Use of postoperative epidural analgesia may be associated with an improvement in postoperative analgesia and patient-reported outcomes such as patient satisfaction[38] and HRQL.[18] When compared with systemic opioids, epidural local anesthetics consistently provide superior analgesia.[75,76] The data on the analgesic superiority of postoperative epidural analgesia reflect that seen with epidural analgesia during labor.[133] Although the concept of satisfaction is complex and difficult to measure accurately, the analgesic benefits of postoperative epidural analgesia may contribute to greater patient satisfaction[38] and improved HRQL.[18]

Risks with Epidural Analgesia

The benefits of perioperative epidural anesthesia-analgesia must be weighed against the risks associated with this technique. Risks and benefits should be evaluated for each patient. Some complications are associated with placement of an epidural catheter, and several risks related to the use of indwelling epidural catheters (e.g., epidural hematoma and abscess) should be discussed in the context of postoperative epidural analgesia. A review of neurologic complications after regional anesthesia revealed that the rate of neurologic complications after central neuraxial blockade is less than 4 in 10,000 (0.04%); the rate of neuropathy after a peripheral nerve block is less than 3 in 100 (3%).[134] However, permanent neurologic injury after either central neuraxial or peripheral nerve block is rare in contemporary anesthetic practice.[134] Elements of routine monitoring of patients receiving neuraxial analgesia are presented in Box 87-1.

The concurrent use of anticoagulants and neuraxial anesthesia and analgesia has always been a relatively controversial

issue but has been highlighted over the past decade by the increased incidence of spinal hematoma after the introduction of low-molecular-weight heparin in North America in 1993. Traditionally, the incidence of spinal hematoma is estimated to be approximately 1 in 150,000 for epidural blocks, with a lower incidence of 1 in 220,000 for spinal blocks.[135] Before its introduction in North America, low-molecular-weight heparin was used in Europe without significant problems; however, the incidence of spinal hematoma rose to as high as 1 in 40,800 for spinal anesthetics and 1 in 6600 for epidural anesthetics (1 in 3100 for postoperative epidural analgesia) in the United States between 1993 and 1998.[136] The estimate of the higher incidence of spinal hematoma after removal of the epidural catheter is based in part on the Food and Drug Administration's MedWatch data, which suggest that removal of an epidural catheter may be a traumatic event, although this issue is still relatively controversial.[137]

Different types and classes of anticoagulants have different pharmacokinetic properties that affect the timing of neuraxial catheter or needle insertion and catheter removal. Despite a number of observational and retrospective studies investigating the incidence of spinal hematoma in the setting of various anticoagulants and neuraxial techniques, no definitive conclusion regarding the absolute safety of neuraxial anesthesia and anticoagulation has been reached. The American Society of Regional Anesthesia and Pain Medicine (ASRA) lists a series of consensus statements based on the available literature for administration (insertion and removal) of neuraxial techniques in the presence of various anticoagulants, including oral anticoagulants (warfarin), antiplatelet agents, fibrinolytics-thrombolytics, standard unfractionated heparin, and low-molecular-weight heparin.[138] The ASRA consensus statements include the concepts that the timing of neuraxial needle or catheter insertion or removal should reflect the pharmacokinetic properties of the specific anticoagulant, that frequent neurologic monitoring is essential, that concurrent use of multiple anticoagulants may increase the risk of bleeding, and that the analgesic regimen should be tailored to facilitate neurologic monitoring, which may be continued in some cases for 24 hours after removal of the epidural catheter. An updated version of the ASRA consensus statements on neuraxial anesthesia and anticoagulation[138] can be found on their website (www.asra.com), and some of these statements address the newer anticoagulants.

Infection associated with postoperative epidural analgesia may result from exogenous or endogenous sources.[74] Serious infections (e.g., meningitis, spinal abscess) associated with epidural analgesics are rare (<1 in 10,000),[139] although some researchers report a higher incidence (approximately 1 in 1000 to 2000).[139] Closer examination of the studies that reported a higher incidence of epidural abscess reveals that the patients had a relatively longer duration of epidural analgesia or coexisting immunocompromising or complicating diseases (e.g., malignancy, trauma).[74,140] Use of epidural analgesia in the general surgical population with a typical duration of postoperative catheterization (approximately 2 to 4 days) is not generally associated with epidural abscess formation.[98] A trial of postoperative epidural analgesia (mean catheterization of 6.3 days) in more than 4000 surgical cancer patients did not reveal any abscesses.[122] Even though serious infectious complications appear to be rare after short-term (<4 days) epidural infusions, there may be a relatively higher incidence of superficial inflammation or cellulitis (4% to 14%) and an even higher rate of catheter colonization (20% to 35%), with the proportion of positive cultures increasing with longer duration of catheterization; however, the catheter colonization rate may not be a good predictor of infection of the epidural space.[141]

Although epidural analgesia may provide superior postoperative analgesia, migration of the epidural catheter out of the epidural space and into the intrathecal, intravascular, or subcutaneous space decreases the effectiveness of this technique. The failure rate (i.e., earlier-than-anticipated discontinuation of the catheter for any reason, placement of a nonfunctioning epidural catheter or "sham dural") ranges from approximately 6% to 25%, with many centers reporting a rate between 10% and 20%, but the incidence of actual premature epidural catheter dislodgment may be lower (mean, 5.7%; 95% confidence interval, 4.0% to 7.4%).[66,98,122] Fortunately, the rate of intrathecal (~0.15%) and intravascular (0.07% to 0.18%) migration of an epidural catheter is much lower than the failure rate.[142] Despite the less frequent occurrence of intravascular and intrathecal migration of postoperative epidural catheters, use of an epinephrine-containing test dose, administration of local anesthetic in fractionated doses, and aspiration of the catheter before bolus administration of local anesthetics may prevent complications (e.g., high or total spinal, seizures, neurotoxicity) associated with accidental administration of local anesthetics into the intravascular or intrathecal space.[74] The issue of whether lower extremity compartment syndrome can be consistently masked by the use of a local anesthetic–based epidural analgesic regimen is unresolved because use of systemic opioid analgesia has also been associated with a delayed diagnosis of compartment syndrome.[143]

Peripheral Regional Analgesia

The use of peripheral regional analgesic techniques as a single injection or continuous infusion can provide analgesia superior to that with systemic opioids[144] and may even result in improvement in various outcomes.[145] A variety of wound infiltration and peripheral regional techniques (e.g., brachial plexus, lumbar plexus, femoral, sciatic-popliteal, and scalp nerve blocks) can be used to enhance postoperative analgesia. Peripheral regional techniques may have several advantages over systemic opioids (i.e., superior analgesia and decreased opioid-related side effects) and neuraxial techniques (i.e., decreased risk for spinal hematoma).[146]

A one-time injection of local anesthetic for peripheral regional techniques may be used primarily for intraoperative anesthesia or as an adjunct to postoperative analgesia. When compared with placebo, peripheral nerve blocks with local anesthetics provide superior analgesia and are associated with reduced opioid use, decreased opioid-related side effects, and improvement in patient satisfaction.[146] The duration of postoperative analgesia resulting from the local anesthetic in the peripheral nerve block varies but may last up to 24 hours after injection. Local anesthetics may also provide effective wound infiltration analgesia postoperatively for a variety of procedures.[147,148]

Continuous infusions of local anesthetics can be administered through peripheral nerve catheters. When compared with systemic opioids, use of continuous infusions or patient-controlled peripheral analgesia results in superior analgesia, decreased opioid-related side effects, and greater patient satisfaction.[144,146] The optimal parameters (i.e., local anesthetic, concen-

tration, opioid, adjuvants, and continuous versus PCA versus intermittent boluses) for peripheral analgesia have not been determined.

Thoracic or Nonepidural Analgesia

Several nonepidural regional analgesic techniques can be used for the management of postoperative thoracic pain, including paravertebral and intercostal blocks, interpleural (intrapleural) analgesia, and cryoanalgesia. The most promising technique appears to be a thoracic paravertebral block, which has been used for thoracic, breast, and upper abdominal surgery and for the treatment of rib fracture pain.[149] Possible sites of analgesia for a thoracic paravertebral block include direct somatic nerve, sympathetic nerve, and epidural blockade.[149] A thoracic paravertebral block can be administered as a single injection or as continuous infusion through a catheter, may provide analgesia equal or superior to that with thoracic epidural analgesia, and is a valuable alternative to thoracic epidural analgesia.[150]

The analgesic efficacy of interpleural analgesia is controversial, as is its mechanism of action (i.e., sensory or sympathetic block, or both).[151] Interpleural analgesia appears to be inferior to epidural and paravertebral analgesia for control of postoperative pain, preservation of lung function after thoracotomy, and reduction of postoperative pulmonary complications.[128,151] Intercostal blocks may provide short-term postoperative analgesia and may be repeated postoperatively; however, the incidence of pneumothorax increases with each intercostal nerve blocked (1.4% per nerve, with an overall incidence of 8.7% per patient).[152] Like interpleural analgesia, intercostal blocks do not reduce the incidence of pulmonary complications postoperatively when compared with epidural analgesia.[128] Cryoanalgesia can be used for postoperative analgesia after thoracotomy but, like interpleural analgesia and intercostal blocks, does not appear to provide any analgesic advantage over epidural analgesia, is not effective for other types of postoperative pain, and is short-lived.[153]

Intra-articular Analgesia

Local peripheral administration of opioids (e.g., intra-articular injection after knee surgery) may provide analgesia for up to 24 hours after surgery[154] and decrease the incidence of chronic pain.[155] Peripheral opioid receptors are found on the peripheral terminals of primary afferent nerves and are upregulated during inflammation of peripheral tissues.[24] Results of the several randomized clinical trials investigating this topic have been summarized.[154] Use of a higher dose of intra-articular morphine (5 versus 1 mg) results in superior analgesia; however, there may be no advantage in the degree of analgesia provided between intra-articular and systemic opioids.[154] A systemic effect of intra-articularly injected morphine cannot be excluded. Intra-articular injection of local anesthetics may provide a limited duration of postoperative analgesia, but the clinical benefit from intra-articular injection of local anesthetics is unclear.[156]

Other Techniques

Other nonpharmacologic techniques, such as transcutaneous electrical nerve stimulation (TENS), acupuncture, and psychological approaches, can be used in an attempt to alleviate postoperative pain. The mechanism by which TENS produces analgesia is unclear but may be related to modulation of nociceptive impulses in the spinal cord, release of endogenous enkephalins, or a combination of these and other mechanisms.[157] Although the analgesic efficacy of these techniques is controversial, TENS and acupuncture may provide postoperative analgesia, decrease postoperative opioid requirements, reduce opioid-related side effects, and attenuate activation of the sympathoadrenal system.[157] In general, both these approaches to postoperative pain are relatively safe, noninvasive, and devoid of the systemic side effects seen with other analgesic treatment options.[157,158] However, there are methodologic issues with many of the available trials, and the precise role of these treatments in postoperative pain management is not clear. It is possible that TENS and acupuncture may be useful adjuncts to the more traditional pharmacologic analgesic drugs, but they may not be effective as the sole technique for severe postoperative or labor pain.[159]

Although this chapter has focused on the neurobiology of nociception and pharmacologic treatments available for the treatment of postoperative pain, the experience of pain is complex, multifaceted, and "an unpleasant sensory and emotional experience," as defined in part by the International Association for the Study of Pain. The differential behavior response to surgical incision may be related to global (i.e., personality, gender, age, and culture) and specific (i.e., fear, depression, anger, and coping) psychological factors.[160] Cognitive behavior therapy and behavior therapy may be efficacious in reducing pain and alleviating psychological factors associated with pain.[161] Identifying and addressing psychological factors can reduce pain, improve the efficacy of pharmacologic analgesics, and diminish patients' distress, in part through enhancement of the placebo effect.[160] Although the placebo effect has traditionally been thought to have a psychological origin, the placebo response may exert part of its effects through activation of endogenous opioids and be useful in reducing the intensity of pain.[162]

Postoperative Analgesia in Special Populations

This foregoing discussion has provided a general approach to the principles and practice of acute postoperative pain management, but this approach may need to be modified for certain populations that may have unique anatomic, physiologic, pharmacologic, affective, and cognitive issues. Management of acute pain should be tailored to the specific needs of a particular population. Although each topic by itself could merit a separate chapter in some textbooks, the general principles and essence of the issues associated with each population are outlined, and references are made to other more extensive sources.

Ambulatory Surgical Patients

The percentage of surgical procedures being performed on an outpatient basis continues to rise. There has been an increase in the number of outpatient surgical procedures, in the complexity of operations being performed, and in comorbid conditions of the surgical outpatients (also see Chapter 78). Optimizing treatment of postoperative and postdischarge pain is especially important in patients undergoing outpatient surgery because inadequate

control of postoperative pain is one of the leading causes of prolonged stays or readmission after outpatient surgery.[163] Although there has been much effort to minimize symptoms such as pain and nausea in the postanesthesia care unit and subsequent (phase II) recovery area to facilitate discharge after outpatient surgery, increasing data suggest that postdischarge pain (i.e., pain that occurs after discharge) is common and may interfere with patients' recovery and the overall health-related cost of outpatient surgery.[164] Despite advances in surgical techniques that minimize surgical trauma and postoperative pain, the incidence of moderate to severe postdischarge pain is still approximately 25% to 35%,[165] and it can be especially troublesome for certain patients, such as those undergoing tubal ligation and orthopedic procedures.[166] After discharge, poorly controlled nausea and vomiting may interfere with the intake of oral analgesics.

In light of these considerations, the traditional reliance on opioid analgesia may not be appropriate for patients undergoing ambulatory surgery because of opioid-related side effects that may delay hospital discharge and postdischarge recovery after outpatient surgery. A multimodal or "balanced" analgesic approach using a combination of opioid and nonopioid analgesic techniques (i.e., NSAIDs or acetaminophen, local anesthetics, and other nonpharmacologic therapies) may be more appropriate in this surgical population. Using nonopioid analgesic techniques with different mechanisms of analgesia diminishes opioid-related side effects, synergistically enhances postoperative analgesia, and facilitates patient recovery. For instance, use of local anesthetics has decreased postoperative pain, and the drugs can be administered as peripheral nerve blocks, tissue infiltration, wound instillation, or topical analgesics. Similar results have been achieved with the use of systemic NSAIDs and acetaminophen.

Although multimodal analgesia may be especially effective in the immediate postoperative period, not all of the options may be routinely available after the patient is discharged home. For example, use of local anesthetics in peripheral nerve blocks, tissue infiltration, or wound instillation may be effective in the immediate postoperative period; however, a single dose of local anesthetic rarely provides more than 24 hours of analgesia. Realistically, most outpatients rely on a combination of short-acting analgesics (e.g., an opioid and acetaminophen) for control of postoperative pain after discharge from the hospital. However, there are several strategies to optimize postdischarge pain, including the routine use of NSAIDs (if there are no contraindications) and the use of small doses of sustained-release opioids in certain surgical populations.[26] Routine use of acetaminophen, especially when an NSAID is added to the regimen, is recommended to maximize postoperative analgesia,[167] although it is important to remember that acetaminophen is a coanalgesic agent in many combination products, which may limit the number of combination analgesic tablets that the patient may consume. The future of postoperative pain control in ambulatory surgical patients may include postdischarge (home) use of continuous infusion of local anesthetic solutions or even use of long-acting, "sustained-release" local anesthetics.

Elderly Patients

The elderly population, which is expected to increase by 33% over the next 2 decades, accounts for approximately 12.5% of the total U.S. population and 38% of all health care spending (approximately 5% of the U.S. gross domestic product) (also see Chapter 71).[168] Changes in the physiology, pharmacodynamics, pharmacokinetics, and processing of nociceptive information that occur with aging may influence the effectiveness of postoperative pain control in the elderly. This group may have communication, affective, cognitive, social, and ideologic barriers to effective postoperative pain control. The elderly generally have decreased physiologic reserves and increased comorbid conditions in comparison to their younger counterparts, which may result in a higher incidence of postoperative complications (e.g., postoperative delirium), especially in the presence of severe or uncontrolled postoperative pain.

There is a clinically significant reduction in the intensity of pain perception or symptoms with increasing age.[169] For instance, silent myocardial ischemia is more common in the elderly, who may instead be seen initially with other anginal equivalents. Experimental studies demonstrate a decrease in Aδ and C fiber nociceptive function, delay in central sensitization, increase in pain thresholds, and decrease in sensitivity to low-intensity noxious stimuli.[169,170] However, elderly patients may have an increased response to higher-intensity noxious stimuli, decreased pain tolerance, and decreased descending modulation (i.e., serotoninergic and noradrenergic), which may contribute to the relatively high incidence of chronic pain in elderly patients.[169,171] Despite the methodologic issues in available studies evaluating age-related differences in the perception of pain, there appears to be a clinically relevant decrease in pain perception with increasing age. However, this should not be interpreted that elderly patients experience less pain than younger patients when they do report the presence of pain.

The physiologic and pharmacokinetic effects of aging on acute pain management are complex, and clinical implications include slow titration of opioids, which produces longer circulation times; smaller total doses because of increased sensitivity; and expectation of a longer duration of action because of reduced clearance. In general, analgesic requirements decrease with increasing age. Age has been shown to be the best predictor of postoperative requirements for intravenously and neuraxially administered morphine.[172] Similar to that seen in younger patients, there is large interpatient variability in postoperative analgesic requirements.[172] Use of intravenous PCA in the elderly is appropriate to compensate for the wide interpatient variability, although postoperative titration of intravenous morphine can also allow successful and safe administration to elderly patients.[173] Age itself is not an impediment to effective postoperative use of intravenous PCA or PCEA.[174] Use of postoperative epidural analgesia for elderly patients, especially those with decreased physiologic reserves, may attenuate the perioperative pathophysiology and is reported to improve postoperative outcomes, such as facilitating return of gastrointestinal function after abdominal surgery, decreasing the incidence of myocardial ischemia, lowering pain scores, and decreasing pulmonary complications.

Postoperative pain management in the elderly may be especially challenging because of some of the affective, cognitive, social, and ideologic barriers. Health care providers treating geriatric patients tend to have an unfounded level of fear of complications associated with treating perioperative pain, as reflected by the inadequate treatment of pain in elderly patients, even relative to younger patients.[171] Elderly patients may also contribute to inadequate pain control by their own reluctance to report pain or take opioid medications. Elderly patients have a higher incidence

of affective or cognitive impairment (e.g., depression, dementia) that may interfere with effective pain management.[171]

One of the most devastating complications in elderly surgical patients is postoperative delirium, which is associated with increased mortality rates and longer hospital stays.[175] The cause of postoperative delirium is unknown, although it is believed to result from an imbalance of neurotransmitters (particularly acetylcholine and serotonin) in the presence of decreased neurophysiologic reserve and inflammatory mediators.[176] Although the cause of postoperative delirium is multifactorial, uncontrolled postoperative pain may be an important contributor to its development.[177] Higher pain scores predict a decline in mental status and an increased risk for delirium.[178] Opioids other than meperidine[178] have not been associated with the development of postoperative delirium.[177,179] A multimodal analgesic approach may be useful in elderly patients but must be used with caution because adverse drug reactions in the elderly increase (to a greater extent than in younger patients) as the number of medications administered increases. Although the benefits of intraoperative regional anesthetic techniques on postoperative cognitive function are unclear, the postoperative use of epidural analgesia may diminish postoperative delirium in part through superior analgesia and a decrease in pulmonary complications.

Opioid-Tolerant Patients

Postoperative pain may be difficult to manage in opioid-tolerant patients because the standard approaches used for assessment and therapy in opioid-naive patients are inadequate for opioid-tolerant patients. Although opioid-tolerant patients typically require higher doses of analgesic medications in the immediate postoperative period, many health care providers still do not provide adequate postoperative pain relief, in part because of the fear of addiction or medication-related side effects. In dealing with patients with chronic opioid use, health care providers often mistakenly interchange several pharmacologic terms (i.e., tolerance, physical dependence, and addiction), a practice that may contribute to misunderstanding and inappropriate treatment decisions.

Tolerance refers to the pharmacologic property of an opioid in which an increasing amount is needed to maintain a given level of analgesia. *Physical dependence* is another pharmacologic property of opioids characterized by the occurrence of a withdrawal syndrome on abrupt discontinuation of the opioid or administration of an antagonist. Tolerance and physical dependence are pharmacologic properties of opioids and are not synonymous with the aberrant psychological state or behavior associated with *addiction*, a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm. The exaggerated fear of addiction contributes to the undertreatment of postoperative pain by health care providers; however, data suggest that there is minimal risk of iatrogenic addiction with use of opioids for pain control in patients who do not have a prior history of addiction.[180,181]

Several principles of pain assessment and treatment can be applied to the postoperative management of opioid-tolerant patients. The physician should expect high self-reported pain scores[182]; base treatment decisions on objective pain assessment (e.g., ability to breathe deeply, cough, ambulate) in conjunction with patients' self-reported pain scores[182]; recognize the need to identify and treat two major problems, maintenance of a basal opioid requirement and control of incisional pain; and recognize that detoxification is not usually an appropriate goal in the perioperative period. Likewise, several general strategies can be used for the treatment of postoperative pain in an opioid-tolerant patient. The physician can create a treatment plan early and discuss it with the patient, surgical team, and nursing staff; replace the patient's baseline or basal opioid requirements postoperatively; anticipate an increase in postoperative analgesic requirements[182]; maximize the use of adjuvant drugs; consider the use of regional analgesic techniques; and plan for the transition to an oral regimen. Although chronic pain patients are not synonymous with opioid-tolerant patients, many of these patients are opioid tolerant, and the same general principles and strategies may be applied to chronic pain patients who are opioid tolerant. Recognizing and addressing non-nociceptive sources of distress may be especially important for chronic pain patients.[160]

Even though there is no specific threshold or timeframe for when a patient becomes opioid tolerant, after an opioid-tolerant patient is identified, a perioperative strategy for postoperative pain control should be created and discussed with the patient. Such a strategy may include anticipation or arrangement for a longer than normal length of hospital stay, consultation with the anesthesiology or pain service, and confirmation of the patient's daily opioid intake to facilitate calculation of the patient's basal or maintenance opioid requirement in the postoperative period. Administration of a PRN analgesic regimen alone for opioid-tolerant patients is highly discouraged because replacing the basal opioid requirement in the postoperative period can optimize pain relief and possibly prevent opioid withdrawal. Basal opioid requirements can be administered systemically (typically intravenously or transdermally) until the patient can tolerate an oral analgesic regimen.[28] For example, 50% to 100% of the patient's baseline opioid requirement can be administered by continuous infusion as part of an intravenous PCA regimen, with a demand dose to cover the additional incisional pain. Conversion tables (Table 87-7) may facilitate equianalgesic conversion of opioids (i.e., different routes of administration of one opioid or conver-

Table 87-7 Guidelines for Equianalgesic Dosing of Opioid Agonists

	Equianalgesic Dose (mg)	
Drug	**Parenteral**	**Oral**
Morphine	10	30
Codeine	130	200
Fentanyl	0.1	—
Hydromorphone	1.5-2	6-7.5
Levorphanol	2	4
Meperidine	75	300
Methadone	10	20
Oxycodone	15	20-30
Oxymorphone	1	—

Equianalgesic doses are approximate and intended to serve only as an estimate of opioid requirements. Actual doses may vary, in part because of wide interpatient variability in response to opioids. Doses should be individualized and gradually titrated to effect.

sion between two different opioids); however, these tables provide only estimations to assist health care providers in initiating opioid titration.[183]

Opioid-tolerant patients generally require increased postoperative analgesic levels, including a larger demand dose.[28,182] Patients may need frequent adjustment (e.g., two to three times each day) of the intravenous PCA demand dose or continuous infusion, depending on the analgesic requirements. There is individual variability in response to different opioids, and if a decision is made to switch opioids, the choice of opioid is probably not as important as using an equianalgesic dose. Patients may experience different side effects with different opioids, and rotating to another opioid may be reasonable if the patient is not tolerating the first opioid.[184] Adjuvant agents such as NSAIDs should be administered on a regularly scheduled basis to optimize analgesic efficacy and possibly provide an opioid-sparing effect. Use of regional analgesic techniques with neuraxial opioids may provide excellent analgesia in opioid-tolerant patients while preventing withdrawal symptoms.[185]

After the patient is tolerating oral intake, conversion from intravenous opioids to a form (i.e., oral or transdermal, or both) that would be more suitable for discharge home may be initiated. Opioid-tolerant patients can generally be converted to a combination of a regularly administered, controlled-release formulation of opioid (i.e., sustained-release morphine or transdermal fentanyl) and short-acting, immediate-release opioid on a PRN basis. Although conversion of intravenous opioid to an oral or transdermal form can be accomplished over a period of 1 to 2 days in opioid-tolerant patients, this process may take several days in extremely difficult cases. Converting from an intravenous to an oral or transdermal form of opioid is not an exact science, and the conversion tables available can serve only as a rough guide because of significant interpatient and intrapatient variability in the sensitivity to opioids, lack of complete cross-tolerance between opioids (which may lead to greater than anticipated potency of a new opioid), and changes in the level of pain, which may rapidly decrease in the immediate postoperative period.[183] Because of these factors, conversion of approximately 50% to 75% of the equianalgesic dose to a sustained-release preparation of opioid or a transdermal fentanyl patch, with the remainder converted to a short-acting opioid delivered on a PRN basis, may be a reasonable starting point in patients whose pain is reasonably controlled, although additional titration may be necessary.

Pediatric Patients

As in adults, undertreatment of acute pain occurs in a substantial percentage of children (also see Chapter 82).[186] In addition to anatomic, physiologic, pharmacodynamic, and pharmacokinetic differences between children and adults, there are barriers unique to pediatric patients that may interfere with effective postoperative pain control. Control of postoperative pain is important in pediatric patients because poor pain control may result in increased morbidity or mortality.[181,187]

Some of the most important barriers to pain control in pediatric patients are the myths that children and infants do not feel pain, that pain is not remembered, and that there is no untoward consequence of experiencing pain.[186] These myths and other incorrect assumptions about pain in pediatric patients may hinder management of pain. Because of developmental, cognitive, and emotional differences, assessment of pain in pediatric patients can be difficult. Pediatric patients may have difficulty conceptualizing and quantifying a subjective experience such as pain. The lack of routine assessment and reassessment of pain may interfere with effective acute pain management.[186] Special scales are available to assist young children in self-reporting of pain; however, interpretation of behavior and physiologic parameters may be used to estimate pain intensity in preverbal children or those who cannot self-report their pain.

A plan for postoperative pain management should be discussed with the family and patient before surgery because pediatric patients may have many anxieties about pain and analgesic use after surgery. In general, the oral route of analgesic administration is preferred for mild to moderate pain. Intravenous or regional analgesia is appropriate for moderate to severe postoperative pain.[186] Use of intramuscular injections is strongly discouraged because of the pain associated with injection and variable absorption of analgesic medications. Fear of needles may inhibit control of postoperative pain because pediatric patients may choose to suffer in silence rather than receive a painful and anxiety-provoking intramuscular injection. Addressing medication-related side effects is important to alleviate patient-related distress and improve compliance with the postoperative analgesic regimen.

Use of an intravenous PCA device allows individualization of analgesic requirements and offers pediatric patients autonomy. Children as young as 4 years have the cognitive and physical capability to appropriately use an intravenous PCA device.[188] Although morphine is the standard by which other opioids are compared, morphine does not appear to have an analgesic advantage over other opioids (e.g., hydromorphone) when given in equianalgesic doses.[189] Because of toxicity from its metabolite, meperidine is not an opioid of choice in the acute pain management of pediatric patients.[186] Unlike adult patients, initial use of a background or continuous infusion in addition to the intravenous PCA demand dose appears to be more acceptable in pediatric patients.[188] Some data suggest that addition of an intravenous PCA background infusion is associated with improved sleep,[190] but other studies demonstrate a higher incidence of nausea, sedation, and hypoxemia with the addition of a background infusion.[191] None of these trials demonstrated superior analgesia with the addition of a background infusion. Nurse- or parent-controlled analgesia is also effective and may be used in certain circumstances, but close monitoring of the patient may be needed because significant respiratory depression occurs in approximately 1.7% of patients.[192]

For pediatric patients unable to use intravenous PCA, continuous infusions or intermittent intravenous administration of opioids is effective in providing postoperative analgesia.[193] Although respiratory depression may occur with opioids regardless of the route administered, clinically significant respiratory depression in pediatric patients is rare.[188] Unlike adults, pediatric patients do not appear to exhibit multiple episodes of clinically significant oxygen desaturation postoperatively when treated with neuraxial, intravenous, or intramuscular opioids.[194] Use of nonopioid analgesic agents, such as NSAIDs or acetaminophen, may improve overall analgesia, reduce the amount of opioid used postoperatively, and decrease some opioid-related side effects.[195] Some data suggest that for rectal administration of acetaminophen postoperatively, a higher dose (40 mg/kg followed by three doses of 20 mg/kg at 6-hour intervals) than that previously

recommended may result in appropriate serum analgesic levels.[195,196]

Peripheral and neuraxial regional analgesic techniques are commonly used and effective for acute pain management in pediatric patients. One of the most frequently used techniques is epidural analgesia, which can be delivered as a single dose or by using a continuous-infusion catheter technique. The catheter may be inserted (typically using general anesthesia[197]) anywhere along the epidural space (e.g., thoracic, lumbar, caudal), but the caudal approach seems to be the most common technique because the catheter can be easily advanced cephalad to the appropriate dermatome.[198] Local anesthetics or opioids, or both, can be administered through the epidural catheter or needle to provide effective postoperative analgesia. Although epidural (caudal) analgesia may be safely administered to neonates, the clinician should recognize that the maximal continuous infusion dose is probably lower than that in older children because of lower levels of α_1-acid glycoprotein (which binds local anesthetics) and diminished ability of the relatively immature liver to metabolize amide local anesthetics.[198] The addition of adjuvant drugs such as clonidine in the epidural infusion may enhance postoperative analgesia.[199]

Continuous epidural (caudal) analgesia may be used safely in the postoperative setting,[200] and the infection rate associated with continuous epidural analgesia is extremely low despite the relatively high colonization rate.[141] Continuous peripheral catheter techniques can be used effectively in pediatric patients. Regional analgesic techniques may be useful in providing analgesia for wound incision (e.g., herniorrhaphy or orchiopexy), thoracotomy, and orthopedic procedures.[189] Local anesthetics may also be administered topically to provide analgesia. Despite a lack of data comparing outcomes for regional analgesia versus systemic opioids in the pediatric population, some evidence suggests that the use of epidural analgesia is associated with improvement in some outcomes such as earlier tracheal extubation, return of gastrointestinal function, and length of hospital stay.[201]

Obesity, Obstructive Sleep Apnea, and Sleep

Patients with obesity and obstructive sleep apnea (OSA) may be at higher risk for postoperative complications (see Chapter 64). Obesity and OSA are separate disease states, but there is some association between the two because OSA occurs in a relatively higher percentage of obese than nonobese patients.[202] Although some data suggest that epidural analgesia may decrease postoperative complications in obese patients,[203] the optimal postoperative analgesic and monitoring regimen for patients with OSA is not clear. Data suggest that sleep is disrupted in the immediate postoperative period and may influence postoperative morbidity and patient-oriented outcomes.

Obesity is defined as a body mass index (BMI) of greater than 30 kg/m^2, with morbid and supermorbid obesity defined as a BMI of greater than 35 and 55 kg/m^2, respectively. The prevalence of obesity has increased to include approximately 22.5% of the U.S. population.[204] Although obese patients do not necessarily have OSA, obesity is the most important physical characteristic associated with OSA. Approximately 60% to 90% of OSA patients are obese, and at least 5% of morbidly obese patients have OSA, which is defined as more than five episodes per hour of cessation of airflow for more than 10 seconds despite continued ventilatory effort.[202] It is estimated that approximately 4% of men and 2% of women (18 million Americans overall) have OSA and that OSA is underdiagnosed in up to 95% of persons.[202] Patients with OSA are generally at higher risk for chronic cognitive impairment, pulmonary hypertension, cardiomyopathy, systemic hypertension, and possibly myocardial infarction.[205,206] The pathophysiology of airflow obstruction is related primarily to upper airway pharyngeal collapse, including the retropalatal, retroglossal, and retroepiglottic pharynx, during sleep, especially during rapid eye movement sleep.[202] During these obstructive episodes, OSA patients may exhibit hypoxia, bradyarrhythmias or tachyarrhythmias, myocardial ischemia, abrupt decreases in left ventricular stroke volume and cardiac output, or increases in pulmonary and systemic blood pressure.[206]

Based on our understanding of the pathophysiology of OSA, it is easy to see how postoperative pain management can be difficult in this population. Patients with OSA are at higher risk for respiratory arrest.[207] Use of sedative doses of benzodiazepines and opioids may result in frequent hypoxemia and apnea, which may be especially dangerous in OSA patients.[207] Avoiding respiratory depressants by optimizing the use of NSAIDs and epidural analgesia with a local anesthetic–based regimen may attenuate the risk for respiratory depression and arrest, because the use of epidural and systemic opioids is associated with sudden postoperative respiratory arrest.[207,208]

The American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea created guidelines that include recommendations for postoperative analgesia in patients with OSA.[209] Although the consultants acknowledged that the conclusions regarding postoperative analgesic options were based on insufficient literature evaluating the effects of various analgesic techniques, the presence of equivocal literature regarding the use of epidural opioids versus intramuscular or intravenous opioids in reducing respiratory depression, and insufficient literature regarding the addition of a basal infusion to systemic patient-controlled opioids, the consultants nevertheless recommended that regional techniques rather than systemic opioids be used in an attempt to reduce the likelihood of adverse outcomes in patients at increased perioperative risk from OSA.[209] In addition, the consultants recommended the exclusion (versus inclusion) of opioids from neuraxial postoperative analgesia to reduce perioperative risk and the use of NSAIDs to reduce adverse outcomes through their opioid-sparing effect. The consultants were equivocal regarding whether avoiding a basal infusion of opioids in patients with OSA reduces the likelihood of adverse outcomes.[209] Unfortunately, there is a paucity of randomized clinical trial data to provide definitive high-quality evidence-based recommendations for the provision of postoperative analgesia to OSA patients.

Postoperative Pain Services

Although dedicated health care professionals can improve postoperative pain control for a few patients, more comprehensive perioperative pain management programs (i.e., acute pain services) developed specifically to treat this problem can address the

needs for all patients within an institution. The organizational aspects of such comprehensive services are considerable and necessary for effective and safe care and may include issues such as education, administration, nursing, and documentation (Box 87-2; see also Box 87-1). With skills in regional anesthetic techniques and knowledge of the neurobiology of nociception and the pharmacology of analgesics and local anesthetics, anesthesiologists have been leaders in postoperative pain relief and the development of acute pain services. Provision of perioperative analgesia, along with other services such as critical care medicine and preoperative evaluation, is highly compatible with the emerging identity of anesthesiologists as perioperative physicians and enhances the role of anesthesiologists as valued consultants outside the operating room.

Although there are several models for the development of acute pain services,[210,211] the key organizational aspects are similar (see Box 87-2). Development and maintenance of acute pain services require a commitment and financial support at the national and local (institutional and departmental) level. In the United States there appears to be a dichotomy at the national and third-party payer level between the call for improved postoperative pain control, along with the introduction of practice guidelines or expanded roles for acute pain services, and decreased reimbursement for the provision of such services. Because there are financial burdens associated with the establishment of an acute pain service, high-volume or larger hospitals may be more likely to have acute pain services and access to more high-tech analgesic techniques such as epidural analgesia.[212,213]

Whether acute pain services actually improve outcomes is unclear. Two systematic reviews have examined the impact of acute pain services on patient outcomes,[214,215] and although both systematic reviews suggest that the introduction of acute pain services is associated with a decrease in pain scores, the effect of acute pain services on the incidence of analgesic-related side effects (e.g., nausea, vomiting), satisfaction, and overall costs is uncertain. Despite the direct costs (e.g., personnel, equipment, medication) associated with managing an acute pain service, there is no properly conducted pharmacoeconomic study available to examine the cost-effectiveness (or lack) of an acute pain service. Use of postoperative epidural analgesia in the context of acute pain services may decrease the cost of patient care through shorter intensive care unit stays and a decreased rate of complications.[13] Despite the costs associated with implementation of an acute pain service and acute pain management practice guidelines, acute pain services provide a valuable service at the individual, institutional, and societal levels.

Box 87-2 Organizational Aspects of an Acute Pain Service

Educational Activity
Anesthesiologists
Health insurance carriers
Hospital administrators
Nurses
Patients and families
Pharmacists
Surgeons

Administrative Activity
Economic issues
Evaluation of equipment
Human resources: pain service personnel, administrative-secretarial support
Institutional administrative activity
Quality improvement and assurance
Research (if applicable)
Residency-fellowship teaching (if applicable)

Nursing
Continuing education and in-service training
Defining of roles in patient care
Nursing policies and procedures
Pain service nurse (if applicable)
Quality improvement and assurance

Documentation
Bedside pain management assessment flow sheet
Daily consultation notes
Educational packages
Policies and procedures

88 Postoperative Intravascular Fluid Therapy

Key Points

1. Water is the most abundant component in the body: total body water accounts for approximately 50% of the lean body weight in women and 60% in men. Derangements in the fluid homeostasis are common in the postoperative period.
2. The goal of fluid management in the postoperative period is to provide the optimal amount and type of fluid to the patient. Thus, patients should remain euvolemic with a normal electrolyte distribution.
3. Besides physical examination and routine patient monitoring, different devices are available for advanced hemodynamic monitoring. They can be clinically used in a stepwise escalating approach—from invasive blood pressure measurement, to central venous cannulation, to less invasive, advanced hemodynamic monitoring, to pulmonary artery catheterization, to transesophageal echocardiography.
4. For adequate assessment of a patient's fluid balance, all available variables (i.e., cardiac filling, heart function, or end-organ perfusion) have to be considered like the "pieces of a puzzle."
5. Maintenance fluid therapy in the postoperative period aims at preserving the water and electrolyte balance. It should replace the ongoing losses of water and electrolytes under normal physiologic conditions.
6. Replacement fluid therapy in the postoperative period corrects any existing and additionally occurring water and electrolyte deficits. These deficits result from bleeding, third space sequestration, evaporative losses (e.g., mechanical ventilation without humidifier, surgical field if wound is left open), profuse sweating, and additional gastrointestinal as well as other fluid losses.
7. Fluid therapy must be individualized to each patient and balanced according to the benefits and risks of intravascular fluid administration. Therefore, the patient's characteristics and the type of procedure that has been performed should determine whether to choose a more liberal or a more restrictive fluid regimen.
8. To optimize the fluid status and to avoid fluid overload, frequent re-evaluations are required, especially during a "fluid trial," which is the intravenous administration of a specified amount of fluid over a short period of time.
9. A variety of manufactured fluid formulations exist for intravenous fluid therapy that differ in two fundamental ways: the *component electrolyte solution* and the *suspended material* providing colloid osmotic (oncotic) pressure.

Intravascular fluid therapy is of prime importance for maintenance of and to correct various alterations in normal fluid balance. Several other chapters (see Chapters 49, 54, and 55) also deal with fluid therapy.

The emphasis in this chapter is on fluid therapy in the postoperative period, especially in patients who have complications. After a brief review of basic fluid balance physiology, the assessment and the treatment of abnormalities with regard to the postoperative period are discussed.

Basic Physiology of Fluid Balance

Total Body Water and Fluid Compartments

Water is the most abundant component in the body. Total body water (TBW) accounts for approximately 50% of the lean body weight in women and 60% in men. This difference is attributable to variations in the relative proportions of adipose (water content

Table 88-1 Body Water Distribution (%) Relative to Lean Body Weight

	Men	Women	Term Infant
Intracellular compartment	40	33	50
Extracellular compartment	20	17	25
Intravascular space	5	4	6
Interstitial space	15	12	19
Total body water	60	50	70-75

10%) and muscle tissue (water content 75%) in women and men. TBW is distributed in two major compartments: the intracellular and extracellular compartments. The latter is further divided into the intravascular and interstitial spaces. Their relative size in men, women, and infants is summarized in Table 88-1. In children, the contribution of the TBW to weight varies with age and constitution: it ranges from 80% or greater in the premature infant, to 70% to 75% in the term infant, to 65% to 70% in toddlers. The higher percentage in TBW mainly reflects an increased extracellular fluid (ECF) compartment that is even more pronounced in preterm infants. In the elderly, TBW decreases with increasing age. This decrease is mainly due to losses in the intracellular fluid (ICF) compartment, preserving the ECF compartment.

Composition of Body Fluids and Distribution of Fluid

The ICF and ECF compartments are separated by the cell membranes. The composition of solutes in each compartment is markedly different based on disparities in permeability and the presence of transporters and active pumps. The major ECF particles are sodium (Na^+) and its accompanying anions chloride (Cl^-) and bicarbonate (HCO_3^-). Minor contributions come from potassium (K^+), magnesium (Mg^{2+}), and plasma proteins (mainly albumin). In the ICF compartment, however, K^+ is the main cation and electroneutrality is preserved by organic phosphate esters (adenosine triphosphate [ATP], creatine phosphate, and phospholipids) (see Chapter 54).

Osmotic forces are the primary determinants of the water distribution in the body. Osmolality is determined by the number of moles of a chemical compound that contributes to the solution's osmotic pressure and is expressed as milliosmoles per kilogram of water (mOsm/kg). Solutes that cannot freely cross the cell membrane are restricted to a specified compartment, determine the *effective osmolality (or tonicity),* that is, the osmotic pressure of that compartment, and generate fluid shifts. On the other hand, solutes that passively equilibrate across the cell membranes (e.g., urea with its high lipid solubility) are called *ineffective osmoles* and do not contribute to water shifts across cell membranes.

The *distribution of water between ECF and ICF compartment* depends largely on Na^+ and K^+ content of each compartment. Because Na^+ and K^+ are the predominant ions in, and largely restricted to, the ECF and ICF compartments, respectively, the effective osmolality of each compartment is primarily determined by the content of Na^+ and K^+ salts. Because water can freely cross almost all cell membranes, the osmolalities of the ECF and ICF compartment are kept in an osmotic equilibrium: a change in osmolality in one compartment will trigger water movement across the cell membranes from the compartment of low osmolality to the one of a higher osmolality.

Although the total-body Na^+ content is a reflection of the ECF compartment, there is not necessarily a positive correlation between plasma Na^+ concentration and ECF volume. These parameters change in parallel when Na^+ salts are administered but in an opposite direction when water administration or retention occurs (low plasma Na^+ concentration, high ECF volume). However, the ICF volume typically varies inversely with the plasma Na^+ concentration, decreasing with hypernatremia and increasing with hyponatremia. This may have important clinical relevance, because acute changes in the plasma Na^+ concentration alter brain cell volume and may therefore cause neurologic symptoms.

The distribution of water between the intravascular and interstitial space differs from that across cell membranes. The primary sites of exchange are the capillaries and small postcapillary venules. Because these "exchange vessels" are freely permeable to Na^+, K^+, and glucose, Na^+ and K^+ become ineffective osmoles and do not contribute to the water distribution between the intravascular and interstitial spaces. However, several other mechanisms are involved in this exchange, most importantly, bulk flow and diffusion. The rate of exchange in either direction (i.e., net filtration) can be calculated by the law of Starling.[1,2] Net filtration is determined by the physical factors hydrostatic pressure (P) and oncotic pressure (π) multiplied by the reflection coefficient of proteins across the capillary wall (σ, with values ranging from 0 if completely permeable to 1 if completely impermeable), and the physical nature of the barrier separating the blood and the interstitium (i.e., permeability of the capillary barrier, $C_{Permeability}$, and the surface area available for fluid movement).

$$\text{Net filtration} = C_{Permeability} \times \text{Area} \left[\left(P_C - P_T \right) - \sigma \left(\pi_C - \pi_T \right) \right]$$

There are two important, opposing hydrostatic forces: capillary (P_C) and tissue (P_T) hydrostatic pressure. Because P_C is much greater than P_T under normal circumstances, the net hydrostatic pressure gradient across the capillaries is positive, meaning that hydrostatic forces are driving fluid out of the capillaries. Furthermore, proteins (primarily albumin) have a limited ability to traverse the capillaries and act as effective osmoles influencing the fluid exchange. Normally, capillary plasma oncotic pressure (π_C) is much greater than tissue (interstitial) oncotic pressure (π_T), thereby reabsorbing fluid from the interstitium into the capillaries, if unopposed by hydrostatic forces. Altogether, there is a slightly positive net filtration across the capillary beds (i.e., filtration exceeds reabsorption), with the filtrate being returned to the systemic circulation by the lymphatic system. Edema results if net filtration exceeds the capacity of the lymphatics to clear excess interstitial fluid.

Capillaries in different organs have different hemodynamic and permeability characteristics. The hydrostatic pressure in glomerular capillaries of the kidneys is uniquely high, owing in part to a low precapillary resistance. This is physiologically important because the high pressure gradient *plus* the high capillary permeability allows the glomerula to maintain a very high rate of filtration. By contrast, in skeletal muscle, the capillary pressure is much lower than the systemic pressure (high precapillary resistance) and the capillary wall is relatively impermeable to proteins. Alveolar capillaries in the lungs on the other hand have both a lower capillary hydrostatic pressure (low pressure pulmonary circulation) and a lower transcapillary oncotic pressure gradient (because of a higher permeability to proteins). The result is a

small gradient favoring filtration, which is slightly larger than that in skeletal muscles.[2] The smaller transcapillary oncotic pressure gradient across the alveolar capillary wall has important clinical implications, because the rate of filtration is relatively unaffected by changes in the plasma oncotic pressure. As an example, a fall in the plasma albumin concentration might be expected to promote fluid movement into the interstitium as a result of the reduced plasma oncotic pressure. However, if the onset of the hypoalbuminemia is subacute or chronic, the interstitial oncotic pressure will undergo a parallel decline, attributable in part to less albumin movement from the vascular space into the interstitium. The net effect with mild to moderate hypoalbuminemia is therefore an unchanged transcapillary oncotic pressure gradient without the development of pulmonary edema.

Body Fluid Homeostasis

Under normal circumstances, the water and electrolyte content in the body is maintained within narrow limits as variations in dietary intake are exactly matched by corresponding changes in urinary excretion. Nevertheless, it is important to understand the potential physiologic effects of alterations in solute or water balance, because these disturbances often occur in the perioperative period. Body fluid homeostasis is being maintained by two different mechanisms, the volume regulation and osmoregulation (Table 88-2). Preservation of an effective circulating volume is critical for adequate tissue perfusion, and maintenance of a physiologic osmolality is essential for best cell function.

Intravascular Volume Regulation

The effective circulating volume is a nonmeasurable entity and refers to that part of the ECF that is perfusing the tissues.[3] Under physiologic circumstances, the effective circulating volume is dependent on and varies directly with the ECF volume and both parameters are proportional to the total body Na^+ content. Therefore, maintenance of the effective circulating volume is primarily related to the regulation of the Na^+ balance.

