered a risk factor for PONV. However, establishing a policy for the routine use of antiemetics for the prevention of PONV for women having gynecologic surgery, but not other surgeries, would not acknowledge that lengthy non-gynecologic surgeries in women are associated with incidences of PONV well over 50%,[4,5] whereas short gynecologic procedures such as dilatation and curettage may be associated with PONV incidences as low as 7%.[37] Therefore, the current categories of surgeries are generally too broadly defined to be reliable predictors for PONV.[38] It is more useful to consider PONV multifactorial in its origin, that is, as a consequence of emetogenic agents (inhaled anesthetics, opioids) applied to susceptible patients (females, those with a history of motion sickness, nonsmokers). These have been shown not only to be associated with an increased incidence of PONV but also to be important independent predictors of PONV. A better prediction can be obtained by focusing on these well-established independent predictors that appear to cause PONV.[38] Therefore, the following text distinguishes between factors that are merely associated with increased risk (risk factor or associated risk factors) and factors that appear to be causally related to PONV (independent risk factors or independent predictors). Table 86-1 lists the relative importance (as delineated by the odds ratio) of independent predictors as determined in large cohort studies.

Factors That May Not Be Relevant

Many reviews or book chapters list large numbers of PONV risk factors, irrespective of the evidence or the magnitude of effect. This has contributed to a divergence between commonly held clinical beliefs about PONV risk factors and the published evidence. For example, Eberhart and colleagues reported that over 80% of German anesthesiologists considered obesity to be a risk factor for PONV.[39] Yet Kranke and coworkers found that an increased body mass index was not associated with an increased incidence of PONV.[40] Similar discrepancies exist for the influence of facemask ventilation,[41,42] use of a nasogastric or orogastric tube,[43-45] intravenous use of neostigmine to reverse neuromuscular blockade,[46,47] phase of menstrual cycle,[48] and even weather or phase of the moon.[49,50] Thus, the following discussion of risk factors for PONV will focus on these factors, which are well supported in the literature. Of course, other unknown or insufficiently studied PONV risk factors may yet be found. For example, it may be possible that rapid patient transport from the operating room to the PACU, especially fast turns or decelerations, can trigger nausea and vomiting. However, this has never been formally studied and therefore its importance cannot be determined. Accordingly, the following discussion focuses on the best available evidence.

Patient-Related Independent Predictors

Female Gender

Most prospective cohort studies using logistic regression analyses have identified female gender (in adults) as the strongest independent predictor for postoperative nausea,[3,8] vomiting,[8,51,52] use of antiemetic rescue treatment,[53] and overall PONV (see Table 86-1)[2,4-6,37,54-61] independent of anesthetic technique. Yet women have a lower threshold for motion sickness[62] and for hyperemesis gravidarum.[63] The reason for increased female susceptibility to nausea and vomiting is unclear but persists well after menopause and most of the rest of a woman's life.[64]

Not Smoking

Individuals often experience nausea and diarrhea when smoking their first cigarette.[65] This is likely an acute effect of nicotine, because nausea is a known side-effect of nicotine patches.[66] While one might predict that smokers have a higher risk of PONV than nonsmokers,[39] Cohen and associates found that nonsmokers were 1.8 times more likely than smokers to have PONV.[3] These findings were subsequently confirmed by several but not all other large-scale studies.[4-6,37,54-58] The mechanism by which a smoking habit reduces the risk of PONV is not entirely clear, but one may speculate that chronic smokers are desensitized to nausea. Nicotine stimulates indirect GABA-mediated cerebral dopamine release,[67] and nicotine withdrawal in the perioperative period may lead to low postoperative cerebral dopamine levels, reducing activation of dopaminergic circuits in the CRTZ known to be associated with nausea and vomiting (my conjecture).

History of PONV, Motion Sickness, or Migraine

Susceptibility to emetogenic stimuli varies among individuals according to history of PONV,[2,4,6,8,37,54,55,57] history of motion sickness,[2,4,6,55,57] and history of migraine.[4,8] Although one would intuitively expect that a history of PONV is the strongest predictor for subsequent PONV, it is important to realize that this is not the case. In fact, in the majority of studies, female gender is a stronger predictor than a history of PONV.

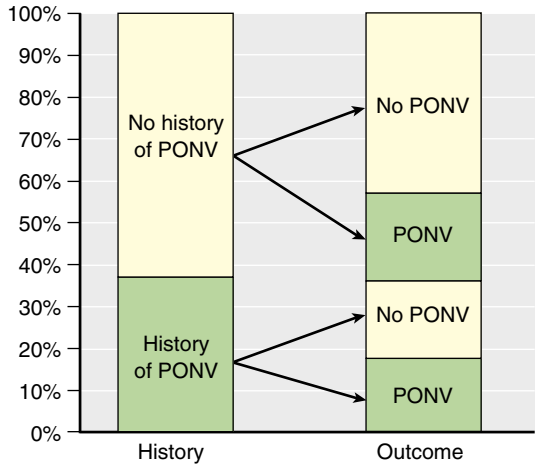

Figure 86-3 Limited sensitivity of a single predictor to identify patients at risk for PONV, with history of PONV as an example. (*From Apfel CC, Kranke P, Eberhart LH: Comparison of surgical site and patient's history with a simplified risk score for the prediction of postoperative nausea and vomiting. Anaesthesia 59:1078-1082, 2004.*)

This is illustrated by a study of 1566 patients (Fig. 86-3).[38] About a third of patients (569) presented with a history of PONV, of whom every second patient (280) experienced PONV. Two thirds of patients (997) did not have a history of PONV, of whom one third (320) experienced PONV. Clearly, patients with a history of PONV were at higher risk for experiencing PONV. However, of the total 600 patients who developed PONV, fewer than half (280 of 600) would have been correctly identified if the history of PONV had been used as a single predictor. Indeed, the use of PONV history as a single predictor has been associated with a sensitivity of less than 50% to identify patients at risk for PONV, that is, fewer than half the patients who develop PONV were correctly identified in advance (which is less than one would expect from a random guess).[38]

Age

In adults, although the incidence of PONV decreases with age, it has not always been a strong risk factor.[3,37,51-54,57,64,68] In children, however, Eberhart and coworkers have shown that an age of 3 years or older is associated with an increased risk for PONV.[69]

Anxiety

Anxiety may influence PONV, although this was not supported in a study with a small cohort of children.[70] However, in secondary analyses of the considerably larger AIDA trial in adults conducted by the group around Kalkman,[7] anxiety was assessed using two standardized psychometric instruments and a statistically significant but fairly weak association was demonstrated.[68] Although anxiety increases PONV, a preoperative assessment of anxiety is unlikely to result in a significant improvement in prediction for PONV.

Anesthesia-Related Independent Predictors

Preoperative Opioids

Only few studies compared different opioids given in conjunction of premedication. Eger and colleagues found no difference between morphine and meperidine.[71] Of note, in the same study, the $GABA_A$-enhancing drug pentobarbital was associated with a less frequent incidence of PONV compared with placebo.

Intraoperative Opioids

No large prospective cohort study has demonstrated that type or dose of intraoperative opioid influences PONV in adults. In children, the liberal intraoperative use of morphine (analgesic ED_{50} 0.18 mg/kg) is associated with a frequent incidence of POV in children undergoing tonsillectomies (see Chapter 82).[72]

Whether the type of intraoperative opioid used is a relevant consideration remains controversial. One recent paper has suggested that alfentanil is associated with less PONV compared with fentanyl or sufentanil.[73] Another group hypothesized that the ultra-short half-life of remifentanil would result in less carryover effect into the postoperative period and thereby decrease PONV. However, there was no significant difference in the overall incidence of PONV when remifentanil was compared with fentanyl, probably because the study design included predominantly larger operations requiring significant amount of opioids for postoperative pain relief, masking any potential benefit.[47] Finally, morphine-6-glucuronide, an active metabolite of morphine, has been reported to be associated with less PONV compared with morphine,[74] although it was not statistically significant in another study.[75] In conclusion, regardless of whether opioids are used intraoperatively or postoperatively, the available evidence suggests that the dose of opioid, rather than type, is one of the main predictors (or causes) for PONV.

Postoperative Opioids

Most large studies using multivariable analyses demonstrate that use of postoperative opioids doubles the risk for PONV.[2,4,5,38,54,56,76] The dose of postoperative opioid appears to be important[77] but not the type (e.g., morphine versus piritramide).[78] As a consequence, opioid-sparing strategies should reduce the incidence of PONV. Indeed, PONV tended to be decreased when cyclooxygenase-2–selective nonsteroidal anti-inflammatory drugs (NSAIDs) reduced opioid use by 20% to 40%. However, regional anesthesia definitely reduces the incidence of PONV (see also Chapters 51 and 52).[79]

Propofol and Inhaled Anesthetics

Propofol is widely believed to have antiemetic properties. By using propofol in patient-controlled analgesia (PCA) pumps in the PACU as "patient-controlled antiemesis," Gan and associates found that "non-sedating" plasma concentrations of 343 ng/mL reduced nausea in 50% of cases.[80,81] However, using a similar design, Scuderi and colleagues were unable to demonstrate any antiemetic effect of propofol.[82] In another study, healthy volunteers were randomized to propofol, midazolam, or placebo and then exposed to an infusion of apomorphine.[83] At nonsedative doses, neither propofol nor midazolam provided protection. However, at sedative doses, both propofol and midazolam increased the threshold for nausea. As a result, the antiemetic activity of propofol-induced sedation is not clear.

Compared with a purely regional anesthetic technique, general anesthesia is associated with a significantly higher incidence of PONV.[37] This raises the question of the individual contribution of the drugs used for the general anesthetic, namely, opioids, inhaled anesthetics, and nitrous oxide. Although previous meta-analyses have demonstrated a lower incidence of nausea

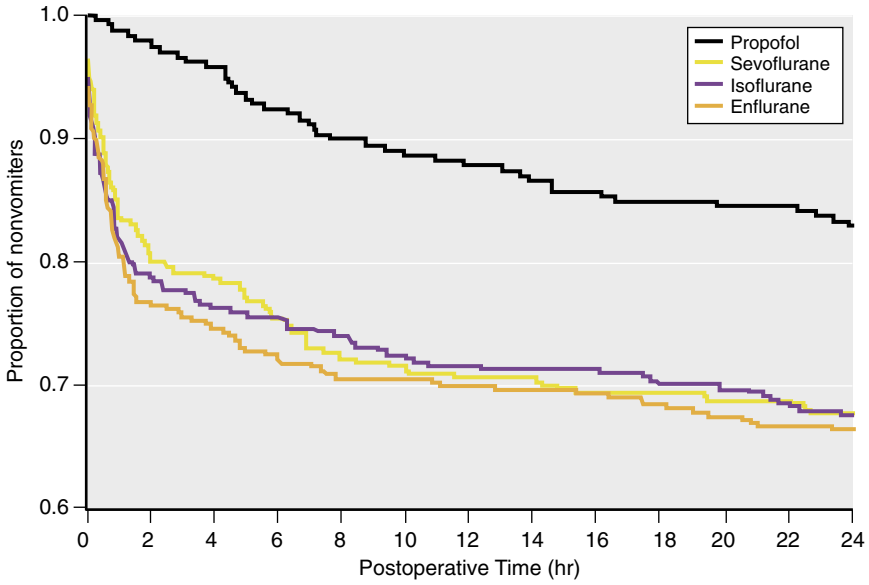

Figure 86-4 Kaplan-Meier chart for postoperative vomiting after isoflurane, enflurane, sevoflurane, and propofol. (*From Apfel CC, Kranke P, Katz MH, et al: Volatile anaesthetics may be the main cause of early but not delayed postoperative vomiting: A randomized controlled trial of factorial design. Br J Anaesth 88:659-668, 2002.*)

and vomiting with propofol compared with inhaled anesthetics,[84,85] in volunteer studies an 8-hour anesthetic with sevoflurane was associated with nausea and vomiting in over 80%, strongly suggesting the emetogenicity of volatile anesthetics.[86] In addition, a large clinical single center study with patients demonstrated that (1) the difference in vomiting between inhaled anesthetics and propofol occurs predominantly in the first 2 to 6 hours postoperatively (Fig. 86-4) and, more importantly, (2) the difference in early vomiting is clearly dose related (Fig. 86-5) so that the difference is not due to propofol but rather related to the dose-dependent emetogenic effect of the volatile anesthetics.[76] There are no differences in PONV among the volatile anesthetics isoflurane, enflurane, and sevoflurane. This finding is consistent with a meta-analysis by Gupta and coworkers (comparing propofol, isoflurane, sevoflurane, and desflurane),[87] a meta-analysis by Macario and associates (comparing sevoflurane with desflurane),[88] and a very recent study by Wallenborn and colleagues (comparing isoflurane, sevoflurane, and desflurane).[58]

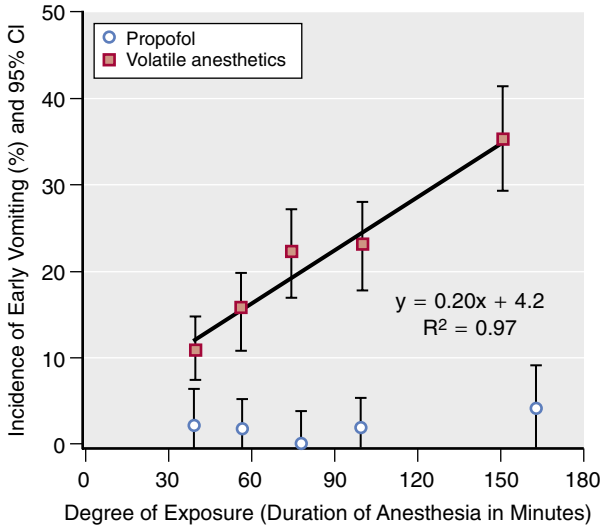

Figure 86-5 Incidence of early vomiting (0-2 hr) after maintenance with volatile anesthetics or propofol. (*From Apfel CC, Kranke P, Katz MH, et al: Volatile anaesthetics may be the main cause of early but not delayed postoperative vomiting: A randomized controlled trial of factorial design. Br J Anaesth 88:659-668, 2002.*)

Nitrous Oxide

Numerous studies in the 1980s and meta-analyses in the 1990s emphasized the emetogenic effect of nitrous oxide.[89,90] However, the emetogenic effect of nitrous oxide may not be quite as strong as that associated with volatile anesthetics.[56] Moreover, the emetogenic effects of nitrous oxide and volatile anesthetics are independent, that is, they are additive.[56] What is probably more notable than the emetogenic effect of nitrous oxide is the recent landmark trial from the Australian group led by Paul Myles comparing a nitrous oxide group (70% N_2O, 30% O_2) with an oxygen-enriched air group (80% O_2, 20% N_2) that found not only more PONV but also significantly more severe adverse events (pulmonary complications, wound infections, and fever) in the nitrous oxide group.[91] A second large multicenter study comparing a nitrous oxide group (70% N_2O, 30% O_2) and nitrous oxide–free group (70% N_2, 30% O_2) is attempting to provide further evidence regarding nitrous oxide and the association with more severe medical complications.

Duration of Anesthesia

The effect of duration of anesthesia on PONV is described in a number of studies.[4,37,55,56,58,76] The magnitude of this time-dependent dose response varies widely as reflected in odds ratios per hour ranging from 1.15[56] to 2.53.[37] As referenced earlier, the effect size may be large when inhaled anesthetics are used and small when propofol is used (see Fig. 86-5) and depend on the amount of opioids used.[56] In any event, it is generally correct to assume longer and more invasive surgeries to be associated with more PONV. In fact, in a cross validation that developed a simplified risk score, there was a co-linearity between the duration of anesthesia and the postoperative intravenous use of opioids. Because intravenous opioid use was the slightly stronger predictor, that variable remained an independent predictor as opposed to duration of anesthesia.[5]

Surgery-Related Independent Predictors

Many surgeries are associated with a high incidence of PONV.[9] This has led to many hypothesized causal mechanisms for various types of surgeries—tympanoplasty and vestibular stimulation, adenotonsillectomy and swallowed blood, breast surgery and emotional load, laparoscopic surgery and peritoneal irritation, abdominal surgery and serotonin release, and hysterectomy and vagal stimulation[92-94]—all resulting in a tendency to narrowly specify the type of surgery in antiemetic trials. There is no question that patients undergoing large abdominal and gynecologic surgeries have increased risk for PONV, with incidences of at least 50%. However, in many instances, these incidences may often be a reflection of other underlying factors, in this example most likely prolonged exposure to emetogenic volatile anesthetics and/or large doses of intraoperative opioids. In fact, if volunteers are exposed to volatile anesthetics (without any surgery) for an extended period of time, almost all experience nausea or vomiting afterward.[86] Therefore, risk assessment should be based on the underlying independent predictors rather than the type of surgery. In addition, several studies support the notion that the type of surgery is not an independent predictor for postoperative nausea,[4] vomiting,[4,8,51] PONV,[5,54] or need for rescue treatment (see Table 86-1).[53] However, there are other studies that have identified several types of surgery as independent predictors for postoperative nausea,[3,8] vomiting,[52] or PONV.[37,55,56,68] Nevertheless, most types of surgery have not consistently been shown to be independent predictors for PONV in the majority of studies; possible exceptions to this rule are laparoscopic cholecystectomy and hysterectomy.[3,56] Of note, although strabismus surgery is not a risk factor in adults,[95] it is a well-established and clinically relevant independent predictor for POV in children.[69,96]

One might argue that it would be enough to know which types of surgeries are risk factors, whether or not they are independent predictors of PONV, to decide on the need for prophylactic antiemetics. The incidence of PONV in many so-called emetogenic procedures (laparoscopy, adult strabismus surgery, middle ear surgery, herniorrhaphy, tonsillectomy, adenoidectomy, and uvulopalatopharyngoplasty) is not much higher than for other types of surgery. In fact, when Scuderi and colleagues stratified patients according to "emetogenic procedures," the incidence of PONV in the PACU was 37% (80/215) compared with 31% (112/360) for all other surgeries, which is not significantly different.[97] These findings are also consistent with a study in which the PONV incidence over 24 hours was 42% (283/681) for "emetogenic procedures" and 36% (317/885) for other procedures.[38] In conclusion, although certain types of surgeries are associated with a more frequent incidence of PONV, causality has not been clearly established. With the exception of strabismus surgery in children, the incidence of PONV with most surgeries likely reflects underlying patient- and anesthesia-related factors.

Risk Assessment

PONV is multifactorial. Therefore, a patient's risk can better be estimated by accounting for several independent predictors simultaneously.

Palazzo and Evans in the United Kingdom were the first who applied multiple logistic regression analysis to 148 patients undergoing minor orthopedic procedures, thus developing a predictive model for "postoperative sickness."[2] One year later, logistic regression analysis was applied to data from a Canadian four-center survey of 16,000 inpatients.[3] Of note, the binary logistic regression analysis is a multivariable statistical method that quantifies the relative impact of *independent* predictors (e.g., female gender, nonsmoking) of a dichotomous outcome (here PONV) by determining their coefficients according to

$$p = 1/(1+e^{-z})$$

with $z = \alpha \bullet x_1 + \beta \bullet x_2 + \gamma \bullet x_3 + \ldots + \omega$, and α, β, γ, etc., being the coefficients for the factors x_1, x_2, x_3, etc. These coefficients are directly related to the odds ratio of a predictor through the formula odds ratio$_{(a)} = e^a$, a measure that is similar to the previously mentioned relative risk or risk ratio.

This is important to realize when comparing papers that report the coefficients with those that report the odds ratio.[8] Table 86-1 thus displays the odds ratios that quantify the impact as independent predictors and not only as risk factors for PONV.

Subsequently, two groups independently started to conduct large surveys and to apply logistic regression analyses to develop more generalizable predictive models.[4,51,52] Koivuranta and colleagues were the first to publish predictive models for PONV based on logistic regression analyses and developed a simplified model by selecting the five strongest predictors: female gender, previous PONV, duration of operation over 60 minutes, history of motion sickness, and nonsmoking.[4] When 0, 1, 2, 3, 4, or 5 of these independent predictors were present, the risk for PONV was 17%, 18%, 42%, 54%, 74%, and 87%. One year later, a predictive model for POV in patients undergoing ENT surgery was published that showed a tight correlation between predicted and observed incidence in a validation cohort (Fig. 86-6).[51] Because the latter model was developed in patients undergoing ENT surgery its applicability for other type of surgeries was unclear. In a subsequent study that included a wide range of surgeries, type of surgery turned out to be an *independent* predictor (at the

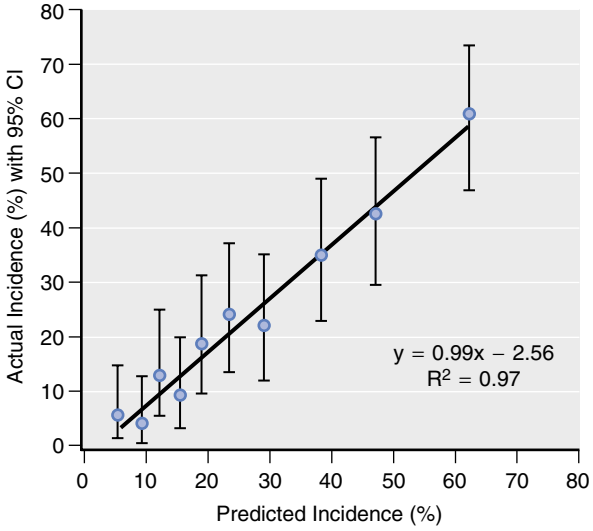

Figure 86-6 Correlation between average predicted and actual incidence of postoperative vomiting in 10 percentile groups. (*From Apfel CC, Greim CA, Haubitz I, et al: The discriminating power of a risk score for postoperative vomiting in adults undergoing various types of surgery. Acta Anaesthesiol Scand 42:502-509, 1998.*)

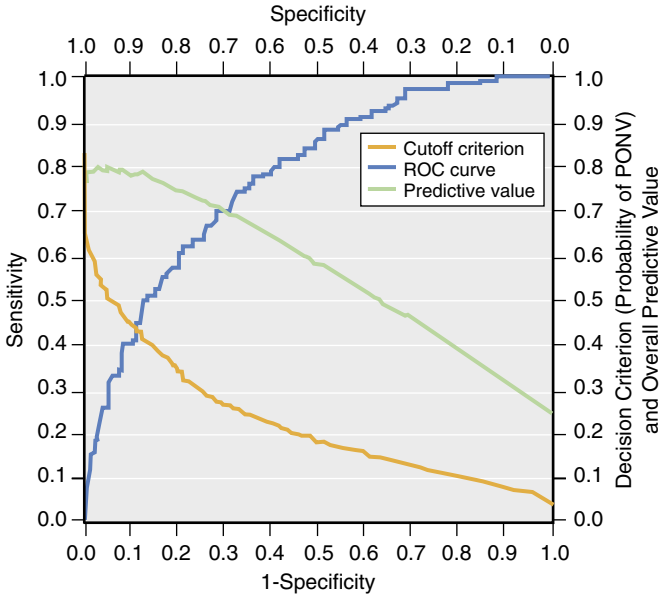

Figure 86-7 Receiver operating characteristic (ROC) curve characterizing the relationship between sensitivity and specificity. (*From Apfel CC, Greim CA, Haubitz I, et al: The discriminating power of a risk score for postoperative vomiting in adults undergoing various types of surgery. Acta Anaesthesiol Scand 42:502-509, 1998.*)

expense of duration of anesthesia) but the discriminating power as described by the area under the receiver operating characteristic (ROC) curve was at least as good using the prior risk score (independent of surgery type). Notably, the area under the ROC curve (ROC-AUC) was 0.77 (Fig. 86-7), meaning that on average the prediction was correct in about three fourths of cases.[52] The two groups then performed a cross-validation and found that risk scores derived from one center were able to predict PONV from the other center (ROC-AUC = 0.65 to 0.75) and that simplification of the score did not weaken the discriminating power (ROC-AUC = 0.63 to 0.73).[5] The final score consisted of four predictors: female gender, history of motion sickness or PONV, nonsmoking, and the use of postoperative opioids; if none, one, two, three, or four of these risk factors were present, the incidences of PONV were 10%, 21%, 39%, 61%, and 79% (Fig. 86-8).[5] While this score was developed for the prediction of PONV over 24 hours in inpatients, Chung's group developed a fairly complex predictive model for PONV in outpatients.[37] That score included type of surgery as a predictor, but it appeared to be inferior to the simplified risk scores[54,55]; however, this may have occurred, in part, because the validations were performed in inpatients. A recent validation from the Kalkman group in the Netherlands found that the predictive characteristics of the simplified risk scores were rather limited, with ROC-AUCs of only 0.63 to 0.66.[57] In their patient population, however, use of postoperative opioids—invariably shown to affect the risk for PONV in previous studies and a key independent predictor in the simplified risk models—was not associated with an increased incidence of PONV, likely accounting for the limited predictive power.

These models have been developed for prediction in adults and are not applicable for pediatric patients.[98] However, the risk for POV can be predicted with a simplified risk score in children by Eberhart and colleagues taking the following four variables into consideration: duration of surgery greater than or equal to 30 minutes, age older than or equal to 3 years, strabismus surgery, and a personal history of POV or PONV in immediate relatives.[69] The presence of 0, 1, 2, 3, and 4 risk factors was associated with a POV incidence of 9%, 10%, 30%, 55%, and 70% (and an ROC-AUC of 0.72) (see also Chapter 82).[69]

Prophylactic Antiemetic Strategies

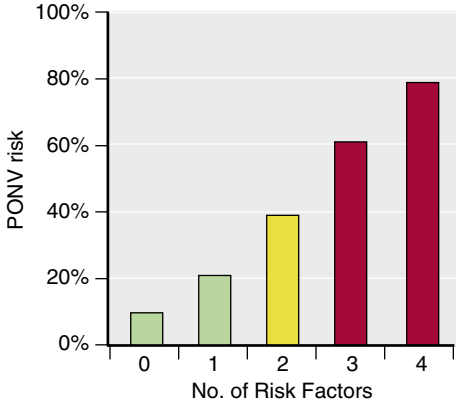
Methodological Background

Measurement of Nausea and Vomiting/Retching

Understanding the various definitions and methodologies used in publications is critical for interpretation of results. For instance, even though the occurrences of nausea and vomiting are correlated, they can occur independently and should therefore be assessed and reported separately so that results can be compared across publications. This is true for both inhaled and intravenous anesthesia in both inpatient and outpatient procedures (Fig. 86-9).[7] Failure to realize this essential point has resulted in difficulties in assessing results for a significant portion of the available literature. Similar difficulties have arisen from the use of various scales that are generally inadequate to properly assess PONV. For example, assessing PONV on a 4-point severity scale ranging from "*no symptoms, mild nausea, severe nausea or up to two*

Risk factors	Points
Female gender	1
Nonsmoker	1
History of PONV	1
Postoperative opioids	1
Risk score =	0...4

Figure 86-8 The simplified risk score for adults. (*From Apfel CC, Laara E, Koivuranta M, et al: A simplified risk score for predicting postoperative nausea and vomiting: Conclusions from cross-validations between two centers. Anesthesiology 91:693-700, 1999.*)



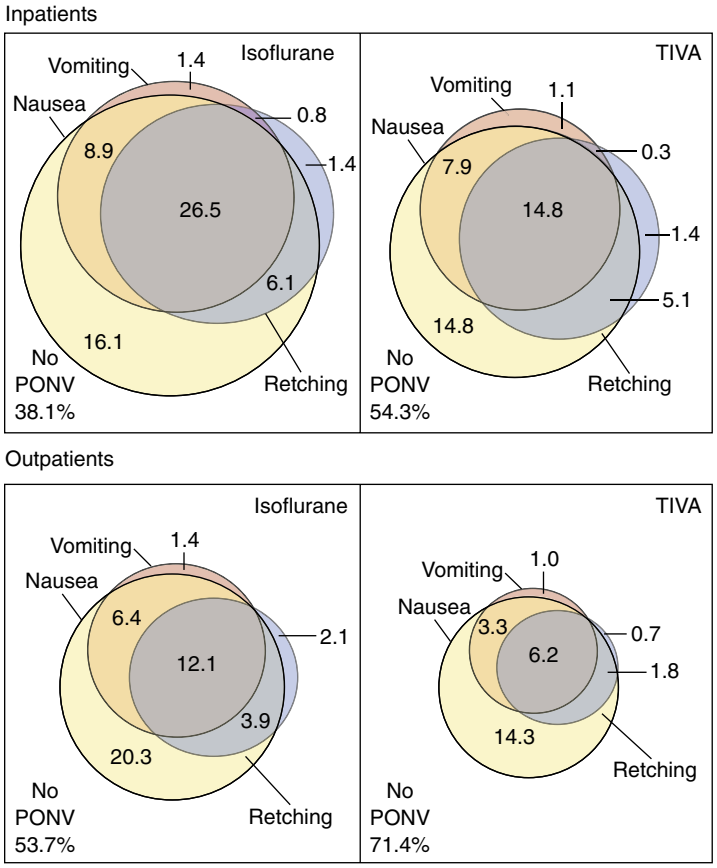


Figure 86-9 Venn diagrams for nausea, vomiting, and retching in patients after general inpatient or outpatient anesthesia with inhalational or propofol anesthesia. (*From Visser K, Hassink EA, Bonsel GJ, et al: Randomized controlled trial of total intravenous anesthesia with propofol versus inhalation anesthesia with isoflurane-nitrous oxide: Postoperative nausea with vomiting and economic analysis. Anesthesiology 95:616-626, 2001.*)

vomits, or more than two vomits" fails to reflect the underlying physiology and presentation of these symptoms and does not allow determination of the proportion of patients experiencing nausea, vomiting, or both.[99]

Nausea (from the Greek *nautia* meaning "seasickness") is often described as a "sensation of unease and discomfort in the stomach with an urge to vomit." Nausea may present at different intensities, may last a variable period of time, and may be waxing and waning (cyclic change of intensity over time). There are three ways to assess the intensity of these symptoms.

The most widely accepted measurement technique for intensity utilizes a Visual Analog Scale (VAS). The VAS consists of a 10-cm horizontal line with the left end corresponding to *no nausea* and the right end corresponding to *worst imaginable nausea.* Patients are asked to choose a point on the line that represents the intensity of their current state. VAS is considered the criterion standard, because its reliability and sensitivity have been well established in pain studies.[100] Another common approach is the use of a written or verbal 11-point numeric rating scale (NRS), with which the patient is asked to rate severity of nausea between 0 and 10, with 0 corresponding to *no symptoms* and 10 corresponding to *worst possible symptoms.* The NRS approach has the advantage of ease of use and maintains a sensitivity similar to the VAS gold standard.[101] The easiest approach appears to be a categorical verbal rating scale (VRS), in which patients describe their symptoms as *none*, *mild*, *moderate,* or *severe*. Unfortunately, even though Boogaerts and colleagues have demonstrated a good correlation between VRS and VAS for nausea,[102] pain studies have found that VRS is not as sensitive as the VAS.[101] All told, the NRS approach may provide the best balance between sensitivity and ease of use.

Usually, the intensity of nausea varies over time so that repeated measurements would be needed for an overall severity assessment. Thus, nausea assessment may not be accurate if the intervals between assessments are considerably longer than the duration of nausea episodes. As a rule of thumb it might thus be advantageous to have patients estimate their *average* and/or *severest* level of nausea, rather than limit the patient to rating the current nausea at the time of questioning. Therefore, assessments of nausea should be performed covering a time *interval* rather than assessing a time *point*.

Vomiting, as a clinical symptom, is the forceful expulsion of gastric contents through the mouth or nose. *Retching* is similar to vomiting with the exception that no gastric content enters the pharynx (dry heaves). An *emetic episode* is often operationally defined as one or more instances of vomiting and/or retching separated by no more than 1 minute of respite. However, for the sake of simplicity and because vomiting is much more frequent than retching, many authors' reports of *vomiting* will include both vomiting and retching. In such instances, use of the term *emetic episode* is preferable. The measurement of vomiting and emetic episodes is simpler than that of nausea, because the former involves a distinctive and recognizable muscular reflex. Severity is therefore best evaluated by number of episodes, and recording of the times of each individual episode allows secondary analysis with regard to the time course.

Because there is no universally accepted standard for how to measure and report nausea and vomiting, publications should at the minimum report separate incidences for nausea and for vomiting, even if the primary outcome is a combined measure such an incidence of PONV. Whenever possible, the frequency and success of rescue treatment should be reported as well, to allow comparison of treatment effects in subsequent meta-analyses.[99] It should also be kept in mind that patients may experience benefit as mild (instead of severe) nausea, and this is not reflected by the crude incidence, a dichotomous outcome. This may also be a reason why a joint severity score that considers the severity of nausea and vomiting may be a valuable adjunct to be reported and analyzed with more statistical power than the binary variables.

Measures of Efficacy and Effectiveness

From an epidemiologic perspective, *efficacy* refers to the impact of an intervention in a clinical trial while *effectiveness* refers to the impact in real world situations. For PONV trials, *efficacy* of a prophylactic strategy is probably best described by the relative risk (a synonym would be the risk ratio [RR]) or the odds ratio (OR) that measures the drug-specific antiemetic potential. In contrast, the *effectiveness* of a prophylactic intervention is probably best measured by the absolute risk difference (ARD; synonym: absolute risk reduction) or number-needed-to-treat (NNT) that describes the actual benefit of that intervention when given to patients of a population with a certain risk for PONV. To fully appreciate the meaning of the different measures of treatment effects described in the literature, it is essential to conceptualize the fundamental differences between measures of *efficacy* and *effectiveness*, that is, relative risk and absolute risk difference. Understanding this difference is key when comparing the efficacy between antiemetic trials and when determining the effectiveness of interventions in specific clinical situations.

Absolute Risk Difference and Number-Needed-to-Treat

When using binary outcomes such as the incidence of PONV, the clinical benefit or *effectiveness* of prophylactically administered antiemetics for an individual (or a population) with a particular underlying risk profile is best described by the absolute risk difference (ARD). For example, when a patient is at very high risk for PONV, say 80%, the use of an antiemetic such as ondansetron may reduce the risk to 60%, that is, the ARD is 20% (Fig. 86-10A). Thus, ondansetron given to 100 individuals with a baseline risk of 80% will prevent PONV in 20% of cases, and therefore 1 of 5 such patients will benefit from the intervention. To put it another way, 5 high-risk patients would need to be treated prophylactically to prevent 1 of those 5 patients from experiencing PONV: the NNT is 5. Thus, the following formula applies:

$$NNT = 1/ARD$$

However, when ondansetron is given for prophylaxis to patients at low risk for PONV, say 10%, the risk will only be reduced to 7.5%; thus the ARD is only 2.5% and the NNT is 40. Thus, ARD and NNT, both measures of *effectiveness,* are critically dependent on the patient's baseline risk. As a corollary, ARD or NNT determined in one study cannot be taken as a measure of *efficacy* for patients in a population with a different (higher or lower) baseline risk. This emphasizes the importance of an objective risk assessment to tailor the use of prophylactic antiemetic treatment to those patients who benefit most.

Relative Risk Reduction and Risk Ratio

The aforementioned examples have one characteristic in common. The use of ondansetron reduced the risk by about a fourth. Thus, in both examples the relative risk reduction (RRR) was 25% and the risk ratio (RR) was 0.75.

$$RR = 1 - RRR$$

The fact that the RR is a relatively robust measure of efficacy for a wide range of baseline event rates has been described in other medical areas[103] but was first described in the field of PONV in the IMPACT (an **I**nternational **M**ulticenter **P**rotocol to assess **A**ntiemetic **C**ombinations in a controlled Clinical **T**rial of factorial design) study.[56,161] In addition, this study demonstrated that the *efficacy* of each of the three antiemetics tested (ondansetron, dexamethasone, and droperidol) was independent of one another and by and large of other risk factors.[56] In other words, RR and RRR were reliable measures for the *efficacy* of prophylactic antiemetics and were independent of the patient's baseline risk.

As a consequence, the *effectiveness* in terms of an absolute risk reduction (ARD) of an antiemetic that can be expected in

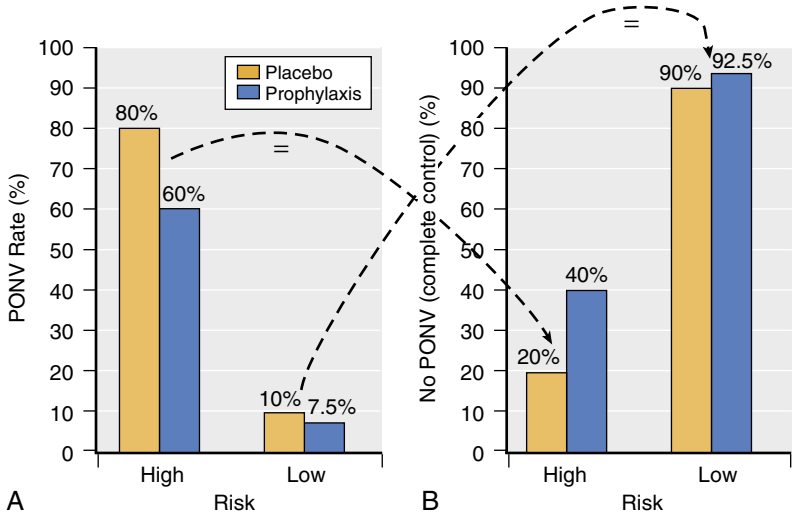

Figure 86-10 **A** and **B,** Relative risks (risk ratios) or relative risk ratios are independent of the patient's baseline risks. Note, that both **A** and **B** represent the same data, yet efficacy of a drug can be judged only from the risk ratio of the events (e.g., PONV) but not from the risk ratio of the absence of events (e.g., no PONV).

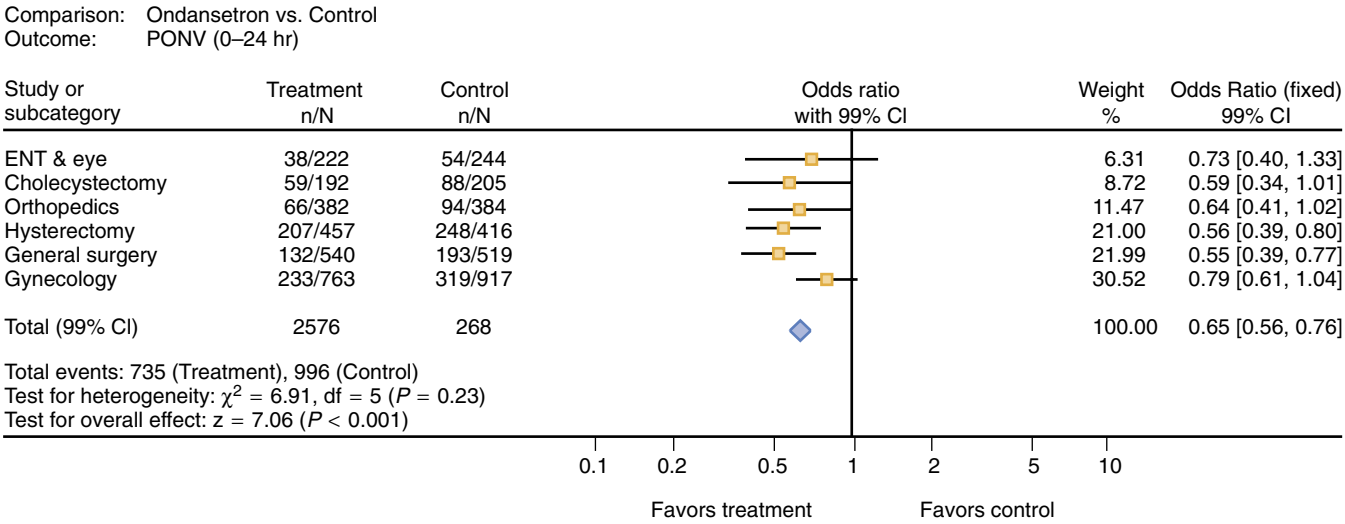

Figure 86-11 Efficacy of ondansetron is independent of the type of surgery. (*Based on data from Apfel CC, Korttila K, Abdalla M, et al: A factorial trial of six interventions for the prevention of postoperative nausea and vomiting. N Engl J Med 350:2441-2451, 2004.*)

clinical practice can be estimated from the baseline risk multiplied by the RRR using the formula:

$$\text{ARD} = \text{baseline risk} \cdot \text{RRR}$$

Alternatively, the remaining risk can be estimated using the formula:

$$\begin{aligned}\text{Remaining risk} &= \text{baseline risk} - \text{ARD}\\ &= \text{baseline risk} \cdot (1 - \text{RRR})\\ &= \text{baseline risk} \cdot \text{RR}\end{aligned}$$

Relative Benefit for Freedom from Symptoms

However, it is important to note that the RRR or RR is only independent of the patient's baseline risk when the outcome is "PONV" but not "no PONV." In the first example (i.e., in the high-risk group), the incidence of no PONV was 20% without prevention and 40% with prevention (see Fig. 86-10B), so that twice as many patients were free of PONV; that is, the relative benefit (RB) for no PONV was 2. However, in the second example (i.e., in the low risk group), the incidence of no PONV was 90% without prevention and 92.5% with prevention; that is, the RB for no PONV was only 1.03 (92.5/90) even though there was a 25% decrease in the incidence of PONV. This demonstrates that the RB for "no PONV" or "freedom from symptoms" is again highly dependent on the patient's baseline risk. Similarly, this applies to complete response (no vomiting and no rescue treatment) or complete control (no nausea, no vomiting, and no rescue treatment). Thus, a ratio cannot be taken as a measure for drug *efficacy* when the reported outcome is a measure of freedom from symptoms such as "no nausea," "no emesis," "complete response," or "complete control." For this reason, future publications should report vomiting or nausea rather than no vomiting or no nausea and compound measures should report PONV or rescue treatment rather than complete response or complete control.