In the body, the effective circulating volume is indirectly being measured and regulated by three groups of baroreceptors sensing changes in pressure or stretch rather than volume. First, receptors in the carotid sinuses and aortic arch regulate the sympathetic activity and, to a minor degree, the release of arginine vasopressin (AVP, formerly antidiuretic hormone). Because these receptors are indirectly sensing blood flow to the brain, their major goal is to maintain cerebral perfusion. Second, receptors in the juxtaglomerular apparatus of the kidneys (glomerular afferent arteriole) and macula densa affect the volume balance by influencing the activity of the renin-angiotensin-aldosterone system and the release of endothelin and nitric oxide. Third, the atria and ventricles can release natriuretic peptides in response to increased wall pressure as a result of volume overload. These effector systems will be discussed in detail later (see "Effector Systems for Volume Regulation and Osmoregulation").

Table 88-2 Volume Regulation and Osmoregulation

	Volume Regulation	Osmoregulation
Variables	Effective circulating volume	Plasma osmolality
Sensors	Baroreceptors	Osmoreceptors
Location	Carotic sinus, aortic arch Afferent glomerular arteriole Atria, ventricles	Hypothalamus (supraoptic and paraventricular nuclei)
Effectors	Sympathetic nervous system Renin-angiotensin-aldosterone Natriuretic hormones Pressure natriuresis Arginine vasopressin	Thirst Arginine vasopressin
Results	Sodium excretion	Water intake and excretion

Osmoregulation

The normal plasma osmolality (Posm) is kept within a narrow range (275-295 mOsm/kg) by osmoreceptors located in the hypothalamus, capable of sensing a 1% to 2% change in tonicity. Posm is measured in the laboratory by analyzing the freezing point of the plasma (the freezing point of a solution inversely correlates with the amount of osmotic active particles). Furthermore, Posm can be calculated as follows[4]:

$$\text{Plasma osmolality}\left(\text{mOsm/kg}\right) = 2 \cdot \left[Na^+\right] + [\text{Urea}] + [\text{Glucose}]$$

Na^+ is multiplied by the factor 2 to account for accompanying anions that provide electroneutrality (mostly Cl^- and HCO_3^-). Urea and glucose are entered in millimoles per liter (mmol/L) (if these values are reported in milligrams per deciliter, they have to be converted to mmol/L [i.e., BUN/2.8 and glucose/18]). The contributions of urea and glucose to Posm are small, except in conditions such as diabetes mellitus and renal failure. However, to calculate the effective Posm, the formula can be rewritten omitting the urea concentration, because urea is an ineffective osmole, as mentioned earlier. The osmolar gap in the plasma (i.e., laboratory measured plasma osmolality minus calculated plasma osmolality; normal: < 10 mOsm/kg) increases under certain clinical situations when large amount of osmotic active substances are present. Causes of a raised osmolar gap may be recalled by the mnemonic "I AM DEEEP" (Isopropyl alcohol, Acetone, Methanol, Diuretics [e.g., mannitol], Ethanol, Ethylene glycol, Ethyl ether, Paraldehyde). Acid-base disturbances may accompany an increased osmolar gap. To consider a list of causes that may otherwise be overlooked, further evaluation of the acid-base status is necessary and includes the calculation of the anion gap (i.e., $Na^+ - (Cl^- + HCO_3^-)$; normal range: 8-16 mEq/L). An increased anion gap combined with a metabolic acidosis may typically result from ingestion of methanol, ethanol, ethylene glycol, and paraldehyde. Other causes include lactic acidosis, diabetic ketoacidosis, uremia, and excessive salicylate intake.

Regulation of the plasma Na^+ concentration, and therefore the plasma osmolality, occurs by changes in water intake (via thirst) and excretion (via AVP). Although it is tempting to assume that the maintenance of the plasma Na^+ concentration must be related to Na^+ balance, this is not the case. Alterations in Na^+ balance are used to maintain the plasma volume and tissue perfusion, not the plasma Na^+ concentration.

Effector Systems for Volume Regulation and Osmoregulation

Sympathetic Nervous System

Sympathetic neural tone and the secretion of catecholamines from the adrenal medulla (norepinephrine and epinephrine) are

the key regulators of vascular tone and cardiac function. Sympathetic volume regulation is mediated through baroreceptors (stretch-sensitive mechanoreceptors) located in the heart and the arterial system (carotid sinuses, aortic arch). They are part of the baroreceptor reflex, providing a negative feedback loop in which an elevated blood pressure causes blood pressure to decrease. In contrast, a decreased blood pressure depresses the baroreceptor reflex, causing blood pressure to rise. Because hypovolemia typically results in a low blood pressure, hypovolemia indirectly induces an increase in peripheral sympathetic tone, initiating a series of events that act to restore normal tissue perfusion: enhanced venous return (venous constriction), rise in cardiac output (myocardial contractility and heart rate), and increase in systemic vascular resistance by arteriolar constriction. Furthermore, sympathetic activation enhances renin secretion, resulting in the generation of angiotensin II, which contributes to the systemic vasoconstriction. Finally, renal tubular Na^+ reabsorption is increased because of a direct adrenergic effect and an increase in angiotensin II and aldosterone secretion.

Renin-Angiotensin-Aldosterone System

A major physiologic stimulus to renin secretion is renal hypoperfusion; it is initiated by hypotension or volume depletion and is sensed by baroreceptors in the wall of the afferent glomerular arteriole. A second important mechanism is sympathetic neural activity and the level of circulating catecholamines, both of which enhance renin secretion via β_1-adrenergic receptors. Third, the release of renin is governed by macula densa cells in the early distal tubule, which appears to be stimulated by a reduction in the Cl^- concentration. Renin initiates a sequence of steps that begins with cleavage of angiotensin I from angiotensinogen, an α_2-globulin produced in the liver (and other organs including the kidneys). Angiotensin I is then converted into angiotensin II and catalyzed by the angiotensin-converting enzyme (ACE), which is primarily located in the lungs. Angiotensin II has two major actions: (1) it increases blood pressure by arterial vasoconstriction, both directly and by enhancing the norepinephrine release and effect, and (2) it induces renal Na^+ retention, directly and by increasing the secretion of aldosterone.

Natriuretic Hormones

Atrial natriuretic peptide (ANP) is primarily released from myocardial cells in the atria (and ventricles in some cases) in response to volume expansion, which is sensed as an increase in atrial stretch. Although both atria appear to participate, there is suggestive evidence that the right atrium may be quantitatively more important. There is also evidence that the carotid and renal baroreceptors contribute to ANP release. ANP directly lowers the systemic blood pressure and increases urinary Na^+ and water excretion. Besides ANP, there are other ANP-like hormones, such as B-type natriuretic peptide (BNP) and C-type natriuretic peptide (CNP). BNP is homologous to ANP and was initially identified in the brain but can also be found in ventricles of the heart. The circulating concentration of BNP is 20% lower than that of ANP in normal subjects but can equal or exceed ANP levels in patients with congestive heart failure. Because of this relationship, measurement of plasma BNP, which is available as a rapid bedside assay, is increasingly being used in the differential diagnosis of dyspnea and as a guide to the therapy and prognosis of heart failure.[5] Furthermore, CNP is structurally similar to the other natriuretic peptides and is produced by vascular endothelial cells and in the kidneys. Initial studies suggested that its major function may involve regulation of local blood flow. However, its exact pathophysiologic role in humans remains to be determined. In addition to ANP and related hormones, there is evidence of other natriuretic hormones presenting with a potential digitalis-like effect (ouabain-like hormone reduces Na^+/K^+-ATPase pump activity, thereby decreasing renal tubular Na^+ reabsorption).[6]

Pressure Natriuresis

The phenomenon of pressure natriuresis is an essential "backup" feature of the volume regulatory system that can compensate for an abnormality in the humoral control of Na^+ excretion. In contrast to other mediators of tubular Na^+ transport, pressure natriuresis does not require neural or humoral sensor and effector mechanisms. The exact mechanism, however, is incompletely understood. It is possible that the increase in systemic pressure is transmitted via the vasa recta capillaries to the medullary interstitium. This rise in interstitial pressure can impair NaCl transport with the net effect of a decreased loop NaCl reabsorption. Furthermore, increased release of renal prostaglandins and nitric oxide may contribute to pressure natriuresis.[7]

Arginine vasopressin is the primary physiologic determinant of the rate of free water excretion. AVP is a polypeptide hormone that is synthesized in the hypothalamic supraoptic and paraventricular nuclei. Secretory granules containing AVP migrate down the axons into the posterior lobe of the pituitary, where they are stored and subsequently released after appropriate stimuli. Some of the synthesized AVP of the paraventricular nuclei enters the cerebrospinal fluid or the portal capillaries in the median eminence and has therefore access to the systemic circulation. This finding may explain why lesions of the posterior pituitary below the median eminence do not usually lead to permanent diabetes insipidus. Factors affecting AVP secretion are summarized in Table 88-3. The most important stimuli to release AVP are increased plasma osmolality and decreased effective circulating volume. The osmotic threshold for AVP release is 280 to 290 mOsm/kg in humans. Below this level there is little if any circulating AVP and the urine is maximally diluted to an osmolality less than 100 mOsm/kg. Above the osmotic threshold, there is a linear rise in AVP secretion. The osmoreceptors are sensitive, responding to alterations in the Posm of as little as 1% to 2%.[8,9] Interestingly, the osmotic threshold for thirst has been reported to be 5 mOsm/kg higher than that for AVP release.[10] The sensitivity of changes in effective circulating volume is different from that of osmolality. Small, acute reductions in volume that are sufficient to increase the secretion of renin and norepinephrine have little effect on the release of AVP. However, if there is a large enough change in the effective circulating volume to produce a significant reduction in systemic blood pressure, AVP is markedly being

Table 88-3 Factors Regulating the Secretion of Arginine Vasopressin

Stimulate Release	Inhibit Release
Hyperosmolality	Hypo-osmolality
Reduced effective circulating volume	Increased effective circulating volume
Angiotensin II	Cortisol
Stress, pain, nausea	Drugs, e.g., caffeine, ethanol, phenytoin
Hypoglycemia	
Pregnancy	
Drugs, e.g., morphine, nicotine	

released, resulting in circulating hormone levels that can substantially exceed levels induced by hyperosmolality.

There are two classes of AVP receptors, V2 and V1a/b receptors (V2R and V1a/bR, respectively), both of which are seven transmembrane G protein–coupled receptors. V2R are located primarily at the apical membrane of the cells lining the collecting ducts of the kidneys (especially the cortical and outer medullary collecting ducts). Stimulation of V2R leads to insertion of aquaporin-2 (water channels) into the cell membrane, thereby allowing water to be reabsorbed down an osmotic gradient and mediating the antidiuretic response of AVP. Activation of V1aR induces vasoconstriction and enhancement of renal prostaglandin production (particularly prostaglandin E_2 and prostacyclin), and stimulation of V1bR facilitates the release of ACTH in the pituitary gland. AVP, when secreted into the plasma, is rapidly metabolized in the liver and kidneys (half-life in circulation: 15-20 min).[11]

Thirst is the most important mechanism for water intake in the conscious patient. Plasma osmolality and effective circulating volume are the main determinants of regulating the thirst mechanism. Additionally, other signals may stimulate (e.g., angiotensin II, relaxin) or inhibit (e.g., ANP) thirst.[12]

Fluid Balance in the Postoperative Period

Maintaining an optimal fluid balance is challenging in the perioperative period. Patients arrive in the operating room with a negative fluid balance after a certain fasting period. The intervention may cause bleeding, evaporative fluid losses, and third space fluid sequestration. Furthermore, anesthesia may affect the fluid balance by interactions of anesthetic drugs with normal fluid physiology and distribution; for example, neuraxial anesthesia may induce a sympathicolysis with vasoplegia of the dependent part of the body. Additionally, the regulation of the fluid balance by thirst is ineffective in the perioperative period because patients may not be fully awake and alert. Although the occurring fluid deficits are being treated during the interventions with various fluids (crystalloid, colloids, blood products), derangements in the fluid homeostasis are common when patients arrive in a recovery place (e.g., recovery room, intermediate care, or intensive care unit).

The goal of fluid management in the postoperative period is to provide the optimal amount and type of fluid to the patient. Thereby, patients should remain euvolemic with a normal electrolyte distribution. Hypovolemia and hypervolemia are the extremes of a disturbed fluid balance and will be discussed in this section, because the pathophysiology of these clinical syndromes has to be well understood for optimal fluid management. The focus of this chapter is on fluid balance, not electrolyte balance. For further reference on the electrolyte balance, see Chapter 54.

Hypovolemia

Absolute hypovolemia, or true volume depletion, generally refers to a state of combined Na^+ and water loss exceeding fluid intake or administration, leading to a reduced ECF volume. Dehydration, by contrast, relates to an isolated water loss that results in an elevation of plasma Na^+ and subsequent intracellular water deficit (osmotic movement of water from ICF to the ECF compartment). *Relative* hypovolemia, on the other hand, refers to a state with decreased effective circulating volume but normal or expanded ECF volume. Depending on the patient (age, physical status, coexisting disease), some volume depletion is usually well tolerated. However, with an increase in degree of hypovolemia (absolute or relative) and progressive dehydration, tissue perfusion may become limited, resulting in a clinical syndrome referred to as *shock* (Table 88-4). The oxygen delivery no longer matches tissue oxygenation needs, and a metabolic acidosis develops. In the early stage, the acidosis is the result of a decreased clearance (not overproduction) of lactate by the liver, kidneys, and skeletal muscle.[13] However, as shock progresses and circulatory failure with tissue hypoxia occurs, anaerobic cell metabolism is increased with an enhanced production of lactate, worsening the acidemia. Although the effects of inadequate tissue perfusion are initially reversible, prolonged oxygen deprivation leads to generalized cellular hypoxia and derangement of critical biochemical processes, including impaired function of ion pumps of the cell membrane, intracellular edema, and leakage of intracellular contents into the extracellular space. These abnormalities rapidly become irreversible and result sequentially in cell death, end organ damage, multiple organ system failure, and death.

Table 88-4 Causes of Impaired Effective Circulating Volume and Classification of Shock Syndromes

Pathophysiology	Clinical Syndrome
ECF Volume Reduced	**Hypovolemic shock**
Extrarenal volume/Na^+ loss	Nonhemorrhagic shock
Skin and respiratory	
Gastrointestinal	
Third space sequestration	
Hemorrhage	Hemorrhagic shock
Renal volume/Na^+ loss	Nonhemorrhagic shock
Osmotic diuresis, diuretics	
Salt-wasting nephropathies	
Hypoaldosteronism	
Diabetes insipidus	
ECF Volume Normal or Expanded	**Cardiogenic, distributive shock**
Cardiac and extracardiac pathology	Cardiogenic shock
Myocardial: pump failure	
Mechanical: valvular defects, ventricular septal defect, tumors	
Arrhythmias	
Extracardiac (obstructive): pericardial diseases, massive pulmonary embolism, severe pulmonary hypertension, tension pneumothorax	
Redistribution of fluids	Distributive shock
SIRS, sepsis	SIRS, septic shock
Bacterial and other toxins	Toxic shock syndrome
Anaphylaxis and anaphylactoid reactions	Anaphylactic shock
Injury of central nervous system or spinal cord	Neurogenic shock
Myxedema coma, addisonian crisis	Endocrine shock
Chronic liver disease	

SIRS, systemic inflammatory response syndrome.

Therefore, it is obvious that derangements of the fluid balance have to be recognized early and treated promptly.

The clinical presentation of shock varies with both the type and the cause of the shock, but all shock syndromes have several factors in common. The syndrome is associated with a marked increase in sympathetic activity characterized by tachycardia. Relative (compared with the patient's baseline, early stages) or absolute (systolic blood pressure <90 mm Hg, advanced stages) hypotension occurs in most shock patients. As a compensatory mechanism to the decreased effective circulating volume, efficient vasoconstrictive mechanisms redirect blood flow from the periphery to the vital organs, thereby maintaining cerebral, coronary, and splanchnic perfusion, causing the cold and clammy skin of the shock patient. However, an exemption is the peripheral vasodilation in early distributive shock and terminal shock states (failure of the mechanisms maintaining peripheral vasoconstriction) resulting in a hyperemic, flushed skin. As a consequence of shunting blood to vital organs, the urinary output drops and the patient becomes oliguric to anuric. With ongoing depletion of the intravascular volume, the cerebral blood flow is finally impaired and the patient presents with agitation, confusion, and frank coma. However, it has to be emphasized that several confounding factors profoundly alter the clinical presentation, including the classic hemodynamic response to acute intravascular volume depletion. These factors include the patient's age, medications used for chronic conditions, the type and location of the fluid loss, the time lapse between volume loss and initiation of treatment, and previous fluid treatment.

Hypovolemia Due to Decreased ECF Volume

Extrarenal Volume or Na^+ Loss

Insensible, nonmeasurable fluid losses from the skin and respiratory tract (water evaporation) account for 600 mL/day and 200 mL/day under normal conditions, respectively. During febrile illnesses, fluid losses increase significantly and lead to volume depletion. Losses from the skin by sweating increase with each 1°C above 37°C (additional loss of 200-1000 mL/day). The Na^+ concentration of sweat is normally 20 to 50 mEq/L and decreases with profuse sweating due to the action of aldosterone (Table 88-5). Because sweat is hypotonic, the loss of water exceeds that of Na^+. Furthermore, evaporative water loss from the respiratory tract may be enhanced in febrile patients especially associated with mechanical ventilation and with hyperventilation. Finally, burns and exudative skin disorders may result in large losses of fluid and a depletion of the intravascular volume (see Chapters 54 and 72).

Table 88-5 Sweat and Gastrointestinal Fluids: Electrolyte Composition and Common Sources of Losses in the Perioperative Period

		Composition (mEq/L)			
Common Losses	**Body Fluid**	**Na^+**	**K^+**	**Cl^-**	**HCO_3^-**
Sweating (fever)	Sweat	20-50	5-10	45-55	
Gastrointestinal					
Nasogastric tube, vomiting	Gastric	40-80	5-15	90-130	
Tracheostomy tube, fistula	Biliary	130-150	5-10	80-120	30-40
Fistula	Pancreatic	120-140	5-10	60-90	90-110
Duodenal tube, fistula	Duodenal	130-140	5-10	70-90	0-50
Ileostomy, fistula	Ileal	100-140	5-10	80-110	20-30
Diarrhea, colostomy	Colon	50-70	20-40	30-50	20-30

Na^+, sodium; K^+, potassium; Cl^-, chloride; HCO_3^-, bicarbonate.

Approximately 9 L of fluid enters the gastrointestinal tract daily, 2 L by ingestion and 7 L by secretion. Almost 98% of this volume is reabsorbed so that fecal fluid loss accounts only for 100 to 200 mL/day. External drainage of gastrointestinal fluids, fistulas, impaired gastrointestinal reabsorption, or enhanced secretion leads to volume depletion (see Table 88-5). Because gastric secretions have a low pH (high H^+ concentration) and biliary, pancreatic, and intestinal secretions are alkaline (high HCO_3^- concentration), vomiting and diarrhea are often accompanied by metabolic alkalosis and acidosis, respectively.

Hypovolemia can occur by the sequestration of interstitial and intravascular fluid into a third space, not in equilibrium with either the ECF or the ICF compartment. Although this fluid may be moved back into the ECF compartment over a period of days to weeks, the acute reduction in blood volume, if not corrected, can lead to severe volume depletion. Examples of third space losses include the retroperitoneal space in acute pancreatitis, bowel lumen in gastrointestinal obstruction, the peritoneal cavity in peritonitis, crush injuries, and the hematoma in the adjacent tissue to a long bone or pelvic fracture.

Hemorrhage from any source is a frequent cause of volume depletion in the postoperative period. Careful postoperative evaluation of the patient and a high index of suspicion are often required for a successful diagnosis of occult bleeding. The different classes of hemorrhage and hemorrhagic shock are summarized in Table 88-6. Class I hemorrhage is a minor blood loss resembling a condition of an individual who has donated a unit of blood, and class II is an uncomplicated hemorrhage but crystalloid fluid resuscitation is required. Class III, however, is a complicated hemorrhagic state, and class IV hemorrhage should be considered a preterminal event for which very aggressive measures have to be taken to restore the volume status and control the bleeding.

Renal Volume or Na^+ Loss

In a healthy adult, 130 to 180 L of plasma is filtered across the capillary membranes of the glomerula each day. More than 98% of the filtrate is reabsorbed by the renal tubule, resulting in a urinary output of 1 to 2 L/day. Many conditions are associated with excessive urinary NaCl and water losses, including diuretic intake. Diuretics inhibit specific pathways of Na^+ reabsorption along the nephron with a consequent increase in urinary Na^+ excretion. Enhanced filtration of nonreabsorbed solutes, such as glucose or urea, can impair tubular reabsorption of Na^+ and water, resulting in an osmotic or solute diuresis. This often occurs in poorly controlled diabetes mellitus and in patients receiving high-protein hyperalimentation. Mannitol is a diuretic that produces an osmotic diuresis because this drug cannot be reabsorbed in the renal tubule. Healthy subjects are able to maximally conserve Na^+ and to reduce Na^+ excretion less than 5 mEq/day. However, renal function may be impaired de novo in the postoperative period as a result of anesthesia- and surgery-related events, such as impaired renal perfusion due to hypovolemia, vasodilation, positive-pressure ventilation, surgical manipulation, impaired autoregulation, and perioperatively administered nephrotoxic medications. Furthermore, many preexisting tubular and

Table 88-6 Classification of Hemorrhage/Hemorrhagic Shock*

Variable	Class I	Class II	Class III	Class IV
Blood loss, mL (% blood volume)	<750 (<15%)	750-1500 (15-30%)	1500-2000 (30-40%)	>2000 (>40%)
Pulse rate	Normal	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Respiratory rate	Normal	20-30	30-40	>35
Urine output	Normal	20-30 mL/h	5-15 mL/h	Anuric
Mental status	Slightly anxious	Mildly anxious	Confused, anxious	Confused, lethargic
Response to fluid bolus	Yes	Yes	Transient	No

interstitial renal disorders may deteriorate postoperatively and are associated with Na^+ wasting. Patients with renal insufficiency (glomerular filtration rate < 25 mL/min) may have an obligatory Na^+ loss of 10 to 40 mEq/day. In rare cases of tubular and interstitial renal diseases, a higher degree of Na^+ wasting may be present and obligatory urinary losses may exceed 100 mEq of Na^+ and 2 L of water per day.[14] Excessive renal Na^+ and water losses may also occur during the diuretic phase of acute tubular necrosis and after the relief of bilateral urinary tract obstruction. Finally, mineralocorticoid deficiency (hypoaldosteronism) causes salt wasting in the presence of a normal intrinsic renal function. Massive renal water excretion can also lead to hypovolemia. Conditions associated with excessive urinary water loss include central diabetes insipidus (impaired secretion of AVP) and nephrogenic diabetes insipidus (renal unresponsiveness to AVP). For details on renal function, renal dysfunction, and replacement therapy see Chapters 45 and 96.

Disturbed renal fluid regulation with hyponatremia is also a common late complication of transsphenoidal pituitary surgery, occurring in 21% to 35% of cases.[15,16] Although relative cortisol deficiency may contribute, the major cause is inappropriate AVP release from the injured posterior pituitary gland. The fall in the plasma Na^+ concentration is most severe on the sixth to seventh postoperative days. This form of isolated hyponatremia (or isolated second phase) appears to be a subset of the classic triphasic cycle in which initial polyuria is followed by transient syndrome of inappropriate AVP secretion (SIADH) and then either recovery or, in severe cases, a third phase of permanent central diabetes insipidus. Rarely, the hyponatremia after pituitary surgery is due to cerebral salt wasting (see Chapter 13).

Hypovolemia Due to Normal or Increased ECF Volume

Cardiac and Extracardiac Pathology

The effective circulating volume may be decreased in patients with cardiac disease, owing to an impaired systolic or diastolic function (or both) with a reduction in cardiac output (relative hypovolemia).[17] Myocardial pathogenesis includes infarction involving more than 40% of the left ventricular myocardium, right ventricular infarction, stunned myocardium after prolonged ischemia or cardiopulmonary bypass, dilated cardiomyopathies, myocarditis, myocardial contusion, and the myocardial depression of advanced shock. Furthermore, mechanical complications of a myocardial infarction (acute mitral regurgitation caused by papillary muscle rupture, ventricular septal defect, free wall rupture, pericardial tamponade), valvular pathologic processes (critical aortic stenosis, acute aortic insufficiency caused by dissection of the ascending aorta into the aortic valve ring), and tumors obstructing ventricular filling (e.g., atrial myxoma) may impair cardiac function. Finally, arrhythmias and obstructive, extracardiac factors may reduce cardiac output (see Table 88-4).

In clinical conditions with a reduced cardiac output, the sympathetic nervous and renin-angiotensin-aldosterone systems become activated. These systems together with a reduced renal perfusion then promote Na^+ and secondary fluid retention. Initially, these changes may be appropriate because the retained fluid increases plasma volume and therefore may normalize preload, cardiac output, and the effective circulating volume. However, with progressive, chronic disease (e.g., chronic heart failure) low cardiac output can no longer be compensated and the effective circulating volume remains low despite an expanded ECF volume. As a result of a continuing stimulus to retain Na^+ and water, the retained solute and volume ultimately extravasates from the repleted intravascular space and causes peripheral or pulmonary edema or both.

Redistribution of body fluids is another cause of decreased effective circulating volume despite normal or expanded ECF volume (see Table 88-4). The distributive fluid pathology typically results from a severe decrease in systemic vascular resistance (vasodilation) or endothelial barrier dysfunction or both and is often associated with an increased cardiac output (at least in early stages).

Noninfectious disorders (e.g., acute pancreatitis, burns, multiple traumatic injuries) may be complicated by tissue injury secondary to activation of the inflammatory system. The term *systemic inflammatory response syndrome* (SIRS) is used in this setting to refer to the consequences of a dysregulated inflammatory response in absence of infection with the release of proinflammatory mediators creating a chain of events that leads to widespread tissue injury. SIRS is characterized by vasodilation, increased microvascular permeability, and leukocyte accumulation in tissues remote from the original insult. For example, cardiac surgery with cardiopulmonary bypass may result in overt activation of the inflammatory cascade owing to the extracorporeal circulation. Therefore, SIRS is frequently observed in the postoperative period of cardiac surgery patients.[18] In sepsis, the clinical signs that define SIRS are present and are due to either a

culture-proven infection or an otherwise identified infection. The severity of sepsis is graded according to the associated hemodynamic compromise and organ dysfunction.[19,20] Hypotension is the most severe expression of circulatory dysfunction in sepsis (i.e., septic shock) and is caused by a redistribution of the intravascular fluid volume: sepsis is characterized by a reduced arteriolar vascular tone leading to increased capillary pressure and increased endothelial permeability. Other changes that occur include venous dilation (thereby diminishing venous return to the heart) and the release of myocardial depressant substances.[21] When hypotension complicates sepsis, anomalies in the distribution of flow at the regional and microregional circulation are accentuated, thereby accelerating the progression of tissue injury. Isolated bacterial and other toxin exposure (e.g., toxic shock syndrome) may result in a similar inflammatory response and has many characteristics in parallel with SIRS and sepsis.

Anaphylaxis describes allergic, IgE-mediated, immediate hypersensitivity reactions to protein substances. In contrast, anaphylactoid responses are clinically indistinguishable reactions that are not IgE mediated. Both syndromes are most frequently mediated through neuromuscular blocking agents, antibiotics, and latex in the perioperative period. They are characterized by a decreased peripheral vascular resistance, increased vascular permeability, and consequently a reduced effective circulating volume. In addition, cardiac output is initially elevated but may become depressed at later stages.

Fluids may be redistributed by a sudden loss of the sympathetic outflow due to a severe trauma to the spinal cord or brain resulting in a sudden decrease in peripheral vascular resistance, hypotension and, eventually, decreased cardiac output (i.e., neurogenic shock). Furthermore, endocrine disorders may lead to a distributive fluid pathology: acute adrenal insufficiency (addisonian crisis) is frequently the result of discontinuing corticosteroid treatment without tapering the dosage. However, stress (e.g., surgery) may also induce an acute adrenal insufficiency in patients on corticosteroid therapy if the dosage has not been adjusted to accommodate for the increased requirements perioperatively. In addition, long-standing hypothyroidism can lead to diastolic hypertension due to increased systemic vascular resistance and a reduction in blood volume. However, myxedema coma is associated with bradycardia, decreased myocardial contractility, low cardiac output, fluid retention, and generalized edema.[22]

Finally, hepatic cirrhosis deserves special consideration when summarizing clinical entities with a redistributed fluid volume status. Splanchnic vasodilatation and portosystemic shunts are responsible for the hyperdynamic circulation and abnormal distribution of the blood volume. The effective circulating blood volume is reduced and the baroreceptors and volume receptors activated. Patients with hepatic cirrhosis have an increased perioperative risk. Enhanced perioperative vasodilatation and hypotension may impair perfusion of vital organs, finally ending with multiorgan failure.[23]

Hypervolemia

Fluids are being administered intraoperatively to correct for preoperative and intraoperative deficits and to substitute the ongoing blood losses. Furthermore, certain anesthetic techniques (anesthetics per se, neuraxial blockades) may decrease the peripheral vascular resistance and impair cardiac function. To maintain an effective circulating volume intraoperatively, excess fluids or sympathomimetic therapy (vasoconstrictive or inotropic agents) have to be administered. However, because part of the negative impact of anesthetics on cardiovascular physiology is transient (adverse effects during administration of anesthetic drugs only), these effects are no longer present in the postoperative period and the body has to deal with an increased effective circulating volume. Patients with preexisting disease (e.g., congestive heart failure, valvular disease, renal disease) and patients at the extremes of the aging scale (infants, elderly) are at particular risk to develop a clinically relevant hypervolemia, most likely presenting as acute heart failure with pulmonary edema.

Assessment of the Fluid Balance

Incorrect fluid therapy is associated with a considerable morbidity and mortality.[24] Multiple factors have to be considered when devising a rational approach to fluid management for patients in the postoperative period. All available information related to a patient's preexisting diseases, preoperative fluid status, surgical interventions, and intraoperative anesthetic management have to be known. To complete the picture, in-depth clinical examination, hemodynamic monitoring, and laboratory tests have to be performed (Table 88-7). Different fluid compartments cannot be measured easily in the clinical setting, except for the intravascular fluid space. Therefore, intravascular volume status (normovolemia, hypovolemia, and hypervolemia) is most frequently assessed according to cardiac filling, heart function, and end-organ perfusion. Because every single variable is nonspecific, these variables may best complement each other and the clinical evaluation. For adequate assessment of a patient's fluid balance, all available data have to be taken into account like the pieces of a puzzle. Furthermore, to optimize the fluid status and to avoid fluid overload, frequent re-evaluations are required, especially during a "fluid trial," which is the intravenous administration of a specified amount of fluid over a short period of time.

Physical Examination and Routine Monitoring

There is a sequence of compensatory mechanisms of the body after intravascular fluid loss (i.e., hypovolemia due to dehydration or bleeding) to maintain adequate tissue perfusion and end-organ oxygenation. In the acute phase, this is mediated predominantly by an increased sympathetic outflow. At fluid losses more than 15% of the blood volume, filling of the jugular veins, preload, and stroke volume decrease. To maintain optimal cardiac output, the heart rate raises more than 100 beats/min. Simultaneously, afterload is being increased by peripheral vasoconstriction. Therefore, blood pressure is sustained during ongoing volume losses and decreases only with a loss greater than 30% to 40% blood volume (see Table 88-6). The mucous membranes become increasingly dry, and turgor of the skin decreases. As signs of a reduced tissue perfusion and end-organ oxygenation, a decreased urinary output (<0.5 mL/kg/hr) and an impaired mental status (confusion, somnolence, or coma in severe fluid losses) are observed. Unfortunately, some of these typical pathophysiologic signs of hypovolemia are not reliable indicators of a reduced intravascular fluid status in the postoperative period. Anesthetic drugs and stress reactions (due to pain, postoperative nausea and vomiting, body temperature derangements, or respiratory insufficiency) alter pulse rate, blood pressure, and cerebral function. Nevertheless, thirst in an awake patient, dry or parched mucous membranes, collapsed jugular veins, and reduced urinary output are still important signs of hypovolemia in the postoperative clinical setting.

In contrast with the evaluation of the fluid balance in adults, the assessment in children requires additional understanding of the age-specific physiology (see Chapters 82 to 84). Cardiac output is regulated primarily via heart rate and not stroke volume, owing to the relative myocardial stiffness. Furthermore, elasticity of the child's vessels is higher than that in the adult. Under normal circumstances, the heart rate of children is higher and the blood pressure is lower than those of adults, thus limiting the validity of these parameters to assess hypovolemia in pediatric patient. Evaluation of the capillary refill (i.e., the microcirculation of the skin) is an important test to assess the volume status in children. For its assessment, the skin is examined after pressure relief performed by the index finger. Delayed restoration of the skin color (>3 seconds after pressure release) indicates a prolongation of capillary refill and therefore reduced skin and end organ perfusion. The formation of a skin fold at the child's back of the hand between the examiner's thumb and index finger and its persistence after pressure relief indicates a decreased skin turgor and is another sign of hypovolemia in the child. However, this may be rarely seen in the postoperative period.

Postoperative hypervolemia may become manifest as arterial hypertension, increased urinary output, and pulmonary edema (especially in patients with cardiovascular compromise). Signs of pulmonary edema include crackles, wheezing, and frothy sputum. The diagnosis is confirmed by a chest radiograph showing edema of the alveoli, increased vascular filling, and upper lobe diversion. Decreased pulmonary gas exchange may lead to hypoxemia with cyanosis. Ankle edemas and anasarca (edema at the back of a bedridden patient) are chronic signs of hypervolemia and prompt the re-evaluation of the patient's history in the postoperative period.

Advanced Hemodynamic Monitoring

Different devices are available for advanced hemodynamic monitoring. They can be clinically used in a stepwise escalating approach—from invasive blood pressure measurement, to central venous cannulation, to pulmonary artery catheterization, to less invasive, advanced hemodynamic monitoring, to transesophageal echocardiography (see Table 88-8). Indications are primarily based on the patient's physical status, related cardiovascular and pulmonary comorbidities, and the scheduled intervention. For example, invasive blood and central venous pressure monitoring are typically applied to a patient with the ASA classification I to III undergoing a surgical intervention with anticipated large fluid shifts and losses. Additional sophisticated monitoring including assessment of cardiac output is highly desirable for the same interventions in a patient with considerably limited cardiac function. The standard technique for the past 30 years to measure cardiac output is pulmonary artery catheter monitoring. Its routine use, however, is being questioned and a matter of debate based on studies demonstrating conflicting results for its impact on patient's outcome.[25,26] Today, several less invasive advanced hemodynamic monitoring techniques are commercially available. They can replace the pulmonary artery catheter under certain clinical circumstances, and some of these techniques allow an even more refined fluid assessment by measuring additional fluid variables.[27]

In this section, traditional and newly available techniques of hemodynamic monitoring are discussed with the aim of evaluating a patient's fluid status. For a profound technical overview, indications and related complications, we refer the reader to Chapters 40 and 41.

Invasive Blood Pressure Monitoring

Invasive blood pressure measurement is very important in the evaluation of a patient with ongoing intravascular volume losses or limited cardiac function or both. It allows continuous measurement and is more reliable at hypotonic states than intermittent noninvasive blood pressure measurement. Additionally, in the patient whose ventilation is controlled mechanically, the observation of increased respiratory variations of the arterial blood pressure waveform may help in the assessment of the fluid balance. During inspiration, increased intrathoracic pressure reduces venous return, that is, preload, and thus diminishes stroke volume. As a result, systolic and diastolic pressure decreases and increases with a short delay after inspiration and expiration, respectively (Fig. 88-1A). The effect is more pronounced for the systolic pressure and is typically amplified with progressive hypovolemia. Furthermore, arterial cannulation allows convenient withdrawal of blood for repeated blood gas analysis and additional laboratory parameters.

Cardiac Output Measurement

Continuous cardiac output measurement may help to evaluate the volume status and to guide fluid resuscitation in patients with impaired cardiac function. As mentioned earlier, the standard device for its assessment is the pulmonary artery catheter. Alternatively, less invasive devices can be used considering their specific characteristics and limitations. The most frequently applied techniques are pulse contour/wave analysis and transesophageal Doppler flow measurements.[27]

Table 88-8 Advanced Hemodynamic Monitoring to Assess the Fluid Status

Measured Parameter	Abbreviation	Standard Value
Monitoring Device		
Invasive blood pressure		
Visual evaluation of pressure variation		
Arterial blood gas analysis		
Central venous catheter		
Central venous pressure	CVP	2-8 mm Hg
Central venous oxygenation	$Sc\bar{v}o_2$	>70%
Invasive, Advanced Hemodynamic Monitoring ("Gold Standard")		
Pulmonary artery catheter		
Pulmonary capillary wedge pressure	PCWP	8-18 mm Hg
Cardiac index	CI	2-3.5 L/min/m^2
Stroke volume index	SVI	35-50 mL/m^2
Continuous end-diastolic volume index	CEDVI	100-200 mL/m^2
Mixed venous oxygen saturation	$S\bar{v}o_2$	>75%
Less Invasive, Advanced Hemodynamic Monitoring		
Transpulmonary thermodilution		
Global end-diastolic volume index	GEDVI	700-800 mL/m^2
Intrathoracic blood volume index	ITBVI	875-1000 mL/m^2
Extravascular lung water	EVLW	≤10 mL/kg
Pulse contour/wave analysis		
Pulse pressure variation	PPV	<10-13%
Stroke volume variation	SVV	<10-13%
Transesophageal Doppler		
Aortic flow measurements		
Transesophageal, transthoracic echocardiography		
Visual evaluation		
End-diastolic area	EDA	
End-diastolic volume	EDV	

More important than a single value for cardiac output is the analysis of the time course of these values (trends), such as the response of cardiac output to fluid administration. Furthermore, cardiac output has to be evaluated in context with clinical examination and other hemodynamic parameters. For example, when cardiac output is low, fluid administration should only be performed when other signs of hypovolemia coexist. However, if the patient is hypervolemic (cardiac failure), treatment with β-sympathomimetic catecholamines is required to improve cardiac function.

Cardiac Filling Pressures: Central Venous and Pulmonary Artery Occlusion Pressure

Traditionally, central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) have been considered to indirectly reflect heart filling, that is, right and left ventricular preload (Fig. 88-2A). CVP is widely being used to assess the fluid status in patients without significant right ventricular dysfunction and pulmonary alterations when large and rapid changes of the volume status occur. Recent studies, however, revealed only a weak correlation between cardiac filling pressures and volumes.[28] These findings may be primarily explained by the fact that transduced intrathoracic as well as intra-abdominal pressures interfere with these pressure measurements. Preload, according to the Frank-Starling law, is defined as end-diastolic myocardial fiber tension.[29] Because this cannot be measured in a clinical setting, only surrogate markers of preload can be determined. Although pressure is a determinant of a compliant system like the heart, this refers to transmural but not intravascular pressure. Moreover, frequently observed alterations of the cardiac valves or obstructions of the heart cavities may introduce false measurements.

Despite these limitations, CVP and PAOP are still being used in clinical practice worldwide. It is important that interpretation of these parameters has to be done in the clinical context. Furthermore, trends toward low or high values are more predictive for hypovolemia or hypervolemia than absolute values, and the dynamics of changes are essential: for example, a small increase in filling pressures during a fluid trial in a hypovolemic patient may indicate the need for additional fluid administration whereas a dramatic increase in filling pressures may indicate imminent fluid overload and restriction of fluid administration.

Volumetric Preload Parameters

Because cardiac filling pressures do not necessarily reflect the patient's volume status, easy accessible parameters to determine end-diastolic volumes are highly desirable. Two thermodilution-based techniques provide volumetric preload parameters, which are calculated from cardiac output using the modified

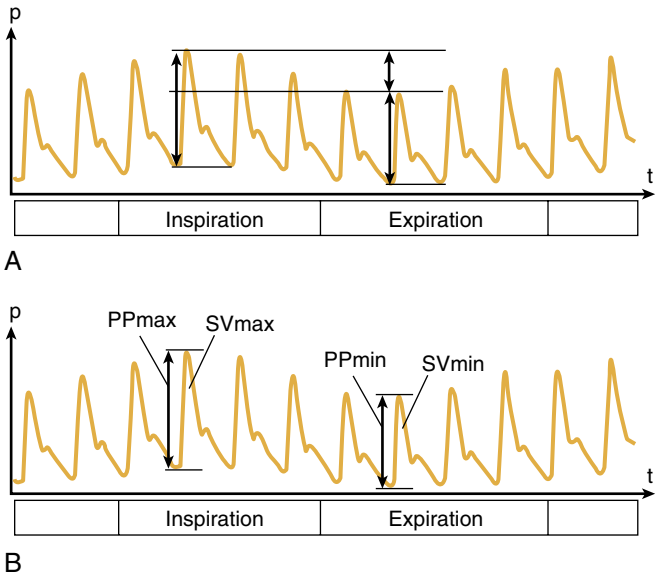

Figure 88-1 Arterial waveform analysis. **A,** Visual assessment of pulse pressure variation. Typical pulse pressure variation caused by hypovolemia as a result of intermittent positive-pressure ventilation. Note the changes in both the systolic and diastolic arterial pressures, with a higher decrease of the systolic pressure than of the diastolic pressure as a result of a reduced preload caused by mechanical inspiration, that is, an increase in intrathoracic pressure. p, pressure; t, time. **B,** Quantitative assessment of pulse pressure (PPV) and stroke volume (SVV) using less invasive hemodynamic monitoring device (pulse contour analysis). PPmax, maximal pulse pressure; PPmin, minimal pulse pressure. PPV is assessed as the percentage of change during the ventilatory cycle according to the following equation:

$$PPV\ (\%) = (PPmax - PPmin)/PPmean$$

PPmax/PPmin = means for the four extreme values of pulse pressure; PPmean, average value for this time period. SVmax, maximal stroke volume; SVmin, minimal stroke volume. SVV as the percentage of change of stroke volume (SV) can be determined during the same time interval:

$$SVV\ (\%) = (SVmax - SVmin)/SVmean$$

SVmax/min, means for the four extreme values of stroke volume during a period of 30 sec; SVmean, average value for this time period; p, pressure; t, time.

Stewart-Hamilton equation and indicator passage times.[30] Continuous end-diastolic volume index (CEDVI) is assessed by a modified pulmonary artery catheter (CCOmbo CCO/$S\bar{v}O_2$/CEDV catheter 774HF75, Edwards Lifescience LLC, Irvine, CA). Based on the site of measurement, CEDVI reflects right-sided heart end-diastolic volume (see Fig. 88-2B). Global end-diastolic volume index (GEDVI) and the closely related intrathoracic blood volume index (ITBVI) are determined via transpulmonary thermodilution (see Fig. 88-2C), which is used for the calibration of one of the less invasive cardiac output monitoring systems based on pulse contour analysis ($PiCCO_{plus}$, Pulsion Medical Systems, Munich, Germany). This concept assumes that the thermal indicator travels from the site of injection (central venous catheter) through different central compartments connected in series (i.e., right atrium and ventricle, pulmonary vessels and lungs, left atrium and ventricle) to the indicator detection site (a thermistor-tipped arterial catheter typically inserted in the femoral artery). Based on different indicator passage times through these compartments, different volumes can be calculated (Fig. 88-3). Thus, GEDVI includes the volume of all heart cavities and of the descending aorta. ITBVI additionally includes the volume of the pulmonary vessels. All volumetric preload parameters have shown to be superior preload indicators than cardiac filling pressures.[31-33]

Apart from to the assessment of GEDVI and ITBVI, the PiCCO system further allows calculation of the extravascular lung water (EVLW) (see Fig. 88-2D). EVLW may be useful to better characterize pulmonary edema and acute respiratory distress syndrome (ARDS), to evaluate the success of different ventilatory strategies, and to predict outcome in ARDS. However, careful interpretation of EVLW data is required in the presence of significant pulmonary vascular obstruction (e.g., pulmonary emboli), focal lung injury, or lung resection.[30,34]

Pulse Pressure and Stroke Volume Variation

Variations in pulse pressure (PPV) and stroke volume (SVV) occur due to cyclic changes of intrathoracic pressure induced by mechanical ventilation. The major determinant is a reduced venous return during inspiration of positive-pressure ventilation. PPV and SVV were recognized as potential parameters for guiding fluid replacement therapy more than 20 years ago. However, automated quantification of this phenomenon only became clinically available recently with the introduction of cardiac output monitoring devices based on pulse wave/contour analysis (see Fig. 88-1B). The method appears to visualize the individual cardiac response (changes in stroke volume) related to myocardial contractility due to diastolic volume loading: in the presence of hypovolemia, high stroke volume variations can be observed and the preload dependence of left ventricular function is pronounced; that is, the ventricle operates on the ascending limb of the Frank-Starling curve. During volume expansion, there is a rightward shift of left ventricular function on the Frank-Starling curve, which is thought to correspond to the observed decrease of stroke volume variation (Fig. 88-4). PPV and SVV have been used to assess fluid responsiveness and have shown to be sensitive in predicting the ventricular response to fluid administration (i.e., sensitive detection of fluid responders). However, alteration of vasomotor tone may influence PPV more than SVV. Moreover, the fact has to be stressed that this dynamic preload assessment is only reliable in fully sedated, mechanically ventilated patients with a regular heart rhythm.[35,36]

Transesophageal Echocardiography

Different echocardiographic approaches allow preload quantification either by measuring and calculating left ventricular end-diastolic area (LVEDA) or volume (LVEDV). LVEDA is determined at midpapillary level in a short-axis view. However, different echocardiographic positions and measurements are required for the volumetric calculation of LVEDV. These calculations are typically based on the Simpson algorithm assuming that the ventricle consists of a sum of small cylinders and a truncated ellipse.[37] Conflicting results have been reported using the Simpson algorithm; and, in daily practice, LVEDA is widely used as surrogate of left ventricular preload.[38] However, because this technique is highly operator dependent, the real benefit of echocardiography is the visualization of ventricular function, wall motion abnormalities, and cardiac filling and the "real-time" guiding of fluid therapy in acute, critical hemodynamic situations. The detection of "kissing papillary muscles," that is, the end-systolic contact of these structures, is highly pathognomonic for a hypovolemic state, whereas in hypervolemia a distended left ventricle with

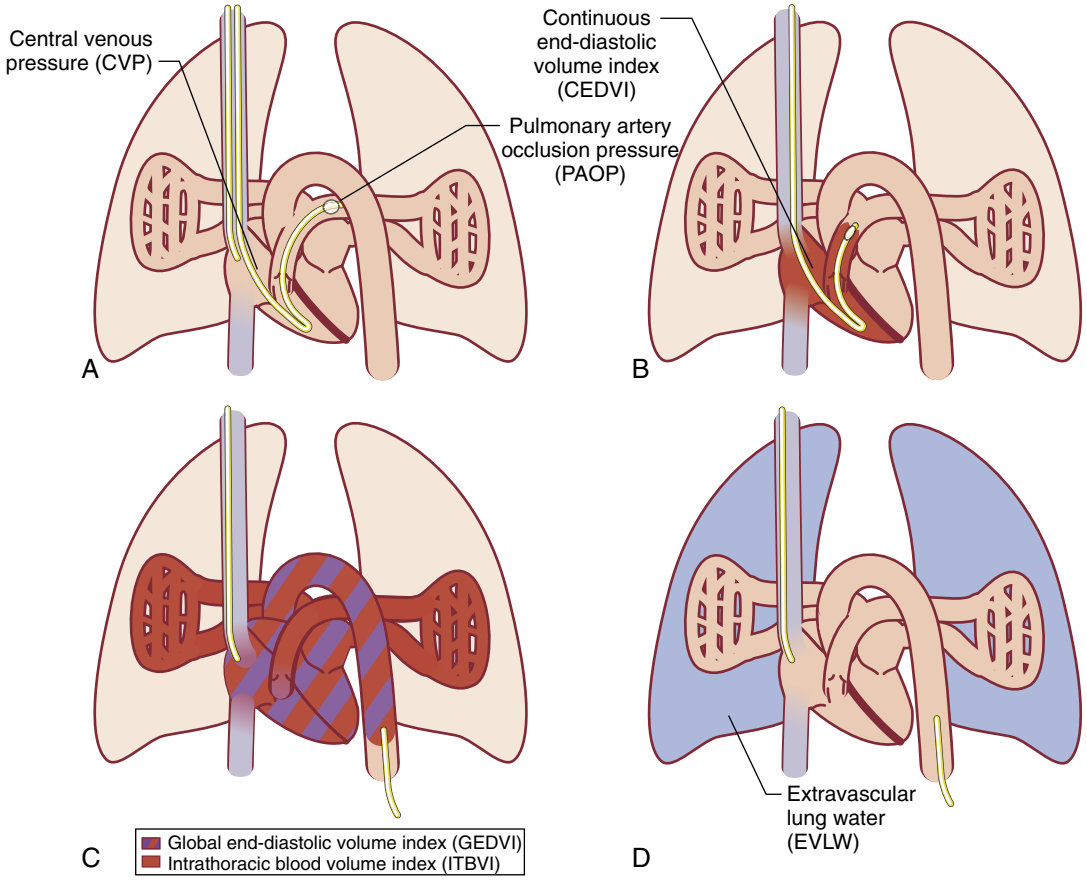

Figure 88-2 Basic and advanced hemodynamic monitoring. **A,** Right- and left-sided heart filling pressures: central venous and pulmonary artery occlusion pressure. Central venous pressure (CVP) is measured at the transition of the superior vena cava and the right atrium. For pulmonary artery occlusion pressure (PAOP) measurement, the balloon at the tip of the pulmonary artery catheter is inflated and floats to the wedge position. The blood flow ceases, and a hydrostatic column is created between the tip of the catheter and the left atrium. **B,** Continuous end-diastolic volume index (CEDVI). Continuous end-diastolic volume is determined from continuous cardiac output monitoring and the indicator travel time in the right side of the heart (indicator: intermittent release of small heat quantities from the thermal filament). **C,** Global end-diastolic volume index (GEDVI) and intrathoracic blood volume index (ITBVI). Global end-diastolic volume and intrathoracic blood volume are calculated from cardiac output and different indicator passage time after injection through a central venous catheter and the detection by a thermistor-tipped arterial catheter in the femoral artery (see Fig. 88-3). **D,** Extravascular lung water (EVLW). EVWL is calculated from cardiac output and different indicator passage time after injection through a central venous catheter and the detection by a thermistor-tipped arterial catheter in the femoral artery (see Fig. 88-3).

decreased function and mitral insufficiency as expression of an enlarged mitral annulus can be seen. Furthermore, echocardiography is of invaluable help as a diagnostic tool (e.g., detection of a papillary muscle rupture, pericardial tamponade, acute valvular pathologies, and dissection of the ascending aorta).[39,40]

Microcirculation and Regional Blood Flow

The maintenance of microcirculatory perfusion aims at providing an adequate tissue oxygenation. Consequently, different methods to directly visualize microcirculation have been developed in the past years. Nailfold microvideoscopy was the first technique available for bedside measurement. Unfortunately, local alterations of the vascular structure due to temperature changes and influences of vasoactive substances rendered these readings unreliable. Furthermore, results may fail to represent microcirculation of target organs like the intestines or the brain. The recently introduced orthogonal polarization spectral imaging and the sidestream dark-field technique are applied to the sublingual mucosal surface. The significance of these techniques has also been questioned for the same reasons as those of nailfold microvideoscopy. However, the use of these monitoring techniques revealed interesting insights into the hemodynamic pathophysiology of macrocirculation and microcirculation; for example, in sepsis, when microcirculatory alterations are most likely to occur, microcirculation improved as a result of a dobutamine infusion unrelated to cardiac output and mean arterial pressure.[41] Furthermore, in a comparative model of septic and hemorrhagic shock, changes of microcirculation were also observed in hemorrhagic shock but they were less pronounced than in septic shock. Resuscitation and restoration of the macrocirculation resulted in an increased microcirculation in hemorrhagic shock, whereas treatment failed to improve capillary blood flow in septic shock.[42] It seems that these techniques of microcirculation monitoring provide additional and necessary information for the optimization of end organ perfusion. However, because they are time-consuming and because clearly defined end points are lacking, they have to be considered experimental.[43]

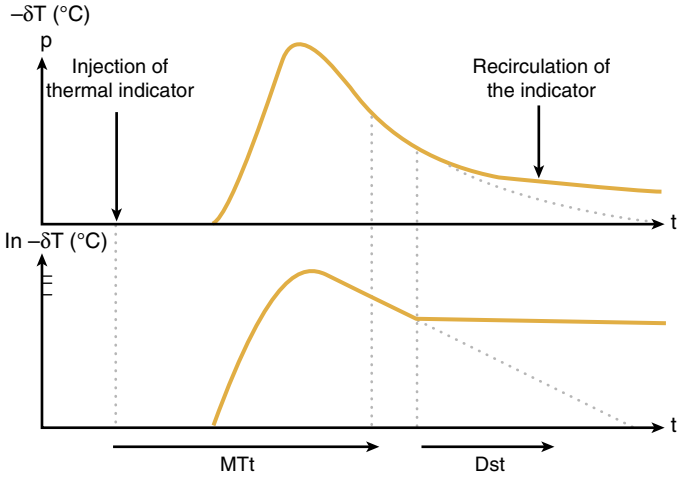

Figure 88-3 Transpulmonary thermodilution curve and typical indicator passage time required for the calculation of global end-diastolic volume index (GEDVI), intrathoracic blood volume index (ITBVI), and extravascular lung water (EVLW). MTt, Mean transit time of the indicator; DSt, downslope time of the indicator; δT, temperature change as result of thermal indicator injection; BSA, body surface area. GEDVI, ITBVI, and EVLWI are calculated according to the following formulas:

$$GEDVI = CO \times (MTt - DSt) \times BSA$$

$$ITBVI = 1.25 \times GEDVI \qquad EVLW = CO \times (MTt - 1.25 \times [MTt - DSt])$$

Laboratory Evaluation

Laboratory evaluation supports the assessment of a patient's fluid status primarily by providing information on the effects of an inadequate end organ perfusion. Parameters assessed by blood gas analysis reflect global tissue hypoperfusion but also allow the calculation of tissue oxygen extraction (in combination with cardiac output measurement). Furthermore, renal function and the electrolyte composition of the urine provide information on the global fluid status and end organ perfusion of the kidneys. Finally, hormones released from myocardial cells in response to volume expansion and possibly increased wall stress (e.g., BNP; see earlier section on natriuretic hormones) may provide some information on the patient's volume status and help to differentiate noncardiogenic and cardiogenic pulmonary edema (Table 88-9).

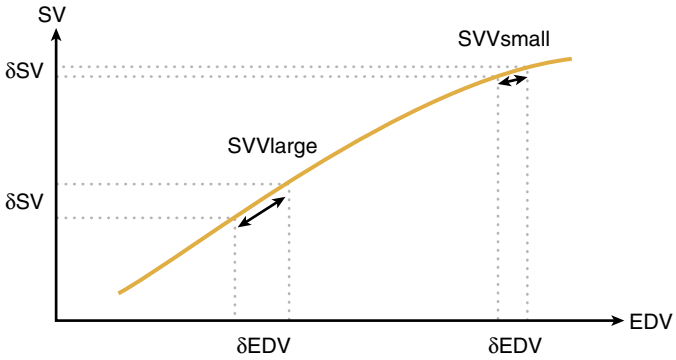

Figure 88-4 The concept of fluid responsiveness based on the assessment of stroke volume variation (SVV). EDV, end-diastolic volume; δEDV, change of end-diastolic volume induced by fluid administration; SV, stroke volume; δSV, change of stroke volume induced by fluid administration; SVVlarge = stroke volume variation typically higher than 15%; SVVsmall, stroke volume variation smaller than 12%. Fluid administration in a patient with a large SVV typically results in an increased EDV and an increased SV (so-called fluid responder). During additional fluid administration, SVV decreases and travels up along an imaginary individual Frank-Starling curve. If SVV becomes low, further fluid administration will induce only small changes in both EDV and SV (shallow part of the Frank-Starling curve) (so-called fluid nonresponder).

Table 88-9 Laboratory Parameters to Assess the Fluid Balance

Arterial blood gas analysis		
Metabolic acidosis (pH)	7.36-7.44	
Lactate	<2 mEq/L	
Base excess (BE)	–2 to +2 mEq/L	
Laboratory parameters of renal function		
Creatinine (Creat)	70-110 mmol/L (0.8-1.25 mg/dL)	
Blood urea nitrogen (BUN)	2.1-8.9 mmol/L (6-25 mg/dL)	
	PRA	**ATN**
BUN:creatinine ratio	≥20:1	10:1-20:1
Fractional sodium excretion (FENa) $= (Na_U \times Creat_P):(Na_P \times Creat_U) \times 100$	<1%	>2%
Urinary sodium (Na_U)	<10-20 mEq/L	>20-40 mEq/L
Urinary osmolality (Osm_U)	>450 mOsm/kg	<350 mOsm/kg
Laboratory parameter of cardiac failure		
Brain natriuretic peptide (BNP)	<125 pg/mL	

ATN, acute tubular necrosis; P, plasma; PRA, prerenal azotemia; U, urinary.

Arterial Blood Gas Analysis

Inadequate tissue perfusion, that is, impairment of oxygen delivery and regional hypoxia, induces a change of the energy supply from aerobic to anaerobic metabolism: instead of 36, only 2 ATP molecules are produced per metabolized glucose molecule, while pyruvate is converted to lactate. Anaerobic metabolism results in the formation of large amount of hydrogen ions, and a metabolic lactic acidosis develops with decreased pH and increased lactate level (>2 mEq/L). Independent of global hypoperfusion and anaerobic metabolism, lactate levels may also be elevated during administration of large amounts of lactated Ringer's solution and reduced hepatic clearance of lactate. On the other hand, pH is a function of the available amount of plasma HCO_3^- and arterial CO_2. The interaction between pH, HCO_3^-, and $Paco_2$ is explained by the Henderson-Hasselbalch equation:

$$pH = pK + \log HCO_3^- / 0.03(Paco_2)$$

For clinical purposes a simplification may be sufficient:

$$pH \approx HCO_3^- / Paco_2$$

Typically, levels of bicarbonate and base excess decrease during the development of tissue hypoperfusion and progressive metabolic lactic acidosis, because plasma HCO_3^- acts as a hydrogen ion buffer. *Base excess* is defined as the amount of base required to raise 1 L of blood to a pH predicted from actual Pco_2 and is a derived parameter from HCO_3^- and pH:

$$\text{Base Excess} = HCO_3^- - 24.8 + \left(16.2 \times [pH - 7.4]\right)$$

Base excess has shown to be a better indicator of global hypoperfusion and the development of metabolic acidosis than pH, primarily because of the compensatory physiologic mechanisms to maintain the pH in a normal range.[44,45] However, base excess can also be altered by causes other than global hypoperfusion. For example, hyperchloremic metabolic acidosis induced by infusion of normal saline, diabetic ketoacidosis, and acidosis due to chronic renal failure may result in a decreased base excess (increased base deficit).[46]

Apart from these main parameters indicating global hypoperfusion, arterial blood gas analysis together with advanced hemodynamic monitoring may further allow calculation of how much oxygen is being delivered into the tissue of the body, expressed as the oxygen delivery index (Do_2I):

$$Do_2I\left(mL/min/m^2\right) = CI \cdot 13.4 \cdot Hb \cdot Sa_{O_2}$$

where CI = cardiac index, Hb = hemoglobin concentration, and Sa_{O_2} = arterial oxygen saturation.

Do_2I may help to estimate a deficit in oxygen supply. Several studies demonstrate an improved outcome, when supranormal Do_2I levels (>600 mL/min/m^2) have been achieved during preoperative resuscitation.[47] However, conflicting results have been reported in studies applying this concept to trauma and septic patients.[48,49]

Venous Blood Gas Analysis

The oxygen saturation of venous blood is either measured in the pulmonary vein (mixed venous oxygen saturation [$S\bar{v}O_2$]) or in the superior vena cava (central venous oxygenation saturation [$Sc\bar{v}O_2$]) using co-oximetry to determine the balance between systemic oxygen delivery and consumption (i.e., tissue oxygen extraction). Hypoperfusion due to hypovolemia, for example, results in a decreased oxygen delivery. The determination of $S\bar{v}O_2$ requires the placement of a pulmonary artery catheter and, in order to avoid the inherent risk related to its use, assessment of $Sc\bar{v}O_2$ via a central venous catheter is advocated.[50] $S\bar{v}O_2$ reflects the oxygen extraction of the total body, with $Sc\bar{v}O_2$ only that of the brain and the upper part of the body. Under physiologic conditions $Sc\bar{v}O_2$ values are lower than $S\bar{v}O_2$ values (higher oxygen extraction by the brain), whereas in a sedated patient after major abdominal surgery $S\bar{v}O_2$ values may be significantly lower (higher oxygen extraction by the intestines). Thus, it has been argued that $S\bar{v}O_2$ and $Sc\bar{v}O_2$ may not necessarily be used interchangeably.[51] However, because trends of these two parameters show a good correlation,[52] $S\bar{v}O_2$ and $Sc\bar{v}O_2$ are helpful tools for the fluid assessment and resuscitation in complex hemodynamic situations. Because frequent blood gas analyses are required, the use of a modified pulmonary artery or central venous catheter (with fiberoptic sensors to measure oxygen saturation) has to be considered.

Parameters of Renal Function

In a patient without renal disease and diuretic therapy, hypovolemia and renal hypoperfusion leads to increased urea reabsorption and a proportionately greater elevation in BUN than plasma creatinine. Therefore, the BUN:creatinine ratio can increase from 10:1 to greater than or equal to 20:1 and help to assess this patient's volume status. However, increased urea production (hyperalimentation, glucocorticoid therapy, gastrointestinal bleeding) may also increase this ratio.

Because the appropriate response to fluid deficits is an enhanced renal Na^+ and water reabsorption, the urine composition typically reflects the patient's fluid status. In a hypovolemic patient, the urine osmolality and specific gravity are generally greater than 450 mOsm/kg and 1.015 g/mL because of maximal concentration of the urine (enhanced AVP secretion). Furthermore, the urine Na^+ concentration is usually less than 20 mEq/L in hypovolemia. For example, if the urine Na^+ concentration remains less than 20 mEq/L after fluid therapy, then the kidneys are sensing persistent intravascular volume depletion and more fluids should be given. However, the use of urine Na^+ concentration cannot be applied to an edematous patient with heart failure or cirrhosis. In these patients, the urine Na^+ concentration is a marker of effective circulating volume depletion but not necessarily an indicator for the need of more fluid. Additionally, urine Na^+ concentration does not reflect the volume status in conditions associated with impaired Na^+ reabsorption, as in acute tubular necrosis. Another exception is hypovolemia due to vomiting, because the associated metabolic alkalosis and increased filtered HCO_3^- impair proximal Na^+ reabsorption. In this case, the urine Cl^- is low (<20 mEq/L). Finally, in hypovolemia due to a diabetes insipidus, urine osmolality and specific gravity are indicative of inappropriately dilute urine.

Therapy for Alterations in Fluid Balance

Maintaining an optimal fluid balance is challenging but critical in the postoperative period to adequately perfuse tissue and organs. If the fluid homeostasis is altered, therapeutic interventions are required to bring the patient back to an optimal fluid balance. The goal of fluid therapy in postoperative patients is to maintain the effective circulatory volume while avoiding interstitial fluid overload whenever possible. The appropriate type and amount of fluid and or cardiac support should be provided if the effective circulating volume is low (absolute and relative hypovolemia). On the other side, fluid restriction and removal (pharmacologic, renal replacement therapy) need to be considered if a patient has excessive intravascular fluid volume.

Maintenance Fluid Therapy

Maintenance fluid therapy in the postoperative period aims at preserving the water and electrolyte balance. It should replace the ongoing losses of water and electrolytes under normal physiologic conditions. Because these losses account for 30 to 35 mL/kg/day (approximately 2100-2500 mL/day for a 70-kg adult), the same amount of fluids have to be provided to maintain the physiologic fluid balance. Maintenance fluid requirements may be calculated according to the 4-2-1 rule in the postoperative period and replaced intravenously with isotonic crystalloid solutions as long as the patient remains NPO (Table 88-10).

Besides estimating and measuring the net fluid input and output (according to the amount of fluids administered and lost), the patient should be weighed on a daily basis to estimate net gain or loss of fluids because gastrointestinal, urine, and insensible

Table 88-10 Empirical Maintenance and Replacement Fluid Therapy

Maintenance Fluid Therapy	
Ongoing losses of water and electrolytes under physiologic conditions	
4-2-1 Rule*	
≤10 kg	4 mL/kg/hr
11-20 kg	*Add* 2 mL/kg/hr
≥21 kg	*Add* 1 mL/kg/hr
Replace with balanced, isotonic crystalloid solutions (e.g., lactated Ringer's solution)	
Replacement Fluid Therapy	
Hemorrhage	Replace 1 mL of blood loss with 3 mL balanced, isotonic crystalloid solution or 1 mL colloid solution/blood.
Third space losses	Replace with balanced isotonic crystalloid solutions (e.g., lactated Ringer's solution).
Profuse sweating	Replace with D_5W ¼ NS with 5 mEq KCl/L.
Gastric and colonic losses	Replace with D_5W ½ NS with 30 mEq KCl/L.
Bile, pancreas, and small bowel losses	Replace with balanced isotonic crystalloid solutions (e.g., lactated Ringer's solution).

D_5W, 5% dextrose (glucose) in water; NS, normal saline (0.9% NaCl); KCl, potassium chloride.
*Example: Empirical maintenance fluid therapy per hour for a 70-kg person is approximately 110 mL/hr, i.e., 40 mL/hr *plus* 20 mL/hr *plus* 50 mL/hr.

losses may be unpredictable and difficult to monitor in patients after surgery.

Replacement Fluid Therapy

Replacement fluid therapy in the postoperative period corrects any existing and additionally occurring water and electrolyte deficits. These deficits result from bleeding, third space sequestration, evaporative losses (e.g., mechanical ventilation without humidifier, surgical field if wound is left open), profuse sweating, and additional gastrointestinal as well as other fluid losses (see Table 88-6). There is no formula that can be used to accurately estimate the total fluid deficit (as is the case for maintenance fluid requirements). Estimated and measured fluid losses, clinical examination, and laboratory values must be used to assess the severity of intravascular volume depletion. The plasma concentration of Na^+ provides the best estimate for water balance in relation to Na^+ but does not give any information on the volume status.

To preserve fluid homeostasis, the type of fluid given for replacement therapy is largely dependent on the type of fluid that has been lost and any concurrent fluid and electrolyte disorders (see Table 88-10). Thus, patients with blood loss usually require isotonic fluids and or blood if the hemorrhage is severe. Other examples are patients with hypernatremia in whom hypotonic solutions are preferred. The choice of replacement fluid in hypernatremia depends on the source of fluid loss: D_5W alone (5% dextrose in water) can be given if there has been only water loss (as in diabetes insipidus), whereas a hypotonic saline solution (such as D_5W ¼ normal saline [NS] or D_5W ½ NS) should be administered in patients who have lost both salt and water (as with profuse sweating, gastric losses, and diarrhea). Patients with hyponatremia should be administered isotonic or hypertonic saline. In addition, K^+ replacement may be required in patients who have developed K^+ depletion as evidenced by hypokalemia. It is important to emphasize that K^+ is as osmotically active as Na^+. Thus, the addition of 30 mEq of KCl to 1 L of D_5W ½ NS (containing 77 mEq/L of each, Na^+ and Cl^-) creates a solution that is essentially a two-thirds normal saline solution and therefore contains less free water. This could be important in patients with hypernatremia.

The optimal rate of volume repletion for mild to moderate volume deficits is somewhat arbitrary. However, severe volume deficits (e.g., hypovolemic shock) require immediate repletion in an attempt to restore tissue perfusion, and fluid administration has to be continued at a rapid rate until clinical signs of hypovolemia normalize. Clinical and laboratory parameters must be followed to assess the efficacy and adequacy of volume repletion. Repletion of intravascular volume in patients with hyponatremia or hypernatremia requires extra attention, because overly rapid correction of the plasma Na^+ concentration can lead to potentially irreversible neurologic damage. The preferred rate at which the plasma Na^+ concentration should be elevated in hyponatremia varies with the clinical presentation. Acute hyponatremia (e.g., hyponatremia during transurethral resection of the prostate due to massive reabsorption of free water) can and should be corrected faster than chronic hyponatremia. The rate of correction over the first 24 hours is more important than the maximum rate in any given hour. Demyelinating lesions in the central nervous system are most common when the plasma Na^+ concentration in severe hyponatremia is raised more than 15 mEq/L/day and are rare at a rate below 10 to 12 mEq/L/day.

Controversies of Liberal, Restrictive, and Optimal Intravascular Fluid Therapy

Perioperative fluid therapy has a direct bearing on patient's outcome, and prescriptions should be tailored to the needs of the patient. Too much or too little fluid can both adversely affect clinical status, with increased morbidity and mortality. The goal of fluid therapy in postoperative patients is to maintain the effective circulatory volume while avoiding interstitial fluid overload whenever possible.[24,53]

Liberal Intravascular Fluid Therapy

During outpatient surgery in healthy patients the administration of relatively liberal amounts of crystalloids perioperatively (up to 20-40 mL/kg crystalloids) appears to both improve the quality of a patient's recovery and decrease the time after surgery until ready for discharge.[54,55] Applying these protocols has led to fairly consistent results across studies. Therefore, they can be recommended with the caveat that they may apply only to healthy individuals undergoing minor surgical procedures.

Perioperative hypovolemia (absolute and relative) induced by many forms of anesthesia, and the use of vasoconstrictors, is considered the most important trigger for perioperative acute renal failure in patients with comorbid conditions and in patients undergoing major surgery. Therefore, a liberal fluid regimen has been proposed and has been clinically used for many years to prevent anesthesia-induced hypotension and to protect organ function, especially the kidneys.[56] However, this regimen is not evidence based and it has not been shown to decrease the incidence of acute renal failure. By contrast, excess fluid administration may result in adverse clinical outcomes from tissue edema

formation with compromised pulmonary gas exchange, impaired microvascular perfusion and tissue oxygenation, coagulation abnormalities, and acid-base disturbances. As a result, the traditional liberal perioperative fluid regimen has been questioned.[24] Furthermore, patients with one-lung ventilation after thoracic surgery are at risk for postoperative pulmonary complications (see Chapter 59). Excess positive fluid balance has been shown to be the strongest risk factor for postoperative pulmonary complications and increased in-hospital mortality rate in these patients.[57]

Restrictive Intravascular Fluid Therapy

As a result of the adverse effects of a liberal fluid regimen in some patients, restrictive fluid protocols have been developed and applied perioperatively with conflicting results. Protocol based fluid restriction has been shown to reduce the incidence of perioperative cardiopulmonary complications and disturbances of bowel motility while improving wound healing and decreasing the occurrence of anastomotic insufficiency in major abdominal procedures.[58,59] Other studies, however, did not confirm these findings.[60] The most likely cause for these controversial findings is the lack of a standardized definition of liberal and restrictive fluid therapy. To date, different studies used different definitions, making any pooling of data impossible. However, there is consensus in most studies that fluid overload in major surgical procedures may be harmful.[59]

Optimal Fluid Intravascular Therapy

The idea behind goal-directed fluid therapy and optimization is to obtain normal to supranormal values of tissue oxygen delivery.[61] With this concept transferred to the general surgical patient, a maximum stroke volume, achieved by esophageal Doppler-monitored fluid boluses, was considered to represent the optimum intravascular fluid load. Indeed, compared with fluid substitution at the discretion of the anesthesiologist, this goal-directed approach led to a significantly reduced hospital stay and fewer intermediate and major postoperative complications after elective colorectal surgery.[62] Additionally, patients treated intraoperatively with colloid boluses to maintain a predefined minimum aortic flow and to optimize stroke volume individually tolerated diet significantly earlier.[62] Also, several indirect variables were tested as predictors of fluid responsiveness. Less invasive measurements, such as variation in the systolic arterial or pulse pressure (on the principle that intrathoracic pressure changes cyclically during mechanical ventilation, decreasing venous return and consequently stroke volume, preferentially in hypovolemic patients) strongly distinguish between responders and nonresponders to fluid challenge.[63] However, circulatory optimization, achieved by optimizing these easily applicable surrogate variables, has not yet been reliably translated into improved outcomes and, for practical reasons, esophageal Doppler imaging cannot be routine.[64]

In summary, fluid therapy to each patient must be individualized and balanced according to the benefits and risks of intravascular fluid administration. Therefore, the patient's characteristics and the type of procedure should determine whether to choose a more liberal or a more restrictive fluid regimen. With more invasive or traumatic surgery and with increasing blood losses, greater alterations in fluid balance are expected and the fluid therapy should be optimized with a rational concept, that is, protocol-based, goal-directed fluid therapy under careful and continuous assessment of the fluid balance.

Types of Fluids: Crystalloids, Colloids, and Blood Products

A variety of manufactured fluid formulations exist for intravenous fluid therapy (see Chapters 49, 54, 55, and 57) that differ in two fundamental ways: the component electrolyte solution and the suspended material providing colloid osmotic (oncotic) pressure. Crystalloids are aqueous solutions of inorganic and small organic molecules, the main solute being either normal saline or glucose. Depending on the concentration of the solute, manufactured crystalloid solutions are isotonic, hypotonic, and hypertonic. Colloids, in contrast, are homogeneous noncrystalline substances containing large molecules. Because colloids have much greater capacity to remain within the intravascular space, these solutions may restore the plasma volume more efficiently and may act as volume expanders. Colloids used in clinical practice include hydroxyethyl starch (HES), gelatin, and dextran preparations dissolved in crystalloids and human plasma products such as albumin or blood products (fresh frozen plasma) (see Chapter 55).

Crystalloids

Crystalloid solutions are safe, nontoxic, reaction free, and inexpensive. Multiple different formulations are commercially available; the most commonly used are summarized in Table 88-11. Besides different tonicity, crystalloids can be further categorized into unbalanced (unphysiologic electrolyte composition, no buffers) and balanced (physiologic mixture of electrolytes with buffers) formulations. A major disadvantage of hypotonic and isotonic crystalloids is the limited ability to remain within the intravascular space. Therefore, to maintain an effective circulating volume, administration of large volumes of crystalloid solutions is required. Accumulation of fluid in the interstitial space with edema formation occurs as a typical side effect.

Isotonic crystalloids are favored in the perioperative period. Because NaCl is the predominant salt in crystalloids and because Na^+ equilibrates over the whole ECF compartment, only 25% of the administered crystalloid solution remains intravascular. Therefore, to completely replace an intravascular fluid loss with isotonic crystalloid solutions, three to four times the volume lost has to be administered. The major consideration in selecting a solution is its specific electrolyte composition (mainly Na^+, K^+, and Cl^-) and buffer capacity. Normal saline may induce a nongap, hyperchloremic metabolic acidosis associated with impaired end organ perfusion and function if large volumes are given intravenously.[65] On the other hand, buffers in lactated Ringer's solution (i.e., lactate) or Plasma-Lyte (i.e., acetate and gluconate) are being metabolized to HCO_3^- in the liver and may result in a metabolic alkalosis. These balanced crystalloid solutions should be used with caution in patients with preexisting hyperkalemia (e.g., end-stage renal disease) because of their K^+ content. Alternatives are normal saline or balanced, K^+ free solutions. Furthermore, calcium present in lactated Ringer's solution prohibits its use in the presence of citrated blood products and may precipitate different drugs (e.g., amphotericin B, thiopental).

Hypotonic crystalloids are being used to provide free water to patients with hypertonic dehydration or hypernatremia. Several formulations are available, such as D_5W, ½ NS, and ¼ NS with or without D_5W. The intravascular volume effect is minor in comparison with that of isotonic crystalloids. As an example, D_5W

Table 88-11 Composition of Plasma and Routinely Used Crystalloids

D_5W ½ NS	77				77		50	5.0	406
Hypertonic									
7.5% NaCl	1284				1284			6.0	2568

*Normal saline, 0.9% NaCl.
Acet, acetate; Bic, bicarbonate; D_5W, 5% dextrose (glucose) in water; Gluc, gluconate; Lac, lactate; Prot, plasma proteins; Posm, calculated osmolarity.

consists entirely of free water because glucose is being metabolized and water equally distributes in the ICF and ECF compartments. Therefore, only 8% of the administered D_5W remains in the intravascular space. As a general rule, dextrose-containing solutions should be used with caution in the absence of disease states affecting glucose metabolism because hyperglycemic-induced hyperosmolality, osmotic diuresis, and cerebral acidosis are known complications.

Hypertonic solutions such as 7.5% NaCl are being used in the postoperative period to treat severe hyponatremia. Furthermore, hypertonic saline alone or combined with colloids refers to the concept of "small volume resuscitation" in patients with severe hemorrhage.[66] The theory of a rapid restoration of an effective circulating volume is convincing, and animal studies are promising so far, demonstrating an improved microcirculation, decreased intracerebral pressure, induction of stress protein response and cellular protection, as well as a balanced inflammatory response. However, these effects have been difficult to replicate clinically and a systematic review of hypertonic saline in resuscitation of patients with trauma, burns, or those undergoing surgery was unable to reach a conclusion regarding benefit or harm.[67]

Hydroxyethyl Starches

Hydroxyethyl starches are modified natural polysaccharides similar to glycogen (Fig. 88-5). They are derived from amylopectin, a highly branched corn or potato starch. Starches are rapidly being cleaved by α-amylase, and, as a result, plasma levels of α-amylase may significantly increase after administration of starches (typically twofold to fivefold). To delay α-amylase breakdown with subsequent elimination from the blood, natural starches are being substituted with hydroxyethyl groups (carbon position C2, C3, and C6), resulting in the clinically used HES preparations. Their most important physicochemical characteristics are the molar substitution, C2/C6 ratio, and molecular weight. Molar substitution (MS) is defined as the mol hydroxyethyl residues per mol glucose subunits. According to the MS, hydroxyethyl starch preparations can be classified into solutions with high (hetastarch, hexastarch; 0.7 and 0.6, i.e., 7 and 6 hydroxyethyl groups for every 10 glucose units, respectively), medium (pentastarch; 0.5), and low substitution (tetrastarch; 0.4). High MS prolongs degradation. The C2/C6 ratio refers to the pattern of hydroxyethylation at the carbon atoms of the glucose rings and is considered high (>8) or low (<8). Substituted hydroxyethyl groups at

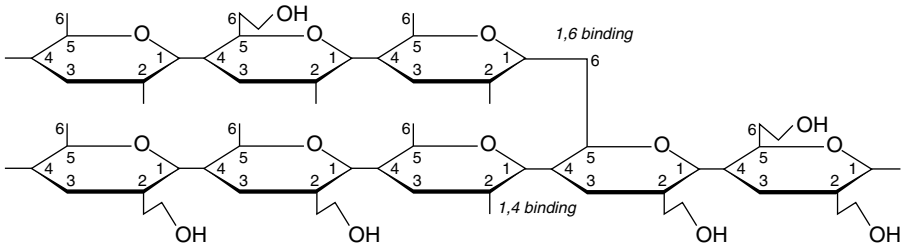

Figure 88-5 Molecular structure of hydroxyethyl starch solutions. Hydroxyethyl starches are modified natural polysaccharides similar to glycogen. The glucose units are bound together primarily by 1,4 and occasionally by 1,6 linkage. To delay α-amylase breakdown with subsequent elimination from the blood, natural starches are being substituted with hydroxyethyl groups (carbon positions C2, C3, and C6). Their most important physicochemical characteristics are the molar substitution, C2/C6 ratio, and the molecular weight.

the C2 position are being cleaved much more slowly than at position C6. Therefore, formulations with high C2/C6 ratio are being slowly degraded and have longer plasma half-lives. The low-molecular-weight fraction (<60-70 kD) is rapidly excreted by the kidneys, whereas the larger molecules have to be hydrolyzed by serum α-amylase before elimination. As a result, the plasma half-life of an HES preparation increases with increasing molecular weight. HES has recently become the subject of renewed interest in Europe and some non-European countries because of the introduction of a new, rapidly degradable formulation with reduced side effects (i.e., HES 130/0.4).[68] Furthermore, HES 670/0.75 and HES 130/0.4 are now clinically available in a carrier solution other than 0.9% NaCl (i.e., in a balanced electrolyte formulation; see later).

The plasma expanding effect (volume effect) primarily depends on the concentration of the HES solution. Specific physicochemical properties affect primarily the extent and duration of plasma volume expansion, their effects on blood rheology, and the coagulation system. The rheologic effects of HES are determined by their high hemodilutional capacity in combination with their specific pharmacologic effects on red cell aggregation, platelet function, plasma viscosity, and blood corpuscle/endothelial cell interactions. Vascular resistance is reduced by lowering whole blood viscosity, which will enhance venous return and increase cardiac output. The net result would be improved blood fluidity, which might beneficially influence tissue perfusion and oxygenation. Negative effects on coagulation have been reported after the use of HES, especially by first-generation preparations with high MS (hetastarches).[69] HES solutions decrease the levels of von Willebrand factor (vWF) and associated factor VIII activity (acquired, type I von Willebrand–like syndrome), impair platelet function (coating), and may induce platelet damage.[70] Patients with blood group O have significantly lower levels of vWF/VIII than patients with other blood groups, and these levels are further reduced significantly after HES administration.[71] Administration of HES solutions may be associated with renal dysfunction probably because of hyperviscosity of the urine in dehydrated patients. Glomerular filtration of hyperoncotic colloid molecules causes hyperviscous urine and stasis of tubular flow, resulting in the obstruction of the tubular lumen. Additionally, tubular cells may swell and show vacuolization ("osmotic nephrosis–like lesions"). In the case of HES, the risk of high plasma oncotic pressure and thus the risk of acute renal failure is probably increased by high concentrations of the colloid (10% HES) or repeated administration of HES with a high MS and molecular weight (slowly degradable HES). However, the critical creatinine level when HES should be avoided is not known. Depending on their physicochemical characteristics, HES molecules may pass the endothelial barrier and enter the interstitial space. Most of the extravasated HES will be collected by the lymph system and reenter circulation. A smaller amount is taken up by the reticuloendothelial system where the starch is broken down slowly. Thus, trace amounts of the preparations can be detected for several weeks after administration. The degree of plasma and tissue accumulation is highly dependent on the type of HES used for volume replacement. Especially HES solutions with a high MS and molecular weight are associated with considerable accumulation, particularly after multiple dosing. Pruritus after administration of HES has been described in some reports and seems to be associated with extravascular HES deposition after large volume administration. This may occur after a latency period and may persist for weeks to months. Allergic reactions may occur after administration of HES; however, the incidence is lowest compared with the other colloids. The following recommendations for maximum daily administration have been established: 1.5 (slowly degradable, e.g., HES 670, 0.75), 2.0 (intermediate degradable), and 3.0 (rapidly degradable, e.g., HES 130/0.4) g/kg body weight, respectively.

Gelatins

Produced by degradation of bovine collagen and chemical modifications, gelatins are polydispersed colloidal solutions. Three types of gelatins are available: oxy-crosslinked, urea-crosslinked, and succinylated gelatins. Different gelatin molecules have comparable molecular weight (average 30-35 kD), and the commercially available preparations have similar gelatin concentrations (3.5%-5.5%) and volume-restoring efficacy (volume effect 70%-100%). Because of the small molecular weight, gelatins are rapidly being cleared from the bloodstream by glomerular filtration (>80% are being excreted unchanged by the kidneys) and, to a minor extent, undergo cleavage by proteases into small peptides in the reticuloendothelial system. Therefore, repeated infusions of gelatins are necessary to maintain adequate blood volume. Gelatins do not accumulate in the body, have no dose limitations, and appear to be almost without adverse effects on the kidneys. Although gelatins were considered for a long time to have only an influence on blood coagulation via dilution, this has been questioned lately.[72] It seems that hemostasis could be impaired by an interference of gelatin with the function of coagulation factors and by a disturbance in the quality of fibrin polymerization. The exact mechanism however remains to be elucidated.[73]

Disadvantages of gelatins are their bovine origin with the hypothetical potential of transmitting prion diseases (e.g., bovine spongiform encephalopathy). Furthermore, they have the most frequent incidence of allergic reactions among all colloids (six times higher compared with HES; incidence 0.35%).[74]

Dextrans

Dextrans are polydispersed colloids that are biosynthesized from sucrose by the bacterium *Leuconostoc mesenteroides*. The formulations most frequently selected are dextran 40 and dextran 70, with molecular weights of 40 and 70 kD, respectively. After intravenous administration, small dextran molecules less than 50 kD are rapidly eliminated by the kidneys (filtration). All other molecules are being metabolized to carbon dioxide and water by cell-bound enzymes in the kidneys, liver, and spleen. Dextran solutions improve blood rheology, especially by decreasing blood viscosity, which should ultimately translate into improved microcirculatory blood and tissue perfusion. The rheologic effect of dextran 40 is especially pronounced because these solutions reduce whole blood viscosity more for any given degree of hemodilution than all other plasma substitutes. Indeed, dextran 40 is frequently used by vascular and plastic surgeons to assist in keeping microvascular anastomoses patent.

Dextran infusion induces a dose-dependent hyperfibrinolysis and an acquired von Willebrand's syndrome with decreased levels of vWF and associated factor VIII (VIII:c) activity. Consequently, there is a maximal daily dosage recommendation of 1.5 g dextran/kg body weight to avoid serious bleeding complications.

Impaired renal function may be a further problem with the use of dextrans. Because there is no known nephrotoxic effect of dextrans, the most likely mechanism of a dextran-induced renal dysfunction may be a tubular obstruction, swelling, and vacuolization of tubular cells (osmotic nephrosis–like lesions) due to the production of hyperviscous urine. Dextrans may cause severe anaphylactic reactions. A high frequency of preformed antibodies against dextrans has been noted in patients with prior exposure to high-molecular-weight dextrans in food or from bacteria and bacterial products. To prevent these anaphylactic reactions, dextran 1 (Promit), a low-molecular-weight hapten, has to be administered a few minutes before any dextran infusion. In summary, dextran 70 is generally preferred for volume expansion whereas dextran 40 is thought to improve blood flow in the microcirculation, presumably by decreasing blood viscosity. Despite these positive macrohemodynamic and microhemodynamic effects, the use of dextrans is declining in most countries because of their significant adverse effects.

Human Albumin

Albumin is purified from pooled human plasma and is commercially available as a 5% (iso-oncotic), 20%, or 25% (hyperoncotic) solution. Because albumin is heated and sterilized by ultrafiltration, the risk of bacterial or viral disease transmission should be eliminated.

Albumin is the most abundant plasma protein. It is essential for maintaining the plasma oncotic pressure needed for proper distribution of body fluids between intravascular and interstitial space. Furthermore, albumin acts as a transport protein by binding, for example, several hydrophobic steroid hormones and fatty acids and is an important buffer in the plasma. Serum albumin concentration is an independent predictor of mortality risk in patients with acute and chronic illness. A systematic review estimated that for each 2.5-g/L decrement in serum albumin concentration the risk of death increases by 24% to 56%.[75] The association persists after adjusting for other known risk factors and preexisting illness, suggesting a direct protective effect of the albumin molecule. Largely as a result of these observations, human albumin solutions have been used in the management of a diverse range of medical and surgical problems, including the acute restoration of an effective circulating volume due to hemorrhage, the acute management of burns, and clinical situations associated with hypoproteinemia. However, there is no evidence that albumin reduces mortality rates in patients with hypovolemia, burns, or states of hypoproteinemia.[76] In a large, multicenter trial on fluid resuscitation performed in a heterogeneous population of patients in an intensive care unit, use of either 4% albumin or normal saline for fluid resuscitation resulted in similar outcomes at 28 days (SAFE study).[77] Furthermore, for patients with burns and hypoproteinemia, albumin administration may even increase mortality rates.[76] As a result of these recent findings and the high costs of albumin, routine use of albumin for volume replacement should be reconsidered and reserved for selected patients only. The relative risk of albumin to develop an allergic reaction is 3.4 times less than that of gelatins and almost identical to that of HES.[74]

Controversy on Crystalloids Versus Colloids

There has been an ongoing debate for decades on whether crystalloids or colloids are superior in perioperative volume replacement therapy. The supporters of crystalloids argue that crystalloids are inexpensive and that adverse effects are rare or absent: There is no renal impairment, only minimal interaction with coagulation other than dilution, no tissue accumulation, and no allergic reactions. Colloid supporters, on the other hand, emphasize the much better volume-expanding properties, minor edema formation, and improved microcirculation with the use of colloid. For example, intravascular volume replacement with colloids has been shown to improve tissue oxygenation in patients undergoing major abdominal surgery. In contrast, administration of equivalent volumes of lactated Ringer's solution were associated with a significantly impaired microcirculation with decreased tissue oxygen tensions as a result of edema with subsequent capillary compression.[78]

However, a recent review by the Cochrane Collaboration in critically ill patients showed that there is no evidence from randomized controlled trials that resuscitation with colloids reduces the risk of death, compared with resuscitation with crystalloids, in patients with trauma or burns or after surgery.[79] Because colloids are not associated with an improvement in survival, and because they are more expensive than crystalloids, the routine and liberal use of colloids in the perioperative period should be questioned.

Controversy on Balanced Versus Unbalanced Fluids

The optimal electrolyte formulation of intravenous solutions has been questioned recently.[80,81] Large volume resuscitation with normal saline (unbalanced, unbuffered solution) causes hyperchloremic metabolic acidosis,[82] which, in turn, has been associated with organ hypoperfusion and increased morbidity, especially gastrointestinal, neurologic, and renal damage, as well as blood loss.[65,83] By contrast, buffered balanced electrolyte formulations (e.g., lactated Ringer's solution, Plasma-Lyte) maintain a higher plasma pH and less chloride load, leading to fewer incidences of hyperchloremic metabolic acidosis.[84] Low concentration electrolytes present in buffered solutions (e.g., Ca^{2+}, K^{+}) may also be responsible for a reduction in postoperative morbidity. Therefore, balanced crystalloid solutions are often preferred in the perioperative period.

The majority of colloids are suspended in unbalanced crystalloid solutions, mainly normal saline. However, the newest generation of HES preparations is now available in balanced crystalloid solutions (balanced HES 670/0.7 [Hextend] and balanced HES 130/0.4 [Voluven balanced]).[85] In addition to maintain a normal acid-base status, colloids suspended in these solutions may also have fewer adverse effects on coagulation and improved gastrointestinal microcirculation.

Treatment of Hypervolemia

Volume overload in the postoperative period may be the result of excess intraoperative and postoperative fluid administration and or impaired renal fluid excretion. Besides fluid restriction, nonspecific pharmacologic therapies may relief the patient from symptoms of pulmonary edema (i.e., morphine, nitroglycerin). Furthermore, diuretics may help to correct the positive fluid

balance by increasing the urine production. Patients with end-stage renal disease, however, may require dialysis to remove excess fluid. Intermittent or continuous hemodialysis should be started (see Chapter 96).

End Points of Intravascular Fluid Resuscitation

The primary end points of fluid therapy are improved patient outcome with reduced mortality and morbidity, especially reduced organ dysfunction and shortened recovery. These end points are being used in clinical trials to compare different fluid resuscitation protocols and to make a clinically relevant conclusion. For clinical use, however, protocols with secondary end points such as hemodynamic and metabolic parameters (see Tables 88-8 and 88-9) to achieve should help the clinician to provide optimal fluid therapy: immediate restoring or maintaining an optimal effective circulating volume with sufficient oxygen-carrying capacity and normal electrolyte composition is the primary goal (fluid and electrolyte balance). Measurement of end organ function (e.g., urinary output, mental status) indirectly reflects adequate effective circulating volume. If the effective circulating volume is not restored in a timely manner, and if the patient remains in global hypoperfusion, acute tubular necrosis may develop. This is independently associated with an increased mortality in the postoperative and critically ill patient.[86,87]

Currently, there is no single end point that universally diagnoses hypovolemia and hypoperfusion or identifies when the goals of resuscitation have been met. Neither pH, bicarbonate, base excess, lactate, nor regional perfusion end points have been demonstrated to be superior in the diagnosis of hypovolemia. The trends of the resuscitation end points over time and their ability to be restored to normal values within 24 hours after severe trauma have definitively been proved more useful. Only with frequent reevaluation of end point parameters can the resuscitation be tailored specifically to the individual patient and change a "nonresponder" into a "responder." Serum pH, bicarbonate, base deficit, and lactate are all metabolic indicators of the severity of hypovolemia and help determine the adequacy of resuscitation. They are more useful than estimated blood loss, heart rate, and blood pressure.[88] Which end point is used to guide resuscitation is less important than how the results are interpreted and how the therapy is altered to return the patient to adequate global tissue oxygenation.[46]

89 Cognitive Dysfunction and Other Long-Term Complications of Surgery and Anesthesia

Key Points

1. The selection, measurement, and analysis of neuropsychological tests (NP tests) will influence findings with postoperative cognitive dysfunction (POCD).
2. Patients' subjective reports after surgery are unrelated to assessed neuropsychological change and appear to be driven by mood.
3. There is good evidence of POCD after cardiac surgery where the mechanism is multifactorial but includes microemboli.
4. POCD after noncardiac surgery is evident in larger studies with good methodology although the mechanisms are less clear than after cardiac surgery.
5. Increased age is a risk factor for POCD.

Brain function is clearly affected during the immediate period after anesthesia, with depressed level of consciousness and impairment of attention, memory, and reaction time often being reported. Patients may experience complete amnesia for several hours after general anesthesia in spite of being apparently completely awake, and as a consequence it is not uncommon for patients to ask the same questions over and over again. Because of these issues, when patients are discharged from the hospital or outpatient clinic on the day of surgery, it is common practice, in many institutions, to ensure that the patient is accompanied by an adult during transportation and throughout the first postoperative night.

There is no simple answer to the question as to when brain function is back to normal after anesthesia. If all the difficulties were due to the anesthetic, one would expect cognitive function to have recovered to a preoperative level of functioning when any drugs affecting cognition have been cleared. One may expect that inhaled anesthetics and propofol differ from hypnotics such as barbiturates and benzodiazepines, which are much more slowly eliminated. It is clear, however, that anesthetic agents and their concentrations are only among many factors of importance for recovery. The duration of the recovery of cognition after anesthesia and surgery is multifactorial and among other factors is dependent on the type of anesthesia used, the type of surgery, and the patient. In some individuals, cognitive recovery is fast (within a matter of hours), whereas, in others, brain function may be disturbed for a much longer time.