Generalizability of Study Results

As described earlier, the number of patients required to demonstrate antiemetic efficacy of a drug in a clinical trial depends critically on the baseline risk (often described as control event rate). A table for sample size estimations for PONV trials can be found in the article "How to Study Postoperative Nausea and Vomiting."[99] Fewer patients need to be studied when the control event rate is high, that is, when patients at high risk are selected. In addition, patients at high risk are much more likely to benefit from prevention given that their absolute risk difference will be larger. Therefore, most PONV trials specify certain types of surgeries that are assumed to be "high risk procedures." However, as pointed out earlier, patients at risk are more reliably identified by using a simplified risk score.[38]

The other rationale for the selection of just one type of surgery is to increase study strength by minimizing heterogeneity. Although this is a well-recognized approach for any continuous outcome, it does not apply to binary outcomes where the confidence interval is solely a function of the number and proportion of patients.

The third reason why most studies are limited to a certain type of surgery is the notion that type of surgery might play a critical pathophysiologic role for PONV. If that were true, study results for one type of surgery might not be applicable to other surgical populations. Carlisle and Stevenson addressed this question in a subgroup analysis of their meta-analysis but could not find any evidence that the type of surgery affects the efficacy of an antiemetic.[104] One theoretical limitation of their subanalysis is that it is based on "inter-study" comparisons. However, two large sufficiently powered randomized controlled trials were also unable to identify any interaction between antiemetics and type of surgery (Fig. 86-11).[56,76]

In conclusion, currently published data suggest that the efficacy of an antiemetic is independent of the type of surgery. Therefore, the clinician may assume similar antiemetic *efficacy* for

other types of surgeries or similar settings from those in the randomized trials. For the clinical researcher, it would be better to address more novel questions rather than repeating PONV trials that have already been studied in other types of surgeries. As a corollary, it appears that separate meta-analyses on PONV for specific types of surgeries[105,106] are unlikely to advance our knowledge and understanding.

Perioperative Pain Management

Local Anesthesia

Data from multivariable analyses suggest that the main cause of PONV is exposure to emetogenic triggers, namely, inhaled anesthetics and opioids. If both can be avoided, PONV incidence can be expected to be quite infrequent. In fact, a 5-year review of 1264 cases using an opioid-free propofol/ketamine sedation technique for a wide range of ambulatory surgeries under local anesthesia reported only 7 patients (0.6%) with vomiting and 21 patients (2%) requiring postoperative antiemetics.[107] However, the lack of a control group in this study necessitates a cautious interpretation. Nevertheless, this result is in accordance with small-scale, high-quality randomized controlled trials, such as the comparison of anesthetic techniques by White and colleagues.[108] In that study, ilioinguinal-hypogastric nerve block, spinal anesthesia, or general anesthesia (with volatile anesthetics and opioids) was associated with PONV incidences of 7%, 12%, or 62%, respectively.

Regional Anesthesia

Consistent with the low incidence of PONV after primarily regional techniques (with or without sedation) (also see Chapters 51 and 52) are the results of a meta-analysis from Liu and associates that compared single-shot regional anesthesia (peripheral nerve block or central neuraxial blockade) versus general anesthesia as the primary anesthetic technique for ambulatory surgery.[79] Patients who were randomized to receive a peripheral nerve block had a more than fourfold lower incidence of nausea than those receiving a general anesthetic (6.8% versus 30%). The RR was 0.23, which corresponds to an RRR of 77%, an antiemetic efficacy that can only be achieved by a quadruple antiemetic combination (see later).[56]

Similarly, a central neuraxial blockade was also associated with a numerically lower incidence of nausea (5% versus 14.7%), an RR of 0.34, and an RRR of 66%; however, it needs to be noted that this failed statistical significance and that further research is needed to confirm this finding ($P < .06$). Of note, anesthetic solutions for epidural anesthesia often contain opioids to increase the density of the block, which may be the reason why opioid-free paravertebral blocks are associated with a lower incidence of PONV compared with epidural anesthesia.[109]

In this respect, intraoperative nausea and vomiting after spinal anesthesia is different. Two large cohort studies of spinal anesthesia have been conducted[59,60] and identified the following independent predictors for nausea and vomiting in the perioperative period: female gender, history of motion sickness, preoperative tachycardia, preoperative intravenous opioids, intrathecal procaine, use of phenylephrine or epinephrine, and hypotension or high intrathecal block (T4 or higher).

Non-opioid Analgesics

Although individual studies have been able to demonstrate a reduction in pain and/or opioid consumption by NSAIDs (see also Chapter 26), most were unable to demonstrate benefits in their secondary outcomes, such as incidence of PONV. Bonnet's group conducted a quantitative systematic review (of randomized controlled trials), and although there was insufficient evidence to demonstrate a significant reduction of pruritus, urinary retention, or respiratory depression, they were able to demonstrate an RR of 0.7 for PONV, that is, an RRR of 30%.[110] Although the efficacy of NSAIDs is not as high as that of regional anesthetic techniques, they are equal to antiemetics such as 4 mg of ondansetron.

Antiemetics

To date, more than 2000 articles on PONV have been published, with over 200 articles added yearly. Most are reports of randomized controlled trials for the prevention of PONV, yet it is apparent that the elusive "holy grail" of how to prevent PONV has yet to be found.

One reason might be that relatively little effort has been made to understand the causes of PONV. For example, few reviews acknowledge that the strongest known causes of PONV are inhaled anesthetics and opioids and that an opioid-free regional anesthetic technique is probably the most effective way to prevent PONV. However, for a particular patient there may be medical and logistical reasons why a local or regional anesthetic technique may not be practical. Therefore, even though the efficacy of antiemetics is limited, and avoiding the causes for PONV appears to be more effective, antiemetics remain important tools for the prevention of PONV in many other clinical situations.

Meta-analyses

Given the abundance of published PONV studies, it is highly desirable to (1) identify all available evidence and, if possible (2) reconcile controversial results and (3) determine the treatment effect based on the best available evidence. This can be achieved through a systematic review such as a Cochrane review with prespecified study question, inclusion/exclusion criteria, and well-established search algorithms to ensure identification of all relevant papers. Of note, the term *systematic review* characterizes the scientific rigor to identify and consider all available evidence while the term *meta-analysis* characterizes the statistical approach to synthesize the various study results to come up with the most accurate point estimate for the treatment effect. Thus, a systematic review that uses a meta-analysis to quantify the treatment effect is often described as a "quantitative systematic review."

The first systematic review on PONV was by Tramer and associates on the effect of nitrous oxide.[89] Because systematic reviews tend to focus on a well-defined, specific question, dozens of other systematic reviews have been subsequently published requiring reviews on the systematic reviews.[111,112]

Fortunately, Carlisle and Stevenson have created a comprehensive Cochrane review for all drugs that have been studied for the prevention of PONV.[104] The first edition encompasses 737 studies involving 103,237 patients: the largest PONV meta-analysis to date and clearly the most important for clinicians seeking a single reference for drugs that may prevent PONV. In addition, in contrast to many previous systematic reviews that focused on the NNT, that—as described above—is not a useful estimate to characterize the efficacy, the Cochrane review from Carlisle and Stevenson used the RR.

Antiemetics (Table 86-2)

Dopamine Antagonists

Metoclopramide has been used for decades to prevent PONV. Its antiemetic properties are primarily mediated through its antidopaminergic action and it also probably has prokinetic properties.[113] In the past, use of large doses of metoclopramide (e.g., 200 mg every 6 hours) was a mainstay for prevention of chemotherapy-induced nausea and vomiting. These large doses likely have anti-serotoninergic properties.[114] Unfortunately, these large doses cause extrapyramidal side effects in more than 10% of patients, which can be treated with antihistamines and benzodiazepines.[115]

As a result, small doses of metoclopramide (10 mg) became established in clinical practice. However, this amount has been not proven to be clinically effective.[116] Consequently, Wallenborn and associates conducted a large randomized placebo-controlled trial comparing 8 mg dexamethasone alone or combined with either 10, 25, or 50 mg metoclopramide.[117] The risk ratios for the prevention of PONV for these three combinations compared with dexamethasone alone were 0.89, 0.74, and 0.63, respectively. Thus, the efficacy of 25- or 50-mg doses seems to be comparable to that of other well-established antiemetics. Efficacy needs to be balanced against the potential side effects (the most frequent ones were treatable hypotension and tachycardia) and the incidence of dyskinetic and/or extrapyramidal symptoms, which were 0.1%, 0.4%, 0.8%, and 0.8% in those four groups. Of note, in children undergoing tonsillectomies a moderate dose of 0.5 mg/kg of metoclopramide was not equivalent to 0.1 mg/kg of ondansetron.[118]

Droperidol is a highly potent D_2-antagonist with well-proven antiemetic properties at intravenous doses as small as 0.625 to 1.25 mg[104,119,120] and an overall RR of 0.65, 0.65, and 0.62 for nausea, vomiting, and PONV, respectively.[104] Furthermore, it is similarly effective compared with ondansetron,[56,121] with an RR for PONV of 0.99.[104] Compared with placebo, droperidol is associated with increased sedation (RR, 1.32) but with a decreased incidence of headache (RR, 0.79).[104] Although droperidol has been investigated in over 200 papers, its minimal effective dose and optimal time of administration have not yet been established. Because of its relatively short plasma half-life of about 3 hours, it should be given at the end of surgery and at the lowest effective dose of 0.625 mg to minimize potential sedative side effects. For the same pharmacokinetic reason, the supplementation of a morphine-loaded PCA pump with droperidol appears to be a highly effective approach to reduce opioid-induced nausea and vomiting. In a dose response study by Tramer and colleagues, adding 5, 15, or 50 μg to 1 mg of morphine led to an RR of 0.88, 0.63, and 0.44.[122] Although 50 μg of droperidol per milligram of morphine appears to be the most effective dose, it was associated with sedative side effects, so the authors concluded that a dose of 25 μg droperidol per milligram of morphine was optimal.

Low-dose droperidol has also been reported to lead anxiety and restlessness,[123] akathisia,[124] and dystonia.[125] However, data are conflicting.[126] In addition, the U.S. Food and Drug Administration (FDA) has received reports of severe arrhythmias (torsades de pointes) and deaths in association with the use of low-dose droperidol, leading to the following black box warning:

> Droperidol is contraindicated in patients with known or suspected QT prolongation, including patients with congenital long QT syndrome. In patients who fail to show an acceptable response to other adequate treatment, a 12-lead ECG must confirm the absence of QT prolongation (440 ms for males, 450 ms for females) prior to administration of droperidol, and ECG monitoring should be continued for 2-3 hours after drug administration. Also, it should be administered with extreme caution to patients who may be at risk for the development of a prolonged QT syndrome, such as in patients with electrolyte disturbances or those receiving volatile anesthetics and IV opioids.

The FDA black box warning for droperidol has created controversy among physicians who continue to see a value in its low-dose use for PONV prevention. According to the study from White and associates, general anesthesia itself leads to a QT prolongation from about 400 to 430 msec and the mean maximal QT prolongations when placebo, 0.625 mg, or 1.25 mg droperidol was administered during anesthesia were 12, 15, and 22 msec.[127] Of note, the anesthetic had a much stronger overall effect on the average QTc interval compared with droperidol and was associated with considerably more interindividual variability. On the other hand, one instance of QT prolongation of 133 msec was observed in a single patient who received 1.25 mg of droperidol. Charbit and colleagues investigated the effect of 0.75 mg of droperidol or 4 mg of ondansetron on the QTc interval when given as rescue treatment in the PACU.[128] Over 40% of patients had a prolonged QTc interval after anesthesia, and the mean maximal additional QTc prolongation was 17 msec after droperidol and 20 msec after ondansetron (Fig. 86-12). This raises a question about the clinical relevance of QT prolongation. In general, the Committee for Proprietary Medicinal Products in the United Kingdom considers QT prolongation less than 30 msec unlikely to be clinically relevant. Furthermore, based on data from patients with congenital prolonged QT syndrome, a prolongation of 10 msec corresponds to a hazard ratio of 1.056, which translates to an 18% increased risk (RR, 1.18) with 30 msec but doubles the risk (RR, 2.06) at 133 msec.[129] Based on these data, the risk of droperidol for healthy patients with a normal electrocardiogram appears to be negligible. It is, however, difficult to exclude the possibility that the addition of droperidol in a clinical context of an unrecognized conduction abnormality alongside other QTc-prolonging drugs may be the trigger of a clinically relevant QT prolongation leading to torsades de pointes.[130]

Because of the droperidol black box warning, haloperidol has garnered more interest, with recent studies showing an efficacy similar to ondansetron.[131,132] However, cardiac arrhythmias and death associated with haloperidol have also been reported to health agencies so that the FDA has issued an alert that it is only approved for the intramuscular route and that intravenous injection is off-label use.

Alizapride, perphenazine, (Decentan, Trilafon) and prochlorperazine (Compazine) (the latter two are highly potent neuroleptics) are less frequently used dopamine antagonists that have further mechanism of actions. Although their efficacy appears comparable to that of other antiemetics these drugs have not been studied extensively so that the limited number of patients provides insufficient power to detect all treatment effects.[104] A main reason for their rather infrequent use may be sedative side effects that can delay recovery.

Table 86-2 Mechanisms, Doses, and Measures of Efficacy of all Investigated Antiemetics with Statistically Significant Outcome

Antiemetic (U.S. Trade Name)	Primary (Other) Actions, Mechanisms	Frequently Studied Adult Doses, Given Intravenously Unless Noted Otherwise	Risk Ratio (RR) Compared with Placebo That Met Statistical Significance			Evidence Comment
			Nausea	Vomiting	PONV	
Metoclopramide (Reglan)	D_2, prokinetic, (5-HT_3)	10 or 20 mg	0.82	0.76	0.76	
		10 mg		0.80	0.78	SR[116]
		25 mg	0.75	0.71	0.74	Large RCT[117]
		50 mg	0.57	0.60	0.63	Large RCT[117]
Droperidol (Inapsine)	D_2 (α_1)	0.625-1.25 mg	0.65	0.65	0.62	Sedation RR = 1.32, decreased headache RR = 0.79, FDA black box warning
Haloperidol (Haldol)	$D_{2,3,4}$ (D_1), 5-HT_2	0.5 mg IM, 1 mg	0.48	0.23, 0.38		[195,196] FDA safety alert
Alizapride (Vergentan)	D_2, prokinetic	50-200 mg	0.65	0.49		No evidence for dose-response
Perphenazine (Trilafon)	D_2, (D_1), H_1, 5-HT_2	2.5-5 mg IM or IV		0.70		
Prochlorperazine (Compazine)	D_2 (M, α_1, H_1)	6.25-12.5 mg IM or IV or 3-6 mg buccal	0.73	0.68	0.68	
Dimenhydrinate (Dramamine) or Diphenhydramine (Benadryl)	H_1 (M)	31.25-62.5 mg IV, 50-mg suppository		0.61	0.71	Drowsiness RR = 9.0
Cyclizine (Marezine)	H_1 (M)	50 mg IV or IM	0.67	0.55	0.67	
Promethazine (Phenergan)	H_1 (M)	12.5-25 mg or 12.5-50 mg IM			0.46	Risk of vascular necrosis
Hyoscine (Scopoderm)	M	1.5-mg patch	0.63	0.65	0.71	Dry mouth RR = 1.25
			0.49	0.43	0.46	SR of small trials[135]
			0.71	0.68	0.78	SR of large trials[135]
Ondansetron (Zofran)	5-HT_3	4 mg	0.68	0.54	0.56	Headache RR = 1.16. Preferably at the end of surgery
Dolasetron (Anzemet)	5-HT_3	12.5-50 mg	0.82	0.62	0.72	Arrhythmia warning (Canada)
Granisetron (Kytril)	5-HT_3	1 mg	0.67	0.42	0.56	Data from one center excluded[146]
Tropisetron (Navoban)	5-HT_3	All doses	0.77	0.60	0.72	Decreased dizziness RR = 0.37
		2 mg	0.75	0.67	0.71	SR[197]
		5 mg	0.69	0.56	0.69	SR[197]
Diazepam, Lorazepam (Ativan)	$GABA_A$, modulation	10 mg PO, 2-2.5 mg PO	0.50, 0.55			
Midazolam (Versed)	$GABA_A$, modulation	2-5 mg IV, 7.5-15 mg PO		0.73		
Dexamethasone (Decadron)	Unknown	4-8 mg	0.58	0.51	0.48	Slow onset, preferably after induction
Aprepitant	NK_1	40-mg PO capsule				Active control with ondansetron: Similarly effective against nausea but significantly more effective against vomiting: RR = 0.38 (0.13-0.64),[158] 0.55 (0.32-0.79)[159]

RCT, randomized controlled trial; SR, systematic review.
Data are primarily based on the Cochrane Review from Carlisle and Stevenson[104] unless indicated otherwise. Original papers are quoted if data are based on ≤3 RCTs or if a more specific meta-analysis was believed to provide more detailed information. Efficacy fields were left blank if data were not available or did not meet statistical significance.