The concept of postoperative disturbance in cognition is not new and has often been referred to as *postoperative cognitive dysfunction (POCD)*. The term is, however, used variably, and it is useful to distinguish among three types of cognitive deterioration after surgery:

1. Delirium is usually easily recognized, being an acute condition with fluctuating course, characterized by change in level of consciousness and primarily disturbance in attention. The duration is variable and the degree of severity ranges from mild to very severe.
2. Short-term cognitive disturbance may be apparent in the days after surgery. This occurs relatively frequently and may be due to a combination of factors, including surgery and anesthetic agents. This cognitive disturbance is short term, and it does not persist beyond a few days after surgery. It is best assessed by neuropsychological assessment, but frequently screening tests such as the Mini Mental State Examination (MMSE) are used. Studies have often attempted to assess POCD in the first few hours and days after anesthesia. Some results are reported in this chapter, but it must be remembered that although there are sometimes significant differences occurring between groups these changes are usually transitory and do not represent any lasting condition.
3. What we consider true POCD is a subtle deterioration in cognitive function, lasting for weeks, months, or longer; and neuropsychological testing is needed for verification. It can be considered to be a mild cognitive disorder characterized by impairment of memory, learning difficulties, and reduced ability to concentrate.

All of these different forms of cognitive disturbance that can occur after surgery are to be distinguished from dementia. *Dementia* is a syndrome that is due to disease of the brain, usually

of a chronic or progressive nature, in which there is disturbance of multiple higher cortical functions, including memory, thinking, orientation, comprehension, calculation, learning capacity, language, and judgment. Consciousness is not clouded. The impairments of cognitive function can be accompanied, and occasionally preceded, by deterioration in emotional control, social behavior, or motivation.

Detection of Postoperative Cognitive Dysfunction

The reported incidence of POCD varies widely between studies of the same form of surgery and anesthesia. Besides individual patient differences, this may also be due, in part, to methodological issues such as the choice of test battery, the time of postoperative assessments, and the method of analysis of dysfunction.

Neuropsychological Testing in Surgical Patients

Neuropsychological assessments (NP tests) are used to objectively measure cognitive function. The tests used in the detection of POCD, unlike those usually employed in a clinical assessment, need to be sensitive to change. It is important that the assessment tools be sensitive to potentially diffuse brain injury; therefore, these measures should form a battery of tests that attempt to cover a range of cognitive domains, such as memory, attention, concentration, and perceptual-motor ability. Because of the time constraints imposed by the surgical environment the time set aside to conduct these tests is often limited; therefore, the battery of tests, by necessity, frequently represents a compromise. A recent review of POCD studies in noncardiac surgery[1] indicated that 70 different NP tests had been used in this area in conjunction with 9 composite batteries, with between 1 and 13 tests used per study. The domain most often assessed was memory and learning. However, the number of tests used can be problematic; when more tests are used, dysfunction is more likely to be detected (although this also relates to the definition used to determine whether POCD is present). There is also a problem of fatigue in patients caused by their condition or surgery. Therefore, it is important not to make the assessments too long, and an attempt should be made to reduce test fatigue by alternating paper and pencil, computerized, manual, and verbal tasks.

Early studies investigating POCD often used traditional intelligence tests such as the Wechsler Adult Intelligence Scale (WAIS) or screening tests such as the MMSE. Although these batteries tend to be highly reliable they have been shown to be insensitive to the more subtle changes that may occur after surgery.[2,3] More recently, these have been replaced by a wide variety of NP tests designed for repeated assessments, many of which have been computerized to ease administration and improve standardization.

It is common to find studies in which the assessments have been performed by a range of health care and non–health care professionals. The assessment of brain function does require expertise particularly in how to present the tests and how to respond to the responses the patient makes, with an attempt at having the patient present his or her best performance. Ideally, the tests should be administered by the same trained neuropsychologist in the same quiet environment at each testing session.

Timing of Assessments

A very important issue regarding the measurement of POCD is the timing of the assessments. The timings of preoperative assessments have varied widely in studies, with some conducted within weeks of surgery, but many have been conducted at the time of admission into hospital for surgery; this may be 1 day before surgery or even on the day of their operation. Patients are frequently anxious about the surgery they are about to undergo. Although there is little evidence of the impact of preoperative anxiety on the NP tests that have been employed in most POCD studies it remains important to examine whether levels of both anxiety and depression have an impact on the cognitive tests employed. As a result, on each occasion neuropsychological performance is assessed both anxiety and depression should be assessed.

Cognitive problems are frequently observed in patients in the days immediately after surgery and are often transitory. These early assessments may well be detecting a transient disturbance of cognition, and the assessments conducted within days of surgery are likely to be influenced by general postoperative readjustment as well as analgesics, pain, and fatigue. Assessments conducted later in the recovery period (approximately 4 weeks after surgery) are more likely to detect a persistent or permanent change.

An important question is whether the early indications of cognitive disturbance are in any way predictive of longer-term difficulties in cognition. There is an indication that the early predischarge assessments may predict longer-term decline,[4-6] but the exact relationship remains to be clarified.

Analysis

In the POCD literature a number of different methods have been employed to measure and define dysfunction. Some studies have used a significant difference between postoperative and normative scores[7] and others a cut-off on a screening measure.[8-11] In a third approach, researchers have made a comparison between two different surgical/anesthetic groups,[2,13] and in a fourth approach between a surgical and control group.[14,15] In other studies a fifth approach has been to analyze NP test data as multiple comparisons of variables in the test battery. This approach provides the sensitivity to detect even small differences, but the risk of type 1 error is high. In addition, this analysis is not well suited to address whether deterioration has occurred because the analysis is based on group means rather than individual change and no incidence of cognitive decline can be calculated.[11,16]

Many researchers have selected to adopt a sixth method that uses an "individual change" approach in which each participant acts as his or her own control. Here the participant's score postoperatively is compared with the preoperative score. Then a statistically defined criterion is used to rate the participant as having or not having POCD. However, this statistically defined criterion is not uniform over studies; for example, Shaw and associates[17] have defined POCD as a decline in performance equal to or greater than 1 standard deviation (SD) from the preoperative score in 1 or more NP tests, whereas this same decline needed to be present in two or more tests before Treasure and coworkers[18]

rated the participant as having POCD. Other investigators have used the same decline of 1 SD but in 1 of 21 tests or 4 of 21,[19] and yet others have defined POCD as being a 20% decline in 20% of tests.[20] The advantage of this binary approach is that it defines and categorizes individual performance into an entity that appears meaningful in a clinical environment and is easily understood. However, these definitions are statistically derived and have no intrinsic meaning or relationship to brain injury. Another disadvantage is that these methods only take into account deterioration without considering improvement.

Because the NP tests used in studies of the detection of POCD should be sensitive to change, they are amenable to repeated administration. However, as patients undergo at least two assessments with often only a short time separation it is common for some learning to be found. This may be due to an increased familiarity with the tests or differing strategies employed when completing the assessments. Although many attempts are made to reduce these learning effects, such as use of parallel equivalent forms, these effects are almost impossible to remove from repeat testing. It could be argued that one measure of cerebral damage is the inability to learn a task or strategy that is the underlying basis of practice effects. This learning has been apparent in many POCD studies.[9,21] Therefore, it is important that the form of analysis used should take into account any learning, or failure to learn, occurring postoperatively. One such study that took learning into account was that of Williams-Russo and associates,[22] who examined individual change after establishing a clinically important difference (CID) score for each test. Here, the participants' raw change score was converted to a score of −1 (worse than the CID), 0 (within one CID), or +1 (better than the CID). A summed score of −3 or less was defined as a deficit. However, the improvement score was not used in the analysis.

When studies have employed a control group the effect of learning can be assessed. The multicenter International Study of Post-Operative Cognitive Dysfunction (ISPOCD) group[23] compared the mean of the NP test score change obtained from a healthy control group over three assessment intervals to that of a surgical group. The mean of the control group changes were used as an estimation of learning. The mean was subtracted from the surgical participants' change score and the result divided by the SD of the corresponding change in the control group to obtain a Z score for each test. Using a Z score allows for the scores for each individual test to be combined to obtain a composite NP score. The authors also applied a cutoff score to identify POCD, which they defined as when the Z scores on two individual tests or the combined Z score reached 1.96 or more (the higher the score, the more deterioration).

Using a control group strengthens a study considerably and allows for the influence of variables such as learning to be accounted for, but it is important to consider what constitutes an *appropriate* control group. POCD studies have utilized various types of control groups such as healthy volunteers, friends, and relatives of the participants under study, patients with other conditions, and patients with the same condition but not undergoing surgery. However, in POCD there is no "ideal" control. For example, using healthy volunteers fails to take account of any nonspecific effects of having the condition on cognition. Using patients with different conditions as controls assumes equivalence in cognition and learning between the conditions of the control and that of the groups of interest. When considering participants with the same condition who do not undergo surgery because of either a surgical decision or patient choice, then the groups could differ on important clinical factors because the allocation to groups is not random.

Limitations of Neuropsychological Studies

Patients need to be cognitively able to complete NP tests at baseline; therefore, only patients without preoperative brain disease have been included in these studies. Also, patients undergoing emergency procedures have not been studied owing to difficulties with obtaining a reliable evaluation preoperatively.

In all these studies, especially the long-term follow-up studies, some patients die or are too ill to return to be assessed and, in addition, some choose not to be followed up. In some cases those who are particularly well and back working may see no purpose in returning and be lost to follow-up. The attrition is unlikely to be random but may be more influenced by distance to be traveled and inconvenience. Not unexpectedly, attrition rates are lower for shorter follow-ups.[1] Some reports on attrition in the cardiac POCD literature have indicated that sicker patients are more likely to be unavailable for follow-up[24] and that attrition is higher among those with lower IQ[5] and lower education.[25] It is possible that the incidence of POCD may be higher/different if all patients could have been assessed.

Typically, patients with a known large intake of alcohol have been excluded from POCD studies; however, alcohol intake is rarely noted after surgery. Patients' cognitive performance at the follow-up assessment may be affected if their alcohol intake had increased substantially after surgery. It must, however, be considered rather unlikely that alcohol abuse would develop during the first postoperative weeks. In a large Danish sample of the normal population with no or moderate intake of alcohol, Jensen and colleagues[26] found that approximately 7% reported being heavy drinkers (>21 drinks per week for men and >14 drinks per week for women) at follow-up after at least 5 years after the first interview. Thus, although it is unlikely that many patients will have changed their drinking habits it may be interesting to obtain this information at follow-up.

Subjective Cognition and Proxy Ratings of Cognitive Change

Although NP tests are the most frequently used approach to detect POCD, another method sometimes employed is to ask the patients about self-perceived cognitive changes.[27-30] These studies have used measures such as the Cognitive Failures Questionnaire, the Cognitive Behavior Rating Scale, the Cognitive Difficulties Scale, or interviews and have reported subjective cognitive dysfunction after surgery. For example, Khatri and coworkers,[28] using the Cognitive Difficulties Scale, found that 16% of patients rated themselves as having cognitive difficulties 6 weeks after coronary artery bypass graft (CABG) surgery. Also, comparing local anesthesia with general anesthesia, Ward and associates[30] found that a statistically significant impairment of perceived cognitive function using the Cognitive Failures Questionnaire was reported by those patients who had undergone general anesthesia but not those who had undergone local anesthesia 3 days previously.

Although studies have been conducted to ascertain the reliability of proxy respondents in relation to quality of life of patients in a range of clinical cohorts,[31] very little research has been conducted regarding cognition. Thornton and associates[32] examined proxy ratings of cognitive change and found that cognitive changes were likely to be noticed by the patient's spouse or a close relative. Another study by Bergh and associates[33] found that a spouse's ratings of the patient's concentration and memory were in agreement with that of the patient.

However, the relationship between patients' subjective reports and formally assessed cognition is unclear. Many studies have found a stronger correlation between mood and patients' perception of cognitive difficulties than between NP test scores and subjective reports,[28,34-37] with those patients who are more anxious and depressed reporting more cognitive problems. It has been argued that this is due to patients who are emotionally distressed forming a negative information processing bias, which, in turn, leads to distorted perceptions of cognitive performance.[28,34,36]

Incidence and Risk Factors for Postoperative Cognitive Dysfunction after Cardiac Surgery

The incidence of POCD after cardiac surgery (coronary artery bypass and/or valve replacement or repair) has been reported as 50% to 70% in the first postoperative week, 30% to 50% after 6 weeks, and 20% to 40% at months and 1 year (see Chapter 60).[38] This variability is, as discussed previously, due in part to the problems of methodology, such as differing NP tests used, timings of assessments, and definitions of decline. In an attempt to reduce this variability a consensus meeting was held and guidelines were drawn up regarding NP tests conducted to assess cardiac POCD.[39]

Despite variability in incidence, timing, types of tests, and analysis there appears to be a general consensus that POCD after cardiac surgery does appear to exist in a proportion of patients. Several factors have been cited as accounting for this decline, which is often presented as competing hypotheses; however, it is likely that the cause is multifactorial, although the use of cardiopulmonary bypass (CPB) is often implicated.

Interventions to Reduce the Incidence of Cognitive Decline in Connection with Cardiac Surgery

Strategies to reduce the incidence of cerebral complications after cardiac surgery have been based on what was thought to cause these problems. Early research has suggested significant risk factors, including advanced age, poor left ventricular function, and duration of CPB. Of these only the last is modifiable either by changing the management of CPB and the related techniques or by avoiding CPB.

CPB involves numerous violations of normal physiology. The length of time on bypass has tended to be related to POCD, which suggests that there is something in the CPB procedure that is deleterious to the brain.[40,41] Important intraoperative causative agents are cerebral microemboli, which can be either particulate (e.g., atheroma, fat, platelet aggregates) or air. Microemboli occurring in the cerebral circulation can be detected noninvasively using continuous transcranial Doppler (TCD) of the middle cerebral artery (MCA). By using this technique, the numbers of microemboli have been found to be associated with length of time on bypass. A positive relationship has also been reported between microemboli found in the brains of patients who have died soon after cardiac surgery and the length of time on CPB.[42] However, the relationship between POCD in cardiac surgery and microemboli is not always clear cut, with some studies finding an association[43-45] and others not.[46,47] This relationship is complicated by a range of factors, including the size and final distribution in the brain of the microemboli. This final location of the microemboli is an important factor because they may be lodged in an area not covered by the NP tests used or be in an area less important for cognition. The composition of the microemboli has been an ongoing puzzle because it has been presumed that solid microemboli are more likely to cause damage than gaseous microemboli. Currently, techniques have become available that can distinguish between gaseous and particulate microemboli, and the relative importance of air emboli in POCD may soon be established.

Management of Cardiopulmonary Bypass

pH Management

Management of pH during hypothermia can be carried out as pH-stat or α-stat management (see Chapter 60).[48] There is evidence that α-stat management leads to better neurologic and cognitive outcome. Stephan and coworkers[49] found marked cerebral hyperemia and an increase in neurologic events at 7 days after surgery when using pH-stat management. Although Bashein and colleagues[50] found no difference in NP test outcome between these two techniques, both Murkin and associates[51] and Patel and coworkers[48] have shown that α-stat is associated with less NP test result deterioration than that with pH-stat management.

Temperature

Since the early days of cardiac surgery when it was shown that hypothermia could prolong the safe period of circulatory arrest, hypothermic perfusion has been used routinely by the majority of surgeons for both valve and coronary artery bypass graft (CABG) surgery (see Chapter 48). Recently, normothermia and normothermic cardioplegia have been considered as a means of myocardial protection, but this has led to concerns that neuroprotection may be compromised. Studies conducted to investigate this issue have produced conflicting results, some showing that normothermic perfusion may be potentially harmful,[52-54] with others finding no difference.[55-57] Because a small reduction in temperature is known to be neuroprotective, the failure to find an advantage for hypothermia in clinical trials may be surprising. However, brain hypothermia may not be guaranteed in all patients and the process of rewarming to normothermia may be harmful. Neurons may be injured by rewarming to 38°C, and it has been suggested that rapid rewarming may force anesthetic and other gases out of solution and thereby produce microemboli. However,

Buss and associates[58] found no effect on NP test outcome on rewarming to 38°C as compared with lower temperatures. Nathan and colleagues[59] maintained patient temperatures between 34°C and 36°C for 12 hours after surgery and found that avoiding hyperthermia during rewarming may be cognitively beneficial. At a 5-year follow-up study, Nathan and colleagues[60] reported that while fewer participants in the hypothermia groups had deficits at 5 years the difference did not reach significance.

Very little work has been conducted into temperature in the postoperative period. Grocott and coworkers[61] examined POCD in relation to temperature in the first 24 hours after surgery. Although they found no association between the area under the curve above 37°C during this period they did find a direct relationship between POCD at 6 weeks after surgery and maximum temperature achieved.

Arterial Line Filtration

Arterial line filters, which are an optional addition to the CPB circuit, are designed to prevent extraneous matter in the circuit from entering the patient. Two studies[62,63] found that the number of microemboli detected in the middle cerebral artery was significantly reduced when an arterial line filter was used. Although, two earlier studies[64,65] had reported that arterial line filters made no difference to cognitive outcome, a further study by Pugsley and coworkers[63] found less POCD in the filter group (46% filter versus 71% nonfilter; $P = .05$) 8 days after surgery and (8% filter versus 27% nonfilter, $P = .03$) at 8 weeks. The two earlier studies conducted their assessments only during the acute in-hospital phase, which may have confounded the results, whereas Pugsley and coworkers[63] were able to demonstrate an even more pronounced effect at 8 weeks.

Pulsatile Versus Nonpulsatile

Although nonpulsatile CPB is the most commonly practiced form of perfusion, pulsatile flow has been recommended for being more physiologic. A study by Murkin and colleagues[51] examined the neuropsychological benefits of pulsatile over nonpulsatile flow and found no significant differences in outcome.

Hematocrit

Recently, studies have examined the relationship between hematocrit and outcome after CABG. Habib and associates[66] found that the lowest quintile of hematocrit was related to vital organ dysfunction, morbidity, and 6-year survival in a survey of 5,000 consecutive operations. Also, Karkouti and coworkers[67] found a positive association between the risk of perioperative stroke and the lowest operative hematocrit. However, in a study examining cognitive dysfunction Harrison and associates[68] found no correlation between cognitive outcome and level of hematocrit.

Blood Glucose Management

Little research has been conducted into hyperglycemia during CPB. Most of the studies that have been conducted have been small and not of sufficient power to demonstrate any meaningful relationship between POCD and hyperglycemia after cardiac surgery.[69] However, a study conducted by Puskas and associates[70] of 525 patients undergoing CABG found that hyperglycemia was associated with a decrease in cognitive performance at 6 weeks after surgery in nondiabetic patients whereas hyperglycemia had no effect on cognition in the diabetic patients.

Type of Oxygenator

Oxygenators have undergone considerable development over the years. Early studies compared the two types of oxygenators (bubble versus membrane). Padayachee and colleagues[71] demonstrated that membrane oxygenators produced fewer cerebral microemboli on transcranial Doppler when compared with bubble oxygenators. Also, two studies have suggested that POCD is reduced when membrane oxygenators are used compared with bubble oxygenators.[72,73] The almost universal use of membrane oxygenators these days is likely to have a beneficial effect on NP test outcome.

Avoiding Cardiopulmonary Bypass

The resurgence of off-pump coronary artery bypass (OPCAB) surgery as a common technique for multivessel revascularization has paved the way for research into isolating the role that CPB plays in neurologic and neuropsychological decline after CABG surgery. Although many of the early studies conducted were retrospective in design and therefore potentially biased in that the patients were specially selected to undergo OPCAB surgery, they provided some evidence that OPCAB surgery may lead to a reduction in microemboli and strokes. Three recent meta-analysis studies,[74-76] while showing a trend toward an advantage for OPCAB over conventional CABG for incidence of stroke, failed to find a significant difference.

Studies reporting neuropsychological outcome are equally inconsistent. Poorer cognitive outcome at both 1 and 10 weeks was reported in patients undergoing on-pump surgery compared with OPCAB.[77] A large ($N = 281$) randomized study also found that neuropsychological performance at 3 months after surgery was better in patients undergoing OPCAB; however, these differences had disappeared by the 12-month[78] and 5-year[79] follow-up assessments. Subjective accounts of cognitive outcome have also been found to be similar at 1 year after surgery.[80] A further study by van Dijk and colleagues in 2004[6] found that early cognitive decline in patients undergoing first-time CABG predicted cognitive outcome after 3 months but suggested that this early cognitive decline was not significantly influenced by the use of CPB.

Management of Atherosclerosis of the Ascending Aorta

Embolization may result from dislodgment of atheromatous material during handling of the aorta, for instance when cannulation is conducted. Identification of plaques may therefore be advantageous to change the site of cannulation or carry out a coronary artery bypass as an off-pump procedure. That identification is often based on palpation, but ultrasound is clearly more sensitive, and the use of epiaortic ultrasound to detect atheroma has been found to be associated with a reduction in the incidence of POCD.[81]

Pharmacologic Techniques to Protect the Brain in Cardiac Surgery

A number of studies have been performed to attempt to protect the brain from any possible damage by using putative neuroprotective agents. These studies have had variable results (Table 89-1), and it is important to note that many have been underpowered, making the findings of a number of the studies unreliable.

Table 89-1 Randomized Trials of Pharmacologic Intervention to Reduce Cognitive Dysfunction after Cardiac Surgery

Authors	Year	Drug	No.	Result
Nussmeier et al.[136]	1986	Thiopental	182 complete	Neuropsychological test results showed no difference at 5 days
Roach et al.[137]	1999	Propofol	99 complete	No significant difference at days 5-7 or days 50-70
Legault et al.[138]	1996	Nimodipine	149 recruited, complete in 65-69%	No significant difference, at 1 week, 1 month, or 6 months (study terminated early)
Fish et al.[139]	1987	Prostacyclin	74 complete	No significant difference at 1 week or 2 months
Grieco et al.[140]	1996	GM_1 ganglioside	25 complete	No significant difference at 1 week or at 6 months
Arrowsmith et al.[46]	1998	Remacemide	159 complete	Using incidence, no significant difference; but using Z-change score, significantly less POCD with remacemide
Butterworth et al.[141]	1999	Pegorgotein	58 complete	No significant difference at days 5-7 or weeks 4-6
Mitchell et al.[142]	1999	Lidocaine	42 complete	Significantly less POCD with lidocaine at 10 days (40% vs. 75%) and at 10 weeks (46% vs. 75%)
Wang et al.[143]	2002	Lidocaine	88 complete	Significantly less POCD with lidocaine (19% vs. 40%) at 9 days
Kong et al.[144]	2002	Clomethiazole	219 complete	No significant difference at 4-7 weeks
Taggart et al.[145]	2003	Lexipafant	135 complete	No significant difference at discharge or 3 months
Mathew et al.[146]	2004	Pexelizumab	800 recruited	No significant difference at day 4 or at day 30
Harmon et al.[147]	2004	Aprotinin	35 complete	Significantly less POCD in the aprotinin group: 94% vs. 58% at day 4 and at 6 weeks 23% vs. 55%

Incidence and Risk Factors for Postoperative Cognitive Dysfunction after Noncardiac Surgery

For more than 50 years numerous research groups have tried to assess if cognitive function deteriorates postoperatively in noncardiac surgery. The earliest study is that of Bedford performed in 1955. It is a remarkable study that began work in the field, but it is important that his findings were based on subjective observation and questioning of relatives or caretakers. Using these techniques he reported that 7% (18/251) of elderly patients older than age 65 years became "demented" (not in the way it is used earlier) after undergoing general anesthesia. Clearly, there was a lack of objective verification, which, for this purpose, means testing of cognitive function by neuropsychological testing. Subsequently, Simpson and associates[82] reported no significant connection between anesthesia and decreased mental performance in 620 elderly patients, whereas Blundell and colleagues[83] found a significant deterioration in 50% of tests after surgery in 51 patients aged 70 and older.

Many of the early investigations into POCD tended to recruit a small number of participants. Therefore, many of these early studies did not have the statistical power to detect POCD. In addition, a number examined participants on a limited number of NP tests and the analysis was often unclear and different between the studies. Nonetheless, the evidence for POCD after noncardiac surgery began to grow. For example, Grinchnik and coworkers[20] found POCD in 45% of a sample of 29 patients with a mean age of 60 years at 6 to 12 weeks after thoracic or vascular surgery. The definition of POCD was similar to earlier studies in cardiac surgery, using a 20% deterioration in 20% of the tests (11 test variables considered). In a larger study of 98 patients with a mean age of 73 years, Ancelin and associates[19] found deterioration in at least 1 test of 28 in 71% of patients 9 days after surgery and in 56% of patients at 3 months. After knee replacement, POCD was seen in 41% of patients at 1 week and in 18% at 3 months.[84] In a much larger study (228 patients) that examined very early assessment in patients older than the age of 64 years, POCD was found in 16.8% 1 to 2 days after noncardiac surgery. The definition of POCD was based on deterioration in 2 of 3 test variables.[85] Further evidence that POCD does exist after noncardiac surgery was provided by Williams-Russo and colleagues,[22] who reported POCD in 5% of 231 patients older than age 65 at 6 months after knee replacement. In this study POCD was defined by a panel agreeing on what constituted a "clinically important deterioration" in each of the applied tests; however, there was no control group to allow a comparison. One of the important criticisms of these studies is that they investigated a simple incidence using a conventional definition but failed to include any control group.

In contrast, the ISPOCD study[23] recruited 1218 elderly patients and 176 healthy volunteers. The patients underwent major noncardiac surgery with general anesthesia. POCD was found in 25.8% after 1 week and 9.9% after 3 months. This was significantly higher than in the control group in whom the diagnostic criteria were fulfilled in only 3.4% and 2.8%, respectively. These findings were further supported in a single-center study using the same methodology where POCD was found in 41.4% of those older than 60 years of age at discharge and in 12.7% after 3 months.[88] Also, Iohom and colleagues[15] detected POCD more

commonly in patients than in controls, with 53% of patients exhibiting POCD at 6 weeks after laparoscopic surgery compared with 23% of controls.

Risk Factors for POCD after Noncardiac Surgery

In most studies investigating POCD the mean age of the participants assessed has been 60,[1] with many studies specifically selecting participants of an "older" age group. This is in part due to early reports of cognitive dysfunction being associated with "older people." However, age has been shown to be a significant and independent risk factor for POCD; for example, after 3 months, POCD in the ISPOCD study[23] was seen in 7% of those aged 60 to 69 compared with 14% in those older than 69. Also, Ancelin and colleagues[19] found a relationship between increasing age and POCD. However, few studies of POCD have included younger patients. The largest study was conducted by the ISPOCD2 group and included 508 middle-aged patients (40-59 years) and 185 control subjects of similar age.[35] POCD was found in 89/463 (19.2%) of the patients at 7 days and in 26/422 (6.2%) at 3 months; this is compared with 7/176 (4.0%) in the controls at 1 week and in 7/169 (4.1%) at 3 months. The difference in incidence of cognitive dysfunction between patients and controls was statistically significant ($P = .001$) at 1 week but not at 3 months ($P = .33$). Interestingly, when the surgical participants were compared with a previous group older than 60 years they found the younger group showed significantly less POCD at both 7 days ($P = .0064$) and 3 months ($P = .026$) after surgery.[35] These findings are similar to those in a recent study by Monk and coworkers[86] that examined 1064 participants undergoing major noncardiac surgery. A comparison was made between 331 patients aged 18 to 39, 378 patients aged 40 to 59, and 355 patients aged 60 and older. At discharge, POCD was found in 36.6% of the youngest, 30.4% of the middle aged, and 41.4% of those older than 60, with a significant difference between all groups. By 3 months, POCD incidence was similar in the young and middle-aged groups (5.7% and 5.6%, respectively) but a significantly higher rate was detected in the older age group (12.7%).

Risk factors for POCD other than age have been identified. Duration of anesthesia, respiratory complications, infectious complications, second operation, and level of education were all important factors in the ISPOCD1 study.[23] Although episodes of hypoxemia or hypotension have often been presumed to be important, no statistically significant correlation with POCD was found in this study. The most important results from the risk factor analyses of this study are shown in Table 89-2. Other investigators have also examined potential risk factors for POCD. Previous cerebrovascular accident has been identified as a significant risk factor for POCD at 3 months.[86] Ancelin and associates[19] found a relationship between postoperative cognitive deterioration and increasing age, low level of education, poor preoperative test performance, depression, and type of anesthesia (general versus epidural). However, in another study by Leung and coworkers,[85] no significant differences were found between types of general anesthesia used or use of nitrous oxide.

Table 89-2 Proportion of Elderly Patients with Cognitive Dysfunction after Major Surgery with General Anesthesia at 1 Week and 3 Months Postoperatively by Selected Patient, Surgical, and Anesthetic Factors

	1 Week		3 Months	
	No. of Patients	Patients with POCD	No. of Patients	Patients with POCD
Age (yr)				
60-69	586	135 (23%)	532	39 (7%)
≥70	425	125 (29%)	378	52 (14%)
Education				
< High school	576	153 (27%)	518	49 (9%)
High school	290	76 (26%)	260	26 (10%)
> High school	145	31 (21%)	132	16 (12%)
Benzodiazepines before surgery	116	32 (28%)	105	5 (5%)
Duration of anesthesia (min)				
≤120	196	37 (19%)	179	20 (11%)
121-240	503	121 (24%)	448	40 (9%)
≥241	312	102 (33%)	283	31 (11%)
Complication				
Hypoxemia*	115	30 (26%)	98	11 (11%)
Hypotension†	229	59 (26%	214	20 (9%)
Respiratory complication	99	40 (40%)	88	12 (14%)
Infectious complication	91	30 (33%)	138	13 (9%)
Second operation	24	13 (54%)	50	7 (14%)

*One or more episodes of oxygen saturation ≤ 80% for >2 min.
†One or more episodes of mean arterial pressure ≤ 60% for ≥30 min.
Data from ISPOCD1 study.[23]

Type of Surgery

Minor Surgery

Studies of POCD after minor surgery have focused primarily on early outcomes after outpatient surgery. Heath and associates[87] randomized 60 patients aged 18 to 60 years to receive thiopentone or propofol anesthesia. In addition, 30 age-matched control subjects were included. Although significant differences in neuropsychological performance between patients and controls were found at 1 and 2 hours after surgery, this difference had disappeared by 24 hours. In another smaller study of outpatient surgery patients no significant differences in NP tests results were found between 20 patients (aged 21-45 years) and 10 control subjects from the waiting list. Both groups underwent testing on two occasions with an interval of approximately 4 hours.[88] The ISPOCD group recruited 372 patients undergoing minor surgery either as an inpatient or outpatient procedure.[89] At 7 days, POCD was found in 22/323 (6.8%); in 164 inpatients, 16 (9.8%) had POCD and 5 of 141 (3.5%) outpatients had POCD ($P = .033$) but the group allocation was not randomized. At 3 months no significant difference was found in the incidence of POCD between the two groups (8.8% for inpatients and 4.5% for outpatients).

In a smaller more recent study 30 patients aged 65 to 86 years were assessed at 24 hours after surgery and POCD was found in 47% of participants with no difference found between propofol and sevoflurane.[90]

To summarize, POCD after 1 week seems to be much less common after minor surgery than after major surgery. Several factors may be important in explaining this difference in incidence of POCD, including the obvious difference in surgical trauma, postoperative stress response, postoperative pain, and need for analgesia. There is some evidence to suggest a relationship between the inflammatory response and the extent of recovery after surgery. Hall and colleagues[91] report a relationship between inflammatory response as measured by interleukin (IL)-6 and the extent of functional recovery after hip arthroplasty. The relationship between cognitive recovery and the inflammatory response is an area of current research activity.

Carotid Endarterectomy

Carotid endarterectomy has been considered a procedure that calls for special attention (see Chapter 62).

It is performed in patients with a tight (>70% or >90%) stenosis of the internal carotid artery. Postoperatively, neurologic complications may arise as a result of brain ischemia, embolism, or brain hyperperfusion. On the other hand, some authors have suggested that an improvement in brain function could be found if brain perfusion was corrected or perhaps because the carotid plaque is a source of brain emboli. However, neuropsychological studies conducted in this area have produced inconsistent findings that have been highlighted in two systematic reviews.[92,93] Improvement in cognitive performance after carotid endarterectomy was reported in over 50% of studies, with 43% showing no change or decline in one study.[93]

Regional Versus General Anesthesia

If general anesthesia is an important factor leading to the development of POCD, then it would be expected that regional anesthesia would reduce the incidence (see Chapter 51). One early study on 60 patients (mean age, 70 years) reported a significant difference between general and regional anesthesia undergoing hip replacement. They were randomized to receive general versus epidural anesthesia. Although no formal NP testing was performed, they reported "mental changes" (e.g., lack of orientation and amnesia for personal data) in 0/29 in the epidural group and in 7/31 in the general anesthesia group ($P = .01$).[94]

In the randomized studies that have been conducted using NP testing after surgery no clear picture emerges during the first postoperative week. Whereas significantly better NP test performance has been reported at examination from the first 6 hours to 4 days with regional anesthesia[12,95,96] after the first week after surgery, which is a more relevant time point to detect POCD (see earlier), no significant advantage of regional anesthesia has been detected (Table 89-3). Methodologic limitations could be an important confounding factor because in these types of studies blinding of patients and even blinding of examiners may be difficult.

The largest study conducted to date found no significant difference in POCD between general or regional anesthesia at either 1 week (general anesthesia = 37/188 (19.7%), regional anesthesia = 22/176 (12.5%), $P = .06$), or 3 months (general anesthesia = 25/175 (14.3%), regional anesthesia = 23/165 (13.9%), $P = .93$) after surgery.[97] Regional anesthesia was unsuccessful in 24 patients allocated to regional anesthesia for whom general anesthesia was therefore necessary. Also, 35 patients allocated to general anesthesia actually received spinal or epidural anesthesia. Not all of these 59 patients completed the study, but when excluded in a *per protocol analysis*, there was a significant difference in the incidence of POCD between general anesthesia in 33/156 (21.2%) versus regional anesthesia in 20/158 (12.7%) after 1 week ($P = .04$); however, there was no difference at 3 months.

Although there is no firm evidence that cognitive function is less affected after regional anesthesia as compared with general anesthesia, other complications have been shown to be less common after this regimen.[98-100]

Today, such randomized studies are difficult to conduct because many patients, surgeons, and anesthetists have firm opinions regarding which type of anesthesia should be used. The underlying reasons vary greatly but include reduced incidence of deep venous thrombosis or bleeding with regional anesthesia.

Etiologic Considerations

The etiology of POCD has not been elucidated, but perhaps POCD is the result of brain cell damage caused by toxic substances or hypoxia. Toxic substances could be drugs such as general anesthetics or analgesics, but also the surgery-induced release of hormones or inflammatory mediators could be important. Hypoxia may result from arterial hypoxemia or low perfusion either caused by low cardiac output, inappropriate blood flow distribution, thrombosis, or embolism.

Drugs

Anesthetic central nervous system toxicity has been discussed in recent years as a possible explanation for POCD. It is generally

Table 89-3 Randomized Studies Comparing General and Regional Anesthesia using Neuropsychological Testing

Authors	N = Completed	Age	Interval Post Surgery	Type of Surgery	Results
O'Dwyer et al.[148]	255	Mean 55 yr	6 hr, 24 hr, and 3 days	Hernia repair	No significant difference
Casati et al.[149]	30	Median 84 yr	1 and 7 days	Hip fracture repair	No significant difference
Rasmussen et al.[97]	340	Median 71 yr	3 mo	Mixed	No significant difference at 3 months using intention to treat but significant difference at 1 week 21% versus 13% in favor of regional when using per protocol
Somprakit et al.[150]	120	Group 1 = mean 37 yr Group 2 = mean 67 yr	1 and 3 days	Mixed	No significant difference in whole group but the older group had significantly more POCD
Williams-Russo et al.[22]	231	Median 69 yr	1 wk and 6 mo	Knee replacement	No difference between groups
Campbell et al.[151]	157	Mean 77 yr	24 hr, 2 wk, 3 mo	Cataract	No differences between groups
Haan et al.[13]	37	Mean 72 yr	4 days and 3 mo	Urology	No significant difference
Nielson et al.[152]	64	Mean 69 yr	3 mo	Knee replacement	Improvement: no difference between groups
Jones et al.[153]	129 50 controls	>60 yr	3 mo	Knee or hip replacement	Significant improvement in 2/5 variables in general anesthesia group, no change in regional anesthesia group ($P = .03$ and .04 between groups)
Chung et al.[10]	44	Mean 72 yr	6 hr, 1, 3, and 5 days and 1 mo	Urology	No difference
Asbjørn et al.[96]	40	Mean 69 yr	4 days and 3 wk	Prostatectomy	No difference
Ghoneim et al.[154]	105	Mean 61 yr	1-7 days and 3 mo	Mixed	No difference
Hughes et al.[12]	30	Mean 68 yr	24 hr, 48 hr, and 1 wk	Hip arthroplasty	No difference after 1 week
Chung et al.[95]	44	Mean 72 yr	6 hr, 1, 3, and 5 days and 1 mo	Prostate resection	Significantly higher in regional at 6 hr
Bigler et al.[155]	38	79 yr	1 wk and 3 mo	Repair of hip fracture	Improvement in both, with no difference between the two regimens
Riis et al.[156]	30	>60 yr	1 wk and 3 mo	Hip replacement: general, epidural or combined	Initial decline from baseline at 4 days and then improved, with no group differences
Karhunen and Jöhn[157]	47	Mean 73 yr	1 wk	Cataract surgery	After 1 week significantly more deterioration in local anesthesia group in one of two combined scores

assumed that general anesthesia is a completely reversible condition, but this cannot be proved. Exposure of animals to anesthetics has resulted in the detection of several types of changes in the brain. Jevtovic-Todorovic and coworkers have shown histologic changes in the brain after exposure to isoflurane, nitrous oxide, ketamine, and midazolam. In developing rat brain, apoptosis was found in thalamic nuclei and the parietal cortex after exposure to isoflurane and this effect was more pronounced if midazolam or nitrous oxide was added.[101] Memory testing using a water maze revealed inferior performance in the anesthetized rats as compared with controls animals. Also, infant mice showed signs of apoptosis in brain cortex after subcutaneous administration of midazolam or ketamine[102] and after propofol or combinations of ketamine with propofol or thiopental.[103] In adult rat brain cortex, neuronal vacuolization and neuronal degeneration with necrosis have been found after nitrous oxide. The neuronal vacuolization, however, seemed to be reversible with no vacuolated neurons already after 3 hours of recovery and the addition of diazepam or isoflurane blocked the neurodegeneration.[104] These findings are interesting but do not provide convincing evidence for induction of persistent neuronal changes after general anesthesia in humans, where nitrous oxide is not used as the only anesthetic. Finally, neuronal changes could only be demonstrated in adult animals given anesthesia under hyperbaric condition with an inspiratory carbon dioxide concentration of 1% to 3%.

Apoptosis occurred in human neuroglioma cells that were exposed to isoflurane, and increased levels of amyloid precursor protein were also found.[105] Abnormal processing of amyloid precursor protein with accumulation of β-amyloid protein is a feature of Alzheimer's disease, and it is therefore interesting if general anesthetics influence the processing of this protein.

Another possible effect of anesthetics could be related to long-term changes in brain receptor function. A decrease in cholinergic function has been found in Alzheimer's disease, and cholinesterase inhibitors may be beneficial for patients with this condition. In one study, changes in cholinergic binding were found in rat brains after repeated pentobarbital anesthesia given by intraperitoneal injection.[106]

Anesthetics have also been shown to cause changes in gene expression in the brain and in the protein synthesis pattern, as detected by comparison of brain tissue protein contents in anesthetized and control animals.[107-109] These findings in animals or cell cultures are difficult to apply to the clinical situation with POCD in humans. One important limitation in animal studies of anesthetic drug toxicity is that it may be difficult to ensure proper oxygenation, ventilation, perfusion, and temperature regulation. In addition, hypoglycemia may occur in infant rodents exposed to general anesthesia. The brain cell damage of anesthesia in this situation may therefore be caused by mechanisms other than drug effects.

In humans, it is much more difficult to study central nervous system toxicity consequent on anesthetic exposure. Although, large epidemiologic studies have not resulted in the detection of a major long-term effect of anesthesia on cognitive function, such research is associated with important limitations. For example, in a study of 1257 healthy subjects, 946 participants had been previously exposed to at least one general anesthetic and they found no significant correlation between exposure to anesthesia and performance in cognitive tests.[110] However, as with the collection of any retrospective data, subjects may not recall reliably the type and number of anesthetics they have received or the exact date they received the anesthetic. It is therefore difficult to take age at time of exposure into consideration.

Apart from anesthetic drugs, many other drugs are given in connection with surgery. As an example, analgesics may have important effects on cognitive function, but a recent systematic review concluded that the type of postoperative analgesia was not significantly related to cognitive decline in elderly surgical patients.[111] This is in accordance with the findings of Johnson and associates[35] that opioid administration within the 24 hours before the test had no significant influence on the performance. Still, other psychoactive medication cannot be excluded as a potential influence on NP test data obtained in patients during the weeks to months after surgery.

Hormones

Major surgery causes an endocrine response with release of hypothalamic-pituitary-adrenal (HPA) and sympathetic nervous system hormones. Cognitive impairment has been associated with high levels of glucocorticoids, as documented in a variety of experimental and clinical settings.[112,113] Cortisol has been found to be toxic to cells in the hippocampus, and this structure plays a critical role in the consolidation of short-term into long-term explicit memory as well as descending control of the HPA axis. This gave rise to the hypothesis that repeated episodes of stress cause decreased hippocampal inhibition of the HPA axis and, thus, prolonged hyperactivation.[114] This aspect was studied in 187 patients older than 60 years of age undergoing major noncardiac surgery. Saliva cortisol levels were measured preoperatively and at 1 day, 7 days, and 3 months postoperatively in the morning (8 AM) and in the afternoon (4 PM) using Salivettes. After surgery, salivary cortisol concentrations increased significantly. The preoperative ratio between the AM and PM cortisol (AM/PM ratio) concentration was 2.8 and 2.7 in patients with POCD at 1 week versus those without POCD, respectively. The AM/PM ratio decreased significantly postoperatively to 1.9 and 1.6 at 1 week, respectively ($P = .02$ for both). In an analysis considering all AM/PM ratios, it was found that the persistent flattening in AM/PM ratio was significantly related to POCD at 1 week.[115]

In the clinical setting, it is difficult to assess the possible association between cognitive dysfunction and high levels of glucocorticoids, but it seems that cortisol secretion pattern is profoundly affected (i.e., flattened) by major surgery and this flattening is significantly related to the occurrence of early postoperative cognitive dysfunction.

Inflammatory Mediators

Surgery is associated with an important tissue reaction involving an activation of the immune system with release of inflammatory mediators from lymphocytes. Important mediators include cytokines that are able to initiate the activation of other inflammatory mediators and to affect brain function either directly or indirectly.[116,117] A very pronounced inflammatory response is seen in connection with cardiac surgery using CPB, and significantly higher levels of the cytokines IL-1 and IL-10 have been reported in patients with POCD after such procedures.[118]

Hypoxia

Brain hypoxia may lead to irreversible damage depending on the level, duration, and susceptibility. Oxygen delivery to the brain is dependent on blood flow and arterial oxygen concentration, which is primarily related to hemoglobin concentration and arterial oxygen saturation. Brain hypoxia may be caused by a decrease in blood flow or arterial hypoxemia. In connection with anesthesia, inability to ventilate the patient or unrecognized esophageal intubation may cause profound and long-lasting hypoxemia[119] and, subsequently, brain damage. Modest perioperative reductions in arterial oxygen saturation are common, but the importance has probably been overemphasized when compared with the wide fluctuations in cerebral blood flow and blood hemoglobin level.[120] One possible explanation for this is the ease of measuring arterial oxygen saturation continuously by pulse oximetry. It has not been possible to show any connection between modest arterial hypoxemia and postoperative complications, including POCD.[23,121]

Brain Hypoperfusion

A temporary reduction of cerebral blood flow can cause neurologic or cognitive dysfunction without occlusion of cerebral vessels (see Chapter 63). Cerebral blood flow is regulated according to brain metabolism and nearly unchanged within wide variations in blood pressure (autoregulation) mediated through changes in diameter of resistance vessels. This autoregulation has a lower limit at approximately a mean arterial blood pressure of 50 mm Hg in healthy adults but is higher in hypertensive subjects.[122] Below this limit, further dilatation of vessels cannot compensate and cerebral blood flow decreases. Measuring cerebral blood flow or brain oxygenation during surgery is complicated. The techniques used include xenon-133, near-infrared spectroscopy, transcranial Doppler (which really measures velocity), and jugular bulb oxygen saturation. All of these techniques are associated with important limitations. Brain perfusion pressure is therefore frequently used to evaluate brain perfusion in clinical practice. During anesthesia, brain metabolism is reduced and, therefore, a lower brain blood flow may be acceptable. In earlier studies of cardiac surgery prolonged episodes of low blood pressure were found to be a risk factor for brain dysfunction,[40,123] but subsequent studies have not been able to confirm this.

Thrombosis or Embolism

Cerebral infarction can be caused by an embolic or a thrombotic occlusion of a cerebral artery, and necrosis of brain tissue including neurons as well as glial cells may result. Thus, tissue architecture is lost and a well-defined infarct can be identified by autopsy or brain imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Cerebral infarcts may cause no symptoms at all, depending on the size and location, but the usual clinical presentation is a stroke. Several risk factors have been identified in studies of stroke in the general population as well as in relation to surgery. Age is an important factor and other important risk factors include type of surgery, cardiac disease, especially atrial fibrillation, peripheral vascular disease, former cerebrovascular attacks, and diabetes.[124,125] The incidence of major cerebral complications presenting as stroke after general surgery varies between 0.2% and 0.7%. Most cerebral infarcts in the perioperative period are caused by emboli. Macroemboli are more than 200 μm in diameter and typically consist of atheromatous material or thrombi. These may rise from the left atrium, left ventricle, or aorta.

Microemboli are less than 200 μm in diameter and, as stated earlier, are common in cardiac surgery. As opposed to macroemboli, they may often consist of air introduced into the venous circulation for instance through tubings used in the CPB circuit or through arterial lines. In addition, paradox embolization may occur through an open foramen ovale from the venous side because of subatmospheric pressure in veins or bone marrow if the surgical field is above heart level and venous structures are noncollapsible, as in procedures such as back surgery, craniotomy in the sitting position, and knee replacement.

Microemboli have been found to occur in joint replacement surgery. It was specifically assessed in 37 patients in whom cognitive function was studied with a battery of 13 tests at 1 week and at 3 months; POCD was found in 41% and 18%, respectively, but no significant association with microemboli was detected using transcranial Doppler imaging.[84]

Genetic Aspects

Recently, it has been realized that polymorphic genetic variation may explain individual differences in susceptibility to medication, inflammation, trauma, and other harmful factors. Such genetic factors are important for the development of dementia but do not uniquely determine the phenotype.

Apolipoprotein E (ApoE) is a protein that is important for recovery after central nervous system injuries.[126] There are important differences in the three different isoforms of ApoE—E2, E3, and E4, which are encoded by the alleles ε2, ε3, and ε4 of the ApoE gene, respectively. The ε3 allele is the wild-type and present in 75% of the native European population, whereas ε2 and ε4 are less frequent.[127] The ε4 allele seems to increase the risk of Alzheimer's disease, and it is also associated with a poor prognosis after head injury.[128-130] The possible association between the ε4 allele and POCD after cardiac surgery has been studied, but literature presents conflicting information.[131,132] The possible relationship between the ε4 allele and POCD after noncardiac surgery was studied in 976 patients aged 40 and older: the ε4 allele was not a risk factor at 1 week ($P = 0.49$) or 3 months after noncardiac surgery ($P = .28$).[133] It seems, however, that there is a significant relationship between POCD and the presence of the ε4 allele in carotid surgery patients.[134]

Other genetic factors could be important in the general surgical population; for instance, individual differences in inflammation and drug metabolism, with polymorphism of the drug metabolism systems cytochrome P-450, are well described. Very slow metabolism of certain drugs could be associated with prolonged recovery, and very fast metabolism could lead to high concentrations of intermediary degradation products.[135] Both situations could result in a disturbance of receptor function, but the relationship, if any, with POCD remains to be established.

Clinical Significance of POCD

We have discussed the detection of POCD and the likely causes, but what affect does this dysfunction have on the patient? An often-told story is about an elderly patient whose cognitive function has deteriorated profoundly after surgery, especially regarding memory. The relatives describe a loss of function and lack of initiative and interests in activities that previously meant a lot to this particular person. In a retired individual this could be playing cards or doing crossword puzzles. The deterioration may be most noticeable in patients returning to work, when usual tasks may be impossible to carry out in the same manner and at the same speed as before surgery. Such difficulty is also not uncommon in middle-aged or young patients, who also may experience some degree of dysfunction in cognition.

One relevant question is whether POCD in fact results in impairment of function as reflected in activities of daily living. In a study of elderly patients undergoing major noncardiac surgery with general anesthesia, a statistically significant correlation was found between POCD at 3 months and a decline in activities of daily living.[23] This is in contrast with studies of elderly patients after minor surgery in which POCD was not related to instrumental activities of daily living (IADL).[89,97] Another study of middle-aged patients by Johnson and associates[35] found a statistically significant correlation between POCD at 1 week and a decline in IADL at 1 week reported by relatives at 3 months. There was also a statistically significant correlation between POCD at 3 months and the Subjective Cognitive Functioning (SCF) questionnaire both assessed by patients and relatives at 3 months, but only 7% of those with increased SCF scores had POCD. No correlation was found between POCD and depression as assessed by the Geriatric Depression Scale (GDS). However, Moller and colleagues,[23] in common with other investigators in studies in cardiac surgery,[36] found no correlation between subjective reports of cognitive decline and POCD or POCD and depression as measured by the Zung depression rating scale.

90 Postoperative Visual Loss

Key Points

1. Visual loss after anesthesia is a rare but devastating injury that appears more frequently after cardiac, spine, and head and neck surgery.
2. The causes of perioperative visual loss include central or branch retinal artery occlusion, anterior and posterior ischemic optic neuropathy, cortical blindness, and acute glaucoma. Transient visual loss may be experienced after transurethral resection of the prostate. Retinal vascular occlusion in patients who receive nitrous oxide–containing gas mixtures after a vitrectomy procedure with vitreal gas bubble tamponade is caused by acute expansion of the gas bubble and increased intraocular pressure.
3. Signs and symptoms of visual loss in the postoperative period may be subtle and can be incorrectly attributed to the residual effects of anesthetic agents. Any patient complaining of eye pain, an inability to perceive light or motion, complete or partial loss of visual fields, decreased visual acuity, or loss of pupil reactivity must be evaluated immediately by an ophthalmologist.
4. The most common causes of central and branch retinal artery occlusion are emboli from the operative site and compression of the eye. External pressure on the eyes must be scrupulously avoided.
5. The causes of ischemic optic neuropathy have not been clearly determined. This disease may be related to, among other factors, hypotension, blood loss, fluid replacement, patient positioning, emboli, the use of vasopressors, disturbed autoregulation in the optic nerve circulation, anatomic variation in the optic nerve, and systemic patient factors such as hypertension and atherosclerosis.
6. Patients who undergo prolonged operative procedures in the prone position with anticipated large blood loss are at higher risk for the development of ischemic optic neuropathy. There is controversy with respect to the appropriate level of blood pressure and hemoglobin, fluid replacement, and use of vasopressors in these patients. The anesthesiologist should consider the potential risk for ischemic optic neuropathy in the design of the anesthetic plan and weigh the risks versus benefits of interventions that decrease blood pressure and hemoglobin concentration perioperatively. Anesthesiologists should consider informing patients of the risk of visual loss accompanying lengthy surgical procedures with the patient positioned prone and with anticipated large blood loss. Because surgeons may be in a better position to discuss this complication with their patients, anesthesiologists should consider asking surgeons to mention the risk of visual loss at their preoperative visit with the patient.
7. Perioperative visual loss in the presence of focal neurologic signs or the loss of accommodation reflexes or abnormal eye movements suggests a diagnosis of cortical blindness. Neurologic consultation should be obtained.

Visual loss after anesthesia and surgery is a rare but unexpected and devastating complication. In recent years there has been an impression among clinicians, though yet unproven, that the incidence is on the rise, particularly in the setting of spinal fusion surgery. Hence, a major emphasis of this chapter is on perioperative visual loss associated with spine surgery. In this chapter the focus is on familiarizing anesthesiologists with the incidence, suspected risk factors, diagnosis, and treatment of eye injuries leading to visual loss in the perioperative period. The discussion is confined to visual loss that follows nonocular surgery because eye damage after ocular surgery is well described in the ophthalmology literature. Injuries to the retina and optic nerve and the visual connections to the brain are discussed.

Because of the infrequent occurrence of this complication, few clinical studies have been conducted and most incidents in the literature are contained within case reports and small case series. No prospective studies of perioperative visual loss have yet been performed. Case reports have the disadvantage of reporting bias. But case reports over a lengthy period and a few retrospective studies and published surveys largely provide much of the

current knowledge on postoperative visual loss. Two large retrospective studies showed that perioperative ischemic optic neuropathy (ION) is rare, occurring in approximately 1/60,000 to 1/125,000 anesthetic procedures in the overall surgical population.[1,2]

Spine and cardiac surgery appear to be associated with a higher incidence of perioperative visual loss than other operative procedures. The incidence after these procedures is difficult to define precisely, because the studies have far fewer patients than the larger studies of the overall surgical population, and because these studies have been derived from experiences at single institutions. Stevens and associates found 4 ION cases in 3,450 spine surgeries (0.1%),[3] and we reported 2 cases in 3,300 patients after spine surgery (0.06%).[4] Chang and Miller reviewed 14,102 cases of spine surgery over 20 years at Johns Hopkins Hospital, identifying 4 cases of ION, for an incidence of 0.028%.[5] After cardiac surgery, incidence was estimated as high as 1.3% in one study[6] but 0.06% and 0.113% in two more recent larger retrospective studies.[7,8]

Myers and associates[9] conducted a retrospective case-control study of 28 patients with visual loss after spine surgery. The ASA Postoperative Visual Loss Registry reported on 93 cases of visual loss after spine surgery submitted anonymously to the ASA Closed Claims Study (http://depts.washington.edu/asaccp/eye/index.shtml).[10] Nuttall and associates performed a retrospective case-control study of cardiac surgery patients at the Mayo Clinic.[7] Each of these studies is described in detail in subsequent sections of this chapter.

Retinal Ischemia: Branch and Central Retinal Artery Occlusion

Central retinal artery occlusion (CRAO) decreases the blood supply to the entire retina, while occlusion of a retinal arterial branch (BRAO) is a localized injury affecting only a portion of the retina. In most instances this injury is unilateral. Four causes can be distinguished: external compression of the eye; decreased arterial supply to the retina (embolism to the retinal arterial circulation or decreased blood flow from a systemic cause); impaired venous drainage of the retina; and arterial thrombosis from a coagulation disorder.

The most common cause of perioperative retinal arterial occlusion is improper patient positioning resulting in external compression of the eye that produces sufficient intraocular pressure (IOP) to stop flow in the central retinal artery. It is the typical cause of the injury during spine surgery performed with the patient in the prone position. Pressure within the orbit also can be increased internally after retrobulbar hemorrhage, which is associated with vascular injuries during sinus or nasal surgery.

Although rare in most surgical procedures, emboli can directly impair blood flow in the central retinal artery (CRA) itself or a branch of it. Paradoxical embolism originating from the operative site and reaching the arterial circulation through a patent foramen ovale has rarely been reported as a cause of perioperative retinal vascular occlusion.[11] Retinal microemboli, however, are common during open-heart surgery.[12,13] Hypotension itself seems to be a rare cause of retinal ischemia. In a multicenter questionnaire, the incidence of retinal ischemia after hypotensive anesthesia was only 3 cases in 27,930 hypotensive anesthetic procedures.[14]

Venous drainage can be impaired after radical neck surgery by jugular vein ligation.[15] Studies measuring IOP, either in normal volunteers or in those who had spine surgery while positioned prone, show increased IOP, greater increases with the head-down position, and attenuation of the increases by head-up positioning, although extent of the changes differs, and there are some important technical issues in these studies.[16,17] The clinical significance of the changes remains unknown.

Clinical Findings

Patients have painless visual loss and abnormal pupil reactivity. Funduscopic examination shows opacification or whitening of the ischemic retina, and narrowing of retinal arterioles may be visible.[18,19] BRAO is characterized by cholesterol emboli (bright yellowish, glistening), calcific emboli (white, nonglistening), or migrant pale emboli of platelet fibrin (dull, dirty white). A cherry-red macula with a white ground-glass appearance of the retina and attenuated arterioles is a "classic" diagnostic sign in CRAO (Fig. 90-1). The red appearance from pallor in the ischemic, overlying retina makes visible the color of the intact, underlying choroidal circulation. Differential diagnosis from other causes of visual loss appears in Table 90-1.

Mechanisms of Retinal Ischemia

Findings of increased extracellular glutamate concentrations during retinal ischemia[20] and attenuation of ischemic injury in vitro and in vivo by glutamate receptor antagonists[21] support a

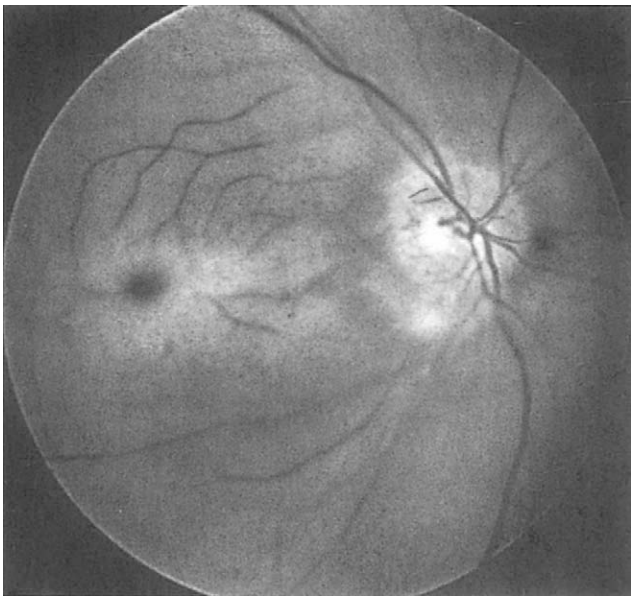

Figure 90-1 Funduscopic appearance of retinal vascular occlusion. Note the pallor of the retina and the cherry-red spot, the clinical hallmark of retinal arterial occlusion, visible in the fovea near the center of the photograph. The ischemic retina loses its normal transparency; and because the fovea is thinner than the surrounding retina, the underlying choroid is visible as a cherry-red spot. (*From Ryan SJ: Retina, 2nd ed. St Louis, CV Mosby, 1995.*)

Table 90-1 Differential Diagnosis: Eye Examination in Retinal, Optic Nerve, or Visual Cortex Injury*

	AION	PION	Cortical Blindness	CRAO	BRAO
Optic disc	Pale swelling, peripapillary flame-shaped hemorrhages, edema of optic nerve head. Late: optic atrophy	Initially normal Late: optic atrophy	Normal	Normal Late: optic atrophy	Normal Late: optic atrophy
Retina	Normal; may have attenuated arterioles	Normal; may have attenuated arterioles	Normal	Cherry-red macula†; pallor and edema, narrowed retinal arteries	Emboli may be present‡; partial retinal whitening and edema
Light reflex	Absent or RAPD	Absent or RAPD	Normal	Absent or RAPD	Normal or RAPD

role for excitotoxicity. It is believed that an increased intracellular Ca^{2+} concentration as a result of enhanced glutamate release ultimately initiates mechanisms that result in cellular destruction.

Two distinct blood flow patterns follow a period of ischemia. In cats, retinal and choroidal blood flow increase dramatically (hyperemia) immediately after the end of ischemia.[22] Hyperemia is of clinical relevance in reperfusion after a period of ischemia; increasing flow when vessels or the blood-retinal barrier is damaged might lead to macular edema.[23] Hypoperfusion is the other extreme in blood flow derangement. Delayed retinal hypoperfusion 1 to 4 hours after the end of a period of ischemia has been shown in adult rats,[24] and these results resemble the low-flow state found in other models after global cerebral ischemia.[25] The mechanism of these changes in blood flow has not been clearly established, although depletion of vasodilators such as adenosine or nitric oxide may be responsible.

The retinal blood supply is derived from the retinal and choroidal vessels.[26] Therefore, after retinal vascular occlusion, some oxygen may still be supplied by diffusion from the outer retinal layers by way of the choroid. In monkeys, eyes with CRAO showed little damage in the macular retina after 97 minutes of ischemia. After 240 minutes, damage was profound and irreversible.[27] These studies were conducted by clamping the central retinal artery (CRA).[28] Interestingly, the same investigators reported that atherosclerosis did not increase sensitivity to ischemia in monkeys and actually may have "preconditioned" the animals against ischemic insult.[27]

Increased IOP from external compression of the eye is a more severe insult than ligation of the CRA because of the profound simultaneous decreases in both retinal and choroidal blood flow[22] and the differential susceptibility of the inner retinal cells to damage from pressure.[29] Ischemic tolerance time is probably shorter with external compression as evident in studies of injury in animal models of retinal ischemia (Table 90-2).

Central Retinal Artery Occlusion

The cause of perioperative CRAO is usually external compression resulting in sufficient IOP to occlude the arterial circulation to the retina. Patient characteristics may increase the risk of CRAO. Those with altered facial anatomy may be predisposed to damage from the external pressure of anesthesia masks or headrests. In osteogenesis imperfecta, fibrous coats of the eye are thin and immature because of a deficiency of collagen fibers, persistent reticulin fibers, and increased mucopolysaccharide ground substance. Sclerae and corneas are unusually thin, and exophthalmos is common as a result of bony facial abnormalities, factors that may render the eye more vulnerable to damage from external

Table 90-2 Animal Studies of Retinal Ischemia and Time Required to Produce Injury

Author(s)	Animal	Ischemia Method	Ischemia Time
Hayreh et al. (1980, 2004)	Monkey	Central retinal artery ligation	>100-240 min
Ettaiche et al. (2001)	Rat (brown-Norway)	Increased intraocular pressure	20 and 40 min
Roth (1998, 2002)	Rat (S-D)	Central retinal artery ligation, increased intraocular pressure	45 and 60 min
Zhu et al. (2002)	Mouse (ND4)	Increased intraocular pressure	30, 45, 60 min

pressure. Those of Asian descent tend to have lower nasal bridges, which may increase the risk of external compression.[30]

Improper positioning of the head with external pressure on the eyes may compress ocular contents and, consequently, occlude retinal blood flow. Most reports of improper positioning involve patients positioned prone for surgery. Two reports described CRAO from improperly fitting face masks. CRAO was found after mask-administered inhalational anesthesia in combination with corneal abrasion, chemosis, and eyelid edema. Some of the patients had profound decreases in blood pressure or were described as being in a shock state.[31,32] These cases, from more than 50 years ago, have not been reported again, either because of changes in anesthetic practice or equipment.

The eye can be compressed directly when the patient is positioned prone for surgery. The horseshoe headrest is of particular concern because improper head position or unintended head movement may place the eye in contact with the headrest. In most of the reports of CRAO in patients positioned prone for surgery, the horseshoe headrest or a similar device (e.g., a rectangular headrest[33]) was used.[30,34,35] Kumar and colleagues[36] reviewed published case reports of CRAO after spine surgery. Signs and symptoms included unilateral loss of vision usually with loss of light perception, afferent pupil defect, periorbital and/or eyelid edema, chemosis, proptosis, ptosis, paresthesias of the supraorbital region, hazy/cloudy cornea, and corneal abrasion. Loss of eye movements, ecchymosis, or other trauma near the eye were also reported. On funduscopic examination, findings included macular/retinal edema, a cherry-red spot, or attenuated retinal vessels. Two reports describing 4 patients who sustained external compression documented the development of retinal pigmentary alterations, suggesting simultaneous choroidal circulatory ischemia.[37,38] Early orbital computed tomography (CT) or magnetic resonance imaging (MRI) showed proptosis and extraocular muscle swelling, although most cases did not have imaging studies to confirm the diagnosis.[36] Findings were similar to the syndrome of "Saturday night retinopathy" in intoxicated individuals who slept while their eyes were compressed.[39]

Hollenhorst and coworkers, who described unilateral blindness in patients positioned prone for neurosurgery, replicated the human findings in monkeys with 60 minutes of elevated IOP by exerting a pressure of 200 mm Hg on the eye together with hypotension. Hypotension was not a feature in 6 of the 8 human subjects in their report. In the monkey, histologic findings were edema of the retina and dilated vascular channels, followed by severe loss of retinal structure and axonal loss in the optic nerve 4 months later, owing to retrograde degeneration after death of retinal ganglion cells.[35]

More recent studies of the effects of increased IOP have been performed on rodents. Bui and colleagues documented that during acute increases in IOP in the rat, changes in visual function assessed by electroretinography progressed from the inner to the outer retina. In other words, retinal ganglion cells were the most sensitive to raised IOP, showing abnormalities on the electroretinogram (ERG) at IOPs of 30 to 50 mm Hg; the photoreceptor cells were not affected until IOP was higher.[40] The duration of increased IOP that injures the retina (see Table 90-2) appears to vary depending on rat or mouse strain, with studies reporting ischemic times between as short as 20 minutes or as long as 30 or 45 minutes.[41-43] The mechanisms of injury with increased IOP from external compression are summarized in Figure 90-2.

Proper use of modern head-positioning devices such as square or circular foam headrests with cutouts for the eyes as well as a mirror to view the eyes (i.e., Prone View, Dupaco, Inc.) should prevent compression of the eyes (see Chapter 36). However, we recently reported a case of unilateral retinal arterial occlusion in a prone-positioned patient whose head was placed in a square foam headrest with goggles to cover the eyes. This practice may be hazardous because of the limited amount of space between the headrest and the goggles and the risk of compression of the eye

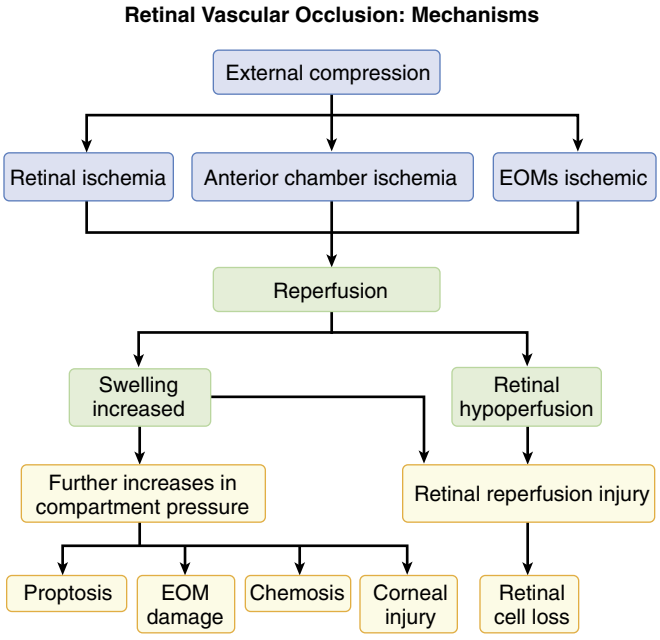

Figure 90-2 Mechanisms of retinal injury after external compression of the eye. EOM, extraocular muscle.

by the goggles. The patient exhibited signs of direct compression of the eye by the goggles, which ironically had been designed by the manufacturer (Dupaco, Inc., Oceanside, CA) to function as eye protectors.[44]

Ischemic ocular compartment syndrome, more typical in the setting of retrobulbar hemorrhage after nasal sinus surgery, was reported in a patient undergoing spine surgery in the prone position.[45] The patient's head had been positioned on a silicone head rest for surgery that lasted 8 hours during which the patient received only 1 L of crystalloids. Postoperatively, he had left ocular pain, no light perception from the eye, facial edema, 4 mm of left proptosis, and a tight orbit. There was corneal edema with a large abrasion, mid-dilated and fixed pupil, advanced cataract, pale optic nerve, retinal hemorrhages, and complete inability to move the eye. The IOP was 45 mm Hg. MRI showed proptosis, extraocular muscle enlargement, and severe globe tenting. Despite lateral canthotomy to relieve the pressure, vision did not improve. The cause in this patient was believed to be related to positioning with possible direct pressure on the eye.

Others have reported orbital compartment syndrome from perioperative intraorbital hemorrhage, orbital emphysema, or intraorbital bacitracin ointment in association with endoscopic sinus surgery.[46] This syndrome is different from cases of ION after spine surgery but may be similar to the early descriptions of ocular compression by Hollenhorst and coworkers.[35] Orbital compartment syndrome is an acute ophthalmologic injury, requiring prompt decompression to relieve the increased IOP.

Head and Neck Surgery

CRAO has occurred after neck and nasal/sinus surgery (see Chapter 75), although most reported cases of visual loss in neck dissection are from ION.[47] The incidence of orbital complications after endoscopic sinus surgery is 0.12%.[48] Orbital hemorrhage from blunt trauma during the procedure can result in orbital compartment syndrome with compression of the arterial and venous circulations and in CRAO and optic nerve injury.[49,50] Indirect damage to the CRA from intra-arterial injections of 1% lidocaine with epinephrine has also been described; the mechanism of action is speculated to be arterial spasm or embolism.[51]

Branch Retinal Artery Occlusion

BRAO usually leads to permanent ischemic retinal damage with partial visual field loss. Symptoms may not be noticed by the patient immediately if the visual field loss is peripheral or if a small scotoma is present. BRAO is primarily the result of emboli, but vasospasm has been reported in a few cases. Most case reports describe embolization of material from intravascular injections and circulating embolic material from the surgical field or cardiopulmonary bypass (CPB) equipment in cardiac surgery.

Microemboli to the retina during CPB have been shown by retinal fluorescein angiography (see Chapter 60). The occurrence and extent of perfusion defects were related to oxygenator type. When a bubble oxygenator was used, all patients had perfusion defects indicative of microemboli; when a membrane oxygenator was used, retinal perfusion defects were found in only half the patients. Neurologic outcome was not reported.[13] In patients who have coronary artery bypass graft (CABG) surgery, multiple calcific emboli in branches of the CRA are not unusual, and these emboli may produce visual field deficits of varying size and location. In pigs, mechanisms of air embolism during CPB included nonperfusion, vascular leakage and spasm, red blood cell sludging, and hemorrhage. Priming with perfluorocarbons blocked many of these mechanisms.[52]

Case reports have described sudden irreversible blindness with BRAO in patients after the injection of various drugs into the head and neck region. Loss of vision was nearly instantaneous when steroids were injected into the nasal mucosa.[53] In approximately half of cases, crystalline emboli could be seen at funduscopy, and one incident appeared to be complicated by vasospasm. Use of other agents, such as superselective injection of carmustine into the internal carotid artery to treat gliomas, or fat injected into the orbit for cosmetic surgery, has also been complicated by visual loss from retinal arterial occlusion.[54] Anesthesiologists providing care for neuroradiologic or angiographic/embolism procedures in the head and neck should be aware of the possibility of this complication.

Local infiltration anesthesia with lidocaine or bupivacaine in combination with epinephrine (1:100,000 or 1:200,000) for nasal septal surgery can cause partial or total visual field defects postoperatively attributable to BRAO (see Chapter 78).[51] No emboli were visible at funduscopy in these cases. It was speculated that the cause of BRAO was vasospasm induced by accidental intra-arterial retrograde injection of epinephrine or the combination of lidocaine and epinephrine into branches of the external carotid artery. Another possible contributing factor might have been epinephrine-induced platelet aggregation with retrograde embolization.[51]

BRAO was described in a patient in the prone position for spine surgery (see Chapters 63 and 70). After surgery a patent foramen ovale was discovered and it was believed that he had sustained a paradoxical air, fat, or bone marrow embolization from the operative site in the lumbar spine.[11]

Prognosis

Perioperative retinal artery occlusion results in permanent loss of vision in most cases. In monkeys, Hayreh and Weingeist[28] found that the critical time limit of irreversible retinal damage is approximately 100 minutes. CRAO lasting 105 minutes produced irreversible damage; recovery was possible if ischemic time was limited to 97 minutes. However, these studies involved surgical occlusion of the CRA. Retinal artery occlusion caused by external compression and increased IOP may produce a greater degree of ischemia and correspondingly shorter retinal survival times. In rodents, when the retinal artery was occluded by increasing IOP, periods of retinal ischemia as short as 20 minutes have produced damage.

Treatment

Currently available methods of treatment are not satisfactory. Treatment with ocular massage to lower IOP (contraindicated if glaucoma cannot be ruled out) and thereby dislodge an embolus, if present, to more peripheral arterial branches could be instituted by the anesthesiologist.[19] Intravenous acetazolamide can be administered to increase retinal blood flow, and the patient may inhale 5% CO_2 in oxygen to enhance dilation and increase oxygen delivery from retinal and choroidal vessels.[26] Further treatment

should be prescribed by the ophthalmologist and may include thrombolysis, although such treatment may be contraindicated after certain surgical procedures. A preliminary clinical study showed that fibrinolysis through a catheter in the ophthalmic artery within 6 to 8 hours after spontaneous CRAO was associated with improved visual outcome. An ongoing multicenter study is testing efficacy.[55] Localized application of hypothermia to the affected eye is a simple technique that has decreased injury in animal studies after ischemia,[56] and it is probably reasonable to institute in humans because of its minimal risk.

Prevention

Because retinal arterial occlusion in the perioperative period is most often caused by unintended application of external pressure to the eye, the anesthesiologist must take steps to avoid compression of the globe. Pressure on the eye from anesthetic masks is avoidable. If surgery is near the face, the surgeon's arm must not be allowed to rest on the patient's eye. In patients positioned prone for surgery, a foam headrest should be used with the eyes properly placed in the opening of the headrest; the position of the head and the eyes should be checked intermittently by palpation or visualization. The horseshoe headrest for the prone-positioned patient must be used with great caution, and there are safer choices available today. For the patient positioned prone for cervical spine surgery, this headrest should not be used because of the greater chance of head movement by the surgeon, leading to compression of the eye.

Intermittent examination of the eyes is advisable while the patient is prone. There are no data from human studies to establish the exact frequency of these checks. Considering results in rodent models of elevated IOP, it is advisable to examine eyes for change in position and the absence of external compression at least every 20 minutes. If the patient's head does not fit the headrest adequately (e.g., it is too large) or for surgery on the cervical spine, consideration should be given to securing the head with a pin head holder. Some surgeons now routinely place the patient's head in a pin head holder even for lumbar spine surgery, which eliminates opportunity for pressure on the eyes. This use must be weighed against the associated risks. For most procedures in which the patient is prone, I recommend any of the commercially available square foam headrests. The head is positioned straight down in the neutral position. The eyes and nose are then placed in the open portion of the headrest, and the anesthesiologist may easily reach underneath to check for pressure intermittently. When a transparent head piece is in use on the operating table, a mirror can be positioned underneath to indirectly view the eyes on the headrest. The ProneView is useful because it combines a foam headrest with a mirror immediately below, which enables the eyes to be seen easily during surgery. The use of goggles to cover the eyes is not advised when the head is positioned prone in a conventional square foam head rest.

In nasal and sinus surgery and in neuroradiologic procedures, the most important principles are avoidance of inadvertent injections into or compromise of the ocular circulation. After endoscopic sinus surgery, patients should be checked for signs of acutely elevated IOP suggestive of orbital hemorrhage. If present, immediate ophthalmologic consultation should be obtained. Embolization during CPB remains a cause of retinal vascular occlusion. Better means of detecting and preventing this complication are needed. Some surgical maneuvers may lower the incidence of arterial emboli.[57,58]

Ischemic Optic Neuropathy

Ischemic optic neuropathy, which primarily presents spontaneously without warning signs, is the leading cause of sudden visual loss in patients 50 years of age or older. The estimated annual incidence of nonarteritic ION in the United States is 2.3/100,000.[59] The two types of ION, anterior (AION) and posterior (PION), can be arteritic or nonarteritic. Arteritic AION, caused by temporal arteritis, responds to steroids. It is a systemic disease, generally occurs in patients 60 years of age or older, and has a female preponderance. Spontaneously occurring ION, unrelated to surgical procedures, is usually caused by AION. The specific mechanism and location of the vascular insult remain uncertain.[60] Only recently has a rodent model for AION been described.[61]

Nonarteritic ION, more common than arteritic, is overwhelmingly the type found perioperatively. It has been reported after a wide variety of surgical procedures, with most after cardiothoracic surgery,[62,63] instrumented spinal fusion operations,[9,10,64-66] head and neck surgery,[67,68] and surgery on the nose or sinuses.[69,70] Cases also have been described after vascular surgery, general surgical and urologic procedures, cesarean section and gynecologic surgery, and liposuction.[1,71-76] Most perioperative cases of ION are in adults, although there are some reports in children.[77]

Although there are many clinical studies of spontaneously occurring AION, there are few concerning PION. The lack of controlled studies, the absence of an animal model, and poorly defined pathology and risk factors limit our understanding of perioperative ION. Most of our knowledge is derived from individual case reports and case collections, of which the largest and best described single series is the ASA Postoperative Visual Loss Registry.[10] There have been one case-control study in spine surgery patients[9] and two in cardiac surgery.[6,7]

Mechanism

Simulated ischemia in optic nerve axons in vitro[78] culminates in axonal destruction. When oxygen delivery decreases, adenosine triphosphate is depleted, leading to membrane depolarization, influx of Na^+ and Ca^{2+} through specific voltage-gated channels, and reversal of the Na^+-Ca^{2+} exchange pump.[79] Ca^{2+} overload damages cells from activation of proteolytic and other enzymes. ION may lead to neuronal injury by apoptotic cell death, which may be stimulated in vitro with reduced oxygen delivery.[80]

Disruption of the blood-brain barrier is an early event in AION, and, as a result, fluorescein angiography in affected patients shows dye leakage in the optic nerve head.[81] Dye leakage correlates with the early onset of optic disc edema, seen even before the onset of symptoms.[82] The relationship between disruption of the blood-brain barrier and ischemic injury is not known. Earlier studies showed classic blood-brain barrier properties in the optic nerve head[83]; however, more recent immunohistochemical studies of microvessels in the monkey and human optic nerve head suggest a lack of classic blood-brain barrier characteristics in the prelaminar region[84] that could explain the early edema in the optic nerve head after ischemia.

Little is known about the in vivo cellular mechanisms leading to ischemic injury in the optic nerve. Guy showed that 30-minute occlusion of the carotid artery in rats produced ischemia and a swollen optic nerve within 24 hours.[85] The positive nitrotyrosine immunostaining found in the ischemic optic nerve[85] suggests a possible role for nitric oxide and perhaps oxygen free radicals, which would be expected to increase with disruption of the blood-brain barrier. Berstein and associates described a rodent model of AION.[61] After AION induction by a photothrombotic method, circulation to the optic nerve was lost within 30 minutes; edema peaked 1 to 2 days later and resolved by 5 days. A pale, shrunken optic nerve was found, similar to that in limited pathologic studies of human AION.[86] By 37 days after ischemic insult, the percentage of retinal ganglion cells was reduced by about 40%. After 6 days, the optic nerve showed axonal swelling and collapse. Permanent changes included septal thickening and axonal loss, most evident in the center, also similar to that found in the human optic nerve.

Clinical studies of AION with fluorescein angiography showed delayed filling of the prelaminar optic disc when disc edema was evident. Delayed filling was present in 76% of subjects and was not found in normal eyes. This suggests that delayed filling is the primary process in AION, and it is not caused by disc edema.[60] Hayreh attributed AION to individual variations in blood supply to the optic nerve.[87] This theory is supported not only by anatomic studies but also by the variability of visual loss in patients with AION. The "watershed concept," that impaired perfusion and distribution within a posterior ciliary artery predisposes the optic disc to infarction, is disputed. Arnold and Hepler showed that delayed filling of watershed zones was more common in normal eyes than in patients with AION.[81] Thus, reduced perfusion pressure in the region of the paraoptic branches of the short posterior ciliary arteries (PCAs) results in optic disc hypoperfusion, rather than a watershed event.[88] Histopathology in AION showed that the infarction was mainly in the retrolaminar region.[89] This implicates as the source of decreased blood flow the short PCAs directly supplying the optic disc.

Some have suggested that variability in blood pressure or IOP may predispose patients to the development of AION. Nocturnal hypotension in patients treated with antihypertensive agents may expose patients to low-level, albeit repeated decreases in perfusion to the optic nerve.[90] The importance of IOP fluctuations in the pathogenesis of AION has not been established.[91] Anatomic or physiologic variations in the circulatory supply of the optic nerve may predispose some patients to the development of AION,[92] especially if systemic arterial blood pressure is decreased. These variations in blood supply could result in underperfused areas.[93]

Hayreh reported nocturnal decreases of 25% to 30% in blood pressure in patients with AION.[94] There was no control group, but the decrease was larger than in age-matched normal subjects. Landau and associates[95] compared blood pressure decreases in normal and AION subjects and found no difference, although daytime blood pressures were slightly lower in those with AION. Thus, the role of chronically or intermittently low blood pressures in the pathogenesis of AION remains controversial. Interestingly, another study suggested an association between AION and sleep apnea syndrome,[96] but whether the mechanism depends on repeated hypoxia, increased IOP, decreased blood pressure, or altered autoregulation of blood flow in the optic nerve is still unclear.

A small optic disc (affected eyes commonly are referred to as having a small "cup-to-disc ratio") may play a role in a subject's susceptibility to AION[97] because axons of the optic nerve pass through a narrower opening as they exit the eye and are therefore prone to injury in the presence of edema or decreased blood flow. Mechanisms of injury due to a crowded disc include mechanical obstruction of axoplasmic flow, axoplasmic stasis, stiff cribriform plate, and decreased availability of neurotrophic factors to retinal ganglion cells after ischemia.[60] Tesser and colleagues reported that in a patient with spontaneous AION, axonal loss was in the superior part of the nerve, largely encircling the central retinal artery. The infarct was in the intrascleral portion of the nerve, extending 1.5 mm posteriorly. From this limited histopathologic evidence, the authors suggested that a tight scleral canal contributed to a "compartment syndrome" in the anterior optic nerve.[86]

The role of systemic diseases such as hypertension and diabetes has been examined in several studies. Hypertension was found in 34% to 47% of subjects with AION but was significantly different from non-AION patients only in those 45 to 64 years of age. Hayreh found increased prevalence of vascular risk factors in all age groups. Increased prevalence of diabetes is present in most studies of AION, but AION has not been consistently associated with stroke and myocardial infarction, cigarette smoking, and elevated cholesterol.[60] Among patients in the Ischemic Optic Neuropathy Decompression Trial (IONDT), 47% were hypertensive, 24% diabetic, 11% had a previous myocardial infarction, and 3% had a stroke.[98] These proportions of patients with "vascular risk factors" might, however, be similar to those in the general population. For ethical reasons, the IONDT could not include a non-ION control group. Smoking might also be a risk factor for the development of ION, but large numbers of patients have not been reported.[99] An association has been suggested between AION and prothrombotic factors, such as deficiencies of protein C, protein S, or factor V Leiden, but reports are conflicting.[60,100,101]

Patient Characteristics

Most of the cases occurring after spine surgery have a diagnosis of PION.[10,64,102] A diagnosis of AION has been more frequently reported after cardiac surgery (see Chapter 60). The onset of perioperative visual loss is typically within the first 24 to 48 hours after surgery, frequently noted on awakening, although later onset has been described, particularly in sedated patients whose lungs were mechanically ventilated postoperatively.[10,64,103] Patients present typically with painless visual loss, afferent pupil defect or nonreactive pupils, complete visual loss, no light perception, or visual field deficits. Color vision is decreased or is absent. In AION, altitudinal visual field deficits may be present. Optic disc edema and hemorrhages are seen on symptom onset in AION; in PION, the optic disc appears normal even though the patient complains of visual loss. Later, over a span of weeks to months, optic atrophy develops. The lesion may be unilateral or bilateral, but most post–spine surgery ION cases have bilateral involvement. In ION, orbital MRI is frequently nondiagnostic,[104] although some reports have described changes such as enlargement of the nerve from edema or perineural enhancement.[105] Visual evoked potential is abnormal, while the electroretinogram is unaffected.[106]

Recently, several reviews of case reports have appeared and a few case series have been published. It is worth reviewing some of the individual case reports where at least some patient-specific data were provided. After presentation of this information, I will discuss the more recent case series and summaries of case reports. There were 51 patients described in case reports in the literature from 1968 to 2002 in whom perioperative AION was diagnosed.[103] Among this group, 59% of subjects underwent open heart surgery; 12%, nasal, head, or neck surgery; and 12%, spine surgery. The average age was 53 years, and 72% were male. In many cases there are missing data concerning the patients and variability in the types of data reported. These patients tended to undergo lengthy operations, with an average operative time of 508 minutes. In patients for whom blood pressure was reported, mean arterial pressure averaged 92 mm Hg preoperatively and the lowest mean arterial pressure averaged 65 mm Hg intraoperatively. Preoperative hemoglobin averaged 13.7 g/dL, the lowest intraoperative value was 8.7 g/dL, and the postoperative hemoglobin concentration was 8.1 g/dL. The patients received considerable amounts of fluid intraoperatively; they averaged 1.4 L of blood replacement, 8.2 L of crystalloid, and 1.0 L of colloid. In 20% of cases, blood loss exceeded 2 L. Coronary artery disease was present in 61%, hypertension in 27%, and diabetes mellitus in 24% of patients. Because of the predominance of patients who underwent CABG surgery, these data may be weighted toward a higher prevalence of these disorders in this group.

In 67% of patients, symptoms of visual loss were not evident until more than 24 hours after surgery, either because of delayed onset of the disease or delayed recognition of the symptoms and signs of AION in the perioperative period due to mechanical ventilation and sedation postoperatively. Virtually all patients had disc edema, pallor, or both. Over 60% of patients had an afferent pupil defect or nonreactive pupils. The visual field deficit was altitudinal in 14%; there was central scotoma in 20%, and in 20% blindness was the initial symptom. Visual loss was bilateral in 55% and unilateral in 45% of patients. Some treatment was attempted in 15 patients, including steroids, aggressive volume replacement, vasopressors, or a combination of these therapies. Treatment did not necessarily result in improvement. Overall, in the 51 patients, 47% had no improvement or a worsening of symptoms, 29% improved, and in 25% the outcome was not described.

Between 1968 and 2002, case reports described 38 patients with perioperative PION.[103] The nature of the surgical procedures that these patients underwent tended to differ from those in the patients reported with AION. In this group, 8% of subjects underwent open-heart surgery; 24%, nasal, head, or neck surgery; and 39%, spine surgery. The average age was 50 years, and 63% were male. Although AION is rarely reported in children, four cases of perioperative PION occurred in children 13 years or younger. As with the AION cases, surgery tended to be lengthy, averaging 448 minutes. In patients for whom blood pressure was reported, mean arterial pressure averaged 90 mm Hg preoperatively, with an average lowest mean arterial pressure intraoperatively of 61 mm Hg. Preoperative hemoglobin averaged 12 g/dL, the lowest intraoperative hemoglobin concentration was 8 g/dL, and postoperative values averaged 10 g/dL. These values are similar to those reported in the AION cases. Hematocrit decreased from 44% to 27% intraoperatively and increased to 29% postoperatively. The patients also received considerable amounts of fluid intraoperatively; they averaged 2.3 L of blood replacement, 8.8 L of crystalloid, and 1.6 L of colloid. In 37% of cases, intraoperative blood loss exceeded 2 L. Coronary artery disease was present in only 8%, hypertension in 32%, and diabetes mellitus in 21%. When compared with patients with AION, the incidence of coronary artery disease was much lower. The onset of symptoms was typically within 24 hours postoperatively. Blindness was reported in 47%, an altitudinal defect in 8%, and a central scotoma in 26%. Twenty-seven (71%) patients had an afferent pupil defect or nonreactive pupils. A normal optic disc on initial funduscopic examination was evident in 92% of patients. Visual loss was bilateral in 63% and unilateral in 34% of patients. Forty-five percent of patients had no improvement, 29% improved, and for 18% the outcome was not described.

In summary, case reports showed similar intraoperative characteristics of patients with AION or PION. Most patients with AION had undergone open-heart surgery. The largest single group of patients with PION had spine fusion surgery. The main differences were a lower incidence of coronary artery disease in the group with PION; the occurrence of PION in younger patients; and somewhat more intraoperative blood replacement, more rapid onset or recognition of visual loss, and a greater likelihood of complete blindness initially in PION cases than in AION cases.

Retrospective Case Series

Sadda and associates retrospectively collected a series of 72 cases of ION from two large academic institutions over a 22-year period. In 38 subjects, PION developed spontaneously, and in 28, it developed in the perioperative period.[107] In the remaining 6, the diagnosis was arteritic PION. For the 38 patients with spontaneous nonarteritic PION the average age was 68 years; 39% had hypertension, 24% had diabetes, 18% had coronary artery disease, and 32% had a history of cerebrovascular disease. Bilateral involvement was evident in 21%, and 90% had some form of visual field deficit. Only 30% improved; 35% worsened. Unlike AION, where there may be a structural difference in the optic nerve such as a small cup-to-disc ratio, these authors could identify a structural abnormality in the optic nerve in only 4% of patients with PION. The 14 patients who had spinal surgery tended to be younger and to have a lower incidence of coronary artery disease and diabetes, but not hypertension, relative to the other two groups. Unfortunately, intraoperative data were not included but the postsurgical patients were more likely to have bilateral involvement (54%) and a worse visual outcome at initial examination and later follow-up compared with PION in nonsurgical cases.

Buono and Foroozan[108] reviewed 83 cases of PION reported in the literature. In 36 cases, there were details of clinical features; in the other 47, aggregate data had been reported. About 54% of the cases followed spine surgery, 13% radical neck dissection, and 33% other surgery. Mean age was 52 years; patients who had spine surgery were younger (mean age, 44 years) than those in the other groups. About two thirds of patients were men. In three fourths of cases, visual loss was apparent within 24 hours of surgery. Visual acuity was "counting fingers" or worse in 76%, and 54% of eyes had an initial visual acuity of no light perception. Over 60% of cases were bilateral. In 38% of patients, vision improved, but of 14 with no light perception initially, 12 (85%) had no improvement. Among patients with PION, 65% had one or more of the following: hypertension, diabetes, cigarette use, hypercholesterolemia, coronary artery disease, congestive heart failure,

arrhythmia, cerebrovascular disease, or obesity. Mean lowest hemoglobin value was 9.5 g/dL (5.8 to 14.2 g/dL). Mean lowest systolic blood pressure was 77 (48-120 mm Hg). Mean intraoperative blood loss was 3.7 L (0.8-16 L). Mean operative duration was 8.7 hours (3.5-23 hours).

Spine Surgery

Cheng and colleagues surveyed neurosurgeons in the United States who performed spine surgery.[65] There were 24 cases of visual loss reported by 22 surgeons. The mean age was 47 ± 15 years. Lumbar spine surgery was the procedure performed most frequently, and mean duration of surgery was 4.8 ± 3.5 hours. Mean hematocrit changed from 42 ± 5% to 35 ± 7%. Mean estimated blood loss was 793 ± 1142 mL. In 5 patients, estimated blood loss exceeded 1800 mL; 3 received blood transfusions. Of the 24 patients, 21 were normotensive intraoperatively and 2 had deliberate hypotension; 4 had diabetes mellitus, 1 had peripheral vascular disease, and 1 had diabetes and peripheral vascular disease.

Ho and associates[64] reviewed reported cases of AION and PION in the literature after spine surgery. There were 5 cases of AION and 17 of PION; median ages were 53 and 43 years, respectively. Most of the cases followed lumbar spine fusion surgery. Mean operative time for AION cases was 522 minutes, and for PION cases, 456 minutes. For AION, range of the lowest mean arterial pressure was 62 to 78 mm Hg; for PION, it was 52 to 85 mm Hg. Lowest mean intraoperative hematocrit was 27% in the PION cases. Mean blood loss was 1.7 L and 5 L for AION and PION, respectively. Crystalloid/colloid volumes averaged 6.0/0.8 L and 8.0/2.2 L for AION and PION, respectively. Sixty percent of patients with AION and 27% with PION had diabetes mellitus; coronary artery disease was noted in 20% of patients with AION and in none with PION. Prevalence of hypertension was similar (40% or 53%). Symptoms were reported within 24 hours of surgery in 40% of AION cases; 59% of PION cases reported symptoms immediately on awakening and 88% within 24 hours. Visual acuity improved somewhat in 60% of AION and 65% of PION cases.

Data from spine surgery patients in the ASA Postoperative Visual Loss Registry[10] showed striking differences between patients with ION ($n = 83$) and those with CRAO ($n = 10$). The average blood loss in ION cases was 2.0 versus 0.75 L with CRAO. The lowest hematocrit was 26% with ION and 31% with CRAO. With ION, decreases in blood pressure varied widely from preoperative baseline: in 33% of cases, lowest systolic blood pressures were greater than 90 mm Hg; in 20%, the lowest was less than or equal to 80 mm Hg. About 57% of patients had systolic or mean arterial blood pressure 20% to 39% below baseline, and 25% of patients were at 40% to 49% below preoperative baseline. Deliberate hypotension was used in about a fourth of the patients. Nearly all cases involved surgery longer than 6 hours. In the majority of the cases, estimated blood loss was greater than 1 L, the median estimated blood loss was 2 L, and the median lowest hematocrit was 26%. Large-volume fluid resuscitation was typical in these patients, with median crystalloid administration of about 10 L. Most of the patients underwent thoracic, lumbar, or lumbar-sacral fusion procedures that were often repeat operations that mostly involved multilevel surgery. Surgical positioning devices for these patients were the Wilson frame (30%), Jackson spinal table (27%), and soft chest rolls (20%). A foam pad was used for head positioning for 57%; 19% had the head positioned in a Mayfield head holder. PION accounted for the majority of the cases compared with AION. Patients of ASA class 1 or 2 accounted for 64% of cases. The mean age was 50 ± 14 years. About 41% had hypertension, 16% had diabetes mellitus, and 10% had coronary artery disease. The POVL Registry does not have a control group of unaffected spine surgery patients for comparison to enable a case-control study of risk factors.