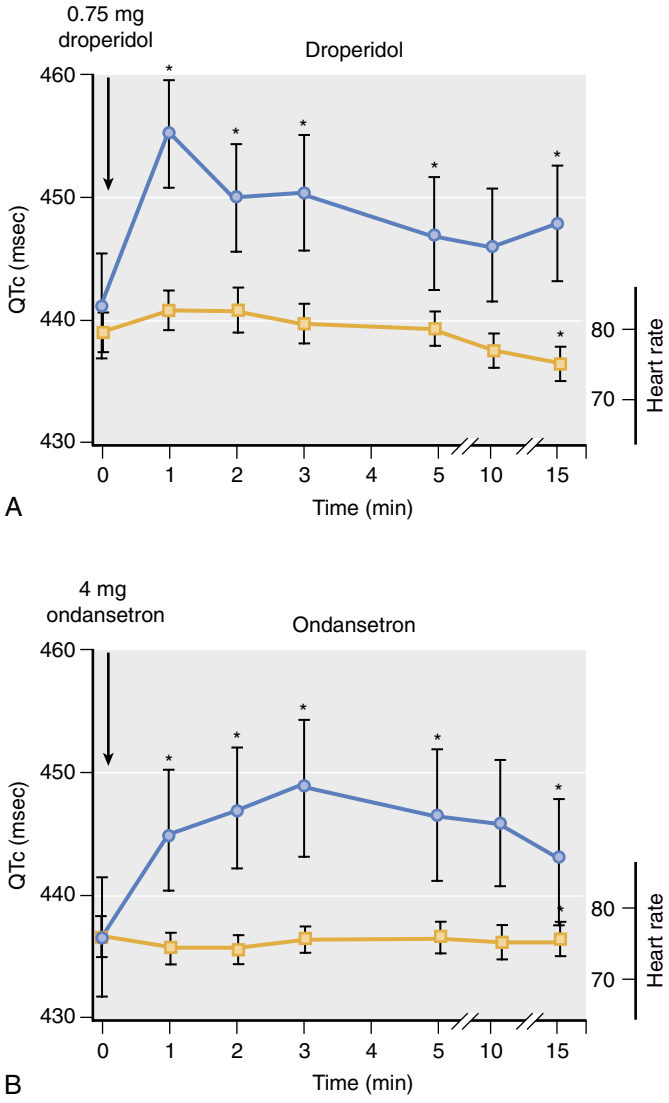

Figure 86-12 Prolongation of QTc interval after postoperative nausea and vomiting treatment by droperidol or ondansetron. (*From Charbit B, Albaladejo P, Funck-Brentano C, et al: Prolongation of QTc interval after postoperative nausea and vomiting treatment by droperidol or ondansetron. Anesthesiology 102:1094-1100, 2005.*)

Histamine Antagonists

Diphenhydramine (Benadryl) and dimenhydrinate (an aminophylline salt of diphenhydramine) are histamine (H_1)-receptor antagonists known for their effectiveness against motion sickness and relatively weak anticholinergic (antimuscarinic) activities (see Table 86-2).[104,133] Cyclizine (Marezine) and promethazine (Atosil, Phenergan) seem to have equal antihistaminic and anticholinergic properties, which poses a contraindication for patients with glaucoma and prostate hypertrophy. All relatively nonspecific histamine receptor antagonists have sedative side effects that may delay recovery when given immediately before the end of anesthesia. Diphenhydramine, cyclizine, and promethazine are effective for the prevention of PONV, with RRs of 0.71, 0.67, and 0.46, respectively.[104] Side effects include drowsiness (RR, 9.0)[104] but also urinary retention, dry mouth, blurred vision, and extrapyramidal symptoms reported too infrequently to draw conclusions.[104,133] Promethazine has also been reported to cause vascular necrosis requiring plastic surgery of skin lesions and/or limb amputations, leading to the FDA safety alert in 2006.

Anticholinergics

Data on the potential antiemetic properties of atropine are conflicting. For example, when coadministered with neostigmine to reverse neuromuscular blockade, atropine was associated with less postoperative vomiting compared with glycopyrrolate.[47,104] One plausible explanation is that atropine, unlike glycopyrrolate, crosses the blood-brain barrier. However, comparisons of atropine versus placebo have been negative,[104] perhaps owing to the drug's short half-life. Scopolamine is another central-acting anticholinergic (antimuscarinergic) that, like atropine, has a relatively short half-life. This limitation is overcome by a transdermal formulation that allows a more favorable pharmacokinetic profile to cover up to 72 hours. Its antiemetic properties are well established for the prevention of motion-induced nausea and vomiting,[134] and the scopolamine patch has also been shown effective for the prevention of PONV, with RRs of 0.63 and 0.65, respectively.[104] Its long duration of action might be especially useful for the prevention of postdischarge nausea and vomiting in ambulatory patients; however, scopolamine is associated with an increased incidence of side effects, such as blurred vision (18%), dry mouth (8%), dizziness (2%), and agitation (1%).[135]

Serotonin Antagonists

Ondansetron was the first serotonin antagonist, and its introduction was a milestone in the prevention of early chemotherapy-induced nausea and vomiting. It was considerably more effective and had fewer side effects (no extrapyramidal symptoms or sedation) compared with all previous antiemetics. Given its superior efficacy for chemotherapy-induced nausea and vomiting, it is not surprising that ondansetron quickly established a reputation as the most effective antiemetic for prevention of PONV. This perception was further nurtured by duplicate publication of positive studies that, according to analyses by Tramer and coworkers, would lead to a 23% overestimation of ondansetron's effectiveness if included in a meta-analysis.[136] In fact, according to the meta-analysis from Carlisle and colleagues the risk reduction for nausea and vomiting are 0.68 and 0.54.[104] This is comparable to the efficacy determined in meta-analyses of other antiemetics such as dexamethasone or droperidol (note that the results from meta-analyses tend to be more positive than subsequent large studies due to publication bias). For example, in IMPACT (a large multicenter randomized controlled factorial-design trial), 4 mg of ondansetron, 4 mg of dexamethasone, and 1.25 mg of droperidol had risk ratios of 0.76, 0.76, and 0.74. That is, each drug led to an RRR of about 25%.[56] Of note, ondansetron has a plasma half-life of 4 hours and is metabolized via CYP2D6 such that select genetic polymorphisms of the P450 enzyme can lead to decreased efficacy due to ultrarapid metabolism.[137] These polymorphisms may also be the reason why ondansetron appears to be more effective when given at the end of surgery rather than immediately after induction of anesthesia.[138,139]

Dolasetron mesylate, and its liver-converted active metabolite hydro-dolasetron, are other highly specific $5HT_3$ antagonists

with plasma half-lives roughly twice as long as ondansetron. In general, all highly selective serotonin antagonists are considered to be equally effective when given at equipotent doses. For ondansetron, 4 mg is well documented to be the minimal effective dose (the minimal dose where any further increase fails to produce additional clinically relevant benefit). For dolasetron, the data from Korttila and associates suggest that 50 mg is superior to 25 mg and equivalent to 4 mg of ondansetron.[140] However, this contrasts to a pooled analysis of three trials by Philip and coworkers that suggests that 12.5 mg is the minimum effective dose, which is the dose approved by the FDA for the prevention of PONV.[141]

Granisetron is another highly specific $5HT_3$ antagonist, with a half-life that is about twice as long as that of ondansetron. The FDA-approved dose for the prevention of PONV is 1 mg. This is based on a dose range study from Wilson and associates in which 0.1, 1.0, and 3.0 mg were associated with risk ratios for postoperative vomiting of 0.94 (not significant), 0.56, and 0.66.[142] A second dose-response study investigated the efficacy of 2, 5, 10, and 20 μg/kg and found that 5 μg/kg appears to be the minimal effective dose, which corresponds to roughly 0.35 mg for a 70-kg adult patient.[143] Despite results from these relatively large randomized controlled trials, some recent studies have reexplored the possibility that doses as low as 0.1 mg are effective for the prevention of PONV. One study compared 0.1, 0.2, and 0.3 mg with placebo in patients undergoing abdominal hysterectomies.[144] Although all three doses were associated with less vomiting within the first 6 hours, no significant difference could be demonstrated over 24 hours. Another study compared the combination of 8 mg of dexamethasone plus either 0.1 mg of granisetron or 4 mg of ondansetron in laparoscopy patients.[145] However, that study was not sufficiently powered to demonstrate a statistically significant difference for the main outcome, that is, vomiting in the first 2 postoperative hours, which was 6% in the granisetron group and 3% in the ondansetron group. Of note, the majority of studies on granisetron suggest that 3 mg is superior to 1 mg for prevention of PONV, but those were published by a single center[146] and there have been serious concerns about the validity of the data.[147] The current evidence suggests that the FDA approved dose of 1 mg—but not 0.1 mg—is an effective does for the prevention of PONV.

Whereas all serotonin antagonists have generally been considered to be similarly effective, palonosetron might be an exception, not only because of the long half-life of about 40 hours but also because it seems to be able to prevent delayed chemotherapy-induced nausea and vomiting for which serotonin antagonists are usually not effective. Whether this will translate into higher efficacy for the prevention of PONV, and perhaps postdischarge nausea and vomiting, has yet to be shown.

Dexamethasone

Dexamethasone is well documented as an effective antiemetic,[56,104] and animal experiments suggest that it exerts its antiemetic effects through central inhibition of the nucleus tractus solitarii but not the area postrema.[148] Most early studies were conducted with 8 to 10 mg of dexamethasone,[120,149] but there is now convincing evidence from several smaller dose-response trials that 2.5 to 5 mg can be considered the minimum effective dose.[150-152] Dexamethasone has a slow onset of action, which might be the reason why its application at the beginning of a case appears to be superior to later use.[153] According to Carlisle and Stevenson, the RR of dexamethasone is 0.58 for nausea and 0.51 for vomiting[104] and direct head-to-head comparisons suggest its efficacy is similar to that of ondansetron or droperidol.[56,104]

Neurokinin-Antagonists

Substance P is a regulatory peptide that binds to neurokinin-1 (NK1) receptors found in vagal afferents in the gastrointestinal tract. More importantly, in the 1950s it was shown to reside in areas of the central nervous system that are thought to be involved in the vomiting reflex.[154] Nevertheless, it took over 40 years before it became apparent that NK1 antagonists could be highly effective against a wide range of emetic stimuli in animal studies.[155] A few years later, Diemunsch and colleagues showed the clinical feasibility for control of established PONV after major gynecologic surgery in a pilot study with the NK1 antagonist GR205171.[156] This was followed by a multicenter study by White's group with CP-122,721.[157] In that study, 200 mg reduced the incidence of postoperative emesis from 50% to 10%, which corresponds to an RR of 0.2 and an RRR of 80%, significantly more effective against vomiting than all other previous antiemetics. The strong antiemetic property of NK1 receptor antagonists is confirmed by studies of aprepitant, the first drug in its class approved for clinical use by the FDA. In a three-arm multicenter study, 4 mg of ondansetron, given intravenously, was compared with 40 mg and 125 mg of orally administered aprepitant.[158] Although the incidence of nausea was similar between the groups, the incidences for vomiting were 26%, 10%, and 5%, respectively. Considering that ondansetron reduces the risk for vomiting by about 26%,[56] if a placebo group had been included in this study, the incidence in the placebo group would likely have been in the range 35%. In that case, the RRs for 40 and 125 mg of aprepitant would have been in the range of 0.3 and 0.15 compared with placebo, that is, an RRR in the range of 70% or 85%, again clearly more effective than other antiemetics. A similar international trial (again without a placebo control group) yielded similar (though less striking)

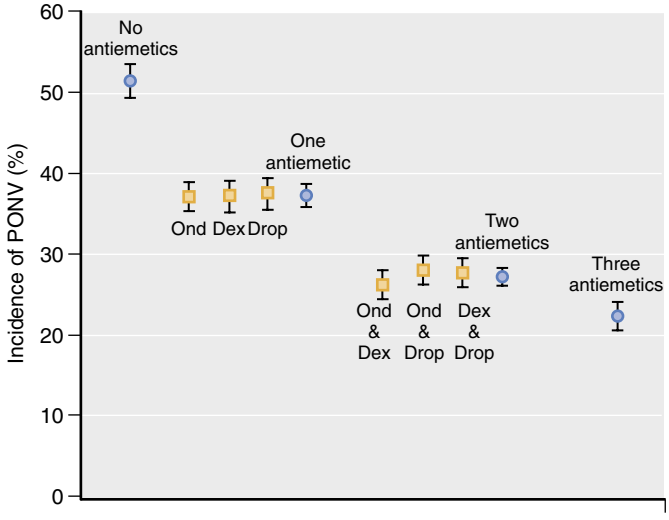

Figure 86-13 Reduction of PONV with ondansetron, dexamethasone, and droperidol when given alone or in combination. (*From Apfel CC, Korttila K, Abdalla M, et al: A factorial trial of six interventions for the prevention of postoperative nausea and vomiting. N Engl J Med 350:2441-2451, 2004.*)

results for aprepitant.[159] In that study, the incidence of vomiting for 4 mg of ondansetron given intravenously, 40 mg of aprepitant, and 125 mg of aprepitant orally were 29%, 16%, and 14%. For the prevention of PONV, 40 mg of aprepitant is the dose approved by the FDA. In the future, it is likely we will see other NK1 receptor antagonists on the market, such as casopitant and rolapitant. However, it should be noted that although NK1 receptor antagonists appear to be superior for prevention of vomiting this may not be true for the prevention of nausea. And because novel drugs are inherently more expensive than generics, it is likely that the use of these drugs will focus on patients at high risk for PONV. Nevertheless, their excellent antiemetic profiles make NK1 antagonists ideal drugs to reduce the medical risk that may be associate with vomiting after certain procedures (e.g., wired jaw, neurosurgical procedures, and upper gastrointestinal surgery).

Combinations and Multimodal Therapy

None of the currently available antiemetics is capable of completely eliminating the incidence of PONV. In fact, according to the meta-analysis from Carlisle and Stevenson, the overall RR for FDA-approved "effective" antiemetics is 0.65, that is, the RRR is 35%.[104] Considering that smaller studies tend to be more often published if they are positive (publication bias), the "true" RRR is likely to be smaller than 35%. In fact, in a large multicenter trial, the RRs for ondansetron, dexamethasone, and droperidol were in the range of 0.75; that is, the RRR was 25% rather than 35%.[56]

Given the limited antiemetic efficacy of prophylactic antiemetics, Scuderi and coworkers were the first to investigate a multimodal approach.[160] In patients undergoing outpatient laparoscopy, they studied a combination antiemetic regimen (group I, n = 60) that consisted of both preoperative interventions (10-30 µg/kg midazolam for anxiolysis, 10 mL/kg crystalloid fluid administration) and intraoperative interventions (0.625 mg of droperidol, 10 mg of dexamethasone, induction and maintenance with remifentanil/propofol, gastric decompression, 30 mg of ketorolac, 1 mg of ondansetron at the end of surgery, and 25 µg of fentanyl 10 minutes before end of surgery). Patients in groups II and III received balanced anesthesia with sevoflurane/nitrous oxide/fentanyl with (n = 42) or without (n = 37) 4 mg of ondansetron. With the multimodal group I regimen, no patients vomited and only 1 of 60 patients (1.7%) experienced nausea before discharge from the hospital. In contrast, 10 patients in group II (24%), and 15 in group III (42%) experienced nausea. Although this study demonstrated an impressive reduction in PONV, the study design could not identify to what extent each individual intervention contributed to the reduction in PONV. Furthermore, it was unclear what interactions might exist among the various antiemetic interventions, for example, whether there is a certain synergistic combination that contributes the most to these positive results.

Inspired by this, IMPACT, "an **I**nternational **M**ulticenter **P**rotocol to assess **A**ntiemetic **C**ombinations in a controlled clinical **T**rial of factorial design (IMPACT) was developed.[56,161] In this trial, 4123 patients were randomly assigned to 1 of 64 possible combinations of six prophylactic interventions: 4 mg of ondansetron or no ondansetron; 4 mg of dexamethasone or no dexamethasone; 1.25 mg of droperidol or no droperidol; propofol or a volatile anesthetic; nitrogen or nitrous oxide; and remifentanil or fentanyl. Ondansetron, dexamethasone, and droperidol each reduced the risk of PONV by about 26% (RR, 0.74).[56] Propofol reduced the risk by 19%, and nitrogen, by 12%; the combined RRR of propofol with no nitrous oxide (i.e., total intravenous anesthesia) was thus similar to that observed with each individual antiemetic. This study provided two major insights. First, it was demonstrated that all interventions acted independently of each other; therefore, the RRs associated with combined antiemetic interventions can be estimated by multiplying the relative risks associated with each intervention. For example, the RR for a triple combination of ondansetron plus dexamethasone plus droperidol is $0.74 \times 0.74 \times 0.74 = 0.41$; that is, the application of three antiemetics that each reduce the risk by about a fourth will result in an RRR of $1 - 0.41 = 59\%$. Figure 86-13 demonstrates that all three antiemetics are similarly effective, and all three double combinations are similarly effective because there are no interactions. Second, it was demonstrated that the efficacy of the drugs as measured by the OR or RR is independent of the patient's risk. As a consequence, the effectiveness (in terms of absolute risk difference or NNT) is primarily dependent on the patient's baseline risk rather than the choice of antiemetic, and each addition of an antiemetic to a combination regimen adds less and less additional benefit as the patient's risk decreases. As an example, a female nonsmoker without a history of PONV or motion sickness expected to require postoperative opioids has a PONV risk of about 60%.[5] If she receives an antiemetic (e.g., 4 mg of dexamethasone), her risk will decrease to 44% (Table 86-3, $0.6 \times 0.74 = 0.44$), which means that the absolute risk difference will be 16%.

$$\begin{aligned} \text{RRR} &= 1 - \text{RR} \\ \text{Absolute risk difference} &= \text{Patient's risk} \times \text{RRR} \\ &= \text{Patient's risk} \times (1 - \text{RR}) \end{aligned}$$

If she receives a triple antiemetic therapy, her risk will decrease to about 24%, and a fourth antiemetic would reduce the risk to 18% (see Table 86-3). Adding a fourth antiemetic would thus result in an absolute risk difference of only 6%, that is, less than half as much reduction as for the first antiemetic. Apparently, the first antiemetic has the greatest effectiveness and additional prophylactic antiemetics are associated with a decreased effectiveness because of the already decreased baseline risk. Another example

Table 86-3 Estimated PONV Incidence as a Function of Baseline Risk, Assuming Each Intervention Reduces Relative Risk by 26% (values given as %)

Number of Interventions				
None*	One	Two	Three	Four
10	7	5	4	3
20	15	11	8	6
40	29	22	16	12
60	44	33	24	18
80	59	44	32	24

*The exemplified baseline risk levels of 10%, 20%, 40%, 60%, and 80% reflect 0, 1, 2, 3, and 4 risk factors considered in a simplified risk score.[5]
Table from Apfel CC, Korttila K, Abdalla M, et al: A factorial trial of six interventions for the prevention of postoperative nausea and vomiting. N Engl J Med 350:2441-2451, 2004.

would be a male smoker with a short procedure that will not require postoperative opioids who will start off with a risk of about 10%.[5] Even the first antiemetic will at best reduce the risk by no more than 3% (see Table 86-3). The key message here is that the patient's baseline risk is the main determinant of the effectiveness of antiemetic interventions, so prophylaxis is rarely justified in patients at low risk, a single antiemetic is likely to be reasonable for patients with a moderate risk, and patients at high risk are likely to benefit from combination treatment.[56]

Alternative or Adjuvant Approaches

Ginger is frequently assumed to have antiemetic properties, even though there are few studies, most of which are negative, and meta-analyses came to conflicting conclusions.[162-164] However, based on data from a comprehensive review from Carlisle and Stevenson, there appears to be a lack of evidence for ginger to be an effective intervention for the prevention of PONV.[104]

Liberal crystalloid fluid supplementation was first described to reduce nausea by Chung's group.[165] However, it is interesting that there appears to be little effect in the early postoperative period[166,167] while the effect becomes stronger in the late period.[165,168] One could speculate that balancing out the preoperative fluid deficit reduces the need to drink larger amounts in the later postoperative period, thereby reducing PONV. Future studies may lend clarity.

Various reports have investigated stimulation of the classic acupuncture P6 point (the 6th point on the pericardial meridian at the volar side of the wrist) for the prevention of PONV.[169-173] A Cochrane review by Lee and associates in 2004 identified 26 trials and found RRs of 0.72 for nausea and 0.71 for vomiting compared with sham.[174] As shown by White and associates, this effect is comparable to that of conventional antiemetics.[175] These positive results bring up the question of why P6 stimulation is only rarely used for the prevention of PONV. Because most studies were small, Lee and colleagues conducted a secondary simulation analysis that suggested that the effect for nausea, but not for vomiting, may be due to publication bias.[176] Based on the published evidence it appears that stimulation of the P6 wrist point by means of acupuncture, electro-acupuncture, transcutaneous nerve stimulation, laser stimulation, acu-stimulation device, and acupressure are effective measures for the prevention of PONV.

Special Settings

Pediatric Anesthesia (See Also Chapter 82)

Fewer studies have been conducted in children, and these generally focus on postoperative vomiting (POV) because the assessment of nausea can be difficult in younger children.[177,178] A limited number of studies have investigated risk factors,[179] but only one well-designed multicenter prospective survey developed a predictive model for POV (see also section "Risk Assessment").[69] Of note, while the impact of the type of surgery remains somewhat controversial in adults, strabismus surgery and especially myopexy (Faden surgery)[96,180] appear to be independent predictors for POV in children as determined by Eberhart and colleagues.[69] At the same time, against widely held belief, there is little evidence to suggest that ENT surgeries or appendectomies are independent predictors for POV.

Regarding antiemetics, it appears that efficacy is comparable to that known for adults. There are few thoroughly conducted dose response studies for antiemetics in adults and even fewer in children. Thus, most pediatric doses are arbitrarily set at about 1/50th to 1/25th of the common adult per kilogram dose.