In a retrospective case-control study of 28 patients with visual loss after spine surgery, Myers and colleagues found no difference in the lowest systolic blood pressure or hematocrit in the affected versus unaffected patients, suggesting that hypotension and anemia do not completely explain the occurrence of ION. About 40% of these patients had no risk factors for vascular disease preoperatively; a similar percentage in the two groups were hypertensive or smokers.[9]

Cardiac Surgery

Two retrospective case control studies of blindness after cardiac surgery (see Chapter 60) have been reported. Shapira and colleagues studied 602 patients at a single institution.[6] Patients underwent CPB under moderate systemic hypothermia (25°C) with pulsatile flow and a membrane oxygenator. Neo-Synephrine was used if perfusion pressure could not be maintained above 50 mm Hg despite a flow index of 2 L/m^2/min, and alpha-stat was used for pH management. There were 8 patients (1.2%) affected by AION. There were no differences in preoperative risk factors for vascular disease between patients with or without visual loss. CPB time was longer in patients with AION (252 versus 164 minutes), and minimum hematocrit was lower (18% versus 21%) compared with unaffected patients. There were no differences in flow indices, perfusion pressures, and P_{CO_2} levels intraoperatively. Patients with AION had a greater 24-hour postoperative weight gain (18% versus 11% increase) and required more epinephrine and amrinone postoperatively to maintain hemodynamics than did patients with unaffected vision. Visual symptoms were usually reported between days 1 and 3 postoperatively, soon after removal of mechanical ventilatory support.

Nuttall and colleagues performed a larger retrospective case-control study of about 28,000 patients who had cardiac surgery at the Mayo Clinic from 1976 to 1994.[7] They found 17 cases of ION (0.06%). By univariate analysis, significant risk factors for ION included lower minimum postoperative hemoglobin, history of clinically severe vascular disease, preoperative angiogram within 48 hours of CPB, longer duration of CPB, red blood cell (RBC) transfusions, and any use of non-RBC blood components. Patients with ION underwent longer CPB runs; there were no differences in pre-CPB or post-CPB systemic blood pressures. There were 9 cases of bilateral ION; disc edema was not found in 5 patients (29%), which may have been cases of PION, not AION. Small cup-to-disc ratio (<0.3) was identified in 5 patients (29%) with ION.

Kalyani and colleagues retrospectively reviewed cases of ION after 9701 cardiac surgeries over a 9-year period at a single institution.[8] Specific risk factors could not be determined from the 11 patients (0.11%) with ION in this series.

Trauma (see also Chapter 72)

Cullinane and coworkers retrospectively reviewed the medical records of over 18,000 trauma cases at a single institution between 1991 and 1998.[109] Of these, 350 required massive resuscitation with more than 20 L of fluid during the first 24 hours after

admission. Volume resuscitation consisted of 21 to 50 L (mean 33 ± 8 L) in the first 24 hours. Incidence of ION was 2.6% (9 patients). Four patients had bilateral blindness. No information was provided on funduscopic examinations. The mean age was 34 ± 13 years. Patients were acidotic, with serum lactate levels ranging from 2.5 to 17.5 mEq/L. Mean lowest hematocrit was 7.5% to 28% (mean 20 ± 8%); blood products included 9 to 39 units of packed RBCs (mean 22 ± 10 units). All patients had coagulopathy, and all developed acute respiratory distress syndrome that required high levels of inspired oxygen and positive end-expiratory pressure (mean level 29 ± 9 cm H_2O). All patients had systemic inflammatory response syndrome, and 66% had compartment syndrome at some location in the body remote from the eye. Mean time until detection of visual loss was 36 days because patients needed prolonged mechanical ventilation and sedation.

Blood Supply to the Optic Nerve

ION affects the anterior portion of the optic nerve in AION or beyond the retrolaminar region behind the eye in PION. The ischemic insult is presumably of vascular origin but has not been conclusively shown. Anatomy of and blood supply to the anterior and posterior optic nerves differ.[26,87] The pathophysiology of PION is even less well understood than that of AION.

The anterior portion of the optic nerve is proximal to the lamina cribrosa, an elastic, collagenous tissue through which the optic nerve and the central retinal artery and the central retinal vein pass as they enter the optic disc. The anterior portion of the optic nerve includes the superficial nerve fiber layer and the prelaminar region. The prelaminar area is a thick tissue that constitutes most of the optic disc volume.[110] The superficial nerve fiber layer, composed of axons extending from the retinal ganglion cells, is anterior to the plane extending across the optic nerve from the peripapillary Bruch membrane. Immediately posterior is the prelaminar region, adjacent to the peripapillary choroid. The laminar region is a transition zone between columns of glial cells and dense connective tissue plates. Astrocytes are predominant in the anterior optic nerve, and oligodendrocytes and microglial cells are more common in the posterior or retrobulbar optic nerve. Neural fibers transit the laminar region through fenestrations. The retrolaminar region is the posterior portion of the optic nerve and consists of meningeal sheaths and myelinated axons. The diameter of the optic nerve is enlarged in this area to about 3 mm.

The superficial nerve fiber layer derives its blood supply mainly from arterioles in the retina, although in the temporal regions it may receive blood from the posterior ciliary arteries. The prelaminar region is perfused by centripetal branches of the peripapillary choroid and vessels from the circle of Zinn-Haller (Fig. 90-3), which are not found in every eye.[87] Whether the region has a choroid-derived source of blood is controversial. The laminar region is supplied by centripetal branches from the short posterior ciliary arteries or by the circle of Zinn-Haller, but the short posterior ciliary arteries are the primary input. Longitudinal anastomoses of capillaries can be seen in the prelaminar and laminar regions and may provide some additional protection against ischemic insult, although their functional importance is not clearly known.

The retrolaminar, posterior portion of the optic nerve, which is affected in PION (Fig. 90-4), is perfused by two main

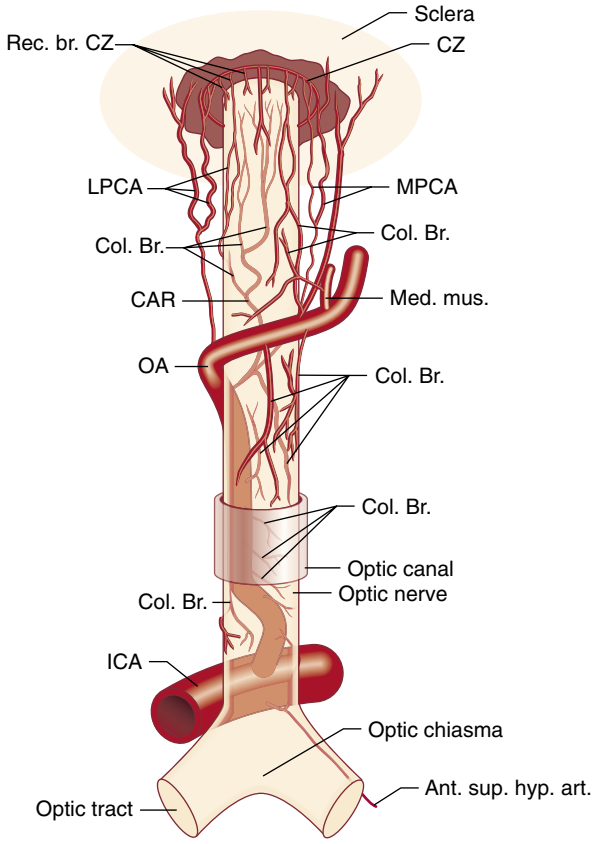

Figure 90-3 The origin, course, and branches of the ophthalmic artery, including the posterior ciliary arteries, as seen from above. Ant. sup. hyp. art., anterior superior hypophyseal artery; CAR, central retinal artery; Col. Br., collateral branches; CZ, circle of Zinn and Haller; ICA, internal carotid artery; LPCA, lateral posterior ciliary artery; MPCA, medial posterior ciliary artery; OA, ophthalmic artery; Rec. br., recurring branches. (*From Pillanut LE, Harris A, Anderson DR, Greve EL [eds]: Current Concepts on Ocular Blood Flow in Glaucoma. The Hague, Netherlands, Kugler, 1999.*)

vascular supplies. The peripheral centripetal vascular system is the major supply and is found in all optic nerves. It is formed by recurrent branches of the peripapillary choroid and the circle of Zinn-Haller. Pial branches of the central retinal artery and other orbital arteries, the ophthalmic artery, and the posterior ciliary arteries also contribute. Branches of the pial vasculature run in the septa of the nerve. The axial centrifugal vascular system is formed by small branches from the intraneural part of the central retinal artery and is not present in every eye; thus, differences in blood supply in the posterior optic nerve may render some individuals more susceptible to PION.[111]

Control of Blood Flow

Studies of autoregulation of blood flow in the optic nerve head have yielded conflicting results because measurement techniques are limited.[87] Blood flow in the optic nerve head is autoregulated within a range of perfusion pressures similar to those in the brain of monkeys and sheep. In a small sample of atherosclerotic monkeys, however, autoregulation was defective.[112] This study did not directly measure blood flow; rather, it measured glucose consumption, and the sample size was small. There is other evidence of autoregulation in the posterior portion of the optic nerve. In

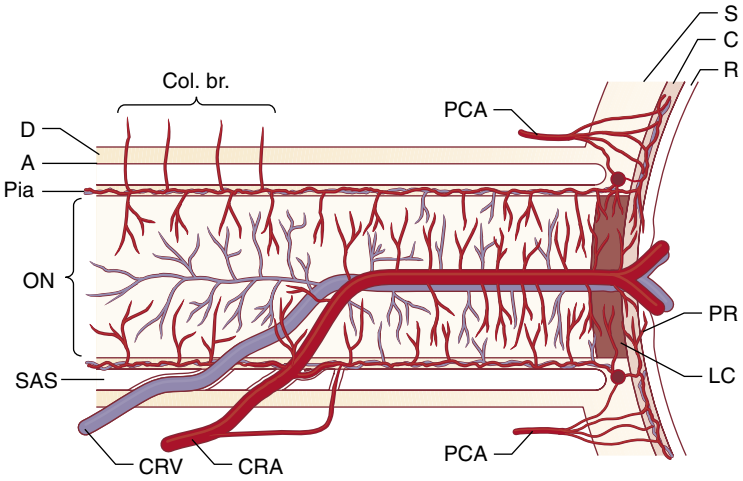

Figure 90-4 The blood supply to the optic nerve is illustrated. The anterior portion of the optic nerve is located to the left, whereas the posterior portion (closer to the brain) is on the right. The anterior portion of the nerve derives its blood supply from the posterior ciliary arteries (PCA) and the choroid (C), whereas the posterior optic nerve derives its blood supply from penetrating pial arteries (collateral branches [Col. br.]) and branches of the central retinal artery (CRA). A, arachnoid; C, choroid; CRV, central retinal vein; D, dura; LC, long ciliary artery; ON, optic nerve; PR, short posterior ciliary artery; R, retina; S, sclera; SAS, subarachnoid space. (*From Hayreh SS: Ischemic optic neuropathy, University of Iowa, Department of Ophthalmology Internet Site. http://webeye.ophth.uiowa.edu/dept/aion/ion_fg2.jpg.*)

cats, blood flow in the optic nerve measured directly by autoradiography remained constant in the prelaminar, laminar, and postlaminar nerve across a range of systemic mean arterial blood pressure values from 40 to more than 200 mm Hg.[113]

In one study in 13 healthy volunteers, blood flow in the optic nerve head measured by laser Doppler flowmetry was constant between ocular perfusion pressures of 56 to 80 mm Hg[114]; in another study, flow was preserved at extremely high IOP that resulted in a minimal perfusion pressure of 22 mm Hg.[115] Other investigators found that flow was preserved in the optic nerve head until ocular pressure reached levels of 40 mm Hg. However, 2 of 10 healthy young volunteers in the study failed to demonstrate autoregulation.[92] Using color Doppler imaging in humans, another group showed that flow velocity in the posterior ciliary arteries decreased at extremely high IOP. These findings seem to support the theory that "watershed" areas in the distribution of the posterior ciliary arteries predispose some patients, including otherwise healthy ones with no known vascular disease, to damage to the anterior portion of the optic nerve when perfusion pressure is decreased, either after systemic blood pressure decreases or IOP is elevated. At present, however, no clinical technique can reliably detect such patients.

Histologic Findings

Only a few cases report histopathologic examination of the optic nerve in ION. Of 3 PION cases evaluated after surgical procedures, all of the patients showed infarcts in the intraorbital portion of the optic nerve, but results were not completely consistent. Two patients had lesions in the central axial portion with peripheral axonal sparing; the other patient had the opposite pattern in one eye and complete axonal loss in the other.[108] Despite a larger autopsy series in AION, the location of the infarct has not been documented. Tesser and colleagues showed that in a patient with spontaneous AION the axonal loss was in the superior part of the nerve, largely encircling the central retinal artery. The infarct was in the intrascleral portion of the nerve, extending 1.5 mm posteriorly.[86]

Possible Pathogenic Factors

Among the possible factors in perioperative ION are decreased systemic blood pressure; blood loss; anemia or hemodilution; altered venous hemodynamics; flow of cerebrospinal fluid in the optic nerve (including the influence of patient positioning and perioperative fluid resuscitation); abnormal autoregulation in the optic nerve; anatomic variants in blood supply to the optic nerve; small cup-to-disc ratio; the use of vasopressors; the presence of systemic vascular risk factors including hypertension, diabetes, atherosclerosis, hyperlipidemia, and smoking history; prone positioning; lengthy surgery for spinal fusion; and other preexisting systemic abnormalities, such as sleep-apnea syndrome and hypercoagulability.[96,101-103,108]

It seems that one or more of the these factors are often present in an individual patient in an unpredictable fashion. In most cases there has been some degree of hypotension or anemia and fluid resuscitation. Many of the patients with ION after spine surgery have been relatively healthy preoperatively. Hypotension, blood loss, lengthy surgery, and large quantities of fluid administration seem to occur frequently in many patients undergoing complex spine surgery.[9,64,65,107,108] As a result, it is possible that combinations of these factors, perhaps together with abnormal autoregulation in the posterior optic nerve, prothrombotic tendencies, and other patient-specific factors lead to decreased oxygen delivery to the optic nerve sufficient to cause ischemic injury.

Current Knowledge and Controversies

Because of the paucity of case-control studies, and the absence of prospective studies, risk factors for ION have not yet been well defined. However, a number of potential factors warrant discussion. Myers and associates showed that *length of surgery* and *estimated blood loss* were higher in patients with postoperative blindness after spine surgery versus unaffected patients.[9] Therefore, patients undergoing anticipated long-duration surgery with large blood loss are recognized as higher-risk patients.[116] Staging

of spinal fusion procedures, particularly those for anterior and posterior surgery, may be advisable. Of course, this is not the primary decision of the anesthesiologist, but it is worth discussing with the surgeon for appropriate cases. Revision spinal fusion procedures are common, and these operations may be expected to be longer and involve greater blood loss.

Intraoperative hypotension has been cited as a risk factor by a number of authors of case reports,[71,117] but because it is not always present, and because some degree of hypotension frequently occurs in anesthetized patients, hypotension itself might not be responsible.[6,118-120] In Cheng and colleagues' survey of 24 cases of visual loss after spine surgery, deliberate hypotension was used in only 2 cases.[65] In a retrospective case-control study of patients undergoing spinal fusion, Myers and colleagues showed that levels of hypotension and anemia were equivalent in patients in whom ION developed after spinal surgery and in those in whom it did not.[9] In the ASA Postoperative Visual Loss Registry, which contains the largest series of visual loss after spine surgery, there was a wide variation in blood pressure decreases intraoperatively among the patients with ION; in 33% of cases, lowest systolic blood pressures were more than 90 mm Hg, while in 20%, the lowest were 80 mm Hg or less. About 57% of patients had systolic or mean arterial blood pressure 20% to 39% below baseline, and in 25% of patients it was 40% to 49% below preoperative baseline. Deliberate hypotension was used in 27% of the patients.[10]

Similarly, in Shapira and associates' retrospective case-control study of 602 patients who underwent open-heart surgery at one institution during a 2-year period, the lowest perfusion pressure intraoperatively was no different between affected and normal patients.[6] Nutall and coworkers' larger case-control study did not report the blood pressures during CPB, but there were no differences in pre- or post-bypass blood pressures between patients with ION and unaffected patients.[7] In open-heart surgery, hypothermia during CPB, and other systemic alterations such as systemic inflammatory syndrome might play a role in the development of ION but these mechanisms have not been studied.

Hypotension can potentially lead to decreases in perfusion pressure in the optic nerve and to ischemic injury either because of anatomic variation in the circulation or because of abnormal autoregulation and an inability to adequately compensate for decreased perfusion pressure. The degree of hypotension that is potentially dangerous is difficult to quantitate because of the lack of data in the literature.[116]

Blood loss may be considerable in reports of perioperative ION. It is apparent that, on average, patients sustained considerable blood loss and had a decreased hemoglobin concentration intraoperatively. Clinical blood transfusion practice in surgical patients, based on ASA practice guidelines,[121] suggests that transfusion is not generally required for hemoglobin values higher than 8.0 g/dL (see Chapter 55). The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists, which reviewed the available evidence base for these practices in cardiac surgery in particular, has issued a recent, similar clinical practice guideline.[122]

Some authors have suggested that allowing *hemoglobin* to decrease, as is common in anesthesia practice, may be putting patients at increased risk for ION[71,102]; however, whether practice should be changed in surgical procedures such as spine or heart surgery—or in any operative procedure—remains controversial. Two retrospective case-control studies examined whether decreased hemoglobin or hematocrit relates to the occurrence of ION. In spine surgery patients, Myers and associates[9] determined that the lowest levels of hematocrit did not differ between patients sustaining ION and those who were not affected. In cardiac surgery patients, Nuttall and coworkers[7] found a somewhat different result. The presence of a lower minimum postoperative hemoglobin was associated weakly with ION (odds ratio, 1.9; $P < .047$). Looked at another way, 13 of 17 patients with ION in their study had a minimum postoperative hemoglobin value less than 8.5 g/dL, versus 14 of 34 control patients with this level. The type of ION sustained by the patients was not specified, and the study had numerous statistical comparisons and a small sample size. Because spine and open-heart surgery patients are different, it is doubtful that the results can be extrapolated to types of surgery other than cardiac. Although visual loss after cardiac surgery is a rare but dreaded complication, the possibility of a relationship among blood loss, hemoglobin value, and visual loss was not a consideration in the clinical practice guideline for blood transfusion in cardiac surgery.[122]

In uncontrolled *hemorrhage* in which blood volume is not maintained, decreased oxygen delivery to the optic nerve could result in either AION or PION.[123] Just how low or for how long the hemoglobin concentration must decrease to lead to this complication is not known. However, the presence of recurrent and profound hemorrhage has been described in many reports. The argument that blood loss in the presence of maintained intravascular volume (hemodilution) is harmful seems less scientifically grounded. It has been shown experimentally in minipigs that blood flow in the optic nerve head, as measured by laser Doppler imaging, was maintained during isovolumic hemodilution with a 30% decrease in hematocrit. Moreover, oxygen tension at the vitreal surface increased 15%.[124] Hemodilution in cats resulted in a nonsignificant decrease in choroidal oxygen delivery[125] and an increase in preretinal oxygen tension.[126] Healthy volunteers tolerated very deep levels of hemodilution (hemoglobin, 50 g/L) without any disturbance in systemic oxygen delivery.[127] The multicenter prospective randomized trial conducted by Hebert and coworkers provided data justifying clinical use of a liberal transfusion strategy (lower hematocrit) in critically ill patients.[128] The effects of combined hypotension and hemodilution on hemodynamics and oxygen delivery in the optic nerve have not been reported.

AION and PION have been reported in the setting of *massive fluid replacement*, and many reports include patients who were operated on in the *prone position*, raising the possibility that positioning itself contributes to altered venous hemodynamics within the optic nerve. It is advisable to position the patient's head level with or above the heart, when possible, and in a neutral position during spine surgery performed with the patient in the prone position. Several studies have measured IOP and found that it increased in the prone position and was influenced by the position of the operating room table. However, there has been no correlation between IOP changes and visual outcome or visual function changes.[16,17] Cheng and colleagues[17] found that in anesthetized patients, IOP increased significantly on initial prone positioning relative to supine (27 ± 2 versus 13 ± 1 mm Hg). After 5 hours in the prone position, IOP remained elevated at 40 ± 2 mm Hg. None of the 20 patients in the study experienced visual loss. The largest increases in IOP were evident near the time that patients were awakening. Although these data suggest that ocular perfusion pressure may decline even during maintenance of normotension,

some experimental design issues must be considered in interpreting these results. The main issue is that the largest increases in IOP were evident near the time of awakening. Accordingly, IOP could have risen because of light anesthesia. Moreover, the study did not include a supine group to control for the effects of fluid administration on IOP. Such control is important because prone positioning itself may not explain the large increases in IOP. These results are valuable as well as of concern, but further studies are needed to fully evaluate their significance.

External pressure on the eye is a potential concern when a patient is positioned prone for surgery. Many cases of ION have been reported in which it was impossible for pressure to have been placed on the eye. Such cases include patients in pin head holders[65,120] and those in whom the head was turned with the affected eye placed upward.[129] But ION would not occur without retinal damage in a situation in which external compression was applied (see earlier). While we showed that high IOP decreased retinal and choroidal blood flows in cats,[22] Geijer and Bill[130] specifically measured the impact of graded increases in IOP on blood flow in the retina and optic nerve in monkeys. When IOP was elevated such that perfusion pressure was decreased to levels above 40 cm H_2O, there were small effects on retinal blood flow and in the prelaminar portion of the optic nerve. When perfusion pressure was below 40 cm H_2O, retinal and prelaminar flows were proportional to the perfusion pressure. At very high IOP, blood flow stopped in the retina and the prelaminar area but flow in the retrolaminar region increased. High IOP results in a redistribution of blood flow that favors the retrolaminar portion of the optic nerve. Therefore, an increase in IOP would not produce an isolated ION without also causing retinal damage. Further support is that sustained increases in IOP significantly decreased both retinal and choroidal blood flow, and even small increases in IOP damaged the retinal ganglion cells, which are sensitive to pressure alterations.[22,40]

The theory that massive *fluid resuscitation* could be a pathogenic factor in perioperative ION remains speculative, but it does have some merit. Fluid resuscitation is a necessity during lengthy, complex spine surgery associated with substantial blood and fluid losses at the operative site.[118,119] Conceivably, fluid administration could result in increased IOP or accumulation of fluid in the optic nerve, or both. Because the central retinal vein exits out of the optic nerve, an internal "compartment syndrome" may occur in the optic nerve. Alternatively, fluid accumulation in the vicinity of the lamina cribrosa may compress axons as they transit this region. In the report of Cullinane and associates,[109] trauma patients received massive blood replacement who were acidotic, and most had abdominal compartment syndrome. Analysis of these patients is complicated because of the presence of numerous systemic alterations. Sullivan and associates described a retrospective series of 13 burn patients with 25% or greater body surface area burns and massive fluid resuscitation. IOP was elevated more than 30 mm Hg in 4 patients at 48 hours after admission, all of whom received more than 27 L of intravenous fluid. Eye findings and vision diagnoses were not described.[131] Large-volume fluid replacement is generally seen in many case reports of ION.[103] Patients in the ASA Postoperative Visual Loss Registry received on average 9.7 L of crystalloid intraoperatively,[10] and increased postoperative weight gain was identified in a case-control study of visual loss after heart surgery,[6] suggesting, although not proving, that fluid replacement may play a role.

Further support of an idea that *increases in venous pressure* within the optic nerve are potentially deleterious can be seen in reports of ION after head and neck surgery in which the internal jugular veins were ligated.[15,67,68] However, there are venous drainage bypass pathways from the head and neck when the internal jugular veins are ligated. Although the relationship to fluid therapy is not clear, Myers and colleagues found that longer surgery was associated with ION.[9] However, cases of ION have been found after widely varying operative times.[10]

Some have speculated that *facial edema* indicates a risk for ION after spine surgery.[132] However, in clinical practice, facial edema is often seen after spinal fusion in many patients in whom ION does not develop, and, therefore, its relevance remains unclear and the notion that facial edema is a risk factor is unproved.

Killer and coworkers sampled cerebrospinal fluid (CSF) from the subarachnoid space of the optic nerve and from the lumbar region in patients with idiopathic intracranial hypertension undergoing optic nerve sheath fenestration.[133] The authors compared content of albumin, IgG, beta-trace protein, and brain-derived protein lipocalin-like prostaglandin D-synthase (L-PDGS). MRI and CT-cisternography were performed. From differences in the ratios of the CSF proteins in the optic nerve versus the CSF proteins in the lumbar region, and the results of cisternography, they concluded that CSF flow was compartmentalized in the optic nerve under these pathologic conditions. The implication of this conclusion is that relatively high CSF pressures in the intraorbital optic nerve can result in compression. Because CSF pressure may increase with fluid resuscitation, this may explain optic nerve compression. However, this theory has not been tested.

Although various theories concerning the role of intraoperative fluids in perioperative ION have been postulated, including extravasation from the central retinal vein, influence of directional CSF flow in the optic nerve, and changes in intracranial pressure, among others, none of these has been examined in either animal or human studies. MRI of the orbit in humans with ION has provided no evidence for any of these theories.[104] No study has shown any relationship among periorbital edema, IOP, and ION. Fluid administration could be a pathogenic factor in ION, especially in patients positioned prone or undergoing cardiac surgery, but the mechanisms involved, as well as the amounts and nature of fluid required, remain undefined.

Anatomic variation in the circulation of the optic nerve may potentially predispose patients to the development of ION. The location of potential watershed zones in the anterior and posterior circulation and the presence of disturbed autoregulation, even in normal patients,[92] are of concern but at present cannot be predicted clinically. There are few human studies of the relationship between perfusion pressure and changes in blood flow in the optic nerve. Human studies generally show preserved blood flow at clinically used or even lower ranges of perfusion pressure, but these studies have focused primarily on the anterior portion of the optic nerve.[92,114] In the studies that utilized laser Doppler flowmetry, depth of penetration of the measuring device is critical. Measurements might have been closer to the retinal blood vessels rather than the optic nerve head, and these do not measure optic nerve circulation. It is not currently feasible to measure blood flow in the human retrolaminar optic nerve. In animal studies blood flow is preserved in various layers of the optic nerve, including the retrolaminar area, at a mean arterial blood pressure as low as 40 mm Hg.[113]

Hayreh and associates theorized that AION is related to excessive secretion of vasoconstrictors, which in turn could lower optic nerve perfusion to dangerously low levels.[134] However, the theory was based on the development of AION in patients who sustained massive hemorrhage. *Vasopressors* are used to maintain blood pressure in circumstances such as after cardiac surgery and where there is decreased vasomotor tone. Shapira and coworkers showed an association between prolonged use of epinephrine or long bypass time and ION in patients undergoing open heart surgery.[6] Lee and Lam[120] reported a case of ION in a patient after lumbar spine fusion during which a phenylephrine (Neo-Synephrine) infusion was used to maintain blood pressure. They later presented a series of four case reports of ION in critically ill patients with significant systemic illness who required prolonged use of vasopressors and inotropic agents to maintain blood pressure and cardiac output.[135] However, α-adrenergic receptors are not known to be located in the optic nerve and the blood-brain barrier prevents entry of systemically administered agents, except possibly in the prelaminar zone of the nerve. Therefore, a role of vasopressor use in ION remains unclear and no clear guidance with respect to risk of ION can be provided at this time.

A *medical history* of high blood pressure, diabetes, and coronary artery or cerebrovascular disease has been cited in case reports but is not present in all patients in whom ION has developed. Moreover, hypertension and coronary artery disease are nearly always found in patients undergoing CABG but ION develops in few of these patients. No case-control data show an association of these factors with the development of ION in spine surgery patients. Case series show that many perioperative PION patients have few vascular disease risk factors.[107] In a prospective study of nonsurgical patients, ION was not associated with the presence of carotid artery disease.[136] Although a basis for the notion that perioperative ION is related to atherosclerosis is that the optic nerve vasculature would respond abnormally to changes in perfusion pressure (i.e., demonstrate disturbed autoregulation), this association has not been studied in humans, and animal data are sparse and inconclusive.[112]

AION has been described in patients who used *erectile dysfunction drugs.* Cause and effect has been debated,[137] but because of the possible increased risk and unknown impact on events in the perioperative period, it seems sensible to discontinue use of these agents 1 or 2 days before surgical procedures.

Because the sphenoidal sinus and ethmoidal cells are close to the orbit and optic nerve and the bone is fragile, *surgery on the nose and paranasal sinuses* poses a special risk of ocular damage. Retrobulbar hemorrhage may follow surgical damage to the fragile lateral wall of ethmoidal cells, the lamina papyracea. Blindness has occasionally been reported after endoscopic sinus surgery[138] due to direct surgical damage to the optic nerve, but indirect damage by compression from retrobulbar hematoma leading to ION is more commonly reported. Paresis of eye muscles (mostly the medial rectus muscle), including ptosis, is often seen; an ocular compartment syndrome may be present, necessitating immediate surgical decompression to preserve vision.[70] The outcome is poor; in only one case was blindness temporary,[139] whereas all other reported cases of retrobulbar hematoma resulted in permanent blindness. The anesthesiologist should maintain a high degree of vigilance for possible retrobulbar hemorrhage so that, if present, rapid surgical decompression can be accomplished.

In summary, the pathogenesis of perioperative ION is incompletely understood. Multiple factors that could contribute are frequently present in patients undergoing open-heart surgery, spine surgery, or head and neck operations. A patient may have anatomic variation and abnormal autoregulation in the optic nerve, but these anomalies are currently undetectable in the preoperative period. Preexisting as well as intraoperative factors may interact in an unpredictable fashion and lead to ION. Clinicians should be aware of the higher risk of visual loss with prolonged spine surgery with the patient positioned prone and in which large blood loss is anticipated. Although there is concern regarding factors such as blood pressure and fluid resuscitation during lengthy spine surgery, further studies are necessary to gain a better understanding of the mechanisms leading to ION in the perioperative period.

Prognosis, Treatment, and Prevention

Unfortunately, there is no proven treatment of ION. There are a few case reports of the outcome of attempts to treat perioperative ION. Williams and coworkers[102] reviewed the attempted treatments. Acetazolamide lowers IOP and may improve flow to the optic nerve head and retina.[140] Diuretics such as mannitol or furosemide reduce edema. In the acute phase corticosteroids may reduce axonal swelling, but in the postoperative period they increase the risk of wound infection. Because steroids are of unproven benefit, their use must be carefully weighed. Increasing ocular perfusion pressure or hemoglobin concentration may be appropriate when ION is found in conjunction with significant decreases in blood pressure and hemoglobin concentration. Maintaining the patient in a head-up position if increased ocular venous pressure is suspected may be advantageous. But its use has to be balanced against decreased arterial supply with the head-up position. Similarly, IOP should be lowered if an increase is documented. Clearly, if a patient has visual loss from ocular compartment syndrome, immediate decompression (lateral canthotomy) is indicated.

In their review of perioperative PION reports in the literature, Buono and Foroozan summarized the lack of proof that treatment altered the course of PION.[108] In a few anecdotal case reports, increasing blood pressure or hemoglobin, or applying hyperbaric oxygen, improved visual outcome.[103] The use of neuroprotective agents or drugs that lower IOP, valuable in theory, has never been shown to result in improvement.[141] Stevens and associates, who compiled a report of ION in patients after spine surgery, showed apparent improvement of vision in two patients when anemia and hypotension were corrected. One patient demonstrated partial improvement that subsequently regressed, and one patient showed more clear signs of improvement.[3] However, as Buono and Foroozan mentioned, it is difficult to ascertain if improvement came from treatment, because some patients recover vision spontaneously after PION.[108]

Prevention strategies depend on the status of the patient's optic nerve circulation, which is not known preoperatively and which cannot be monitored intraoperatively at present. Some general recommendations could be made for spine surgery, but whether any of these can prevent ION remains unknown at this time.

The head should be positioned neutral relative to the back, and head-down positioning is discouraged. In patients with

poorly controlled hypertension or significant atherosclerosis, maintaining systemic blood pressure near baseline seems sensible. Recommendations to maintain blood pressure have to be weighed against possible surgical needs for deliberate hypotension to decrease blood loss and maintain adequate operative exposure. In cardiac surgery, there are special considerations regarding the optimal systemic perfusion pressures to be maintained during CPB. In addition, it is evident that arterial blood pressure management is only one part of the care of the anesthetized patient, considering, of course, the entire patient and not the optic nerve alone. Increasingly, anesthesiologists are encountering patients whose hypertension is controlled with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers, often together with β-adrenergic blockers or calcium channel blockers. These patients frequently become hypotensive intraoperatively, and treatment of hypotension may required.[142] In situations in which blood pressure declines intraoperatively, particularly during spine surgery, vasopressors may be required. Patients may be refractory to ephedrine and Neo-Synephrine and require vasopressin to maintain blood pressure.[142] There are systemic risks of increasing blood pressure with vasoactive agents or by infusion of intravenous fluids, such as decreased renal, liver, and intestinal perfusion, congestive heart failure, and myocardial ischemia. These risks are important considerations in decisions regarding the appropriate range for blood pressure and fluid resuscitation requirements.[143]

Whether hematocrit should be maintained at or near its baseline value is controversial. However, although scientific evidence to guide practice is incomplete, anesthesiologists are advised to be cautious during simultaneous deliberate hypotension and hemodilution to hematocrit less than 25%. Whereas contemporary practice is to conserve blood by initially replacing lost blood with fluids, the effect of such hemodilution will often be a large fluid resuscitation, in some instances further amplifying an already high volume resuscitation, particularly in repeat operations for spine fusion, which typically involve large fluid and blood requirements. A relatively "dry" fluid strategy has been tested in abdominal surgery, but its use is controversial, and outcomes have not been tested in any other surgery.[144] Either earlier blood replacement or greater use of colloids may potentially decrease the volume of infused crystalloids, although the impact of this practice on the occurrence of visual loss is not known. Withholding fluids is inadvisable because of many other risks, including multiple organ failure.[143]

Another strategy not under the direct control of the anesthesia provider is to consider staging of complex spine procedures. However, in some instances the anesthesiologist may be able to persuade a surgeon to follow a less ambitious surgical plan. This decision requires an assessment of the associated risks of multiple surgeries (infection, spinal instability) but may significantly shorten the duration of each procedure. However, ION has still occurred despite use of staging.

A summary of recommendations of the ASA Task Force on Perioperative Blindness that is applicable to patients undergoing spine fusion surgery appears in Box 90-1. The advisory has been endorsed or supported by the North American Neuro-ophthalmological Society and the North American Spine Society.[116]

Whether patients should be warned about the possibility of ION during the process of informed consent, especially those undergoing apparently higher-risk operations such as CABG and complex instrumented spinal fusion surgery, is controversial. The Task Force recommended considering informing high-risk patients, that is, those undergoing prolonged spine fusion surgery with large anticipated blood loss, about this risk.[116] This is difficult to accomplish in the often few rushed minutes of a preanesthetic interview on the day of surgery, typical of modern anesthetic practice in the United States. Accordingly, anesthesiologists may wish to consider requesting that the surgeon discuss the possible complication at an earlier, more relaxed preoperative visit.

Box 90-1 Recommendations of the ASA Task Force on Perioperative Blindness

The consensus of the Task Force is that a high-risk patient's vision should be assessed when the patient becomes alert (e.g., in the recovery room, intensive care unit, or nursing floor). If there is concern regarding potential visual loss, an urgent ophthalmologic consultation should be obtained to determine its cause. Additional management may include optimizing hemoglobin or hematocrit levels, hemodynamic status, and arterial oxygenation. To rule out intracranial causes of visual loss, consider magnetic resonance imaging. The Task Force believes that there is no role for antiplatelet agents, steroids, or intraocular pressure–lowering agents in the treatment of perioperative ischemic optic neuropathy.

- There is a subset of patients who undergo spine procedures while they are positioned prone and receiving general anesthesia who have an increased risk for development of perioperative visual loss. This subset includes patients who are anticipated preoperatively to undergo procedures that are prolonged, have substantial blood loss, or both (high-risk patients).
- Consider informing high-risk patients that there is a small, unpredictable risk of perioperative visual loss.
- The use of deliberate hypotensive techniques during spine surgery has not been shown to be associated with the development of perioperative visual loss.
- Colloids should be used along with crystalloids to maintain intravascular volume in patients who have substantial blood loss.
- At this time there is no apparent transfusion threshold that would eliminate the risk of perioperative visual loss related to anemia.
- High-risk patients should be positioned with the head level with or higher than the heart when possible. In addition, the head should be maintained in a neutral forward position (e.g., without significant neck flexion, extension, lateral flexion, or rotation) when possible.
- Consideration should be given to the use of staged spine procedures in high-risk patients.

Cortical Blindness

Complete cortical blindness is bilateral visual loss with an absence of optokinetic nystagmus and of the lid reflex response to threat.

The pupillary response, eye motility, retina, and optic nerve are normal. Complete blindness implies damage to both the left and right occipital cortex, whereas a more localized injury produces homonymous hemianopia.

Total blindness from bilateral occipital infarction is rare. Because the visual pathway travels through the parietotemporal lobes, a perioperative cerebrovascular accident affecting the internal carotid, or middle, basilar, or posterior cerebral arteries is the more common cause of cortical blindness. Yet because of collateral circulation, the degree of visual damage is difficult to predict.[145] About 80% of cases of cortical blindness postoperatively have followed cardiac or other thoracic surgery. Depending on the sensitivity of the neuropsychological testing, these patients frequently show evidence of postoperative neurologic sequelae.[146]

Initially, total cortical blindness is usually accompanied by signs of stroke in the parieto-occipital region. The patient may suffer agnosia, an inability to interpret sensory stimuli. Often, vision improves over time, with incomplete lesions in the visual field combined with visual disorientation. Pupillary reflexes are preserved and most of the visual field is restored within days, but impairment in spatial perception and in the relationship between sizes and distances may remain. Visual attention may be restricted, and images formed on all parts of retina may not be visualized at one time.

The incidence of cortical blindness after cardiac surgery was 10 in 808 CABG surgeries in one hospital, with brain scans in 5 patients showing occipital infarcts (see Chapter 60).[147] In a retrospective series of 700 CABG surgeries and valve replacements by a single surgeon, 2 patients had unilateral occipital cortical infarcts.[148] Shaw and colleagues[149] prospectively studied 312 patients who had undergone CABG surgery and found a 5% incidence of cortical blindness. At least 50% of the patients had associated neurologic deficits. In another study, the onset of visual deficits followed a time course similar to that of neurologic damage.[150] Among the largest studies of neurologic dysfunction after cardiac surgery is that of Roach and coworkers.[151] In a prospective study of 2108 patients who had CABG at one of 24 different hospitals, incidence of neurologic complications was 6%. Specific incidence of eye complications within this figure was not indicated. Results of subsequent studies are similar and have been reviewed by Newman and associates. Associated factors included age, unstable angina, diabetes, prior stroke or transient ischemic attack, previous CABG surgery, and history of vascular or pulmonary disease.[152] The incidence of visual disorders was not reported in any of these studies.

In case reports of cortical blindness, 55% of cases were reported after CABG surgery and 23% after other thoracovascular operations.[153] Cases have been reported in children. Hypotension was found in 45% of patients and anemia/hemodilution in 23%. Over half the patients had coronary artery disease, but cortical blindness was found in patients with a wide range of systemic disorders, including congenital heart disease, liver failure, postpartum pulmonary embolism, and hypercholesterolemia. Unfortunately, the time of onset of symptoms was not reported in about half the cases. For the remaining 50%, onset was within the first postoperative day. As would be expected, funduscopy was normal in virtually all patients when reported, except one, in whom AION was combined with cortical blindness. Visual defects were bilateral in all but one patient, who had a lesion near the lateral geniculate nucleus. The incidence of other objective neurologic findings was 38%. Confusion was present in 25% of patients. Visual outcome improved in 65% of cases.

Mechanism and Pathophysiology

Cortical blindness can result from global ischemia, cardiac arrest, hypoxemia, intracranial hypertension and exsanguinating hemorrhage, focal ischemia, vascular occlusion, thrombosis, intracranial hemorrhage, vasospasm, and emboli. If blood and oxygen deprivation persists long enough, the cellular energy supply ceases and a series of biochemical events are initiated that ultimately lead to cell death. The pathways responsible for neuronal injury in the cerebral cortex have been reviewed extensively.[154]

CABG surgery is the most common operation associated with cortical blindness, but the pathophysiology of cortical blindness after CABG surgery remains incompletely understood. The major source of brain and visual damage is believed to be embolism from the surgical field, such as fat and atheroma or microemboli of lipid and fibrin-platelet aggregates.[155] A high incidence of emboli in the retinal circulation of patients undergoing CABG surgery has been documented.[156] Patients with aortic atherosclerosis appear to be at particular risk.[151] Cerebral edema also may be responsible for cortical blindness, but a study of MRI of the brain soon after CABG surgery showed cortical swelling within 20 to 40 minutes that was not found on follow-up 1 to 3 weeks later, thus questioning its pathogenic role.[157] Edema may somehow contribute to the vague visual disturbances found in up to 25% of patients after CABG.[158] Another suspected factor is transient decreases in blood flow to border zones of perfusion between the middle and posterior cerebral arteries, especially in patients with preexistent cerebrovascular disease.[159]

Prognosis, Treatment, and Prevention

Visual recovery from cortical blindness may be prolonged, but previously healthy patients are likely to show a considerable degree of recovery. Therefore, when cortical blindness is accompanied by focal neurologic signs, treatment should be directed toward preventing progression of stroke. The optimal strategy to prevent neurologic injury during cardiac surgery remains controversial. Several different techniques have been advocated to decrease intraoperative manipulation of the aorta and embolization.[57,58] Adequate removal of air and particulate matter from the heart during valvular operations may decrease the risk of embolism. In patients younger than 70 years without evidence of cerebrovascular disease, the use of an arterial line filter during CPB significantly reduced the number of microemboli detectable by transcranial Doppler ultrasonography. The frequency of subtle neuropsychological and neurologic changes (including nystagmus) was also reduced. No visual defects were found in the study patients.[160] Maintenance of adequate systemic perfusion pressure may prevent episodes of hypoperfusion in patients with cerebrovascular disease, but no controlled studies have associated visual loss and perfusion pressure in open-heart surgery. The development of better transcranial Doppler techniques may enhance detection of embolic events. As yet, no proven neuroprotective agents whose use is feasible in these patients are available. Nonbypass heart surgery would be expected to avoid, but not eliminate, many embolic complications.[161]

Acute Glaucoma

Acute angle-closure glaucoma is a well-known disease that has been described rarely after general anesthesia. It usually occurs spontaneously and is more common in women and the elderly. Genetic predisposition, a shallow anterior chamber, and increased thickness of the lens are frequently found. The peak age for acute glaucoma is between 55 and 65 years.[162] Three case series in surgical patients have been reported. Gartner and Billet described acute angle-closure glaucoma in 4 of 3437 patients (0.1%) undergoing general or spinal anesthesia.[163] Subsequently, Wang and colleagues reported 5 cases in 25,000 surgical patients (incidence, 0.02%).[164] The highest incidence was found by Fazio and coworkers[165] after reviewing the records of 913 patients who had general or spinal anesthesia. Nine cases were detected, two of which were bilateral (1%). In these studies, no association was made between acute glaucoma and an anesthetic technique or drug.

Acute angle closure results in glaucomatous damage to the optic nerve and occurs when the passage of aqueous humor from the posterior to the anterior chamber is obstructed by apposition of the iris to the anterior surface of the lens. The pupil is mid-dilated, with an associated pupillary block. The diagnosis should be suspected in a patient with a painful red eye and cloudy or blurred vision, possibly accompanied by headache, nausea, and vomiting. This condition is often bilateral. It is distinguished from corneal abrasion, which also produces pain but without the papillary signs, increased IOP, subjective visual loss, and headache.[2] Symptoms may not appear for hours to days after a surgical procedure. Acute glaucoma is an emergency, and ophthalmologic consultation should be obtained immediately. Patients are treated with β-adrenergic antagonists, α-adrenergic agonists, carbonic anhydrase inhibitors, cholinergic agonists, and corticosteroids. Systemic analgesic agents are given as needed. A peripheral iridectomy should be performed later to create a permanent opening between the anterior and posterior chambers.[162]

Visual Changes after Transurethral Resection of the Prostate

Visual changes after transurethral resection of the prostate (TURP) have been recognized for nearly 40 years (see Chapter 65).[166] Changes appear alone or as part of a syndrome after excessive absorption of irrigating fluid (usually 1.5% glycine) with subsequent hyponatremia, cerebral edema, seizures, coma, and cardiac failure from fluid overload.[167] Although utilization of TURP is declining because of economic and regulatory constraints and noninvasive alternatives,[168] complications still occur. Absorption of the irrigant is the major source of nonsurgical complications. Determinants of the amount of irrigant absorbed include the duration of the resection, the extent of the opening of the prostatic venous sinuses, the hydrostatic pressure of the irrigation fluid, and venous pressure at the "irrigant-blood interface."[169] Hamilton-Stewart and Barlow disputed the effect of operative time; they found that a longer resection time did not increase absorption. The veins and capsule of a smaller prostate may be exposed earlier in the resection, so greater absorption during a quick resection leads to the same amount of irrigant absorption as slower absorption during a long resection.[170] Nonetheless, significant quantities of irrigant may be absorbed even if the surgeon believes that no venous sinuses are open, and the operator thus cannot predict or estimate the amount absorbed.

Signs and Symptoms

Visual deficits may occur during the resection, several hours after, or rarely on the second postoperative day as the patient awakens from a TURP-related coma.[171] The range of signs and symptoms is wide, from complete loss of light perception to more subtle defects. The first complaint may be visual halos and a blue visual hue.[172] Dilated pupils that are nonreactive to light, a normal IOP, normal extraocular muscle movement, and normal fundus examination without evidence of papilledema are the objective findings in these cases.[172] Visual changes may resolve over a few hours or persist for up to 80 hours.[171] Permanent visual loss has not been reported.

Mechanisms of Visual Dysfunction

Proposed mechanisms of the visual changes include cerebral edema,[173] glycine toxicity involving the retina and cerebral cortex,[172] ammonia toxicity,[174] and increased IOP.[175] Glycine, the smallest amino acid, enters cells primarily through a carrier-mediated process, but its rate of transport is relatively slow. It easily crosses the blood-brain barrier, and it depresses the spontaneous and evoked activity of retinal neurons and hyperpolarizes cells through blockade of chloride channels.[176] The highest glycine concentration is in the amacrine cells, inner plexiform, and ganglion cell layers of the retina.[177] Because of a profound effect on oscillatory potentials of the electroretinogram, the predominant site of action may be amacrine cells,[178] although other inner retinal cells are probably involved. Glycine altered visual evoked potentials in dogs and in humans, thus suggesting an effect on the optic nerve. The threshold for visual symptoms is a plasma glycine concentration over 4000 μmol/L.[179]

Hyponatremia/hypo-osmolality during TURP produces occipital cortical edema, but such an association has not been confirmed. Segmental vascular disease in the blood supply to the occipital cortex may have placed that portion of the brain at risk for swelling.[167] Ocular hypertension causes enlarged blind spots and paracentral scotoma. In the presence of water overload, it seemed logical that an increase in IOP is part of the TURP syndrome. Yet in a prospective study of 22 patients who had TURP, Peters and colleagues found no change in IOP in the patients with visual changes.[175] Such changes after TURP are transient and often associated with TURP syndrome. The most important means of prevention is to maintain intense vigilance to avoid excessive absorption of irrigating solution.