Postdischarge Nausea and Vomiting

In the United States, more than 60% of surgeries are now performed on an outpatient basis (ambulatory surgery). In addition to being a major cause for delayed discharge and unanticipated readmissions, PONV may also pose a significant problem to the patient after discharge (see also Chapter 78).[181,182] To date, the incidence of postdischarge nausea and vomiting has not been studied on a large scale but a systematic review from Wu and colleagues suggest it to be 8% for emesis and 17% for nausea[183]; moreover, Carroll and colleagues found that 35% of patients were significantly distressed by postdischarge nausea and vomiting such that it delayed resumption of their normal daily activities.[184] Most patients await spontaneous resolution of symptoms without contacting health care professionals for interventions or antiemetics. Thus, the magnitude of the problem has not been fully recognized as yet and studies are ongoing to characterize patients at risk.

Interestingly, the RRR of antiemetics seems to be similar for postdischarge nausea and vomiting as for PONV. For example, according to a systematic review from Gupta and colleagues, the RR for postdischarge nausea is 0.77 for 4 mg of ondansetron, 0.68 for more than 1 mg of droperidol, and 0.55 for dexamethasone.[185] Note that shorter-acting drugs are not as effective, especially when used at the minimally effective dose, and that antiemetics with a longer duration of action appear favorable. Therefore, dexamethasone, scopolamine (due to the sustained release of the patch), palonosetron, and the NK1-receptor antagonists may be reasonable first choices for the prevention of postdischarge nausea and vomiting. Of course, further studies, especially with the novel compounds, are needed to support this hypothesis.

Rescue Treatment

While numerous studies have investigated antiemetics for prevention of PONV, relatively few have addressed their use for rescue treatment of established PONV. In fact, when Tramer and coworkers conducted a quantitative systematic review of rescue treatments for established nausea and vomiting, a total of only 18 randomized placebo-controlled trials met inclusion criteria.[186] They reported an absolute risk reduction between 20% and 30%, consistent with the 20% to 30% RRR known for prevention of PONV in large trials[56] (of note, in studies of rescue treatment, absolute risk reduction and RRR are equivalent measures because all patients who receive treatment have prior symptoms). In fact, Scuderi and colleagues demonstrated that early rescue treatment of PONV results in outcomes including time to discharge, unanticipated admission, and time to return to normal daily activities that are similar to those achieved with routine prophylactic treatment.[97] This finding does not, however, account for patient

comfort even thought this might be difficult to measure in terms of patient satisfaction.

With regard to dosage, early rescue treatment with 1 mg of ondansetron seems to have comparable efficacy and better effectiveness than 4 mg of prophylactic ondansetron.[187,188] Thus only a quarter dose is needed for rescue as opposed to preventive treatment.

Serotonin antagonists are not only the most commonly used antiemetics for prevention but also the most commonly used antiemetics for rescue treatment.[189] One reason may be that serotonin antagonists are currently the only class of intravenously available antiemetics that may have a rapid onset for rescue treatment while being without sedative side effects. As mentioned previously, serotonin antagonists are highly selective and tend to block almost all available receptors. Thus, one can predict that once ondansetron is used for prophylaxis, subsequent use for rescue treatment in the PACU would be ineffective. This has been confirmed by a well-powered study with 428 patients from Kovac and coworkers.[190] Nevertheless, ondansetron is still commonly used as first-line rescue treatment after previous prophylaxis, even though this is contrary to both theoretical considerations and available evidence. Similarly, one would predict that use of rescue granisetron, another serotonin antagonist, would be ineffective in patients who previously received ondansetron for PONV prevention, as has been shown by Candiotti and colleagues.[191] Therefore, as a rule of thumb, it is currently assumed that after administering an antiemetic it is most effective to choose an antiemetic of another class for later rescue treatment. This is corroborated by a secondary analysis from Habib and associates that shows that after prophylaxis with either ondansetron and droperidol, promethazine rescue treatment is significantly more effective than repeat dosing with the same agent.[192]

Dexamethasone has been shown to be as effective as ondansetron for the prevention of PONV.[56] Clinically, it appears to have a fairly slow onset, as supported by observations that it has better efficacy when given at the beginning rather than at the end of the procedure.[153] Nevertheless, Rusch and associates were able to show that adding dexamethasone to either ondansetron or haloperidol for rescue treatment increases the overall RRR during a 24-hour period.[193]

In conclusion, drugs for rescue treatment appear to have the same efficacy and thus, better effectiveness compared with when they are given for prevention. In addition, lower doses are needed for rescue treatment than for prevention and it is preferable to administer drugs that have not been used previously.

A Rational Guideline for the Management of PONV

The wealth of published information poses a challenge for the anesthesia provider to develop a comprehensive and valid strategy for the prevention and treatment of PONV. To this end, consensus guidelines have been developed. However, the fact that a group of individuals agree or compromise on a certain content or wording does not guarantee infallibility. For example, some guidelines report the NNT for various interventions as if this would allow a comparison of drug efficacy among trials even though that would methodologically not be sound (see earlier section to appreciate the difference between efficacy and effectiveness).

Therefore, instead of summarizing various consensus guidelines, this last section describes a rational approach for the prevention and treatment of PONV that is based on the current knowledge and understanding outlined in this chapter. This should be taken as a guide for clinicians but not as a rigid rule because there are certainly a number of other similarly valid approaches. To this end, the rule of three would be helpful: (1) assess the need for prevention, (2) titrate preventive measures (that includes a modification of the anesthetic technique) according to the patient's need, and (3) follow up on your patient and use rescue treatment immediately by targeting mechanisms that have not been tried before.

Consider the Importance of the Prevention of PONV

This is influenced by the patient's risk for PONV, the potential medical problem associated with it, and the perspective and values of both the patient and the health care provider. It is advisable to estimate the patient's risk using a risk score, that is the score from Apfel and associates or Koivuranta and colleagues for adults and the score from Eberhart and coworkers for children.[4,5,69] Even though these scores are far from being perfect, they provide a better prediction compared with the history of PONV or the type of surgery.[38]

Titrate to the Patient's Needs

Patients with Limited Need for Preventive Measures

In general, the use of prophylactic antiemetics is rarely justified when the patient's risk is low (e.g., 10%-20%) (Fig. 86-14).[56] The reason is the low effectiveness at low risk so that many patients need to be treated for one patient to benefit and are thus unnecessarily exposed to an antiemetic that may have—even though it might be rare—associated side effects (e.g., sedation, headache, QT prolongations, torsades de pointes). However, as mentioned earlier, the use may be justified if this is a patient's preference or there are concerns about medical or surgical complications due to vomiting.

Patients Who Require Some Preventive Measures

At moderate risk, one or two antiemetic measures are often appropriate but these do not need to be antiemetic drugs. One approach could be a total intravenous anesthetic (TIVA with propofol, air, and fentanyl) or the use of 4 mg of dexamethasone or both after the induction of anesthesia supplemented with measures to minimize opioid consumption (NSAIDs, lidocaine, low-dose ketamine).

Patients in Whom Significant Preventive Measures Should Be Undertaken

At high or very high risk, avoidance of general anesthesia and minimization of perioperative opioids may be the most effective approach (e.g., peripheral nerve block, spinal anesthesia).[79] However, if a general anesthetic is needed, a TIVA with 4 mg of

Risk factors	Points
Female gender	1
Nonsmoker	1
History of PONV	1
Postoperative opioids	1
Risk score =	0...4

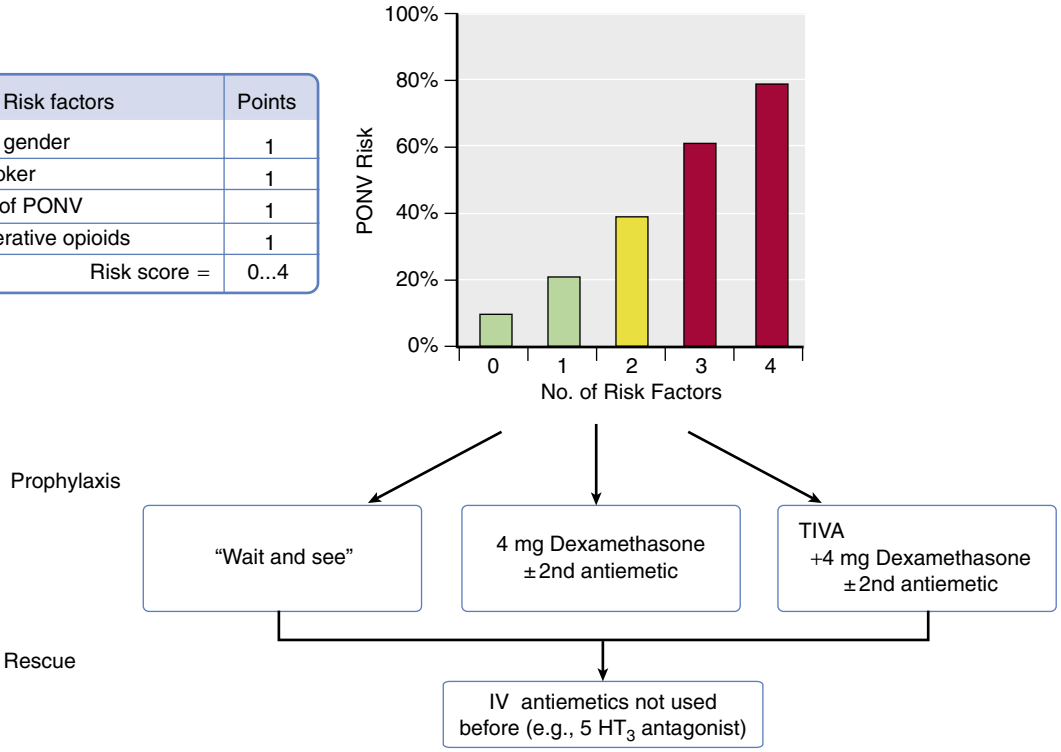

Figure 86-14 Algorithm for the management of PONV.

dexamethasone[56] and an additional antiemetic (e.g., 12.5 to 25 mg of promethazine, 31.25 to 62.5 mg of dimenhydrinate, or 25 to 50 mg of metoclopramide) can be recommended. Which partner drug to choose is most likely not relevant because most drugs appear similarly effective[104] and indirect evidence suggests that interventions with different mechanisms are additive, that is, work independently.[56] Of course, a TIVA could be substituted by an inhaled anesthetic with an additional antiemetic, but this eliminates one rescue treatment option should PONV occur in the PACU. This is particularly true for the use of a serotonin antagonist, which may otherwise be an effective rescue option without sedative side effects.

Rescue without Delay

Options for rescue treatment are interventions that have not been applied before or where the half-life suggests that it is no longer active.[190] Serotonin antagonists, if they were not given in the operating room, may be first choice in the PACU because of their lack of sedative side effects. Also, the addition of dexamethasone to dolasetron or haloperidol might increase the overall risk reduction for rescue treatment (again if it has not been given before).[193] Finally, stimulation of the P6 acupressure point may be another option, given that its efficacy has been demonstrated for the prevention of PONV.

87 Acute Postoperative Pain

Key Points

1. The process of nociception is not a hard-wired characteristic but a plastic and dynamic process (i.e., neuroplasticity) with multiple points of activation and modulation. Persistent noxious input may result in relatively rapid neuronal sensitization and possibly chronic pain.
2. Postoperative pain, especially when poorly controlled, results in harmful acute effects (i.e., adverse physiologic responses) and chronic effects (i.e., delayed long-term recovery and chronic pain).
3. By preventing central sensitization, preemptive analgesia may reduce acute and chronic pain. Although experimental studies overwhelmingly support the concept of preemptive analgesia, the evidence from clinical trials is equivocal because of methodologic issues.
4. By allowing individual titration of analgesic agents, use of patient-controlled anesthesia (intravenous or epidural) may provide several advantages over traditional provider-administered analgesia (e.g., intramuscular injections) in the management of postoperative pain.
5. The incidence of respiratory depression from opioids does not appear to be significantly different among the various routes of administration (i.e., intravenous versus intramuscular versus subcutaneous versus neuraxial). Appropriate monitoring of patients receiving opioid analgesics is essential to detect those with opioid-related side effects such as respiratory depression. Whether patients receiving neuraxial opioid analgesics require monitoring in an intensive care unit is debatable, although there is literature demonstrating the relatively safe use of single-dose and continuous-infusion neuraxial opioids on routine surgical wards under appropriate monitoring conditions.
6. Judicious use of adjuvant agents, such as nonsteroidal anti-inflammatory drugs, may improve postoperative analgesia and diminish analgesic-related side effects.
7. When compared with systemic opioids, perioperative epidural analgesia may confer several advantages, including a facilitated return of gastrointestinal function and decrease in the incidence of pulmonary complications, coagulation-related adverse events, and possibly cardiovascular events, especially in higher-risk patients or procedures. However, the risks and benefits of epidural analgesia should be evaluated for each patient, and appropriate monitoring protocols should be used during postoperative epidural analgesia.
8. Epidural analgesia is not a generic entity because different catheter locations (catheter-incision congruent versus catheter-incision incongruent), durations of postoperative analgesia, and analgesic regimens (local anesthetics versus opioids) may differentially affect perioperative morbidity.
9. Postoperative pain management should be tailored to the needs of special populations (e.g., ambulatory surgical, elderly, opioid-tolerant, pediatric, and obese patients, as well as those with obstructive sleep apnea) who may have different anatomic, physiologic, pharmacologic, or psychosocial issues.

Fundamental Considerations

A revolution in the management of acute postoperative pain has occurred during the past 3 decades. Widespread recognition of the undertreatment of acute pain by clinicians, economists, and health policy experts has led to the development of a national clinical practice guideline for management of acute pain by the Agency for Healthcare Quality and Research (formerly the Agency for Health Care Policy and Research) of the U.S. Department of Health and Human Services.[1] This landmark document includes acknowledgment of the historical inadequacies in perioperative pain management, importance of good pain control, need for accountability for adequate provision of perioperative analgesia by health care institutions, and a statement on the need for involvement of specialists in appropriate cases. In addition, several professional societies (e.g., American Society of Anesthesiologists,[2] Joint Commission on Accreditation of Healthcare Organizations) have developed clinical practice guidelines for

acute pain management or provided new pain management standards.

With their knowledge of and familiarity with pharmacology, various regional techniques, and the neurobiology of nociception, anesthesiologists are continually in the vanguard of clinical and research advances in acute postoperative pain management. Anesthesiologists are leaders in the development of acute postoperative pain services, application of evidence-based practice to acute postoperative pain, and creation of innovative approaches to acute pain management, all of which are a natural part of the anesthesiologist's functions as a "perioperative physician," consultant, and therapist throughout an institution, and as a highly skilled expert in the operating room. Provision of effective analgesia for surgical and other medical patients is an important component of this multidimensional role.

Pain Pathways and the Neurobiology of Nociception

Surgery produces tissue injury with consequent release of histamine and inflammatory mediators such as peptides (e.g., bradykinin), lipids (e.g., prostaglandins), neurotransmitters (e.g., serotonin), and neurotrophins (e.g., nerve growth factor).[3] Release of inflammatory mediators activates peripheral nociceptors, which initiate transduction and transmission of nociceptive information to the central nervous system (CNS) and the process of neurogenic inflammation in which release of neurotransmitters (i.e., substance P and calcitonin gene–related peptide) in the periphery induces vasodilatation and plasma extravasation.[3] Noxious stimuli are transduced by peripheral nociceptors and transmitted by Aδ and C nerve fibers from peripheral visceral and somatic sites to the dorsal horn of the spinal cord, where integration of peripheral nociceptive and descending modulatory input (i.e., serotonin, norepinephrine, γ-aminobutyric acid, enkephalin) occurs. Further transmission of nociceptive information is determined by complex modulating influences in the spinal cord. Some impulses pass to the ventral and ventrolateral horns to initiate segmental (spinal) reflex responses, which may be associated with increased skeletal muscle tone, inhibition of phrenic nerve function, or even decreased gastrointestinal motility. Others are transmitted to higher centers through the spinothalamic and spinoreticular tracts, where they induce suprasegmental and cortical responses to ultimately produce the perception of and affective component of pain.

Continuous release of inflammatory mediators in the periphery sensitizes functional nociceptors and activates dormant ones.[4] Sensitization of peripheral nociceptors may occur and is marked by a decreased threshold for activation, increased rate of discharge with activation, and increased rate of basal (spontaneous) discharge.[4] Intense noxious input from the periphery may also result in central sensitization ("persistent postinjury changes in the CNS that result in pain hypersensitivity"[5]) and hyperexcitability ("exaggerated and prolonged responsiveness of neurons to normal afferent input after tissue damage"[5]). Such noxious input may lead to functional changes in the dorsal horn of the spinal cord and other consequences that may later cause postoperative pain to be perceived as more painful than it would otherwise have been. The neural circuitry in the dorsal horn is extremely complex, and we are just beginning to elucidate the specific role of the various neurotransmitters and receptors in the process of nociception.[3,6] However, it seems that certain receptors (e.g., *N*-methyl-D-aspartate [NMDA]) may be especially important for the development of chronic pain after an acute injury, although other neurotransmitters or second messenger effectors (e.g., substance P, protein kinase C-γ) may also play important roles in spinal cord sensitization and chronic pain.[7] Our understanding of the neurobiology of nociception has progressed from the hard-wired system proposed by Descartes in the 17th century to the current view of neuroplasticity in which dynamic integration and modulation of nociceptive transmission take place at several levels. There still are many gaps in our knowledge of the specific roles of various receptors, neurotransmitters, and molecular structures in the process of nociception.

An understanding of the neurobiology of nociception is important for appreciating the transition from acute to chronic pain. The traditional dichotomy between acute and chronic pain is arbitrary inasmuch as animal and clinical studies demonstrate that acute pain may quickly transition into chronic pain.[4] Experimental studies show that noxious stimuli can produce expression of new genes (which are the basis for neuronal sensitization[7]) in the dorsal horn of the spinal cord within 1 hour and that these changes are sufficient to alter behavior within the same timeframe.[6] Clinical studies also suggest that the intensity of acute postoperative pain is a significant predictor of chronic postoperative pain.[8] Control of perioperative pain (e.g., preventive analgesia) and the fashion in which it is implemented (e.g., multimodality perioperative management) may be important in facilitating short- and long-term patient convalescence after surgery.

Acute and Chronic Effects of Postoperative Pain

Uncontrolled postoperative pain may produce a range of detrimental acute and chronic effects. The attenuation of perioperative pathophysiology that occurs during surgery through reduction of nociceptive input to the CNS and optimization of perioperative analgesia may decrease complications and facilitate recovery during the immediate postoperative period[9] and after discharge from the hospital.

Acute Effects

The perioperative period is associated with a variety of pathophysiologic responses that may be initiated or maintained by nociceptive input. Although these responses may have had a beneficial teleologic purpose, the same response to the iatrogenic nature of modern-day surgery may be harmful. Uncontrolled perioperative pain may potentiate some of these perioperative pathophysiologies and increase patient morbidity and mortality. Attenuation of postoperative pain, especially with certain types of analgesic regimens, may decrease perioperative morbidity and mortality.[10]

Transmission of nociceptive stimuli from the periphery to the CNS results in the neuroendocrine stress response, a combination of local inflammatory substances (e.g., cytokines, prostaglandins, leukotrienes, tumor necrosis factor-α) and systemic mediators of the neuroendocrine response. The dominant neuroendocrine responses to pain involve hypothalamic-pituitary-adrenocortical and sympathoadrenal interactions.

Suprasegmental reflex responses to pain result in increased sympathetic tone, increased catecholamine and catabolic hormone secretion (e.g., cortisol, adrenocorticotropic hormone, antidiuretic hormone, glucagon, aldosterone, renin, angiotensin II), and decreased secretion of anabolic hormones.[11] The effects include sodium and water retention and increased levels of blood glucose, free fatty acids, ketone bodies, and lactate. A hypermetabolic, catabolic state occurs as metabolism and oxygen consumption are increased and metabolic substrates are mobilized from storage depots.[11] The extent of the stress response is influenced by many factors, including the type of anesthesia and intensity of the surgical injury, with the extent of the stress response being proportional to the degree of surgical trauma.[12] The negative nitrogen balance and protein catabolism may impede convalescence; however, attenuation of the stress response and postoperative pain may facilitate and accelerate the patient's recovery postoperatively.

The neuroendocrine stress response may potentiate detrimental physiologic effects in other areas of the body. The stress response may be an important factor in the postoperative development of hypercoagulability.[10] Enhancement of coagulation (i.e., decreased levels of natural anticoagulants and increased levels of procoagulants), inhibition of fibrinolysis, and increased platelet reactivity and plasma viscosity may contribute to an elevated incidence of postoperative hypercoagulable-related events such as deep venous thrombosis, vascular graft failure, and myocardial ischemia.[10,13] The stress response may also potentiate postoperative immunosuppression, the extent of which correlates with the severity of surgical injury.[4] Hyperglycemia from the stress response may contribute to poor wound healing and depression of immune function.

Uncontrolled postoperative pain may activate the sympathetic nervous system and thereby contribute to morbidity or mortality. Sympathetic activation may increase myocardial oxygen consumption, which may be important in the development of myocardial ischemia and infarction,[10,13] and may decrease myocardial oxygen supply through coronary vasoconstriction and attenuation of local metabolic coronary vasodilation.[10] Activation of the sympathetic nervous system may also delay return of postoperative gastrointestinal motility, which may develop into paralytic ileus. Although postoperative ileus is the result of a combination of inhibitory input from central and local factors,[10,13] an increase in sympathetic efferent activity, such as from uncontrolled pain, may decrease gastrointestinal activity and delay return of gastrointestinal function.

Nociceptors are activated after surgical trauma and may initiate several detrimental spinal reflex arcs. Postoperative respiratory function is markedly decreased, especially after upper abdominal and thoracic surgery. Spinal reflex inhibition of phrenic nerve activity is an important component of this decreased postoperative pulmonary function.[10,13] However, control of postoperative pain is also important because patients with poor pain control may breathe less deeply, have an inadequate cough, and be more susceptible to the development of postoperative pulmonary complications.[10] Activation of nociceptors may also initiate spinal reflex inhibition of gastrointestinal tract function and delay return of gastrointestinal motility.[10,13]

Many detrimental pathophysiologic effects occur in the perioperative period and are associated with activation of nociceptors and the stress response. Uncontrolled pain may result in activation of the sympathetic nervous system, which can cause a variety of potentially harmful physiologic responses that may adversely influence the extent of morbidity and mortality. Nociceptor activation may also result in several detrimental inhibitory spinal reflexes. Control of the pathophysiologic processes associated with acute postoperative pain may attenuate the stress response, sympathetic outflow, and inhibitory spinal reflexes and contribute to improvements in morbidity, mortality, and patient-reported outcomes (e.g., health-related quality of life [HRQL], patient satisfaction).[13]

Chronic Effects

Chronic postsurgical pain [CPSP] is a largely unrecognized problem that may occur in 10% to 65% of postoperative patients (depending on the type of surgery), with 2% to 10% of these patients experiencing severe CPSP.[14] Poorly controlled acute postoperative pain may be an important predictive factor in the development of CPSP.[8,15] Increasing experimental and clinical evidence suggests that the transition from acute to chronic pain occurs very quickly and that long-term behavioral and neurobiologic changes occur much earlier than was previously thought.[4] CPSP is relatively common after procedures such as limb amputation (30% to 83%), thoracotomy (22% to 67%), sternotomy (27%), breast surgery (11% to 57%), and gallbladder surgery (up to 56%).[8] Although studies suggest that the severity of acute postoperative pain may be an important predictor in the development of CPSP,[8] a causal relationship between the severity of acute postoperative pain and subsequent CPSP has not been definitively established, and other factors (i.e., area of postoperative hyperalgesia) may be more important in predicting the development of CPSP.[16]

Control of acute postoperative pain may improve long-term recovery or patient-reported outcomes (e.g., quality of life). Patients whose pain is controlled in the early postoperative period (especially with the use of continuous epidural or peripheral catheter techniques) may be able to actively participate in postoperative rehabilitation, which may improve short- and long-term recovery after surgery.[17] Optimizing treatment of acute postoperative pain can improve HRQL.[18] Postoperative chronic pain that develops as a result of poor postoperative pain control may interfere with patients' activities of daily living.

Preventive Analgesia

Central sensitization and hyperexcitability develop after the surgical incision and result in amplification of postoperative pain. Preventing the establishment of altered central processing by analgesic treatment may result in short-term (e.g., reduction in postoperative pain and accelerated recovery) and long-term (e.g., reduction in chronic pain and improvement in HRQL[18]) benefits during a patient's convalescence. Although experimental studies convincingly confirm the concept of preemptive analgesia in decreasing postinjury pain, the results of clinical trials are mixed.[19,20]

The precise definition of preemptive analgesia is one of the major controversies in this area of medicine and contributes to the question of whether preemptive analgesia is clinically relevant. Definitions of preemptive analgesia include what is administered before the surgical incision, what prevents the establishment of central sensitization resulting from incisional injury only (i.e., intraoperative period), what prevents central sensitization resulting from incisional and inflammatory injury (i.e., intraoperative

and postoperative periods), or the entire perioperative period encompassing preoperative interventions, intraoperative analgesia, and postoperative pain management (i.e., preventive analgesia).[5] The first two definitions are relatively narrow and may contribute to the lack of a detectable effect of preemptive analgesia in clinical trials. Timing of the intervention[19] may not be as clinically important as other aspects of preventive analgesia (i.e., intensity and duration of the intervention). An intervention administered before the surgical incision is not necessarily preemptive if it is incomplete or insufficient such that central sensitization is not prevented. Incisional and inflammatory injuries are important in initiating and maintaining central sensitization. Confining the definition of preemptive analgesia to only the intraoperative (incisional) period may not be clinically relevant or appropriate because the inflammatory response may last well into the postoperative period and continue to maintain central sensitization. Other methodologic and study design issues may also complicate the question of whether preventive analgesia is clinically relevant.

A variety of drugs and techniques[19] have been used to study preemptive analgesia. Using the broader definition of preventive analgesia that covers incisional (intraoperative) and inflammatory (postoperative) injury, the combination of experimental data and positive clinical trials strongly suggests that preemptive analgesia is a clinically relevant phenomenon. Maximal clinical benefit is observed when there is complete blockade of noxious stimuli with extension of this block into the postoperative period. By preventing central sensitization, preemptive analgesia along with intensive multimodal analgesic interventions[19] could theoretically reduce acute postoperative pain/hyperalgesia and chronic pain after surgery.[8]

Multimodal Approach to Perioperative Recovery

The analgesic benefits of controlling postoperative pain are generally maximized when a multimodal strategy to facilitate the patient's convalescence is implemented.[21] Postoperative pain treatment may not be enough to provide major improvements in some outcomes because it is unlikely that a unimodal intervention can be effective in addressing a complex problem such as perioperative outcomes.[9,22] Principles of a multimodal strategy include control of postoperative pain to allow early mobilization, early enteral nutrition, education, and attenuation of the perioperative stress response through the use of regional anesthetic techniques[9] and a combination of analgesic agents (i.e., multimodal analgesia). The use of epidural anesthesia and analgesia is an integral part of the multimodal approach because of the superior analgesia and physiologic benefits conferred by epidural analgesia.

A multimodal approach to perioperative recovery to control postoperative pathophysiology and facilitate rehabilitation may result in accelerated recovery and decreased length of hospitalization.[23] Patients undergoing major abdominal or thoracic procedures and who participate in a multimodal strategy have a reduction in hormonal and metabolic stress, preservation of total-body protein, shorter times to extubation, lower pain scores, earlier return of bowel function, and earlier fulfillment of intensive care unit discharge criteria.[23] By integrating the most recent data and techniques from surgery, anesthesiology, nociceptive neurobiology, and pain treatment, the multimodal approach may be seen as an extension of "clinical pathways" or "fast tracks" by revising traditional care programs into effective postoperative rehabilitation pathways.[23] This approach may potentially decrease perioperative morbidity, reduce the length of hospital stay, and improve patient satisfaction without compromising safety. However, widespread implementation of these programs requires multidisciplinary collaboration, change in the traditional principles of postoperative care, additional resources, and expansion of the traditional acute pain service, which may be difficult in the current economic climate.

Treatment Methods

Many options are available for the treatment of postoperative pain, including systemic (i.e., opioid and nonopioid) analgesics and regional (i.e., neuraxial and peripheral) analgesic techniques. By considering patients' preferences and making an individualized assessment of the risks and benefits of each treatment modality, the clinician can optimize the postoperative analgesic regimen for each patient. Essential aspects of postoperative monitoring of patients receiving various postoperative analgesic treatment methods are listed in Box 87-1.[2]

Systemic Analgesic Techniques

Opioids

Advantages and Characteristics

Opioid analgesics are one of the cornerstone options for the treatment of postoperative pain. These agents generally exert their analgesic effects through μ-receptors in the CNS, although there is evidence that opioids may also act at peripheral opioid receptors.[24] A theoretical advantage of opioid analgesics is that there is no analgesic ceiling. Realistically, the analgesic efficacy of opioids is typically limited by the development of tolerance or opioid-related side effects such as nausea, vomiting, sedation, or respiratory depression. Opioids may be administered by the subcutaneous, transcutaneous, transmucosal, or intramuscular route, but the most common routes of postoperative systemic opioid analgesic administration are oral and intravenous. Opioids may also be administered at specific anatomic sites such as the intrathecal or epidural space (see later sections, "Single-Dose Neuraxial Opioids" and "Continuous Epidural Analgesia").

There is wide intersubject and intrasubject variability in the relationship of opioid dose, serum concentration, and analgesic response in the treatment of postoperative pain.[25] Serum drug concentrations may exhibit wider variability with certain routes of administration (e.g., intramuscular) than with others (e.g., intravenous). In general, opioids are administered parenterally (intravenously or intramuscularly) for the treatment of moderate to severe postoperative pain, in part because these routes provide a more rapid and reliable onset of analgesic action than the oral

Box 87-1 Monitoring and Documentation of Postoperative Analgesia

Analgesic Medication*
Name, concentration, and dose of drug
Settings of PCA device: demand dose, lockout interval, continuous infusion
Amount of drug administered (including number of unsuccessful and successful doses)
Limits set (e.g., 1- and 4-hour limits on dose administered)
Supplemental or breakthrough analgesics

Routine Monitoring
Vital signs: temperature, heart rate, blood pressure, respiratory rate
Analgesia
Pain at rest and with activity, pain relief
Use of breakthrough medication

Side Effects
Cardiovascular: hypotension, bradycardia, or tachycardia
Respiratory status: respiratory rate, level of sedation
Nausea and vomiting, pruritus, urinary retention
Neurologic examination
Assessment of motor block or function and sensory level
Evidence of epidural hematoma

Instructions Provided
Treatment of side effects
Concurrent use of other CNS depressants
Parameters for triggering notification of the covering physician
Provision of contact information (24 hours/7 days per week) if problems occur
Emergency analgesic treatment if the PCA device fails

*Postoperative analgesia includes systemic opioids and regional analgesic techniques. This list incorporates some of the important elements of preprinted orders, documentation, and intravenous PCA and epidural analgesia daily care described in the ASA Practice Guidelines for Acute Pain Management.[2]
CNS, central nervous system; PCA, patient-controlled analgesia.

route does. Parenteral opioid administration may be necessary in patients who are unable to tolerate oral intake postoperatively. The transition from parenteral to oral administration of opioids usually occurs after the patient initiates oral intake and postoperative pain has been stabilized with parenteral opioids. Although oral opioids (typically formulated as part of a combination product that includes an adjuvant such as acetaminophen) are generally prescribed on an "as needed" (PRN) basis postoperatively, there may be a role for sustained-release oral opioids, which may provide analgesia superior to that with conventional PRN regimens.[26] Although the traditional form (passive) of transdermal fentanyl is not indicated for the routine treatment of acute postoperative pain, a newer version involving patient-activated electrically facilitated delivery of transdermal fentanyl has been introduced for use in hospitalized adult patients.[27]

Intravenous Patient-Controlled Analgesia

Various factors, including the aforementioned wide interpatient and intrapatient variability in analgesic needs, variability in serum drug levels (especially with intramuscular injection), and administrative delays, may contribute to inadequate postoperative analgesia. It may be difficult to compensate for these factors with the use of a traditional PRN analgesic regimen. By circumventing some of these issues, intravenous patient-controlled analgesia (PCA) optimizes delivery of analgesic opioids and minimizes the effects of pharmacokinetic and pharmacodynamic variability in individual patients. Intravenous PCA is based on the premise that a negative-feedback loop exists; when pain is experienced, analgesic medication is self-administered, and when pain is reduced, there are no further demands. When the negative-feedback loop is violated, excessive sedation or respiratory depression may occur.[28] Although some equipment-related malfunctions have been reported, the PCA device itself is relatively free of problems, and most problems related to PCA use result from user or operator error.[28]

A PCA device can be programmed for several variables, including the demand (bolus) dose, lockout interval, and background infusion (Table 87-1). An optimal demand or bolus dose is integral to the efficacy of intravenous PCA because an insufficient demand dose may result in inadequate analgesia whereas an excessive demand dose may result in a higher incidence of undesirable side effects such as respiratory depression.[29] Although the optimal demand dose is uncertain, the data available suggest that the optimal demand dose is 1 mg for morphine and 40 μg for fentanyl in opioid-naive patients; however, the actual dose for fentanyl (10 to 20 μg) is often less in clinical practice.[28,29] The lockout interval may also affect the analgesic efficacy of intravenous PCA. A lockout interval that is too long may result in inadequate analgesia and decrease the effectiveness of intravenous PCA. A lockout interval that is too short allows the patient to self-administer another demand dose before feeling the full analgesic effect of the previous dose and thus may contribute to an increase in medication-related side effects. In essence, the lockout interval is a safety feature of intravenous PCA, and although the optimal lockout interval is unknown, most intervals range from 5 to 10 minutes, depending on the medication in the PCA pump; varying the interval within this range appears to have no effect on analgesia or side effects.[28]

Most PCA devices allow administration of a continuous or background infusion in addition to the demand dose. Initially, routine use of a background infusion was thought to confer certain advantages, including improved analgesia, especially during sleep; however, subsequent trials failed to demonstrate any analgesic benefits of a background infusion in opioid-naïve patients.[30] Many studies show that use of a background infusion only increases the analgesic dosage used and the incidence of side effects such as respiratory depression.[31] Use of a nighttime background infusion does not improve postoperative sleep patterns, analgesia, or recovery profiles.[32] Although routine use of continuous or background infusion as part of intravenous PCA in adult opioid-naive patients is not recommended, there may be a role for use of a background infusion in opioid-tolerant or

Table 87-1 Intravenous Patient-Controlled Analgesia Regimens

Drug Concentration	Size of Bolus*	Lockout Interval (min)	Continuous Infusion
Agonists			
Morphine (1 mg/mL)			
Adult	0.5-2.5 mg	5-10	—
Pediatric	0.01-0.03 mg/kg (max, 0.15 mg/kg/hr)	5-10	0.01-0.03 mg/kg/hr

*All doses are for adult patients unless noted otherwise. Units vary across agents for size of the bolus (mg versus mg/kg versus μg versus μg/kg) and continuous infusion (mg/kg/hr versus μg/kg/hr). The anesthesiologist should proceed with titrated intravenous loading doses if necessary to establish initial analgesia. Individual patient requirements vary widely, with smaller doses typically given to elderly or compromised patients. Continuous infusions are not initially recommended for opioid-naive adult patients.

pediatric patients (see later sections, "Opioid-Tolerant Patients" and "Pediatric Patients").

When compared with traditional PRN analgesic regimens, intravenous PCA provides superior postoperative analgesia and improves patient satisfaction, but it is unclear whether intravenous PCA can provide any economic benefits.[33] A meta-analysis (55 studies, 2023 subjects) revealed that intravenous PCA (versus PRN opioids) provides significantly greater analgesia and patient satisfaction; however, patients used more opioids and had a higher incidence of pruritus than those treated with PRN opioids, but there was no difference in the incidence of adverse events.[33] With regard to economic outcomes, it is not clear whether intravenous PCA is superior to traditional PRN intramuscular opioid administration because the calculations of cost are complex. Although there appears to be no improvement in hospital length of stay with intravenous PCA, it does require less nursing time than intramuscular injections do, which may be important with the shift toward using a higher percentage of less skilled providers on surgical and medical wards.[34]

Intravenous PCA may provide advantages when assessing other patient-related outcomes such as patient satisfaction; these outcomes have become more important as health care organizations use them as a measure of quality and a tool for marketing purposes. Patients tend to prefer intravenous PCA over intravenously, intramuscularly, or subcutaneously administered PRN opioids.[35] Greater patient satisfaction with intravenous PCA may be the result of superior analgesia and perceived control over the administration of analgesic medications and avoidance of disclosing pain or securing analgesic medication from nurses.[36] However, the reasons for patient satisfaction are complex, and many factors contribute to or predict satisfaction with intravenous PCA.[35,36] Patients' willingness to pay for and the timing of cessation of intravenous PCA may also influence satisfaction ratings.[37] Although intravenous PCA use overall appears to be associated with greater satisfaction, there are many methodologic issues in the proper assessment of patient satisfaction.[38]

The incidence of opioid-related adverse events from intravenous PCA does not seem to differ significantly from that of PRN opioids administered intravenously, intramuscularly, or subcutaneously. The rate of respiratory depression associated with intravenous PCA is low (<0.5%) and does not appear to be higher than that with PRN systemic or neuraxial opioids.[31,39] Factors that may be associated with the occurrence of respiratory depression with intravenous PCA include use of a background infusion, advanced age, concomitant administration of sedative or hypnotic agents, and coexisting pulmonary disease such as sleep apnea.[31,39] Intravenous PCA–related respiratory depression may also be caused by errors in programming or administration (i.e., operator error).