Visual Loss after Vitrectomy and Vitreal Gas Bubble Tamponade

Patients who have undergone vitrectomy with perfluorocarbon gas tamponade (C_3Fl_8) are at risk of gas bubble expansion and loss

of vision from acutely increased IOP (see Chapter 75). Patients anesthetized for a subsequent surgical procedure with gas mixtures containing N_2O after vitrectomy sustained retinal vascular occlusion from acute gas bubble expansion. N_2O anesthesia affects the size of the intraocular gas bubble. Wolf and coworkers showed that N_2O and oxygen resulted in a more than threefold increase in SFl_6 gas bubble volume, compared with a 50% increase with air ventilation and 35% increase with oxygen ventilation alone.[180] Perfluorocarbon gas remains in the eye for at least 28 days. Visual loss has been reported with N_2O anesthesia administered as long as 41 days after vitrectomy and gas bubble tamponade. Therefore, patients should wear a warning tag to alert the anesthesiologist to the presence of the gas bubble in the vitreous, and N_2O should not be used in patients who have had recent vitrectomy and gas bubble tamponade.[181,182]

Conclusion

Visual loss can result in the perioperative period from retinal arterial occlusion, ION, cortical blindness, or acute glaucoma. Visual loss after TURP is transient; visual loss in patients anesthetized with N_2O after a vitrectomy and placement of a gas bubble tamponade may be permanent. The most serious injuries that are likely to result in blindness are retinal arterial occlusion and ION. Even if unintended pressure on the eye is avoided, these complications may still occur, particularly after spine, cardiac, or head and neck surgery. The risk factors for ION in particular remain incompletely explained.

Acknowledgment

Some of Dr. Roth's research on this topic is supported by National Institutes of Health Grant EY10343. Dr. Roth discloses that he has provided expert witness evaluation and testimony in cases of perioperative visual loss on behalf of patients, hospitals, and health care providers.

91 Overview of Anesthesiology and Critical Care Medicine

Key Points

1. By the year 2030, only 35% of the intensivists needed will be available to staff intensive care units.
2. Mandatory intensivist consultation may reduce intensive care unit mortality by as much as 29%.
3. Cortisol replacement, tight glycemic control, and activated protein C are actively being studied in randomized controlled trials as therapy for sepsis.
4. Patients with acute lung injury or acute respiratory distress syndrome should be mechanically ventilated with tidal volumes of 6 mL/kg of ideal body weight.
5. Without liver transplantation, mortality from acute liver failure is high and mainly due to multisystem organ failure, sepsis, and cerebral edema.
6. Earlier institution of dialysis and higher filtration volumes appear to be associated with reduced mortality among patients with acute renal failure.
7. Quality improvement initiatives can reduce nosocomial infections, mortality, and cost.
8. Proposals to prevent ventilator-associated pneumonia include maintenance of gastric pH with sucralfate, positioning the head of the bed at 30 degrees, and subglottic aspiration of secretions.
9. A comprehensive approach to central venous catheter insertion, including ultrasound guidance, maximum sterile barrier precautions, and antibiotic-coated catheters, can reduce the rate of catheter-related bloodstream infections.

The practice of critical care medicine, which originated in the 1940s with anesthesiologists providing life support to patients with polio, has undergone revolutionary changes. The development of new equipment, procedures, and medications has enabled intensivists to treat critically ill patients and support them through increasingly invasive procedures. In the past decade, another revolution has taken place, the introduction of evidence-based medicine into intensive care unit (ICU) practice. In this chapter we discuss the structure of ICU staffing, including studies examining the value of intensivist staffing. We then review how intensivist staffing may lead to improved outcomes, specifically through the implementation of evidence-based practice. Particular attention is paid to the implementation and cost-effectiveness of new clinical practices. Finally, we review the management of some common diagnoses that are encountered while caring for critically ill patients.

Intensive Care Unit Organization

With an aging population and increasing availability of medical technology, ICUs have become a critical component of modern hospital care. It is estimated that 0.5% to 1% of the U.S. gross domestic product is spent on critical care.[1] Given the magnitude of this expense, extensive research has focused on how the most cost-effective care can be delivered. Although ICUs started as open wards where any physician could admit patients, they have increasingly become managed. Most ICUs now have a designated medical director who is responsible for overall management of patient care and policies.

Role of the Medical Director

Each ICU should have a physician who is board certified or board eligible in critical care medicine to function as medical director.[2] The role of the medical director is to ensure the quality and safety of patient care in the ICU. Responsibilities often include patient triage decisions, education of house staff, development of clinical protocols, and improvement of performance. Anesthesiologists frequently serve as medical directors, primarily of surgical ICUs. As hospital-based physicians, anesthesiologists are particularly well placed to appreciate the issues that affect patient care and efficient flow of patients from operating rooms through the ICUs. In 1994, the Society of Critical Care Medicine described the seven organizational duties of an ICU administrator[3]:

1. Triage of admissions and discharges
2. Development of treatment protocols or guidelines
3. Collection of data
4. Involvement in unit budget approval
5. Updating of equipment and unit practices
6. Promotion of efficient use of material and personnel resources
7. Responsibility for coordination and dissemination of continuing education of hospital- and ICU-based personnel

Because of the increasing importance of the medical director and the time commitment required, salary support should be provided by the hospital to allow adequate investment of time in the position.

Staffing

The Committee on Manpower for Pulmonary and Critical Care Societies (COMPACCS) was commissioned by the American Thoracic Society, the American College of Chest Physicians, and the Society of Critical Care Medicine to determine current patterns of care of critically ill patients. More specifically, the committee examined the current and projected demand for critical care services and the supply of physicians based on current supply and training. The survey identified that intensivists provided care to 37% of all ICU patients in American hospitals in 1997.[4] The demand for intensivists is expected to increase, with supply being equal to 35% of demand by the year 2030 (Fig. 91-1). Table 91-1 describes the contribution of various specialties in providing critical care services.

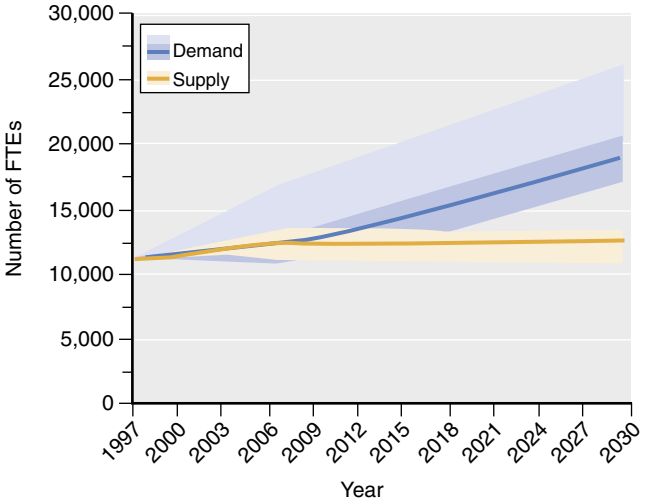

Figure 91-1 Forecast of supply and demand for intensivists through 2030. FTE indicates full-time equivalent. The *lines* represent the base model, whereas the margins of the *shaded areas* represent the widest upper and lower bounds of the sensitivity analysis. *(From Angus DC, Kelley MA, Schmitz RJ, et al: Current and projected workforce requirements for care of the critically ill and patients with pulmonary disease. Can we meet the requirements of an aging population? JAMA 284:2762-2770, 2000.)*

Anesthesiologists in Critical Care Medicine

Although anesthesiologists originated critical care medicine, they represent a shrinking percentage of critical care physicians. The COMPACCS survey, performed between 1996 and 1999, found that anesthesiologists accounted for only 6.1% of all intensivists in the workforce,[4] even though they are particularly well trained to manage critically ill patients and do so on a regular basis in the operating room. A number of factors, however, have led to diminishing numbers of anesthesiologists practicing in the ICU. This trend comes at a time when there is an increasing need for intensivists. The most recent data available from the Accreditation Council for Graduate Medical Education show that there are 53 anesthesia trainees in 52 critical care medicine fellowships whereas there are 1087 pulmonary/critical care medicine trainees in 128 fellowships.[5]

The reason for decreasing representation of anesthesiologists in critical care is multifactorial. Reimbursement for critical care services is generally less than that for surgical anesthesia services. Subspecialty training in critical care medicine for anesthesiologists creates a unique situation in which additional subspecialty training results in lower compensation. In Europe, where there is not such a payment discrepancy between the operating room and the ICU, anesthesiologists provide the majority of critical care services.[6] The American Board of Anesthesiology and American Society of Anesthesiologists have begun to address the diminishing role of anesthesiologists in critical care medicine. Proposed changes include an increasing component of training in critical care medicine during anesthesia residency. There are also proposals for "experimental residencies" that will offer training for anesthesia and critical care concurrently in a blended residency/fellowship.

Rapid-Response Teams

Rapid-response teams (RRTs) were initially developed to identify and treat patients exhibiting physiologic deterioration on the general care hospital floor. The premise was that if appropriate intervention could be initiated early enough, a critical event such as cardiac or respiratory arrest could be prevented. RRT programs can consist of a myriad of personnel ranging from physicians, nurses, and respiratory therapists to pharmacists. A large number of articles have been published on RRT programs, but most are descriptive. Only a handful have compared outcomes between control and intervention groups.[7] Among the five observational studies that examined in-hospital mortality after institution of an RRT program, two studies reported a statistically significant improvement in mortality,[8,9] two had a lower but nonstatistically significant reduction in mortality,[10,11] and one reported equivocal data.[12] Of the two randomized studies looking at in-hospital mortality and RRT programs, one based from a single institution found a significant result favoring RRT programs (odds ratio of mortality, 0.52; 95% confidence interval [CI], 0.32 to 0.85),[13] but the larger multicenter study was unable to show a significant benefit (odds ratio of mortality, 1.03; 95% CI, 0.84 to 1.28).[14]

Despite the paucity of existing data, several organizations have advocated the implementation of RRT programs. The Institute for Healthcare Improvement added RRT programs as one of its six interventions for the 100,000 Lives Campaign,[15] and the

Table 91-1 Characteristics of the Critical Care and Pulmonary Specialist Workforce

Characteristic	Pulmonary*	Internal Medicine†	Anesthesiology	Surgery	All
Total number (%)	8080 (78.9)	1220 (11.9)	620 (6.1)	324 (3.2)	10,244

*Includes physicians whose only specialty practice was pulmonary medicine and physicians who practiced both pulmonary and critical care medicine.
†Includes internal medicine physicians who practice critical care but do not practice pulmonary medicine.
‡Includes Veterans Affairs staff.
Data from Angus DC, Kelley MA, Schmitz RJ, et al: Caring for the critically ill patient. Current and projected workforce requirements for care of the critically ill and patients with pulmonary disease: Can we meet the requirements of an aging population? JAMA 284:2762-2770, 2000.

Joint Commission on Accreditation of Healthcare Organizations is making RRT programs one of its patient safety goals.[16] Many hospital organizations have invested in these teams because of public scrutiny of patient safety. The critical care service is most often asked to staff these teams, and they represent an opportunity for anesthesia critical care providers.

Although the rationale behind RRT programs seems logical, other approaches to achieve the same end point may be equally or more cost-effective. The presence of hospitalists, nurse practitioners, nurses, physician assistants, or automated monitoring systems may be viable alternatives.[7] It could also be that the benefit of the RRT program lies not in the availability of the team but rather in education of staff on how to recognize physiologic deterioration and a patient who is in trouble.[17] Ultimately, each institution needs to critically review its own system for taking care of patients deteriorating on the medical or surgical floor and determine what interventions would be the most beneficial for its patients.

Structure: Open versus Closed Intensive Care Units

ICUs are typically described by their patient population (i.e., medical or surgical), and they are now described by their staffing structure (i.e., open or closed). Most ICUs in the United States are classified as open, which means that a variety of physicians admit patients to the ICU, where they are cared for by their primary physician, with or without the assistance of a critical care specialist. The increasing complexity of caring for critically ill patients, however, has led to recognition of the need for dedicated critical care specialists.

The COMPACCS survey classified ICUs in four categories:

1. ICUs with full-time intensivists, where all or most care is delivered by the intensivist in a role greater than that of a consultant
2. The consultant intensivist model, whereby an intensivist serves as consultant but does not have primary responsibility for patients
3. ICUs with multiple consultants, wherein multiple consultants serve the patient (e.g., a pulmonologist may provide ventilator management) but no one physician is identified as an intensivist consultant
4. The single-physician model, in which the primary physician provides all the care in the ICU without consultation from an intensivist or other consultants

ICUs in larger hospitals tend to have full-time intensivists, with smaller community hospitals more likely to use the single-physician model.[18] The reasons for this tend to be economic inasmuch as smaller ICUs may not have adequate patient volume to support a full-time intensivist. What is the evidence that a particular ICU structure improves patient outcomes? Many studies are small, retrospective reviews of the impact of the addition of an intensivist to an existing ICU. For example, Carson and colleagues[18] performed a prospective cohort study of a single ICU that made the transition from an open to a closed form. They found that risk-adjusted mortality scores decreased in the closed ICU despite higher severity of illness and without additional resource use. Ghorra and coworkers[19] showed in a retrospective review comparing two time periods that mortality and complications were decreased when their open surgical ICU was converted to a closed model. These two studies suggest that there may be an advantage to a closed ICU structure, but a truly randomized, prospective study comparing open with closed ICUs has never been completed.

Rather than "open" versus "closed" ICU structure, the probable determinant of quality care is the presence of intensiv-

ists to implement patient safety and quality programs that reduce patient harm and, in return, improve efficiency. This structure leverages all the personnel present in the ICU to improve outcomes.[20]

The Leapfrog Group Recommendations

Despite the lack of definitive data about the preferred structure of ICUs, there is much more evidence supporting the role of the intensivist in the management of critically ill patients. For general and subspecialty patient populations, most studies suggest that critically ill patients should be cared for by an intensivist. For example, Pronovost and associates[21] studied whether the organizational characteristics of ICUs could influence outcome in patients undergoing surgery for an abdominal aortic aneurysm. They analyzed almost 3000 patients who underwent repair in the state of Maryland and found that in risk-adjusted patients, not having daily ICU rounds by an intensivist was associated with a threefold increase in mortality.[21] In addition to increased mortality, the patients not seen by an intensivist also had an increased risk for cardiac arrest, renal failure, septicemia, platelet transfusion, and reintubation.

In a large meta-analysis examining physician staffing and outcomes of critically ill patients, Pronovost and colleagues[6] compared "low-intensity" ICU staffing consisting of no or elective intensivist consultation with "high-intensity" staffing consisting of mandatory intensivist consultation or a closed ICU. This study found that the relative risk for hospital mortality was reduced by 29% and the relative risk for ICU mortality was reduced by 39% with high-intensity staffing. Table 91-2 demonstrates the overall impact of intensivist staffing on ICU mortality. This and other studies have led to significant consumer and regulatory pressure mandating that intensivists staff all ICUs. The Leapfrog Group (www.leapfroggroup.org) was established by the Business Roundtable, which consists of the chief executive officers of several large corporations. These corporations purchase health insurance for more than 34 million health care consumers and therefore have considerable influence on health policy. The Business Roundtable established the Leapfrog Group to "work with medical experts throughout the United States to identify problems and propose solutions that it believes will improve hospital systems that could break down and harm patients." One of the first recommendations by this group was that trained intensivists should staff ICUs. Although this recommendation has a strong evidence base, the other Leapfrog recommendations are not as strongly supported.[29] In addition to the factors discussed earlier, these pressures will create a significant demand for trained intensivists.

Despite evidence supporting intensivist staffing of ICUs, the number of intensivists from all areas of training is inadequate to meet this mandate. Recognition of this shortage has led to innovations such as the "eICU," whereby a small number of intensivists can monitor and consult on a large number of ICU beds from a remote location. Indeed, the eICU is stated to meet the requirements of the Leapfrog Group.

Table 91-3 Levels of Evidence

Level	Description
1a	Systematic review of randomized, controlled trials (with homogeneity)
1b	Individual randomized, controlled trial with a narrow confidence interval
1c	All-or-none trial*
2a	Systematic review of cohort studies (with homogeneity)
2b	Individual cohort study (including low-quality randomized, controlled trials)
2c	"Outcomes" research
3a	Systematic review (with homogeneity) of case-control studies
3b	Individual case-control study
4	Case series (and poor-quality cohort and case-control studies)
5	Expert opinion without explicit critical appraisal or based on physiology, bench research, or "first principles"

*Met when all patients died before the treatment became available but some now survive with it or when some patients died before the treatment became available but none now die with it.
Levels of evidence were provided by the Centre for Evidence-Based Medicine, Oxford, UK. Available at http://www.cebm.net/levels_of_evidence.asp/ Accessed December 25, 2003.

Quality Measurement in Critical Care

Quality of Evidence

To determine the value of a clinical intervention, it is important to evaluate the quality of the study on which it is based. A number of groups have developed criteria with which evidence can be graded. The Oxford Centre for Evidence-Based Medicine has strict criteria for grading the level of evidence. These criteria are described in Table 91-3. After the evidence level has been determined, specific practices can be graded by using the previously

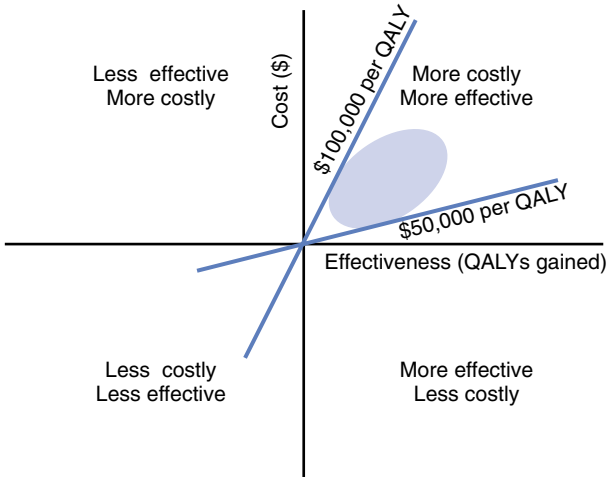

Figure 91-2 Graphic display of the cost-effectiveness of a theoretical treatment that adds additional cost but is effective in extending quality-adjusted life. A quality-adjusted life-year (QALY) is a year of life gained for which the quality of life is judged to be acceptable. The *lines* represent cost per QALY. Cost per QALY depends on the patient population that receives the intervention. For example, patients with a low severity of illness receiving activated protein C have a much higher cost per QALY than do those with a higher severity of illness.

described criteria. Only through rigorous clinical experimentation can we determine practices that will improve the outcomes of critically ill patients. Equally important is analysis of the cost-effectiveness of these interventions. Implementation may require fiscal and personnel expenditure, and it is the role of the medical director to convince hospital administrators of the cost-effectiveness of new interventions. Figure 91-2 describes the cost-effectiveness relationship for a theoretical treatment.

Care of critically ill patients has been revolutionized by technology and drug development, but an equally important contribution has come with the application of evidence-based medicine to critical care practice. Although critical care initially focused on trying to restore homeostasis, there is increasing recognition that normal physiology is not always the most desirable therapeutic target. An important example of this principle is found in the management of patients with acute respiratory distress syndrome (ARDS). When patients with ARDS are mechanically ventilated with higher tidal volumes (12 mL/kg ideal body weight), they improve their oxygenation ratio.[30] However, these patients had significantly higher mortality rates than those mechanically ventilated with lower tidal volumes (6 mL/kg ideal body weight). This example and others illustrate the need for randomized, prospective trials of new and existing therapies.

Implementation of Evidence-Based Practice

Application of evidence-based practice resulting in protocols to standardize patient care has been shown to improve the efficiency of care and reduce resource use.[31,32] Hospitals must customize the protocols to fit their practice, but protocols should not be used in place of good clinical judgment. They should be used as a complementary tool, and physicians should be able to justify departures from the protocol. These departures should be used to further refine the protocol so that it is not viewed as a static entity, but rather as an evolving guideline.[33] For protocols to be effective, the hospital must be willing to invest the resources necessary for implementation, such as providing adequate staffing. For example, inadequate nurse-to-patient ratios have been associated with a longer period of mechanical ventilation for patients.[34] Key personnel such as physicians, respiratory therapists, and nursing staff should be enlisted so that the entire patient care team helps define the standards on which the protocol is based.

Perhaps the most difficult task in the application of evidence-based practice is determining whether a given patient with a particular clinical scenario will benefit from that practice. Are there pathophysiologic differences in a particular patient's illness that may lead to a diminished treatment response? Are there important differences in systems or provider compliance that may diminish the safety or efficacy of the treatment? Does a patient have comorbid conditions that would lead to exclusion from a clinical trial? Despite these limitations, when applied to large populations of patients, these practices decrease mortality and usually reduce cost.

Severity-of-Illness Scoring Systems

Over the past 20 years, numerous efforts have been made to design a model that can objectively quantify physiologic derangements and comorbid conditions to estimate mortality, length of stay, and ICU resource use. The systems allow comparison between groups of patients and provide a means to adjust for differences between groups in nonrandomized or observational studies. Most models estimate the risk for hospital mortality from clinical variables measured near or at the time of ICU admission. Among the scoring systems, the most accepted and used in clinical studies are the Acute Physiology and Chronic Health Evaluation (APACHE), the Simplified Acute Physiology Score (SAPS), and the Mortality Prediction Model (MPM). These scoring systems and the variables measured are listed in Table 91-4.

Acute Physiology and Chronic Health Evaluation Scoring System

The APACHE system was the first illness severity model widely used by ICUs. It was developed in the early 1980s and involved a complex measure of 34 physiologic variables and a chronic health evaluation.[35] The score correlated well with mortality, but it was difficult to administer and complex to score. APACHE II was developed as a simplification of the first version and uses only 12 physiologic variables, patient age, and chronic health evaluation.[36] A 1-point increase in score equates to an increase of about 1% in mortality, but it cannot be transformed to a specific risk for death because the scoring system does not take into account the admission diagnosis. For example, an asthmatic with a score of 25 has mortality different from that of a patient with severe sepsis and the same score.[37] APACHE III was developed in 1991 and now includes weighting for ICU readmission, patient location, and hospital length of stay before ICU admission.[38] The score also consists of points for 17 physiologic abnormalities, age, and chronic health evaluation. This system is complex, more difficult to administer, and proprietary.

Simplified Acute Physiology Score

First reported in 1984, the variables collected for SAPS represent the most deranged values in the first 24-hour period in the ICU.

Table 91-4 Description of Scoring Systems

APACHE II Score = Acute Physiology Score + Age Points + Chronic Health Points									
	+4	**+3**	**+2**	**+1**	**0**	**+1**	**+2**	**+3**	**+4**
Rectal temperature (°C)	≥41	39-40.9		38-38.9	36-38.4	34-35.9	32-33.9	30-31.9	<29.9

Intracranial mass effect
Mechanical ventilation
Age

AIDS, acquired immunodeficiency syndrome; APACHE, Acute Physiology and Chronic Health Evaluation; CPR, cardiopulmonary resuscitation; Cr, creatinine; GI, gastrointestinal; Hct, hematocrit; HR, heart rate; MAP, mean arterial pressure; MPM, Mortality Prediction Model; RR, respiratory rate; SAPS, Simplified Acute Physiology Score; WBC, white blood cell.

Its second iteration, SAPS II, was published in 1993.[39] This score is composed of 12 physiologic variables, patient age, type of admission, and variables related to specific diseases such as hematologic malignancy, metastatic cancer, and acquired immunodeficiency syndrome. Unlike APACHE, the variables used in SAPS are readily available, and the calculations are simple. However, similar to APACHE, there is no correction for the patient's admitting diagnosis.[37]

Mortality Prediction Model

The most recently developed scoring system, MPM II, is less physiologically based than APACHE or SAPS. Each variable is entered as present or absent ("1" or "0"), except age, which is entered in years. The scoring system was designed to estimate mortality risk at 24 and 48 hours after ICU admission, so it gives a revised risk based on the patient's response to resuscitation and early treatment.[40]

Accuracy of Scoring Systems

There are subtle differences between APACHE, SAPS, and MPM in terms of their ability to predict mortality, but no data suggest that one system is substantially better than the others.[41,42] In comparison to a physician's clinical judgment, the data are mixed. Some studies favor the clinician,[43] whereas others favor the scoring system.[44,45] Overall, neither physicians nor scoring systems are sufficiently accurate to rely on these predictions in triage or end-of-life decisions. The scoring systems facilitate comparisons across ICUs and patient populations and allow us to characterize and stratify a patient population for research purposes. They cannot be used for decision-making in individual patients because the systems were designed to predict outcome in a population of patients. If the probability of mortality is 0.53, it means that 53 of 100 patients will be expected to die, but the scoring systems cannot distinguish which individual patient will be in the 53 who will die or the 47 who will live.

Organ Dysfunction Scores

Organ dysfunction scores may be measured daily, unlike prognostic models, which are usually performed near or at the time of ICU admission. They have the ability to capture the dynamic nature of a patient's clinical course in the ICU. These scores and the measured variables are listed in Table 91-5.

Sequential Organ Failure Assessment Score

Developed in 1994 initially as a sepsis-related organ failure assessment, the Sequential Organ Failure Assessment (SOFA) score was renamed when it was found to be applicable to nonseptic patients.[46] This system includes six organ systems (pulmonary, hematologic, hepatic, cardiovascular, central nervous, and renal), records the most abnormal value on each day, and scores the abnormality from 1 (normal) to 4 (most abnormal).

Multiple Organ Dysfunction Score

Published in 1995, the Multiple Organ Dysfunction Score (MODS) includes six organ systems, records the most representative value of the day, and scores the abnormality from 0 (normal) to 4

Table 91-5 Sequential Organ Failure Assessment (SOFA) and Multiple Organ Dysfunction Score (MODS) Scoring Systems

SOFA Scoring System				
Variable	**1**	**2**	**3**	**4**
Pao_2 (mm Hg)	<400, ± MV	<300, ± MV	<200, + MV	<100, + MV
Platelet count ($10^3/mm^3$)	<150	<100	<50	<20
Cardiovascular	MAP <70 mm Hg	Dopa/dobutamine ≤5 μg/kg/min	Dopa >5 μg/kg/min, Epi/NE ≤0.1 μg/min	Dopa >15 μg/kg/min, Epi/NE >0.1 μg/min
Glasgow Coma Scale score	13-15	10-12	6-9	<6
Bilirubin (mg/dL)	1.2-1.9	2-5.9	6-11.9	> 12
Cr (mg/dL) or UO	1.2-1.9	2-3.4	3.5-4.9 or <500 mL/day	>5 or <200 mL/day

MODS Scoring System					
Variable	**0**	**1**	**2**	**3**	**4**
Pao_2/FIo_2	>300	226-300	151-225	76-150	≤ 5
Platelet count ($10^3/mm^3$)	>120	80-120	50-80	21-50	≤20
Bilirubin (mg/dL)	≤1.2	1.2-3.5	3.5-7.0	7.0-14	≥14
HR × CVP/MAP	≤10	10.1-15	15.1-20	20.1-30	>30
Glasgow Coma Scale score	15	13-14	10-12	7-9	≤6
Cr (mg/dL)	≤1.1	1.1-2.3	2.3-4	4.0-5.7	>5.7

Cr, creatinine; CVP, central venous pressure; Dopa, 3,4-dihydroxyphenylalanine; Epi, epinephrine; HR, heart rate; MAP, mean arterial pressure; MV, mechanical ventilation; NE, norepinephrine; UO, urine output.

(abnormal).[47] MODS uses a pressure-adjusted heart rate rather than the dose of vasoactive agents administered, as used in the SOFA score. Another difference between scores is that SOFA uses urine output as the measure of renal dysfunction whereas MODS uses serum creatinine.

Accuracy of Organ Dysfunction Scores

Both organ failure measures (SOFA and MOD) give a more complete picture of the entire ICU course as opposed to the first 24 hours after admission. A potentially important application for organ dysfunction scores is their ability to capture the impact of a therapeutic intervention. For example, Vincent and colleagues[48] demonstrated more rapid resolution of cardiovascular dysfunction in patients who received drotrecogin alfa (activated) than in the group that received placebo. These scoring systems may also be used in innovative ways to predict long-term morbidity and help us move beyond survival as the sole measure of ICU outcome.

Management of Critically Ill Patients

The following sections examine the care of patients with some common diagnoses in critical care: sepsis, ARDS, renal failure, and hepatic failure. Many management plans have data supporting the use of protocol-base therapy. Several of these protocols are discussed in detail in Chapter 92. Others are introductory management ideas that may lead to integration into future protocols but are discussed here because of their importance in critical care.

Sepsis and Multisystem Organ Failure

Sepsis is the leading cause of death in critically ill patients in the United States and develops in 750,000 people annually.[1] Mortality from severe sepsis has remained steady at 30% to 50% despite improvements in critical care, including those discussed in this chapter.[49,50] The economic costs of sepsis are large, with annual expenditures totaling nearly $17 billion.[1] The high mortality rate and economic costs have led to considerable interest in the development of effective therapies for sepsis. As with other areas of medicine, adoption plus integration of new treatment strategies into routine clinical practice has been slow. After many years of unsuccessful clinical trials, randomized, controlled trials have begun to show efficacy. We now discuss three areas that have been intensively studied: cortisol replacement, tight glucose control, and activated protein C (APC).

Cortisol Replacement

With the recognition that severe sepsis represents a state of overwhelming inflammation, corticosteroids were among the first therapies tested in randomized trials of patients with sepsis. At large doses and with short courses, the studies showed a negative effect.[51,52] The adverse effects from large-dose steroids, commonly 30 mg/kg methylprednisolone, were an increased incidence of

gastrointestinal bleeding, secondary infections, and steroid psychosis. Annane and coworkers proposed a different hypothesis in 2002.[53] Prompted by studies showing significantly improved time to withdrawal of vasopressor therapy in patients with sepsis who received small doses of hydrocortisone over a longer period (>5 days),[54,55] they administered low-dose steroids for 7 days. All patients with septic shock received a short corticotropin test and then were randomized to receive hydrocortisone, 50 mg every 6 hours, plus fludrocortisone, 50 μg/day, or placebo. Their results showed that among patients who did not respond appropriately to the short corticotropin test, 63% in the placebo group versus 53% in the corticosteroid group died (P = .02). Vasopressor therapy was withdrawn in 40% of patients in the placebo group as opposed to 57% in the corticosteroid group (P = .001). Although there was no difference in adverse events between the groups, a slight, but not statistically significant trend toward increased mortality was noted in patients who did not have adrenal insufficiency as determined by the corticotropin test but who did receive glucocorticoids.[56]

Administration of steroids to patients with sepsis remains controversial. A large randomized trial recapitulating the study of Annane and coworkers has been completed and documents the lack of efficacy of even low-dose steroids and the association of increased infections with steroid administration.[56] The Corticosteroid Therapy of Septic Shock (CORTICUS) study was carried out to assess whether low-dose corticosteroids improve survival in patients with septic shock and sepsis. A total of 499 patients were enrolled over a period of 3 years from 52 European ICUs.[56] Patients received a tapering steroid regimen over an 11-day period, but no mineralocorticoids. The results were disappointing. The 28-day mortality rate in patients receiving low-dose steroids was not significantly improved from that in the placebo group (34% versus 31%, P = .57).[58]

In summary, large doses of corticosteroids should not be used in patients with severe sepsis. Although it initially appeared that low-dose steroids with mineralocorticoids may be beneficial, the results have not been reproducible in a large multicentered randomized study. One issue raised by these investigations was the role of etomidate in causing adrenal suppression. Patients who received etomidate for endotracheal intubation had worse outcomes, thus leading to suggestions that either etomidate not be used or if it is used, steroid replacement for several days be considered.[57]

Glycemic Control in the Critically Ill

Critically ill patients admitted to the ICU with severe injury or infection, such as burns, trauma, or sepsis, commonly enter into a hypermetabolic state. This state is associated with enhanced peripheral glucose uptake and use,[59] hyperlactatemia,[60] increased glucose production,[61] depressed glycogenesis,[62] and insulin resistance.[61] Glucose intolerance develops after uptake of glucose in skeletal muscle, adipose tissue, liver, and the heart becomes saturated,[63] and hyperglycemia occurs because of defective suppression of gluconeogenesis and resistance to the peripheral action of insulin. These mechanisms all work to generate a hyperglycemic state to satisfy an obligatory requirement for glucose as an energy substrate. The intensity of the metabolic response peaks several days after the initial insult and then diminishes as the patient recovers.[60] However, a prolonged hyperglycemic response may occur in patients who continue to have tissue hypoperfusion or persistent infection, which then predisposes them to progressive metabolic derangements and multisystem organ failure.

"Tight" Glycemic Control

Traditionally, hyperglycemia secondary to sepsis was viewed as a beneficial response because it promoted cellular glucose uptake when cells were energy deprived. A glucose concentration of 160 to 200 mg/dL was commonly recommended and was thought to maximize cellular glucose uptake without causing hyperosmolarity.[64,65] However, neutrophil function is impaired in patients with hyperglycemia because of decreased bacterial phagocytosis.[66] Hyperglycemia in diabetics is associated with an increased rate of postoperative infections.[67] Hyperglycemia is also associated with a poorer prognosis after stroke or head injury.[68,69] Better glycemic control (blood glucose <215 mg/dL) in diabetics with myocardial infarction has been shown to improve long-term outcome in several studies.[70,71]

van den Berghe and coworkers[72] hypothesized that even mild hyperglycemia (i.e., blood glucose level between 110 and 200 mg/dL) could be harmful by predisposing critically ill patients to increased morbidity and mortality. They performed a prospective, controlled study involving 1548 surgical ICU patients randomized to receive intensive insulin therapy (i.e., blood glucose maintained between 80 and 110 mg/dL) or conventional treatment (i.e., blood glucose maintained between 180 and 200 mg/dL). In patients who remained in the ICU for more than 5 days, intensive insulin therapy reduced the mortality rate from 20.2% with conventional therapy to 10% with intensive therapy (P = .005). The group receiving intensive insulin therapy also had a lower incidence of bloodstream infections (4.2% versus 7.8%, P = .003), renal failure requiring dialysis (4.8% versus 8.2%, P = .007), and critical illness polyneuropathy (28.7% versus 51.9%, P < .001). Patients in the intensive insulin group were also less likely to require prolonged mechanical ventilation and intensive care. The results of this trial make a persuasive argument for tighter glucose control, at least in surgical ICU patients.

Opponents of the use of strict glycemic control in critically ill patients argue that the risks of hypoglycemia should be seriously considered and that the therapeutic effect of insulin rather than glycemic control leads to the beneficial outcome. Insulin has multiple effects, including inhibition of tumor necrosis factor-α,[73] which triggers procoagulant activity and fibrin deposition and inhibits macrophage inhibitory factor, thereby contributing to endotoxemia and toxic shock.[74] To determine whether it was insulin effect or glycemic control, van den Berghe and colleagues[75] used multivariate analysis to reanalyze their previous data. It appeared that lowering of blood glucose levels rather than the actual amount of insulin given was most closely correlated with the beneficial reductions in mortality, polyneuropathy, and bloodstream infections. They reported no adverse effects from hypoglycemia in their study. Instead of the glucose level, the dose of insulin was found to correlate with the incidence of renal failure. Investigators thought that this difference might result from a direct effect of insulin on the kidney or the need for less exogenous insulin in patients with renal failure because insulin is cleared through the kidney. Finney and associates,[76] in a prospective, observational study, provided additional evidence that it was glycemic control rather than insulin administration that provided benefit. They examined the effects of glucose control in 523 patients admitted to a single surgical ICU. In this trial the primary determinant of a bad outcome was hyperglycemia rather than

hypoinsulinemia, and a lower mortality rate was associated with glycemic control rather than a protective effect of insulin administration. Increased insulin dosing resulted in an increased mortality rate across all ranges of glycemia. With regression analysis, their data also suggest that keeping blood glucose below 145 mg/dL may provide a survival benefit similar to that achieved with the "tighter" range of 80 to 110 mg/dL used by van den Berghe and colleagues.[75]

A major criticism of the original van den Berghe study was that it was performed on relatively homogeneous surgical populations. Recently, the same group published a follow-up study examining tight glucose control in 1200 medical ICU patients. The results showed reduced morbidity defined as a reduction in newly acquired renal injury, earlier weaning from mechanical ventilation, and earlier discharge from the ICU and the hospital, but no difference in mortality. With subgroup analysis, they were able to determine a mortality benefit from tight glucose control if the patient was admitted to the ICU for 3 days or longer (43% versus 52.5%, $P = .009$).[77] From the study design it is unclear whether intensive insulin therapy for less than 3 days causes harm or perhaps the benefit from intensive insulin therapy requires time to be realized.

A recent study was stopped early due to the increased incidence of hypoglycemia that occurs with tight glucose control.[78] Based on the current studies, it appears that improved glycemic control should be considered for critical care patients, but needs to be instituted carefully because of the risk of hypoglycemia. The optimal glucose target may not be the same for all patients and all clinical scenarios. A sample insulin titration order form used at the University of California, San Francisco, is provided in Figure 91-3.

Activated Protein C

Patients with severe sepsis have systemic inflammation resulting in coagulation abnormalities that range from subtle elevations in plasma D-dimer levels to frank disseminated intravascular coagulation.[79,80] Recognition that sepsis can cause microthrombosis and that patients with sepsis have low circulating levels of APC led to the investigation of APC as a specific therapy for sepsis.[81] APC is a naturally occurring anticoagulant that inactivates factors Va and VIIIa and prevents the generation of thrombin,[82] which is capable of stimulating multiple inflammatory pathways. Additional effects of APC include a permissive effect on thrombolysis that allows clearance of systemic microthrombi.[80] APC also decreases expression of tissue factor and can bind selectins, which activate neutrophils on the endothelial surface.[83] Recent data suggest that APC levels can predict outcome from multisystem organ failure, regardless of the inciting event.[84]

Recombinant human APC (Xigris, Eli Lilly, Indianapolis, IN) is the first pharmacologic drug that has demonstrated efficacy in the treatment of severe sepsis.[83] In a study of 1690 patients with severe sepsis randomized to receive APC or placebo, the mortality rate was 30.8% in the placebo group and 24.7% in the APC group ($P = .005$). Intravenous infusion of APC at 24 μg/kg/hr for 96 hours was associated with a 6.1% absolute reduction in the risk for death. The most important adverse effect was serious bleeding (3.5% versus 2%, $P = .06$), as would be expected because of its anticoagulant effect.[83]

APC is recommended for use in patients with severe sepsis, greater severity of illness (APACHE II score of ≥25), and a reasonable life expectancy if they survive the episode of sepsis.[85] The cost per quality-adjusted life-year gained by APC treatment was estimated to be about $33,000 for patients with an APACHE II score of 25 or higher and more than $958,000 for patients with an APACHE II score of less than 25. Caution is advised with the use of APC in patients with thrombocytopenia (platelet count <30,000) or a coagulopathy (international normalized ratio >3) because of the increased risk of bleeding.

Use of APC remains controversial.[86] A new randomized, placebo-controlled trial of Xigris is currently under way (clinicaltrials.gov, study No. NCT00279214)and may help finally determine the efficacy of this drug in the treatment of severe sepsis.

Acute Respiratory Failure

ICUs were first developed to manage patients with acute respiratory failure as a result of polio. Since then, management of patients with acute respiratory failure has been revolutionized by the development of modern mechanical ventilators. ARDS was first reported in adults in 1967 by Ashbaugh and coworkers.[87] They described 12 patients with acute respiratory distress, cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse bilateral infiltrates on chest radiography. Because this initial definition lacked specific criteria that could be used to identify patients for research, the American-European Consensus Conference Committee recommended new definitions in 1994.[88] The consensus definition included the following:

1. Acute onset
2. Bilateral infiltrates on chest radiography
3. Pulmonary artery wedge pressure of 18 mm Hg or less or the absence of clinical evidence of left atrial hypertension
4. Pao_2/Fio_2 ratio of 300 or less for acute lung injury (ALI) or Pao_2/Fio_2 ratio of 200 or less for ARDS

The first epidemiologic study to use this consensus definition reported an annual incidence of 13.5 per 100,000 people for ARDS in Sweden, Denmark, and Iceland.[89]

Treatment of ALI or ARDS is primarily supportive and consists of mechanical ventilation, which allows time for treatment of the underlying cause of the lung injury and for natural healing.[90] Until recently, most studies of ALI or ARDS reported a mortality rate of 40% to 60%, with death attributed to sepsis or multiorgan failure rather than primary respiratory causes.[91-93]

Several clinical trials have addressed one of the hallmarks of ALI or ARDS—decreased lung compliance. The definitive study on protective mechanical ventilation was reported in 2000 by the National Institutes of Health (NIH) ARDS network.[30] In this prospective study of patients with ALI, the mortality rate was reduced from 40% in patients receiving tidal volume ventilation of 12 mL/kg to 31% in those receiving 6 mL/kg. The low–tidal volume group also had more ventilator-free and organ failure–free days than the higher–tidal volume group did.[30] Several reasons have been postulated for the discrepancy between this study and the previous inconclusive studies.[94] First, the NIH study may have been better able to show a difference because it used lower tidal volumes than the other studies did. Second, the NIH study allowed treatment of respiratory acidosis with high respiratory rates or with sodium bicarbonate. Treatment of respiratory acidosis may have prevented deleterious effects. Third, the NIH study enrolled 861 patients, which was by far the largest study and

   - ☐ D10 W at _____ mL/hr (for patients with fluid restrictions or renal failure)
   - ☐ Other____ at _____ mL/hr
   - ☐ Add KCl _____ mEq/L (generally 20 mEq/L)
3. **Insulin Infusion Bags** ICU Concentration 1 unit/mL*
   Use 100 units of REGULAR human insulin in a 100 mL NS bag.* ***Before connecting to the patient**—Flush and discard the first 20 mL through tubing or whenever tubing is changed. Concentrated insulin infusion must be piggybacked with IV fluid chaser to ensure delivery.*
4. **Start Insulin Infusion Rate.** Blood glucose (BG) level must be ≥ 120 mg/dl before starting.

☐ If patient's normal insulin daily use is 0–30 units/day (or on diet, oral antidiabetic medications or no history of diabetes)	0.5	unit/hr
☐ If patient's normal insulin daily use is > 30 units/day	1	unit/hr
☐ Other (especially if BG > 300)	_____	units/hr

5. **Blood Glucose Goal:** 80–120 mg/dL (Follow monitoring parameters & dose adjustments on page 2)
6. **If the TPN or tube feeds are interrupted for longer than 30 minutes, start $D_{10}W$ at 50 mL/hr and notify MD about change and further action.**
7. **Converting or starting subcutaneous (SQ) insulin:** The first SQ dose should be administered 30 minutes prior to discontinuing insulin infusion (see transition plan for converting to subcutaneous insulin from insulin infusion).

Figure 91-3 Protocol for "tight" glycemic control in critically ill patients in use at the University of California, San Francisco. This protocol involves significant nursing intervention because changes in the infusion rate require rapid measurement of fingerstick glucose concentrations. Changes in the insulin infusion rate are based on the rate of change in glucose concentration over the preceding interval.

increased the statistical power to find a positive effect of low–tidal volume ventilation.

In a second study using the same patient database, Eisner and associates[95] did not find any evidence that the efficacy of the low–tidal volume strategy varied according to the clinical cause of ARDS. Although the mortality rate was highest (43%) in patients with sepsis, intermediate (36%) in patients with pneumonia and aspiration pneumonitis, and lowest (11%) in patients with trauma, there was no evidence of differential efficacy of low–tidal volume ventilation in different groups with ALI or ARDS. The investigators concluded that the recommendations for low–tidal volume ventilation should be applied to all patients with ALI or ARDS regardless of the inciting cause.

Important advances in the ventilatory management of patients with ALI or ARDS have led to improvements in the care of ICU patients. With the impressive 9% reduction in mortality demonstrated by the ARDSnet trial, low–tidal volume mechanical ventilation should be considered the standard of care for patients

ICU INSULIN DOSE ADUSTMENT TABLE

ICU Blood Glucose (BG) GOAL: 80–120 mg/dL

A. If current BG is <60, then

- **STOP** insulin infusion
- Give 50 mL D50 IV push
- Notify MD/HO
- Check BG every 15 minutes and repeat treatment until BG > 80 mg/dL; then, check BG every 30 minutes until BG is 120 mg/dL
- When BG ≥ 120 mg/dl, restart drip at **40%** of previous rate (0.40 × previous rate)

B. If current BG is 60 to 80, then

- **STOP** insulin infusion
- Check BG every 30 minutes until BG is 120 mg/dl
- When BG ≥ 120 mg/dl, restart drip at 50% of previous rate (0.50 × previous rate)
- If 2 episodes of BG below 80 in 4 hours, call HO to reevaluate rate

C. If current BG is 81 to 120 and previous BG was:	Action Step 1	Action Step 2: Check BG in
81–100	↓rate by 0.2 unit	1 hr
101–120	No change	1–2 hr
121–160	↓rate by 0.5 unit	1 hr
161–200	↓rate by 1 unit	1 hr
201–250	↓rate by 1.5 units	1 hr
251–400	↓rate by 2 units	1 hr
> 400	↓rate by 3 units	30 mins
D. If current BG is 121 to 160 and previous BG was:	**Action Step 1**	**Action Step 2: Check BG in**
120	↑rate by 0.2 unit	1 hr
121–160	↑rate by 0.4 unit	1 hr
161–200	No change	1 hr
201–250	↓rate by 0.5 unit	1 hr
251–400	↓rate by 1 unit	1 hr
>400	↓rate by 2 units	30 mins
E. If current BG is 161–200 and compared with previous BG it has	**Action Step 1**	**Action Step 2: Check BG in**
Remained the same or increased	↑rate by 0.5 unit	1 hr
Decreased by ≥1 but <10 then	↑rate by 0.4 unit	1 hr
Decreased by ≥10 but <50 then	No change	1 hr
Decreased by ≥50 but <100 then	↓rate by 0.5 unit	1 hr
Decreased by ≥100	↓rate by 1.5 units	30 mins
F. If current BG is >200 and compared with previous BG it hasa	**Action Step 1**	**Action Step 2: Check BG in**
Remained the same or increased	↑rate by 1.2 unit	1 hr
Decreased by ≥1 but <30 then	↑rate by 1 unit	1 hr
Decreased by ≥30 but <100 then	No change	1 hr
Decreased by ≥100	↓rate by 1 unit	30 min
NOT decreased below 200 after 3 adjustments in infusion rate	Call HO	1 hr

Individualize algorithm for very insulin resistant subjects (insulin infusion > 20 units/hr or BG > 300 for more than 4 hr).

with ALI or ARDS unless a more efficacious strategy is demonstrated. Figure 91-4 shows the protocol used at the University of California, San Francisco, for mechanical ventilation of patients with ALI or ARDS.

Nontraditional Ventilatory Interventions

In addition to low tidal volume, other therapies have been used for the care of patients with ALI. Most have tried to improve the $\dot{V}/\dot{Q}$ mismatching and hypoxemia that result from ALI. The following sections discuss data associated with recruitment maneuvers, prone positioning, inhaled nitric oxide (iNO), and early tracheostomy.