Nonopioids

Nonsteroidal Anti-inflammatory Agents

Nonsteroidal anti-inflammatory drugs (NSAIDs), which include aspirin and acetaminophen, consist of a diverse group of analgesic compounds with different pharmacokinetic properties. The primary mechanism by which NSAIDs exert their analgesic effect

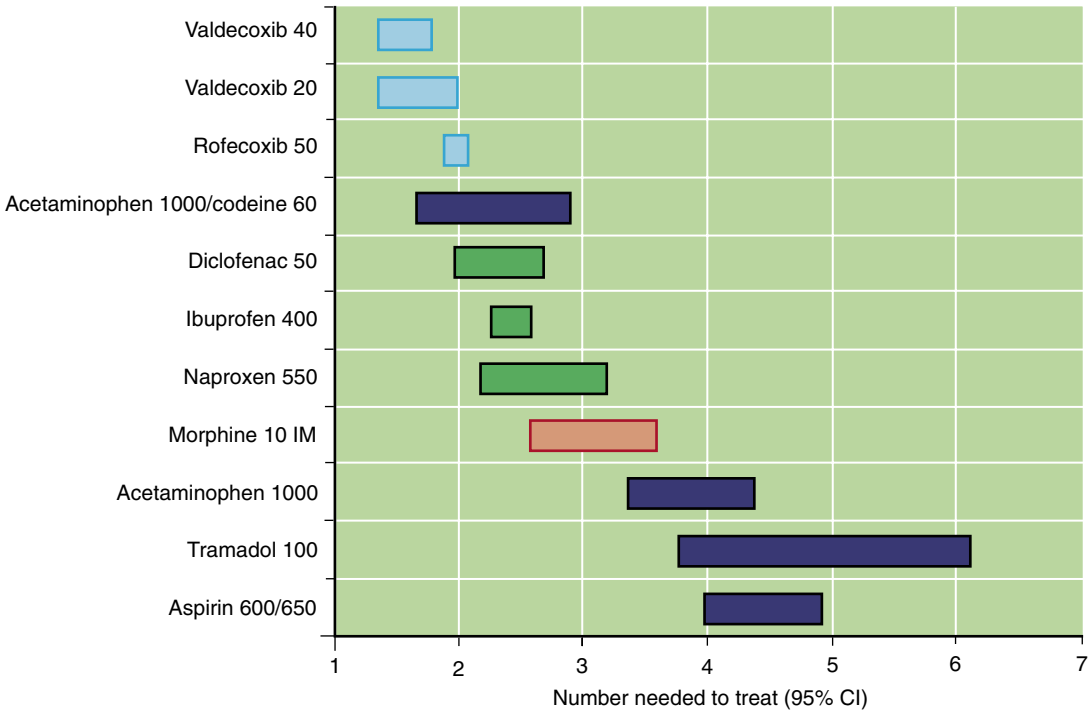

Figure 87-1 Number needed to treat (NNT) for at least 50% pain relief in patients with moderate to severe pain. The mean and 95% confidence interval (CI) for the NNTs are shown for several opioid and nonopioid analgesics from Table 87-2. The NNTs are derived from trials investigating the efficacy of a single dose of nonopioid analgesic versus placebo in providing more than 50% pain relief for moderate to severe postoperative pain. Numbers with drug names are doses in mg. *(From Bandolier. Available at http://www.jr2.ox.ac.uk/bandolier/booth/painpag/Acutrev/Analgesics/Leagtab.html/ Accessed February 8, 2008.)*

is through inhibition of cyclooxygenase (COX) and synthesis of prostaglandins, which are important mediators of peripheral sensitization and hyperalgesia. Though traditionally viewed primarily as peripherally acting agents, NSAIDs can also exert their analgesic effects through inhibition of spinal COX.[40] The discovery of at least two COX isoforms (i.e., COX-1 is constitutive and COX-2 is inducible) with different functions (i.e., COX-1 participates in platelet aggregation, hemostasis, and gastric mucosal protection, whereas COX-2 participates in pain, inflammation, and fever) has led to the development of selective COX-2 inhibitors that differ from traditional NSAIDs, which block both COX-1 and COX-2.[41] The discovery of a COX-3 variant may represent a primary central mechanism by which acetaminophen and other antipyretics decrease pain and fever; however, the precise relationship between COX-3 and acetaminophen is still uncertain.[42]

Used as a sole agent, NSAIDs generally provide effective analgesia for mild to moderate pain. NSAIDs are also traditionally considered a useful adjunct to opioids for the treatment of moderate to severe pain, although some quantitative, systematic reviews suggest that NSAIDs, alone or in combination with opioids, may be more beneficial than previously thought (Table 87-2 and Fig. 87-1). NSAIDs may be administered orally or parenterally and are particularly useful as components of a multimodal analgesic regimen by producing analgesia through a different mechanism from that of opioids or local anesthetics. However, several meta-analyses have examined the analgesic efficacy of NSAIDs (including COX-2 inhibitors) and acetaminophen when added to intravenous PCA with opioids. Only NSAIDs,[44] not acetaminophen,[45] resulted in a statistically significant (but probably not clinically meaningful) reduction in pain scores.[46,47] Although all regimens significantly decreased morphine consumption, only NSAIDs (but not acetaminophen) reduced risk for the opioid-related side effects of nausea, vomiting, and sedation.

Perioperative use of NSAIDs is associated with a number of side effects, including decreased hemostasis, renal dysfunction, gastrointestinal hemorrhage, and deleterious effects on bone healing and osteogenesis. Many of these side effects are related to inhibition of COX and the formation of prostaglandins, which mediate many diverse processes throughout the body. Decreased hemostasis from NSAID use is attributed primarily to platelet dysfunction and inhibition of thromboxane A_2 (generated by COX-1), an important mediator of platelet aggregation and vasoconstriction.[48] Evidence of the effect of NSAIDs on perioperative bleeding is equivocal, and a surveillance study of perioperative ketorolac did not demonstrate a significant increase in operative site bleeding.[49]

Perioperative NSAID-induced renal dysfunction may occur in high-risk patients, such as those with hypovolemia,

Table 87-2 Relative Efficacy of Single-Dose Analgesics in Providing Greater than 50% Relief of Moderate to Severe Postoperative Pain

Drug*	Mean NNT†	95% CI
Diclofenac (100 mg PO)	1.9	1.6-2.2
Rofecoxib (50 mg PO)	1.9	1.8-2.1
Codeine (60 mg) + acetaminophen (1000 mg PO)	2.2	1.7-2.9
Diclofenac (50 mg PO)	2.3	2.0-2.7
Ibuprofen (600 mg PO)	2.4	1.9-3.3
Oxycodone (15 mg PO)	2.4	1.5-4.9
Oxycodone (5 mg) + acetaminophen (325 mg PO)	2.5	2.0-3.2
Ketorolac (10 mg PO)	2.6	2.3-3.1
Meperidine (100 mg IM)	2.9	2.3-3.9
Morphine (10 mg IM)	2.9	2.6-3.6
Ketorolac (30 mg IM)	3.4	2.5-4.9
Acetaminophen (1000 mg PO)	3.8	3.4-4.4
Aspirin (1000 mg PO)	4.0	3.2-5.4
Codeine (60 mg) + acetaminophen (600 to 650 mg PO)	4.2	3.4-5.3
Aspirin (600 to 650 mg PO)	4.4	4.0-4.9
Dextropropoxyphene (65 mg) + acetaminophen (650 mg PO)	4.4	3.5-5.6
Acetaminophen (600 to 650 mg PO)	4.6	3.9-5.5
Tramadol (100 mg PO)	4.8	3.8-6.1
Dextropropoxyphene (65 mg PO)	7.7	4.6-22
Dihydrocodeine (30 mg PO)	8.1	4.1-540
Codeine (60 mg PO)	16.7	11.0-48.0

CI, confidence interval; IM, intramuscular; NNT, number needed to treat; PO, oral route.

†NNT in this case refers to the number of patients who must be treated to obtain greater than 50% relief of moderate to severe postoperative pain.[43] NNT conveys statistical and clinical significance, is useful in comparing the efficacy of different interventions, and summarizes treatment effects in a clinically relevant manner.[43] A lower mean NNT implies greater analgesic efficacy in this example. See Figure 87-1 for a graphic presentation of these data.

abnormal renal function, or abnormal serum electrolytes, because prostaglandins dilate the renal vascular beds and mediate diuretic and natriuretic renal effects.[50] Euvolemic patients with normal renal function are unlikely to be affected; a meta-analysis did not demonstrate any significant reduction in urine volume or cases of postoperative renal failure requiring dialysis, and there does not appear to be a benefit in using COX-2 inhibitors instead of traditional nonselective NSAIDs in reducing the incidence of renal complications.[51] NSAIDs may also have an adverse effect on bone healing and spinal fusion, but preliminary evidence suggests that COX-2 inhibitors may be an alternative when attempting to avoid the detrimental effects of nonselective NSAIDs on bone healing.[52] Perioperative use of NSAIDs is associated with a higher incidence of gastrointestinal bleeding[49] because of NSAID-inhibition of COX-1, which is required for the synthesis of cytoprotective gastric mucosal prostaglandins. Bronchospasm may be induced by NSAIDs (including aspirin) or acetaminophen, and there may be cross-sensitivity with acetaminophen in aspirin-sensitive asthmatic subjects.[52]

Because expression of peripheral COX-2 is increased during inflammation, selective inhibition of COX-2 could theoretically provide analgesia without the side effects associated with COX-1 inhibition. COX-2 inhibitors are associated with a lower incidence of gastrointestinal complications[53] and exhibit minimal platelet inhibition, even when administered in supratherapeutic doses.[54] However, long-term use of COX-2 inhibitors has been associated with excess cardiovascular risk such that rofecoxib was withdrawn from the market.[55] Although cardiovascular toxicity appears to be a class effect of all COX-2 inhibitors, the cardiovascular risks of COX-2 inhibitors appear to be heterogeneous and influenced by many factors such as the specific medication, dosage, and patient characteristics.[55] Issues surrounding the perioperative use of COX-2 inhibitors are slightly different from those of longer-term use of COX-2 inhibitors.[56] Nussmeier and colleagues performed a randomized trial of valdecoxib and its intravenous prodrug parecoxib versus placebo to assess the safety of these drugs in patients undergoing coronary artery bypass grafting (CABG).[57] When compared with the group given placebo alone, both the group given parecoxib and valdecoxib and the group given placebo and valdecoxib had a higher proportion of patients with at least one confirmed adverse event.[57] The use of parecoxib and valdecoxib after CABG was associated with an increased incidence of cardiovascular events, thereby arousing serious concern about the use of these drugs in such circumstances.

Ketamine

Ketamine is traditionally recognized as an intraoperative anesthetic agent; however, increasing interest in the use of low-dose ketamine for postoperative analgesia has developed in part because of its NMDA-antagonistic properties, which may be important in attenuating central sensitization and opioid tolerance.[58] A systematic review of perioperative ketamine use found that perioperative subanesthetic doses of ketamine reduce rescue analgesic requirements or pain intensity.[59] In addition, perioperative ketamine reduced 24-hour PCA morphine consumption and postoperative nausea or vomiting and had minimal adverse effects.[59] In other studies, low-dose ketamine infusion does not appear to cause hallucinations or cognitive impairment, and the incidence of side effects, such as dizziness, itching, nausea, and vomiting, is comparable to that seen with opioids.[60] Ketamine has also been administered epidurally and intrathecally,[61,62] but racemic mixtures of ketamine have been found to be neurotoxic, and therefore the use of neuraxial ketamine is discouraged.

Tramadol

Tramadol is a synthetic opioid that exhibits weak μ-agonist activity and inhibits reuptake of serotonin and norepinephrine. Although tramadol exerts its analgesic effects primarily through central mechanisms, it may have peripheral local anesthetic properties.[63] Tramadol is effective in treating moderate postoperative pain[64] and comparable in analgesic efficacy to aspirin (650 mg) with codeine (60 mg) or ibuprofen (400 mg) (see Table 87-2 and Fig. 87-1).[64] Advantages of tramadol for postoperative analgesia

include a relative lack of respiratory depression, major organ toxicity, and depression of gastrointestinal motility and a low potential for abuse.[65] Common side effects (overall incidence of 1.6% to 6.1%) include dizziness, drowsiness, sweating, nausea, vomiting, dry mouth, and headache.[64] Tramadol should be used with caution in patients with seizures or increased intracranial pressure and is contraindicated in those taking monoamine oxidase inhibitors.[64]

Regional Analgesic Techniques

A variety of neuraxial (primarily epidural) and peripheral regional analgesic techniques may be used for the effective treatment of postoperative pain. In general, the analgesia provided by epidural and peripheral techniques (particularly when local anesthetics are used) is superior to that with systemic opioids,[66] and use of these techniques may even reduce morbidity and mortality.[10,13] However, there are risks associated with the use of such techniques, and the clinician should evaluate the risks and benefits of these techniques on an individual basis in determining the appropriateness of neuraxial or peripheral regional techniques for each patient, especially in light of some of the controversies about the use of these techniques in the presence of various anticoagulants.

Single-Dose Neuraxial Opioids

Administration of a single dose of opioid may be efficacious as a sole or adjuvant analgesic agent when administered intrathecally or epidurally. One of the most important factors in determining the clinical pharmacology for a particular opioid is its degree of lipophilicity (versus hydrophilicity) (Table 87-3). Once they have reacted the cerebrospinal fluid (CSF) through direct intrathecal injection or gradual migration from the epidural space, hydrophilic opioids (i.e., morphine and hydromorphone) tend to remain within the CSF and produce a delayed but longer duration of analgesia, along with a generally higher incidence of side effects because of the cephalic or supraspinal spread of these compounds.

Table 87-3 Properties of Neuraxial Opioids

Property	Lipophilic Opioids	Hydrophilic Opioids
Common drugs	Fentanyl, sufentanil	Morphine, hydromorphone
Onset of analgesia	Rapid onset (5-10 min)	Delayed onset (30-60 min)
Duration of analgesia*	Shorter duration (2-4 hr)	Longer duration (6-24 hr)
CSF spread	Minimal CSF spread	Extensive CSF spread
Site of action	Spinal ± systemic	Primarily spinal
Side effects		
Nausea and vomiting	Lower incidence with lipophilic than with hydrophilic opioids	
Pruritus	Lower incidence with lipophilic than with hydrophilic opioids	
Respiratory depression	Primarily early; minimal delay	Both early (<6 hr) and delayed (>6 hr) possible

CSF, cerebrospinal fluid.
*The duration of analgesia varies.

Neuraxial administration of lipophilic opioids, such as fentanyl and sufentanil, tends to provide a rapid onset of analgesia, and their rapid clearance from CSF may limit cephalic spread and the development of certain side effects such as delayed respiratory depression.[67] The site of analgesic action for hydrophilic opioids is overwhelmingly spinal, but the primary site of action (spinal versus systemic) for single-dose neuraxial lipophilic opioids is not as certain.[68]

The differences in pharmacokinetics between lipophilic and hydrophilic opioids may influence the choice of opioid in an attempt to optimize analgesia and minimize side effects for a particular clinical situation. Single-dose intrathecal administration of a lipophilic opioid may be useful in situations (e.g., ambulatory surgical patients) in which rapid analgesic onset (minutes) combined with a moderate duration of action (<4 hours) and minimal risk of respiratory depression is needed.[69] Single-dose hydrophilic opioid administration provides effective postoperative analgesia and may be useful in patients monitored on an inpatient basis, for whom a longer duration of analgesia would be beneficial.

Single-dose epidural administration of lipophilic and hydrophilic opioids is used to provide postoperative analgesia, with considerations generally being similar to those discussed for single-dose intrathecal administration of opioids. A single bolus of epidural fentanyl may be administered to provide rapid postoperative analgesia; however, diluting the epidural dose of fentanyl (typically 50 to 100 μg) in at least 10 mL of preservative-free normal saline is suggested to decrease the onset and prolong the duration of analgesia, possibly as a result of an increase in initial spread and diffusion of the lipophilic opioid.[70] Single-dose epidural morphine is effective for postoperative analgesia and may decrease postoperative patient morbidity in selected patients.[71,72] Use of a single-dose hydrophilic opioid may be especially helpful in providing postoperative epidural analgesia when the epidural catheter's location is not congruent with the surgical incision (e.g., lumbar epidural catheter for thoracic surgery). Lower doses of epidural morphine may be required for elderly patients and thoracic catheter sites. Commonly used dosages for intrathecal and epidural administration of neuraxial opioids are provided in Table 87-4.

An extended-release formulation of (single-dose) epidural morphine encapsulated within liposomes that results in up to 48 hours of analgesia has recently been introduced.[73] There are some precautions in using this newer formulation of epidural morphine. To resuspend the particles immediately before withdrawal from the vial, the vial should be gently inverted with avoidance of aggressive or excessive agitation. Concurrent administration of liposomal extended-release morphine and local anesthetics may increase peak concentrations of morphine. Accordingly, the manufacturer has recommended that clinicians increase the interval between administration of local anesthetic (including test doses) and liposomal extended-release morphine to at least 15 minutes to minimize this pharmacokinetic interaction. In addition, because the liposomal extended-release morphine does not contain any bacteriostatic agents, it should be administered within 4 hours after withdrawal from the vial. Finally, as with traditional single-dose neuraxial opioids, clinicians should administer a lower dose of liposomal extended-release morphine to the elderly or those with decreased physiologic reserve or coexisting disease. At this time, liposomal extended-release morphine has not been studied or approved in pediatric patients.

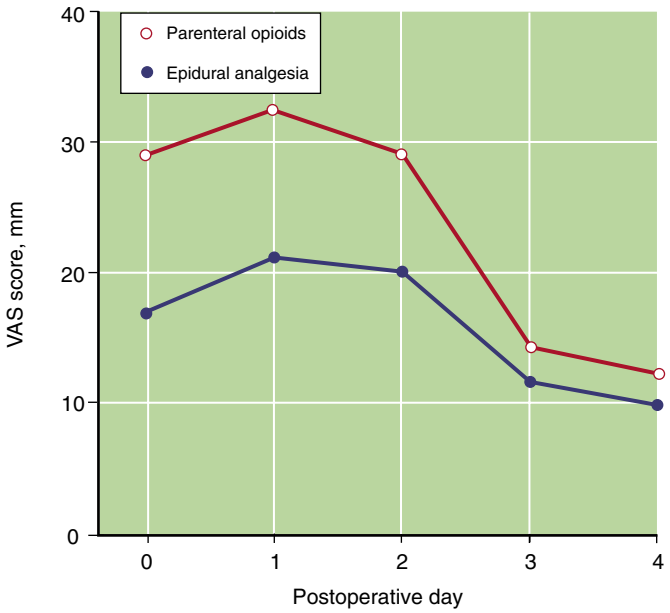
Table 87-4 Dosing of Neuraxial Opioids*

Drug	Intrathecal or Subarachnoid Single Dose	Epidural Single Dose	Epidural Continuous Infusion
Fentanyl	5-25 μg	50-100 μg	25-100 μg/hr
Sufentanil	2-10 μg	10-50 μg	10-20 μg/hr
Alfentanil	—	0.5-1 mg	0.2 mg/hr
Morphine	0.1-0.3 mg	1-5 mg	0.1-1 mg/hr
Diamorphine	1-2 mg	4-6 mg	—
Hydromorphone	—	0.5-1 mg	0.1-0.2 mg/hr
Meperidine	10-30 mg	20-60 mg	10-60 mg/hr
Methadone	—	4-8 mg	0.3-0.5 mg/hr
Extended-release morphine†	Not recommended	5-15 mg	Not recommended

*Doses are based on the use of a neuraxial opioid alone. No continuous intrathecal or subarachnoid infusions are provided. Lower doses may be effective when administered to the elderly or when injected in the cervical or thoracic region. Units vary across agents for single dose (mg versus μg) and continuous infusion (mg/hr versus μg/hr).
†See package insert for details on dosage and administration.

Continuous Epidural Analgesia

Analgesia delivered through an indwelling epidural catheter is a safe and effective method for management of acute postoperative pain.[74] Postoperative epidural analgesia can provide analgesia superior to that with systemic opioids (Fig. 87-2).[75,76] Of note, however, epidural analgesia is not a generic term but incorporates a wide range of options, including the choice and dose of analgesic agents, location of catheter placement, and onset and duration of perioperative use.[74] Although this section focuses on the postoperative management of epidural analgesia, it is important to realize that intraoperative use of the epidural catheter as part of a combined epidural-general anesthetic technique results in less pain and faster patient recovery immediately after surgery than general anesthesia followed by systemic opioids does.[77] Each of



No. of patient observations

Parenteral opioids	1104	2635	1496	794	536
Epidural analgesia	1010	2618	1527	822	566

Figure 87-2 Mean and standard deviation of visual analog pain scores (*y* axis) for both epidural analgesia (represented by *dark blue circles*) and parenteral opioids (represented by *open red circles*) for each postoperative day (*x* axis) up to the fourth day after surgery. *(From Block BM, Liu SS, Rowlingson AJ, et al: Efficacy of postoperative epidural analgesia: A meta-analysis. JAMA 290:2455-2463, 2003, with permission.)*

these options may affect the quality of postoperative analgesia, patient-reported outcomes, and even rates of morbidity and mortality.

Analgesic Drugs

Local Anesthetics. Epidural infusion of local anesthetic alone may be used for postoperative analgesia, but in general it is not as effective in controlling pain as local anesthetic–opioid epidural analgesic combinations are.[75,76] The precise location of action of local anesthetics in the epidural space is not clear, and potential sites include the spinal nerve roots, dorsal root ganglion, or spinal cord itself.[68] Although some anatomic data suggest that the initial site of epidural local anesthetic block is at the nerve root sheath and dorsal root ganglion,[78] experimental data demonstrate that the initial site of action may not be at the spinal nerve root sleeve.[79] Epidural infusion of local anesthetic alone may be warranted for postoperative analgesia in an attempt to avoid opioid-related side effects; however, the sole use of local anesthetics is less common than the use of a local anesthetic–opioid combination because of a significant failure rate (from regression of sensory blockade and inadequate analgesia) and relatively high incidence of motor block and hypotension.[74]

Opioids for Epidural Infusion. Opioids may be used alone for postoperative epidural infusion and do not generally cause motor block or hypotension from sympathetic blockade.[74] There are differences between continuous epidural infusion of lipophilic (e.g., fentanyl, sufentanil) and hydrophilic (e.g., morphine, hydromorphone) opioids. The analgesic site of action (spinal versus systemic) of continuous epidural infusion of lipophilic opioids is not clear, although several randomized clinical trials suggest that it is systemic[80] because there were no differences in plasma concentrations, side effects, or pain scores between those who received intravenous or epidural infusion of fentanyl.[80] Although some data suggest a benefit from epidural (versus intravenous) infusion of lipophilic opioids,[81] the overall advantage of administering continuous epidural infusion of lipophilic opioids alone is marginal.[74]

The analgesic site of action for continuous hydrophilic opioid infusion is primarily spinal.[82] Continuous infusion of a hydrophilic opioid may be especially useful for providing postoperative analgesia when the site of catheter insertion is not congruent with the site of surgery or when side effects (e.g., hypotension, motor block) are attributed to the epidural local anesthetic. Use of a continuous infusion rather than intermittent boluses of epidural morphine may result in superior analgesia with fewer side effects.[82] Continuous epidural infusion of hydrophilic opioids may provide analgesia superior to that of traditional PRN administration of systemic opioids.[83]

Local Anesthetic–Opioid Combinations. Use of a local anesthetic and an opioid in an epidural infusion may have advantages over infusions consisting of a local anesthetic or opioid alone. When compared with a local anesthetic or opioid alone, a local anesthetic–opioid combination provides superior postoperative analgesia (including improved dynamic pain relief), limits regression of sensory blockade, and possibly decreases the dose of local anesthetic administered, although the effect on the incidence is uncertain.[74] Continuous epidural infusion of a local anesthetic–opioid combination also provides analgesia superior to that of intravenous PCA with opioids.[75] It is unclear whether the analgesic effect of the local anesthetic and opioid in epidural analgesia is additive or synergistic. Experimental studies demonstrate a synergistic effect between local anesthetics and opioids[84]; however, clinical trials suggest an additive effect.[85]

The choice of local anesthetic for continuous epidural infusion varies. In general, bupivacaine, ropivacaine, or levobupivacaine is chosen because of the differential and preferential clinical sensory blockade with minimal impairment of motor function.[86] Concentrations used for postoperative epidural analgesia (≤0.125% bupivacaine or levobupivacaine or ≤0.2% ropivacaine) are lower than those used for intraoperative anesthesia. The choice of opioid also varies, although many clinicians prefer a lipophilic opioid (fentanyl, 2 to 5 μg/mL, or sufentanil, 0.5 to 1 μg/mL) to allow rapid titration of analgesia.[74,82] Use of a hydrophilic opioid (morphine, 0.05 to 0.1 mg/mL, or hydromorphone, 0.01 to 0.05 mg/mL) as part of a local anesthetic–opioid epidural analgesic regimen may also provide effective postoperative analgesia.[82]

Although the optimal local anesthetic and opioid dose that provides the lowest pain scores with the fewest medication-related side effects is unknown, a direct search method incorporating various epidural analgesic agents in patients undergoing major abdominal surgery revealed that the two optimal epidural bupivacaine-fentanyl combinations were 8 mg/hr of bupivacaine plus 30 μg/hr of fentanyl and 13 mg/hr of bupivacaine plus 25 μg/hr of fentanyl at a continuous infusion of 9 mL/hr.[87] Further investigation is needed to determine the optimal combinations for other types of surgical procedures with different epidural catheter insertion sites and to compare the efficacy of these optimal continuous infusions with patient-controlled epidural analgesia (PCEA).

Adjuvant Drugs. A variety of adjuvants may be added to epidural infusions to enhance analgesia while minimizing side effects, but none has gained widespread acceptance. Two of the more studied adjuvants are clonidine and epinephrine. Clonidine mediates its analgesic effects primarily through the spinal dorsal horn α_2-receptors on primary afferents and interneurons, as well as the descending noradrenergic pathway, and the epidural dose typically used ranges from 5 to 20 μg/hr.[87,88] Clinical application of clonidine is limited by its side effects: hypotension, bradycardia, and sedation.[88] Hypotension and bradycardia are both dose dependent. Epinephrine may improve epidural analgesia, can increase sensory blockade, and is generally administered at a concentration of 2 to 5 μg/mL.[89,90] Epidural administration of NMDA antagonists, such as ketamine, can theoretically be useful in attenuating central sensitization and potentiating the analgesic effect of epidural opioids, but additional safety and analgesic data are needed.

Location of Catheter Insertion

Insertion of the epidural catheter congruent to the incisional dermatome (i.e., catheter-incision–congruent analgesia) (Table 87-5) results in optimal postoperative epidural analgesia by infusing analgesic agents to the appropriate incisional dermatomes, providing superior analgesia, minimizing side effects (e.g., lower extremity motor block and urinary retention), and decreasing morbidity.[13,74] Observational and randomized data suggest that when compared with catheter-incision–congruent epidural analgesia, catheter-incision–incongruent epidural analgesia (e.g., low lumbar catheter placement for thoracic procedures) results in increased pain and early removal of the epidural catheter because of ineffective analgesia.[91] By targeting delivery of analgesic agents to the appropriate dermatomes, catheter-incision–congruent

Table 87-5 Recommended Catheter Insertion Sites for Surgical Procedures

Location of Incision	Examples of Surgical Procedures	Congruent Epidural Catheter Placement
Thoracic	Lung reduction, radical mastectomy, thoracotomy, thymectomy	T4-8
Upper abdominal	Cholecystectomy, esophagectomy, gastrectomy, hepatic resection, Whipple procedure	T6-8
Middle abdominal	Cystoprostatectomy, nephrectomy	T7-10
Lower abdominal	Abdominal aortic aneurysm repair, colectomy, radical prostatectomy, total abdominal hysterectomy	T8-11
Lower extremity	Femoral-popliteal bypass, total hip or total knee replacement	L1-4

L, lumbar level; T, thoracic level.

epidural analgesia may result in lower drug requirements and decreased medication-related side effects. There is a higher incidence of lower extremity motor block with the use of lumbar epidural catheters, and an earlier-than-anticipated termination of epidural analgesia may also result.[92] Use of a high thoracic epidural does not inhibit sympathetic nerve activity in the lower extremities, which are supplied by sympathetic nerve fibers from T9 to L1.[93] Use of thoracic epidural analgesia for abdominal or thoracic surgery may result in a relatively low incidence of urinary retention and diminish the need for routine bladder catheterization.[94] Placement of thoracic epidural catheters appears to be relatively safe, and there is no evidence of a higher incidence of neurologic complications with placement of a thoracic (versus lumbar) epidural catheter.[95] The benefits of epidural analgesia in decreasing morbidity in patients undergoing abdominal and thoracic surgery are seen only with thoracic (congruent), not lumbar (incongruent) epidural catheter placement.[96,97]

Side Effects of Neuraxial Analgesic Drugs

Many medication-related (opioid and local anesthetic) side effects can occur with the use of postoperative epidural analgesia, but before automatically ascribing the cause to the epidural analgesic regimen, it is important to first consider other causes, such as low intravascular volume, bleeding, and low cardiac output leading to hypotension and cerebrovascular accident, pulmonary edema, and evolving sepsis leading to respiratory depression. Standing orders and nursing protocols for analgesic regimens, neurologic monitoring, treatment of side effects, and physician notification about critical parameters should be standard for all patients receiving neuraxial and other types of postoperative analgesia (see Box 87-1).

Hypotension. The local anesthetics used in an epidural analgesic regimen may block sympathetic fibers and contribute to postoperative hypotension. Although the incidence of postoperative hypotension with postoperative epidural analgesia may be as high as approximately 7%, the average may be closer to 0.7% to 3%.[74,98] Strategies to treat noncritical hypotension caused by epidural analgesia include decreasing the overall dose of local anesthetic administered (by decreasing the rate or concentration), infusing an opioid epidural alone because it is unlikely that neuraxial opioid administration would contribute to postoperative hypotension, and treating the underlying cause of the decrease in blood pressure.[74]

Motor Block. Use of local anesthetics for postoperative epidural analgesia may also contribute to lower extremity motor block in approximately 2% to 3% of patients,[74,98] and this may lead to the development of pressure sores in the heels.[99] A lower concentration of local anesthetic and catheter-incision–congruent placement of epidural catheters for abdominal or thoracic procedures may decrease the incidence of motor block.[100] Although motor block resolves in most cases after stopping the epidural infusion for approximately 2 hours, persistent or increasing motor block should be evaluated promptly, and spinal hematoma, spinal abscess, and intrathecal catheter migration should be considered as part of the differential diagnosis.[74]

Nausea and Vomiting. Nausea and vomiting associated with neuraxial administration of single-dose opioid occurs in approximately 20% to 50% of patients,[101] and the cumulative incidence in those receiving continuous infusions of opioid may be as high as 45% to 80%.[102] Clinical and experimental data suggest that the incidence of neuraxial opioid–related nausea and vomiting is dose dependent.[103] Nausea and vomiting from neuraxial opioids may be related to the cephalad migration of opioid within the CSF to the area postrema in the medulla.[101] Use of fentanyl alone or in combination with a local anesthetic in an epidural infusion is associated with a lower incidence of nausea and vomiting than infusions of morphine are.[102,104] A variety of agents have been used successfully to treat neuraxial opioid–induced nausea and vomiting, including naloxone, droperidol, metoclopramide, dexamethasone, ondansetron, and transdermal scopolamine.[105,106]

Pruritus. Pruritus is one of the most common side effects of epidural or intrathecal administration of opioids, with an incidence of approximately 60% versus about 15% to 18% for epidural local anesthetic administration or systemic opioids.[107] Although the cause of neuraxial opioid–induced pruritus is uncertain, it does not appear to be associated with peripheral histamine release but may be related to central activation of an "itch center" in the medulla or activation of opioid receptors in the trigeminal nucleus or nerve roots with cephalad migration of the opioid.[101] It is unclear whether the incidence of neuraxial opioid–related pruritus is dose dependent because a quantitative systematic review[107] suggested no evidence of a relationship whereas other clinical and experimental studies have indicated a significant correlation.[108] Use of an epidural infusion of fentanyl alone or as part of a local anesthetic–opioid combination appears to generally be associated with a lower incidence of pruritus than is the case with morphine.[104] A variety of agents have been evaluated for the prevention and treatment of opioid-induced pruritus. Intravenous naloxone, naltrexone, nalbuphine, and droperidol appear to be efficacious for the pharmacologic control of opioid-induced pruritus.[107] Although pruritus is a common side effect, it

is relatively easy to treat and not considered an important clinical outcome to avoid.[109] The use of epidural morphine is associated with postpartum reactivation of herpes simplex labialis.[110]

Respiratory Depression. Neuraxial opioids used in appropriate doses are not associated with a higher incidence of respiratory depression than that seen with systemic administration of opioids. The incidence of respiratory depression with neuraxial administration of opioids is dose dependent and typically ranges from 0.1% to 0.9%.[39,111] The incidence of respiratory depression with continuous infusion of epidural opioids appears to be no greater than that seen after systemic opioid administration.[39,111] Although some institutions require that patients with continuous epidural infusion of hydrophilic opioids be monitored in an intensive care unit setting, many large-scale trials have demonstrated the relative safety (incidence of respiratory depression <0.9%) of this technique on regular surgical wards.[112]

Neuraxial lipophilic opioids are thought to cause less delayed respiratory depression than hydrophilic opioids are, although administration of lipophilic opioids may be associated with significant, early respiratory depression.[113] Delayed respiratory depression is primarily associated with the cephalad spread of hydrophilic opioids, which typically occurs within 12 hours after injection of morphine.[114] Risks factors for respiratory depression with neuraxial opioids include increasing dose, increasing age, concomitant use of systemic opioids or sedatives and possibly prolonged or extensive surgery, the presence of comorbid conditions, and thoracic surgery.[114] Clinical assessments, such as the respiratory rate, may not reliably predict a patient's ventilatory status or impending respiratory depression. Treatment with naloxone (and airway management if necessary) is effective in 0.1- to 0.4-mg increments; however, because its clinical duration of action is relatively short in comparison to the respiratory depressant effect of neuraxial opioids, continuous infusion of naloxone (0.5 to 5 µg/kg/hr) may be needed.[115]

Urinary Retention. Urinary retention associated with the neuraxial administration of opioids is the result of an interaction with opioid receptors in the spinal cord that decreases the detrusor muscle's strength of contraction.[101] The incidence of urinary retention seems to be higher with neuraxially administered opioids than when given systemically. However, the exact incidence of urinary retention seen clinically may be difficult to determine because patients who undergo major surgical procedures are often routinely catheterized. Urinary retention does not appear to depend on the opioid dose and may be treated with the use of low-dose naloxone, though at the risk of reversing the analgesic effect.[115] Epidural administration of local anesthetics is also associated with urinary retention, with a reported rate of approximately 10% to 30%.[116] Higher epidural infusion rates of local anesthetics (with a greater extent of sensory block and a higher incidence of motor block) may be associated with a higher incidence of urinary retention.[117]

Patient-Controlled Epidural Analgesia

Epidural analgesia has traditionally been delivered at a fixed rate or as a continuous epidural infusion (CEI); however, the administration of epidural analgesia through a patient-controlled device (PCEA) has become more common. Like intravenous PCA, PCEA allows individualization of postoperative analgesic requirements and may have several advantages over CEI, including lower drug use and greater patient satisfaction.[43] PCEA may also provide analgesia superior to that afforded by intravenous PCA.[75]

PCEA is a safe and effective technique for postoperative analgesia on routine surgical wards. Observational data from two series of over 1000 patients each reveal that more than 90% of patients with PCEA receive adequate analgesia, with a median pain score of 1 (of a possible 10) at rest and 4 with activity.[98,118] The incidence of side effects is 1.8% to 16.7% for pruritus, 3.8% to 14.8% for nausea, 13.2% for sedation, 4.3% to 6.8% for hypotension, 0.1% to 2% for motor block, and 0.2% to 0.3% for respiratory depression.[98,118] These rates are favorable and comparable to those reported with CEI, which is associated with an incidence of 10.2% to 22% for pruritus, 3.1% to 22% for nausea, 7.4% for sedation, 0.7% to 6.6% for hypotension, 3% for motor block, and 0.1% to 1.6% for respiratory depression.[112,119]

The optimal PCEA analgesic solution and delivery parameters are unclear. Use of a continuous or background infusion in addition to the demand dose is more common with PCEA than with intravenous PCA and may provide analgesia superior to that with the use of a demand dose alone.[120] In general, most acute pain specialists have gravitated toward a variety of low-concentration local anesthetic–opioid combinations (Table 87-6) in an attempt to improve analgesia while minimizing side effects, such as motor block and respiratory depression. As for CEI, addition of an opioid to the local anesthetic can provide analgesia superior to that with either agent alone.[121] A lipophilic opioid is usually chosen because its rapid analgesic effect and shorter duration of action may be more suitable for use with PCEA.[98] The roles

Table 87-6 Patient-Controlled Epidural Analgesia Regimens

Analgesic Solution*	Continuous Rate (mL/hr)	Demand Dose (mL)	Lockout Interval (min)
General Regimens			
0.05% bupivacaine + 4 µg/mL fentanyl	4	2	10
0.0625% bupivacaine + 5 µg/mL fentanyl†	4-6	3-4	10-15
0.1% bupivacaine + 5 µg/mL fentanyl	6	2	10-15
0.2% ropivacaine + 5 µg/mL fentanyl	5	2	20
Thoracic Surgery			
0.0625%-0.125% bupivacaine + 5 µg/mL fentanyl†	3-4	2-3	10-15
Abdominal Surgery			
0.0625% bupivacaine + 5 µg/mL fentanyl†	4-6	3-4	10-15
0.125% bupivacaine + 0.5 µg/mL sufentanil	3-5	2-3	12
0.1%-0.2% ropivacaine + 2 µg/mL fentanyl	3-5	2-5	10-20
Lower Extremity Surgery			
0.0625%-0.125% bupivacaine + 5 µg/mL fentanyl†	4-6	3-4	10-15
0.125% levobupivacaine + 4 µg/mL fentanyl	4	2	10

*Regimens listed are samples of local anesthetic–lipophilic opioid combinations from the literature.

of other adjuvant agents, including clonidine, have begun to be addressed. In one study, clonidine added to a mixture of bupivacaine and morphine administered into the epidural space was found to provide improved analgesia with few side effects after total-knee arthroplasty.[122]

Benefits of Epidural Analgesia

Use of perioperative epidural anesthesia and analgesia, especially with a local anesthetic–based analgesic solution, can attenuate the pathophysiologic response to surgery and may be associated with a reduction in mortality and morbidity when compared with analgesia with systemic (opioid) agents.[10,13] A meta-analysis of randomized data (141 trials enrolling 9559 subjects) demonstrated that perioperative use of neuraxial anesthesia and analgesia (versus general anesthesia and systemic opioids) reduced overall mortality (primarily in orthopedic patients) by approximately 30%.[123] Use of epidural analgesia can decrease the incidence of postoperative gastrointestinal, pulmonary, and possibly cardiac complications.[10,13]

By inhibiting sympathetic outflow, decreasing the total opioid dose, and attenuating spinal reflex inhibition of the gastrointestinal tract,[10] postoperative thoracic epidural analgesia can facilitate return of gastrointestinal motility without contributing to anastomotic bowel dehiscence.[124] Randomized clinical trials demonstrate that use of postoperative thoracic epidural analgesia with a local anesthetic–based analgesic solution allows earlier return of gastrointestinal function and fulfillment of discharge criteria.[125] When compared with those who receive epidural opioids for postoperative analgesia, patients who receive epidural local anesthetics have an earlier return of gastrointestinal motility after abdominal surgery.[125]

Perioperative use of epidural analgesia with a local anesthetic–based regimen in patients undergoing abdominal and thoracic surgery decreases postoperative pulmonary complications,[126,127] presumably by preserving postoperative pulmonary function by providing superior analgesia and thus reducing "splinting" behavior and attenuating the spinal reflex inhibition of diaphragmatic function.[10] A meta-analysis of 48 randomized clinical trials[128] and another large, randomized clinical trial[129] demonstrated that use of thoracic epidural analgesia with a local anesthetic–based regimen decreased the incidence of pulmonary infections and complications. However, patients who received postoperative epidural opioids, intercostal blocks, wound infiltration, or intrapleural analgesia did not have a significant decrease in the incidence of pulmonary complications.[128]

Use of postoperative thoracic, but not lumbar epidural analgesia may decrease the incidence of postoperative myocardial infarction,[97] possibly by attenuating the stress response and hypercoagulability, improving postoperative analgesia, and providing favorable redistribution of coronary blood flow.[10] The finding that only thoracic epidural analgesia decreases the incidence of postoperative myocardial infarction corroborates experimental data on the physiologic benefits of thoracic epidural analgesia, such as a reduction in the severity of myocardial ischemia or size of infarction, attenuation of sympathetically mediated coronary vasoconstriction, and improvement of coronary flow to areas at risk for ischemia.[10]

Although postoperative epidural analgesia appears to decrease postoperative gastrointestinal, pulmonary, and possibly cardiac morbidity, the benefits of postoperative epidural analgesia are not as clear in other areas, such as postoperative coagulation, cognitive dysfunction,[130] and immune function. Despite the fact that many randomized clinical trials and meta-analyses show that use of *intra*operative regional anesthesia decreases the incidence of hypercoagulable-related events (e.g., deep venous thrombosis, pulmonary embolism, vascular graft failure),[123,131] evidence of a beneficial effect of *post*operative epidural analgesia in decreasing the incidence of hypercoagulable-related events is not compelling.

The benefits of postoperative epidural analgesia are optimized when the epidural catheter is inserted in a location corresponding to the dermatomes covered by the surgical incision (i.e., catheter-incision–congruent analgesia), which results in a lower dose of drug administered and decreased incidence of drug-induced side effects, such as pruritus, nausea, vomiting, urinary retention, motor block, and hypotension.[98,132] When compared with catheter-incision–incongruent epidural analgesia, catheter-incision–congruent analgesia[132] provides earlier return of gastrointestinal function,[96] a lower incidence of myocardial infarction,[97] and superior analgesia.[91] The ability of postoperative epidural analgesia to attenuate postoperative pathophysiology and improve outcomes also depends on the type of drugs used (opioids versus local anesthetics). Maximal attenuation of perioperative pathophysiology occurs with the use of a local anesthetic–based epidural analgesic solution. The use of a local anesthetic–based (versus opioid-based) analgesic solution is associated with earlier recovery of gastrointestinal motility after abdominal surgery[125] and less frequent occurrence of pulmonary complications.[128] Epidural analgesia is not a generic entity because different catheter locations and analgesic regimens may differentially affect perioperative morbidity.