Lung Recruitment Maneuvers

Gravity-dependent atelectasis is invariably seen in patients with ARDS. The atelectatic lung areas lead to intrapulmonary shunting, ventilation-perfusion mismatching, and regional differences in compliance. Recruitment maneuvers, which involve periods of sustained increased airway pressure, have been proposed to re-expand atelectatic alveoli and avoid atelectrauma.[96] These maneu-

ARDSnet
NIH NHLBI ARDS Clinical Trials Network
Mechanical Ventilation Protocol Summary
UCSF Division of Critical Care Medicine

INCLUSION CRITERIA Acute onset of:
1. $Pao_2/Fio_2 \leq 300$ (corrected for altitude)
2. Bilateral (patchy, diffuse or homogeneous) infiltrates consistent with pulmonary edema
3. No clinical evidence of left atrial hypertension

PART I: Ventilator setup and adjustment
1. Calculate ideal body weight (IBW)
   Male = 50 + 2.3 [height (inches)–60]
   Female = 45.5 + 2.3 [height (inches)–50]
2. Select Assist Control Mode
3. Set initial TV to 8 mL/kg IBW
4. Reduce TV by 1 mL/kg at intervals ≤ 2 hours until TV = 6 mL/kg
5. Set initial rate to approximate baseline $\dot{V}_E$ (not > 35 bpm)
6. Adjust TV and RR to achieve pH and plateau pressure goals below
7. Set inspiratory flow rate above patient demand (usually > 80 L/min)

PART II: Weaning

Definition of weaning tolerance
1. RR ≤35 (may exceed 35 for ≤5 minutes) and:
2. Spo_2 ≥88% (< 15 minutes at <88% may be tolerated) and
3. Respiratory distress is absent (< 2 of the following)
Pulse >120% of usual rate for >5 minutes; marked use of accessory muscles; abdominal paradox, diaphoresis; marked complaints of dyspnea.

A. Conduct a CPAP Trial daily when:
1. $Fio_2 \leq 0.40$ and PEEP ≤ 8.
2. PEEP and $Fio_2 \leq$ values of previous day.
3. Patient has acceptable spontaneous breathing efforts. (May decrease vent rate by 50% for 5 minutes to detect effort.)
4. Systolic BP ≥ 90 mm Hg without vasopressor support.

CONDUCTING THE TRIAL:
Set CPAP = 5 cm H_2O, $Fio_2 = 0.50$
If RR ≤ 35 for 5 min.: advance to Pressure Support Weaning below.
If RR > 35 in <5 min.: may repeat trial after appropriate intervention. (e.g.: suction, analgesia, anxiolysis)
If CPAP trial not tolerated: return to previous A/C settings.

B. Pressure support (ps) weaning procedure
1. Set PEEP = 5 and $Fio_2 = 0.50$.
2. Set initial PS based on RR during CPAP trial:
   a. If CPAP RR < 25: set PS = 5 cm H_2O and go to step 3d.
   b. If CPAP RR = 25-35: set PS = 20 cm H_2O then reduce by 5 cm H_2O at ≤5 min. intervals until RR = 26-35, then go to step 3a.
   c. If initial PS not tolerated: return to previous A/C settings.
3. REDUCING PS (No reductions made after 1700 hrs.)
   a. Reduce PS by 5 cm H_2O q 1-3 hr, then go to step 3d.
   b. If PS ≥ 10 cm H_2O not tolerated, return to previous A/C settings. (Reinitiate last tolerated PS level next AM and go to step 3a.)
   c. If PS = 5 cm H_2O not tolerated, return to PS = 10 cm H_2O. If tolerated, 5 or 10 cm H_2O may be used overnight with further attempts at weaning the next morning.
   d. If PS = 5 cm H_2O tolerated for ≥2 hrs, assess for ability to sustain unassisted breathing below.

Continued

Figure 91-4 Protocol for low–tidal volume mechanical ventilation of patients with acute lung injury or acute respiratory distress syndrome in use at the University of California, San Francisco. The protocol is based on that used in the ARDSnet trial. A/C, assist/control; BP, blood pressure; CPAP, continuous positive airway pressure; ICU, intensive care unit; I:E, inspiratory-to-expiratory ratio; PEEP, positive end-expiratory pressure; RR, respiratory rate; TV, tidal volume; $\dot{V}_E$, minute ventilation.

vers must be performed with caution because venous return may decrease significantly, thereby leading to hypotension, and alveolar ventilation may decrease, thereby resulting in hypercapnia and respiratory acidosis. Other clinically significant events can include pneumothorax, arrhythmias, and bacterial translocation. The optimal pressure, duration, and frequency of recruitment maneuvers have not been defined. In the ARDSnet ALVEOLI trial, patients randomized to the high–positive end-expiratory pressure (PEEP) group also received recruitment maneuvers with airway pressures of 35 to 40 cm H_2O for 30 seconds to assess the effect on oxygenation.[97] After the first 80 patients, recruitment maneuvers had only a modest effect on oxygenation and were not continued for the remainder of the study. At this time, routine use of recruitment maneuvers cannot be recommended because they have been shown to increase oxygenation only transiently without improving mortality.

Prone Positioning

Because atelectasis and ventilation-perfusion mismatching appear to be dependent on gravity, one assumption is that turning a patient from the supine to the prone position would change these relationships and improve gas exchange (see Chapter 36). Prone positioning is fraught with difficulty and can result in accidental extubation, dislodgement of the line or chest tube, and patient

C. Unassisted breathing trial
1. Place on a T-piece, trach collar, or CPAP < 5 cm H_2O.
2. Assess for tolerance as below for two hours.
3. If tolerated, consider extubation.
4. If not tolerated, resume PS 5 cm H_2O.

Definition of Unassisted Breathing Tolerance:
1. RR ≤ 35 and
2. SpO_2 ≥ 90 % and/or PaO_2 ≥ 60 mm Hg and
3. Spontaneous TV ≥ 4 mL/kg IBW and
4. Respiratory distress is absent (< 2 of the following):
   pulse > 120% of usual rate for > 5 minutes, marked use of accessory muscles;
   abdominal paradox, diaphoresis, marked complaints of dyspnea.

OXYGENATION GOAL:
PaO_2 55-80 mm Hg or SpO_2 88-95%
Use incremental FiO_2/PEEP combinations below to achieve goal:

FiO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
FiO_2	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

PLATEAU PRESSURE GOAL: ≤30 cm H_2O
Check Pplat (0.5 sec insp. Pause), SpO_2, total RR, TV and pH at least q4h and after each change in PEEP or TV

If Pplat > 30 cm H_2O: decrease TV by 1 mL/kg steps (min = 4 mL/kg)
If Pplat < 25 cm H_2O: increase TV by 1 mL/kg until Pplat > 25 cm H_2O or TV > 25 cm H_2O or TV = 6 mL/kg

pH GOAL: 7.25-7.45
Acidosis Management:
pH < 7.25 but ≥ 7.20
1. Notify ICU resident of pH < 7.25
2. Increase RR until pH > 7.25 or $PaCO_2$ < 25
3. If RR = 35 and/or $PaCO_2$ < 25, MAY give $NaHCO_3$ or choose to leave as is until pH < 7.20

pH < 7.20
1. Increase RR to 35 (if not already 35)
2. If pH remains < 7.20 and $NaHCO_3$ considered or infused, TV may be increased in 1 mL/kg steps until pH > 7.20 (Pplat target may be exceeded)

Alkalosis Management (pH > 7.45)
1. Decrease ventilator rate if possible.

I:E RATIO GOAL: 1:1 to 1:3. Adjust flow rate to achieve goal.
If FiO_2 = 1.0 and PEEP = 24 cm H_2O, may adjust I:E to 1:1.

Figure 91-4, cont'd

injury, but it can lead to higher functional residual capacity, better drainage of secretions, and improved oxygenation. Gattinoni and colleagues performed a multicenter, prospective randomized trial in patients with ARDS to compare supine positioning with prone positioning for 6 or more hours per day for 10 days.[98] Three hundred four patients were enrolled. Oxygenation was improved in the prone group, but again, mortality did not differ between the two groups. Although there may be specific patients who can benefit from this technique, routine use of prone positioning is not supported by the data. The use of specialized beds that can provide significant side-to-side rotation may be an alternative to prone positioning, but these beds have not been tested in prospective trials.

Inhaled Nitric Oxide

Numerous cells synthesize endogenous nitric oxide (NO) in the human body, including macrophages, mast cells, and smooth muscle cells. NO modulates vascular tone and neurotransmission, inhibits platelet aggregation and cell cytotoxicity, and interacts with free radicals (see Chapter 31).[99,100] It binds to hemoglobin and is then metabolized by conversion to nitrites and nitrates, which are excreted in urine.[101] This process is extremely rapid and results in a half-life on the order of seconds, so the effect of NO is limited to the immediate area in which it is released. Selective delivery of NO by inhalation (iNO) to well-ventilated areas of the lung improves ventilation-perfusion mismatching and improves oxygenation by dilating the local pulmonary capillaries. This

effect is in contrast to other pulmonary vasodilators, which usually worsen gas exchange by indiscriminately dilating vessels. In particular, iNO is inactivated in the lung by hemoglobin, which minimizes harmful systemic vasodilation.

Initially, iNO was used as salvage therapy to improve oxygenation in patients with severe ARDS.[102] Further studies then used iNO earlier in the course of ARDS and were able to demonstrate decreased pulmonary artery pressure, decreased venous admixture, and increased oxygenation with no change in systemic blood pressure, systemic vascular resistance, or cardiac output.[103,104] The average improvement in the Pao_2/Fio_2 ratio was 42%.[105] The beneficial effects appear to be sustained during long-term therapy, but a rebound phenomenon has been reported after abrupt removal of iNO therapy.[106]

Three randomized controlled trials of iNO in patients with ARDS were published in 1998. Two of the studies were small (<40 patients) and the results were consistent with the larger multicenter placebo-controlled, double-blinded trial.[107] Initially in that study, patients in the iNO group had an acute improvement in oxygenation, but no differences in Fio_2 were seen between the iNO and placebo groups from days 2 through 7. Most importantly, no differences in mortality or number of days alive and not requiring mechanical ventilation were found through day 28. In patients who were responders to iNO, defined as a 20% or greater increase in Pao_2, no differences in 30-day mortality were reported between responders given iNO and responders given conventional therapy.[105] A recent meta-analysis examining 12 trials involving 1237 patients also found an increased Pao_2/Fio_2 ratio in the iNO group and, again, no significant effect of iNO on hospital mortality, duration of ventilation, or ventilator-free days. There was, however, an increased risk for renal dysfunction (risk ratio, 1.5; 95% CI, 1.11 to 2.02) in the patients receiving iNO.[108]

Because of the data available, routine use of iNO in patients with ARDS cannot be recommended. However, there are no data to address the use of iNO as rescue therapy for patients with critically low oxygenation. Further randomized studies of patients with specific disease states (i.e., rapidly progressive hypoxia, severe pulmonary hypertension, or right ventricular failure) may identify the subgroup that could potentially benefit from iNO.

Tracheostomy

Tracheostomy is a common procedure in the ICU that is performed in about 10% of critically ill patients who require mechanical ventilation (see Chapter 50).[109] Placement of a tracheostomy is thought to allow a more secure and manageable airway, earlier and safer enteral feeding, easier oral care, and enhanced patient comfort while reducing sedation needs. Complications from tracheostomy include stoma infection, pneumothorax, subcutaneous emphysema, tracheomalacia, and tracheostenosis.[110] Major questions about tracheostomy include which patients with acute respiratory failure should have the procedure done and when should it be performed.

A review published in 1998 concluded that there was insufficient evidence to support the view that timing of a tracheostomy can alter the duration of mechanical ventilation or prevent airway injury in critically ill patients.[111] Since then, individual researchers have reported decreased days of mechanical ventilation,[112] decreased duration of ICU and hospital length of stay,[113] and less damage to the upper airway[112] with early tracheostomy. A meta-analysis attempted to answer this question definitively. Unfortunately, they were able to find only five trials with 406 patients that met their inclusion criteria.[114] They reported that the timing of tracheostomy did not alter mortality or increase the risk for hospital-acquired pneumonia. Early tracheostomy did, however, lower the duration of mechanical ventilation and the overall length of stay in the ICU. Their data are shown in Table 91-6. The results were far from conclusive. Heterogeneity was high in the meta-analysis because of variability in inclusion and exclusion criteria, definitions of "early" and "late" tracheostomy, characteristics of enrolled patients, and diagnostic criteria for hospital-acquired pneumonia.

Table 91-6 Data Comparing Early with Late Tracheostomy

	Relative Risk	95% Confidence Interval	*P* Value
Timing of tracheostomy	0.79	0.45-1.39	.42
Development of pneumonia	0.9	0.66-1.21	.48
Time on ventilator	8.5 days	−15.3 to −1.7 days	.03
Length of intensive care unit stay	15.3 days	−24.6 to −6.1 days	.001

From the results it appears that early tracheostomy may have benefit over late tracheostomy, but the difficulty comes in identifying patients who may have a simple subsequent weaning process after failing the first attempt. Tracheostomies should be performed in patients who will encounter difficult or prolonged weaning. Unfortunately, no validated specific and sensitive test or scoring system is available that can predict the need for prolonged ventilation, so selection of patients for tracheostomy remains a subjective decision.

Percutaneous versus Open Tracheostomy

Percutaneous techniques are emerging as a method of securing the airway of adult critical care patients. Advantages include smaller skin incision, less tissue trauma, lower incidence of wound infection, reduced risk associated with transfer of patients to the operating room, and fewer personnel requirements. Two meta-analyses showed a trend toward fewer complications, cost-effectiveness by releasing operating room resources, and greater feasibility than the open surgical approach in terms of the capability of performing the percutaneous procedure at the bedside.[115,116] One important caveat of these results is to remember the exclusion criteria for most of these studies (i.e., emergency tracheostomy, suspicion or evidence of a difficult airway, previous airway problems, coagulopathies, and previous tracheostomies). Consequently, although the procedure appears to be safe and effective, the favorable data exist only for a particular subset of patients admitted to the ICU.

Fluid Management and Monitoring

The use of pulmonary artery catheters (PACs) in critically ill patients remains controversial. Most studies have failed to show efficacy or have demonstrated harm (see Chapters 88 and 96). The best known of these investigations was the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), which was a retrospective, observational study involving 5735 critically ill patients.[117] In these patients, use of a PAC was associated with increased mortality and cost. Richard and coworkers[118] completed a prospective, observational trial of

PACs versus central venous catheters (CVCs) in patients with ARDS or shock. Clinical management was left to the discretion of the treating physician. In 676 patients in 36 French ICUs, there was no difference in any of the outcome variables measured.[118]

Recently, the Fluids and Catheters Treatment Trial (FACTT) conducted by the National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network compared hemodynamic management guided by a PAC with hemodynamic management guided by a CVC in 1000 patients with established ALI.[119] Patients were treated by clinicians at select academic ICUs who were trained in interpreting hemodynamic data and who were following a very specific management protocol. Although serious catheter-related complications were rare, the PAC group did have a higher incidence of arrhythmias and conduction blocks. The investigators were unable to demonstrate prevention or reversal of organ failure, reduced need for support (e.g., vasopressors, assisted ventilation, or renal replacement therapy), faster discharge from the ICU, or decreased 60-day mortality in the PAC group versus the CVC group. Possibly because of this growing evidence, use of the PAC has decreased by 65% during the last decade in the United States.[120]

The PAC is a monitoring device that can be difficult to interpret, especially in the setting of critical illness. More concerning than the device itself is the therapy that can be driven by misinterpretation of the numbers obtained from the PAC. A recent guideline on hemodynamic monitoring recommends against routine PAC placement in patients in shock and does not specifically recommend it for any clinical scenario.[121]

Recently, in one of the factorial assessments the FACTT study examined whether a conservative or a liberal strategy of fluid management was more effective in patients with established ALI.[122] Although the 60-day mortality was similar in both groups, patients in the conservative fluid management group had improved lung function, improved central nervous system function, and a decreased need for sedation, mechanical ventilation, and intensive care. The patients in the conservative fluid management group also did not have an increased incidence of complications, such as nonpulmonary organ failure or shock.

Perhaps the most prudent approach is to base management on clinical examination findings and appropriately titrate fluid according to the patient's phase of illness. There are important benefits of goal-directed, liberal fluid administration during the acute phase of sepsis. However, excess fluid is not beneficial when it is not needed physiologically during the established phase of ALI.[123]

Acute Liver Failure

Epidemiology

Acute liver failure (ALF) is an uncommon disorder that leads to jaundice, coagulopathy, and multisystem organ failure. It is defined by the development of hepatic encephalopathy within 8 weeks after the onset of jaundice in patients with no known chronic liver disease.[124] ALF affects approximately 2000 people per year in the United States,[125] with 20% to 39% of cases caused by acetaminophen overdose.[126] Mortality from fulminant hepatic failure (FHF) can be high (60% to 80%) in the absence of liver transplantation, depending on the etiology.[127] Causes of death are mainly multisystem organ failure, sepsis, and cerebral edema. Liver transplantation for ALF generally has a worse outcome than transplantation for chronic liver disease does because of the high postoperative mortality caused by sepsis and multiorgan failure.[128]

Table 91-7 Causes of Fulminant Hepatic Failure

Etiology	%
Acetaminophen	39
Idiosyncratic drug reaction	13
Hepatitis B	6
Hepatitis A	6
Other	19
Indeterminate cause	17

Prognostic Factors in Acute Liver Failure

The timing of transplantation and selection of patients are crucial because transplantation is the only therapeutic intervention proved to be beneficial.[129] Although scoring systems have been proposed, the myriad causes of ALF limit their accuracy (Table 91-7). Most case series are limited in number, and some span long periods during which supportive therapies may have changed. The King's College criteria have been shown to have good specificity (92%) for patients who will die without transplantation, but lower sensitivity (69%), thus suggesting that a proportion of patients will die and not fulfill the criteria. The criteria also have low negative predictive value, which could lead to transplantation in a patient who would have recovered without surgery. Other predictors include the Model for End-Stage Liver Disease (MELD),[130] which has been shown to be an excellent predictor of outcome in patients with ALF of various causes, excluding acetaminophen. Also promising are blood lactate levels[131] and hyperphosphatemia.[132]

Management of Fulminant Liver Failure

General Supportive Measures

Patients with ALF should be monitored closely, usually in an intensive care setting. The cause of the ALF should be identified, and suitable candidates for orthotopic liver transplantation should be moved early to a transplantation center. Early intubation may be necessary if neurologic status deteriorates and leads to airway compromise. Volume expansion with crystalloids and colloids is probably required to help maintain blood pressure. Correction of acid-base disturbances, treatment of hyperthermia, and close glucose monitoring are important to prevent cerebral edema. Hyponatremia is a negative prognostic sign, and values of less than 125 mmol/L can be a contraindication to transplantation.[133] Continuous renal support is often required in cases of advanced ALF to help with renal insufficiency, volume status, and cerebral edema.[134] Prophylactic antibiotics are used widely and have been shown to lower infection rates.[135] Current recommendations are to correct the coagulopathy with fresh frozen plasma when bleed-

ing occurs or an invasive procedure is planned. Recombinant factor VIIa has been shown to reverse the coagulopathy in patients with FHF.[136]

Management of Increased Intracranial Pressure

The development of cerebral edema and intracranial hypertension is probably the most devastating complication associated with ALF (see Chapters 46, 63 and 94). Osmotically active compounds, normally cleared by the liver, accumulate in blood and diffuse into the brain parenchyma. Movement of water into neurons and glia results in swelling and can cause herniation. The exact compounds responsible for cerebral edema are unknown, but ammonia is probably a major contributor.

Diagnosis of cerebral edema can be difficult. Serial neurologic examination is essential, and frequent computed tomography of the head can identify early signs of edema. Many centers implement early monitoring of intracranial pressure, although this practice has not been shown to improve outcome.[137] This can be achieved with either cranial or lumbar epidural monitors because traditional intraventricular monitors carry an unacceptable risk of bleeding.

Techniques to reduce intracranial pressure include removal of ammonia with continuous renal replacement therapy (CRRT), hypothermia, barbiturate coma, and administration of mannitol and hypertonic saline.[138]

Liver Support Devices

Bioartificial Livers. Bioartificial livers use hepatocytes to mimic the synthetic, detoxifying, and excretory function of the dying liver. Porcine hepatocytes are used preferentially because human hepatocytes are difficult to grow in culture.[139] The device works by passing the patient's plasma through hollow-fiber capillaries while the hepatocytes are placed in the extracapillary space. Molecules are exchanged between hepatocytes and plasma across a membrane that prevents passage of immunoglobulin, complement, and cells. A prospective, multicenter, randomized controlled trial using the HepatAssist liver support system was published in 2004.[140] The results did not show any improvement in survival in the treated group. Only during subgroup analysis were patients with fulminant/subfulminant liver failure found to have improved survival, but the results were marginal.

Artificial Extracorporeal Devices. Artificial extracorporeal devices have received renewed interest because of technology allowing the production of membranes that can increase selectivity through small pores. The system can be tailored for albumin-bound substances, which include most of the toxins that accumulate in FHF. Larger molecules such as immunoglobulins cannot cross.[139] Recent studies have found that this system is associated with significant improvements in encephalopathy in patients with acute-on-chronic liver failure,[141] but controlled clinical data in patients with FHF are lacking.

Overall, the systems appear to be safe, but adverse events can include bleeding, systemic infection, disseminated intravascular coagulation, and allergic shock. A meta-analysis of the use of artificial and bioartificial life support systems in eight randomized controlled trials involving only 139 patients concluded that the support systems evaluated have no significant effect on mortality in patients with ALF.[142] Randomized clinical trials are limited given the patient's severity of illness. More controlled trials addressing survival are warranted before this therapy can be strongly recommended.

Acute Renal Failure

Epidemiology

The incidence and outcomes of acute renal failure (ARF) in the ICU are highly variable. Reported incidences range between 1% and 31%,[143,144] and mortality ranges between 28% and 82%[144,145] Part of the variability is due to the fact that there is no consensus on the diagnostic criteria or clinical definition of ARF. A recent survey determined that at least 35 definitions were used in the literature.[146]

Diagnosis

A group of experts consisting of nephrologists and intensivists have proposed new criteria for describing renal dysfunction. They recognized the clinical importance of milder forms of renal insufficiency and that stratifying renal dysfunction (mild to severe) would better describe the disease. They proposed the RIFLE criteria (Table 91-8), which stands for risk, injury, failure, and two outcome classes (loss and end-stage kidney disease). For each increasing RIFLE class, there is a stepwise increase in mortality[147] and an increasing proportion requiring renal replacement therapy.

Management of Acute Renal Failure

General Supportive Measures

Patients with ARF should be monitored closely. The cause of the ARF should be identified by looking at prerenal, renal, and postrenal causes. Laboratory evaluations should include serum and urine electrolytes, urinalysis, and examination of urinary sediment. Careful assessment of volume status is necessary to determine hypovolemia leading to prerenal azotemia versus hypervolemia from oliguria. Correction of acid-base disturbances may be necessary, as well as correction of electrolyte abnormalities. Continuous renal support is often required in patients with advanced renal failure to help with volume overload and electrolyte disturbances. Antibiotics and other medications should be dosed according to creatinine clearance, and serum levels, if available, should be monitored closely. Platelet dysfunction may occur as a result of uremia and require desmopressin (DDAVP) for support if bleeding is problematic.

Table 91-8 The RIFLE Criteria

	GFR criteria	UO Criteria
Risk	Cr increased × 1.5 or GFR decreased >25%	UO <0.5 mL/kg/hr × 6 hr
Injury	Cr increased × 2 or GFR decreased >50%	UO <0.5 mL/kg/hr × 12 hr
Failure	Increased Cr × 3, GFR decrease >75%, or Cr ≥ 4 mg/dL	UO <0.3 mL/kg/hr × 24 hr or anuria × 12 hr
Loss	Complete loss of renal function >4 wk	
ESRD	End-stage disease	

Cr, creatinine; ESRD, end-stage renal disease; GFR, glomerular filtration rate; RIFLE, risk, injury, failure, and the two outcome classes loss and ESRD; UO, urine output. Data from Hoste EAJ, Kellum JA: Acute kidney injury: Epidemiology and diagnostic criteria. Curr Opin Crit Care 12:531-537, 2006.

Renal Support

ARF in the ICU often requires some type of renal replacement therapy (see also Chapter 96). Commonly, this is accomplished by continuous venovenous hemofiltration (CVVH), a form of CRRT. The timing and dosing of this therapy and the patients most likely to benefit from it remain unclear.[148,149] Recently, it appears that the difference in efficacy lies not in the type of dialysis (intermittent hemodialysis versus CVVH) but in the dialysis dose. Undertreatment appears to be harmful,[150] whereas earlier application and higher filtration volumes appear to be associated with decreased mortality in patients with ARF.[151] Extended daily dialysis offered hemodynamic stability and small solute control comparable to that achieved with CRRT.[152] Even with intermittent hemodialysis, when studies are controlled for dialysis dose, polymer membrane, and bicarbonate-based buffer, 60-day mortality did not differ between the groups (CRRT versus intermittent hemodialysis).[153] Although there has been a trend to use CRRT, the favorable data with intermittent hemodialysis is intriguing because it would allow more ICU resources to be allocated elsewhere.

Complications of Intensive Care Unit Management

Even though ICU care has advanced and improved, some limitations on our ability to further reduce mortality are due to complications of the ICU care that we give. Nosocomial infections occur in approximately 10% of ICU patients at a rate of 21 to 25 infections per 1000 ICU patient-days.[154,155] The most common nosocomial infections in medical ICUs are urinary tract infections (31%), followed by pneumonia (27%) and primary bloodstream infections (19%).[156] Several studies have shown that quality improvement initiatives can reduce nosocomial infections, mortality, and cost.[157,158] The next section reviews the data available for the prevention of ventilator-associated pneumonia (VAP) and catheter-related bloodstream infections (CRBSIs).

As of 2008, the Center for Medicaid and Medicare Services, which administers federal-sponsored health care, will no longer reimburse hospitals for additional costs associated with common ICU complications, including urinary and CVC-associated infections. This pay-for-performance measure, in addition to the widespread adoption of public reporting of infection rates, will catalyze significant scrutiny of these infections.

Ventilator-Associated Pneumonia

VAP is defined as pneumonia developing in mechanically ventilated patients after more than 48 hours of intubation, with no clinical evidence suggesting the presence or probable development of pneumonia at the time of initial intubation.[159] VAP is a leading cause of morbidity and mortality in mechanically ventilated, critically ill patients. The incidence of VAP is estimated to be 10% to 25%,[160] and the estimated mortality rate from VAP is 5% to 27%.[161,162] VAP also increases hospital length of stay and cost.[161,163] Additional hospitalization cost because of an episode of VAP has been demonstrated to be as high as $40,000.[164,165] The pathogenesis of VAP probably involves microaspiration of oropharyngeal or gastric secretions contaminated with bacteria. Risk factors include previous exposure to antibiotic therapy and the presence of invasive devices.[166]

The diagnosis of VAP is challenging. Frequently, a presumptive diagnosis of pneumonia is made when fever, leukocytosis, purulent secretions, and a new infiltrate on chest radiography develop and when bacteria are isolated by nonquantitative analysis of endotracheal aspirates.[167] These nonspecific diagnostic criteria may lead to unnecessary antibiotic use, increased hospital cost, emergence of resistant microorganisms, and a potential delay in diagnosis of the true cause of the fever. These problems led several investigators to propose an invasive management strategy for the diagnosis of VAP.

Fagon and colleagues[168] used fiberoptic bronchoscopy to obtain protected specimen brush samples or bronchoalveolar lavage samples for quantitative culture. Patients were considered to have VAP if at least 10^3 colony-forming units (CFU)/mL of bacteria grew from the protected specimen brush sample or at least 10^4 CFU/mL of bacteria grew from the bronchoalveolar lavage fluid. The patients in the invasive management group had reduced mortality at day 14 (16.2% versus 25.8%, $P = .022$) and an increased number of antibiotic-free days (5.0 ± 5.1 versus 2.2 ± 3.5 days, $P < .001$). This study makes a compelling argument for a more definitive diagnosis of VAP before initiating antibiotic therapy. Along the same idea but with a less invasive approach, other studies[169,170] have shown that nonbronchoscopically guided placement of protected brush catheters or protected bronchoalveolar lavage is just as sensitive as directed bronchoscopy in detecting bacteria in the lungs.

Prevention of Ventilator-Associated Pneumonia

Gastric pH

As in all nosocomial infections, prevention is the most efficacious approach. Excessive use of gastric pH–altering medications for stress ulcer prophylaxis increases gastric pH and the risk for VAP.[171] The use of sucralfate, an agent that does not increase gastric pH, may be preferable to H_2 receptor antagonists or proton pump inhibitors. Three studies found decreased mortality rates in patients treated with sucralfate rather than H_2 receptor antagonists or proton pump inhibitors.[171-173]

Positioning

Positioning of the head of the bed at 30 degrees is the most cost-effective intervention for prevention of VAP. This position results in decreased gastroesophageal reflux. With this intervention, Drakulovic and coworkers[174] found a decreased rate of VAP with no adverse effects. This intervention is easily implemented and monitored.

Subglottic Aspiration of Secretions

Pooling of secretions above the endotracheal tube cuff may increase the volume of bacteria that enter the airways. Removal of these secretions by continuous aspiration in the subglottic region requires the use of a specialized endotracheal tube with a second lumen that permits a suction catheter to exit proximal to the endotracheal tube cuff. Three randomized, controlled trials have examined the efficacy of aspiration of subglottic secretions. Mahul and associates[175] studied 145 patients randomly assigned to prevention of aspiration by hourly drainage of subglottic secretions or prevention of gastric colonization with sucralfate or ant-

acids. Drainage of subglottic secretions was associated with a lower incidence of VAP (13% versus 29.1%), a prolonged time to onset of VAP (16.2 days versus 8.3 days), and a decrease in the colonization rate of subglottic secretions (2.1% versus 33.4%). Valles and colleagues[176] randomized 153 patients to subglottic aspiration or usual care. The intervention group had a reduced incidence of VAP (19.9 episodes per 1000 ventilator days versus 39.6 episodes per 1000 ventilator days). They also found that episodes of VAP occurred later (12 ± 7 versus 5.9 ± 2.1 days, P = .003) in the continuous aspiration group.[176] The third trial by Kollef and coworkers[177] randomized 340 patients undergoing cardiac surgery to continuous aspiration of subglottic secretions. VAP was seen in 5% of the interventional group as opposed to 8.2% of the control group (P = .238), but episodes of VAP occurred statistically later in patients receiving subglottic aspiration (5.6 ± 2.3 days) than in those who did not (2.9 ± 1.2 days, P = .006).[178] Unfortunately, none of the studies were able to show a mortality benefit from continuous aspiration of subglottic secretions. At this time, aspiration of subglottic secretions looks promising for prevention of VAP but cannot be recommended because of the mixed results from randomized studies.

Catheter-Related Bloodstream Infections

It is estimated that more than 5 million CVCs are inserted every year in the United States.[179] Unfortunately, more than 15% of patients have complications from these lines.[180] Infectious complications are reported to occur in 5% to 26% of patients with CVCs.[181,182] The mortality rate attributable to CRBSIs ranges from 12% to 25%,[183,184] and the attributable cost is estimated to be between $3700 and $29,000 per episode.[184,185]

Prevention of Central Venous Catheter Infections

Antibiotic-Impregnated Central Venous Catheters

Several studies have been conducted to examine the efficacy of antimicrobial-impregnated catheters in an effort to decrease the incidence of CRBSI. CVCs coated with the antimicrobials chlorhexidine and silver sulfadiazine or impregnated with the antibiotics minocycline and rifampin are commercially available. Chlorhexidine/sulfadiazine-coated catheters lowered the rate of bloodstream infection from 7.6 to 1.6 infections per 1000 catheter-days (P = .03).[186] A cost-effectiveness analysis conducted by Veenstra and associates[187] concluded that these catheters would decrease cost by $196 per catheter inserted if the institutional CRBSI rate was higher than 2%.

Later evidence suggests that minocycline/rifampin-impregnated catheters are even more efficacious. In a randomized trial performed in 12 university hospitals in which minocycline/rifampin-impregnated catheters were compared with chlorhexidine/silver sulfadiazine–coated catheters, the catheters with minocycline/rifampin were a third as likely to be colonized as those coated with chlorhexidine or silver sulfadiazine (7.9% versus 22.8%, P < .001) and half as likely to lead to CRBSI (0.3% versus 3.4%, P < .002).[188]

The use of antimicrobial-impregnated catheters should be considered in all critically ill patients who require long-term (at least 3 days) indwelling central venous access. Immunocompetent patients who will be catheterized for less than 3 or 4 days may not need these catheters because infection is rare during this period. Additional studies are required to further elucidate the benefit of catheters impregnated with minocycline/rifampin over chlorhexidine/silver sulfadiazine.[189] Although theoretically possible, no studies have shown the development of significant antibiotic resistance with these catheters. However, continued surveillance for resistance is recommended as part of the increased use of these devices.[182,188]

Sterile Technique

Optimal sterile technique is the most cost-effective means of reducing the incidence of central line colonization and CRBSI. Use of maximal sterile barrier precautions such as mask, cap, sterile gown, sterile gloves, and a large sterile drape as opposed to small towels has been shown to reduce the rate of CRBSIs and to save $167 per catheter inserted.[190,191] Use of chlorhexidine solution for skin decontamination reduces the risk of catheter colonization and is therefore preferred over the use of povidone-iodine solution.[192] With widespread implementation of these sterile techniques, Pronovost and associates were able to markedly reduce CRBSI rates in 108 ICUs in the state of Michigan.[193]

Ultrasound Guidance

With the development of portable, inexpensive ultrasound machines, use of real-time ultrasound guidance has been promoted as a technique for reducing the complications associated with central venous cannulation (see Chapter 40). Ultrasound guidance has been shown to reduce the number of complications, unsuccessful attempts, and time required for insertion of an internal jugular vein catheter,[194] but it has not been demonstrated to be efficacious for subclavian venous access.[195] Clinical trials assessing whether use of ultrasound can decrease the incidence of central venous line infections remain to be completed, but this technology can decrease the number of attempts required to locate the internal jugular vein and should be used routinely when available.[189] All three practices—maximum sterile barrier precautions, antibiotic-coated catheters, and ultrasound guidance—have been recommended as among the top 11 patient safety practices by the Agency for Healthcare Research and Quality in its report Making Health Care Safer: A Critical Analysis of Patient Safety Practices.[196]

Duration

The need for a CVC should be reassessed daily, and unnecessary catheters should be removed because the probability of catheter-related infections increases with time. The risk of infection with catheterization stays relatively low until about the fifth to seventh days and then increases exponentially.[197,198] Several trials have studied scheduled replacement of catheters over a guidewire or in a new site, but none of these strategies were able to show an improved outcome.[199,200] Optimal catheter insertion technique and maintenance can minimize infectious risks, but the most efficacious maneuver is to remove CVCs as soon as they are no longer required. The need for central venous access should be reassessed again before discharging the patient from the ICU because this is often an opportune time to remove any indwelling lines, including bladder catheters.

Conclusion

Critical care medicine is a growing specialty as the population ages and new procedures and technologies are brought into practice. Anesthesiologists represent a small proportion of intensivists in the United States but constitute the majority in Europe and other parts of the world. Critical care training represents a significant opportunity for anesthesia practitioners. We have reviewed management of a number of commonly encountered clinical conditions in the ICU, and the reader should refer to Chapters 92 through 98 for additional information related to critical care practice. The ICU is a nexus not just for promising therapies but for complications of treatment as well. To avoid patient harm, all practitioners must be aware of best practices, from the simplest interventions such as hand hygiene to the latest technologic advances.

92 Critical Care Protocols

Key Points

1. Protocols allow for standardization of research protocols and minimization of confounding variables.
2. A multidisciplinary team is required and a specific educational plan is necessary to properly implement all facets of a protocol.
3. Protocols must be devised with the intention of not only improving the quality of patient care but also improving patient outcome and the efficiency of care, while at the same time decreasing practice variation and costs.
4. The ability to measure the effect of a particular protocol and adapt appropriately is the key to successful protocol application.
5. Quality measures that were found to be valuable (based on effect, feasibility, and strength of evidence) included: (a) percentage of patients with ventilator-associated pneumonia, (b) percentage of patients with resistant infections, (c) percentage of patients with central venous catheter infections, (d) number of complications per patient, (e) average days of mechanical ventilation, (f) rate of gastrointestinal bleeding, (g) average intensive care unit (ICU) length of stay, and (h) patient satisfaction.
6. With appropriate standards, definitions, defined pathways, and explicit interventions, the interpretation of research findings, whether prospective randomized or observational, will enhance clinical equipoise.

The demand for critical care services in the United States is estimated to increase dramatically in the coming years.[1] Because the future supply will unlikely be able to match this demand, intensivists will undoubtedly face a larger, sicker population with fewer resources.[2,3] While few would argue that an intensivist-led unit benefits from decreased morbidity and mortality, the impending staffing shortage and population growth will necessitate care paradigms that maximize efficiency, reduce practice variation, and standardize patient care.[4-6] Increasingly, intensive care units (ICUs) have adopted and implemented pathways and clinical protocols to achieve this goal. Designing such protocols, however, is not trivial. Protocols must be devised with the intention of not only improving the quality of patient care but also improving patient outcome and the efficiency of care, while at the same time decreasing practice variation and costs. Lohr and colleagues defined *quality* as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[7] It is imperative that health care providers maintain this characterization whether creating new or implementing known protocols. Furthermore, it is critical that clinicians not view protocol-driven care as a constraint on clinical judgment. To the contrary, protocols require a greater consideration of individual subtleties among patients and it is the attentive clinician who understands the need to deviate from protocol. The goal then becomes a process: a process of learning, a process of observation, and a process of educated response. Without this goal, critical care becomes "cookbook medicine" and protocols become recipes for disaster.

In this chapter we will discuss the rationale for care protocols in the context of achieving five goals: (1) enhancing quality of care, (2) improving efficiency, (3) decreasing cost, (4) decreasing errors, and (5) enabling rigorous clinical research. The focus is on more technical aspects of protocol design, including team development, evaluation of best evidence and/or consensus, preservation of flexibility, and continuous quality improvement. Factors necessary to implement protocols are also discussed. This process begins with identifying priorities and setting goals and culminates with the ability to continuously revise as new evidence builds. We will discuss three protocols that have been embraced among ICUs widely, all of which illustrate an important concept in protocol design. Finally, we will discuss the future of protocolized medicine including the role of computer-driven decision models and handheld computers in addition to areas that likely will see protocol implementation in the near future. As has been shown repeatedly in the literature, protocol development and implementation, for all its intricacies and details, will fail without the help, understanding, and sense of ownership of a large multidisciplinary team.

Rationale for Protocol Development

Critical care protocols or clinical practice guidelines (CPGs) were borne out of the need to establish a reduction in practice variability while improving the quality of care and patient outcome using the best available evidence. A 1994 editorial in the *British Journal of Medicine* predicted: " 'Evidence based medicine' is a phrase that is currently familiar to only a few doctors, but all will know it by the millennium."[8] While it turns out this forecast was accurate, no one could have predicted the care paradigm shift this would create. Rather than treating patients based on empirical evidence or anecdote, today's intensivists are faced with a plethora of objective data from which they must determine what will work best for their particular patient or population. The quality of this objective data and robustness of statistical analysis continues to improve. While many current protocols are based on data from multiple randomized controlled trials (RCTs), it is interesting to note that over one half of the clinical guidelines published before the year 2000 were based on no RCT evidence.[9]

There are a large number of interventions in critical care that have been shown to improve morbidity and mortality while at the same time decreasing costs.[10-14] Despite this, there continues to be a disparity between best evidence and best practice.[15,16] This may be due to physicians' respect for mentors or an inability to incorporate new evidence into traditional dogma. Evidence-based medicine and the inevitable consequence, protocol development, are a result of new types of evidence being generated. As new evidence accrues, it is incumbent on practitioners to critically analyze the data in a way that is fair and equitable to others performing similar research. Using a uniform approach for each piece of evidence has advantages and disadvantages (Table 92-1).[17] Protocol or guideline development should explicitly state what, if any, objective grading system was used to categorize and classify the data.

Table 92-1 Advantages and Disadvantages of Using the Same System for Grading Evidence to Implement ICU Protocols

Advantages	Disadvantages
• Having different systems for evaluation of various interventions might be confusing. • There is less chance for individuals with vested interests to bias results by selecting a particular grading scheme. • Limitations of the evidence become more apparent when comparing two disparate conclusions with a similar grading scheme. • Better research can be generated as a result of identifying gaps in evidence.	• Interventions that cannot be studied with randomized trials may not be evaluated or may lead to a false-negative conclusion. • A single system that can adequately grade evidence across a broad range of interventions may be overly complex.

Adapted from Schunemann HJ, et al: Improving the use of research evidence in guideline development: 9. Grading evidence and recommendations. Health Res Policy Syst 4:21, 2006.

The basis of CPG development includes (1) improving patient outcome; (2) establishing standards of care (either institutionally or within a specialty); and (3) changing practice patterns.[18] While these points form the rationale for CPGs, the primary goal of any new protocol is enhancement of the quality of care. Defining quality is a subject of debate; however, we will use the Institute of Medicine's definition: "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge.[7,19]" Continuous quality improvement (CQI) is a term that originated in the business realm and was coined by W. Edward Deming. Deming was a trained statistician but is best known for the positive impact he had on production in the United States during World War II. He taught management executives how to improve design and product quality through objective evaluation, testing, and re-evaluation. CQI contrasts to the traditional, reactive, root-cause analysis, which focuses on recognizing a problem and then identifying a "seminal event" (or events) causally related to this event. In CQI, all facets of the critical care setting are evaluated and considered as potential targets for improvement initiatives.[20,21] Once an initiative is identified, a system is devised to measure the efficacy or outcome of a particular intervention.[22] This change is then continuously re-evaluated and modified via an internal evaluation system.[23] Depending on the goals of a particular critical care unit, interventions can be targeted appropriately.

Selecting a particular goal for quality improvement is not to be taken lightly, because an inappropriate goal may lead to incorrect conclusions and thus unsuitable interventions. One example may be a goal of "decreasing ICU readmission." Although there are certainly good data to support that patients who are readmitted to the ICU have significantly increased mortality and length of stay, readmissions may more likely represent a quality issue in the post-ICU setting or may represent an epiphenomenon associated with severity of illness.[20,24-27] Quality goals need not be limited to outcome measures such as morbidity and mortality. A "change in process" goal may be equally as important, such as use of aspirin or β-blockers in patients with acute coronary syndrome. Similarly, "perceptions of care" goals (e.g., patient satisfaction, pain relief, nausea) are appropriate and require the same process of re-evaluation as any other outcome.[28] A recent review identified interventions and quality measures that, after a systematic review of the literature, improved patient outcome.[11] Quality measures that were found to be valuable (based on effect, feasibility, and strength of evidence) included the following:

1. Percentage of patients with ventilator-associated pneumonia
2. Percentage of patients with resistant infections
3. Percentage of patients with central venous catheter infections
4. Number of complications per patient
5. Average days of mechanical ventilation
6. Rate of gastrointestinal bleeding
7. Average ICU length of stay
8. Patient satisfaction

Once a protocol has met the standard of "quality," it is necessary to evaluate the effect this process will have on efficiency and cost. Inefficient protocols (or protocols that create a systems

inefficiency) are undesirable and unlikely to be adhered to by clinicians. Efficiency refers not only to the ease of implementation but also to the overall financial impact and the timing of intervention. Additionally, efficient protocols reduce management variability and, at least theoretically, reduce errors and save lives.[4,29] Protocol development, while inundated with evidence-based practice, is at a local level a trial-and-error process. Systems theory provides us with many of the crucial aspects inherent in protocol design and necessary to maximizing practicality.[30,31] Testing a new process and then evaluating the impact on the overall system was first described by Walter Shewhart, founding theorist of the field of statistical process control. Shewhart described a form of learning through action termed the Plan-Do-Study-Act (PSA) cycle.[32] One of the best examples of using the PSA cycle to implement a change in practice comes from work done by the Northern New England Cardiovascular Disease Study Group over a decade ago.[33] By continuously reevaluating variations in practice and morbidity and mortality from large databases, members of the group were able to develop protocols for such practices as anesthesia, hemostasis, and cardiopulmonary bypass pump management, achieving a 24% reduction in mortality from coronary artery bypass graft surgery within the region.

Paradoxically, protocol development and implementation can have undesirable effects, if, by impacting negatively on other high-cost therapies, overall inefficiencies result. An example of this can be seen with ICU protocols that were designed to optimize sedation and analgesia efficacy. While the initial goals of anxiolysis and pain relief were attained, adverse effects include prolonged mechanical ventilation, increased risk of nosocomial pneumonia, and hemodynamic instability.[34,35] The final aspect of protocol efficiency that deserves mention is the timing of intervention. Ill-timed implementation of evidence-based practices is at best useless and at worst harmful. An example includes protocols designed to aggressively treat severe sepsis in the emergency department.[36] The execution of these practices late in the disease process (even by 1 day) is now known to increase mortality.[37] Thus, a protocol designed to treat a disease without identifying, or at least addressing, at-risk populations and diagnosis is wasteful and potentially unsafe.

Finally, protocols facilitate rigorous clinical research. Without standards, definitions, defined pathways, and explicit interventions, the interpretation of research findings, whether prospective randomized or observational, will enhance clinical equipoise. Protocols define a standard that attempts to control for confounding variables. As they are tested and replicated, new research is being generated. There is a wealth of RCTs demonstrating improved outcome with protocol implementation.[38-42] For meaningful advances in critical care, protocols must continually embrace new findings and intensivists must be willing to adhere to guidelines. The ability to discern the applicability of a particular guideline or protocol based on the population studied is a challenge faced by all.

Protocol Design

Protocol design usually requires a multidisciplinary team[29]; however, the process mandates an appreciation of the affected variables, the ability to grade the data, a method for continual reevaluation, and inherent flexibility (Table 92-2). Affected variables are factors that will be affected indirectly (positively or negatively) by the proposed protocol. An example would be a sedation/anxiolysis protocol that does not take into account time on ventilator, incidence of nosocomial pneumonia, nausea, vomiting, and so on. In other words, they are by-products of a purposeful change in practice. Affected variables can be universal, as in the example above, or institutional. A ventilator weaning protocol may look good on paper but practically is unrealistic depending on the local staffing paradigm of respiratory therapists at a particular institution. Similarly, an ICU glycemic control protocol may work at one institution but not be as effective in another or even be deleterious.[43,44]

Table 92-2 Process for Developing Guidelines

Establishing the Process
Prioritize problems
Select a panel
Declare conflicts of interest
Agree on processes
Preparatory Steps
Systematic review of problem
Defining outcomes of interest
Preparing evidence for outcomes
Grading Quality of Evidence and Strength of Recommendations
Define quality of evidence for each outcome
Define the relative importance of outcomes
Judge *overall* quality across all pieces of evidence
Balance benefit and harm
Balance net benefits and costs
Determine strength of recommendation
Subsequent Steps
Implementation and evaluation

Reprinted from The GRADE Working Group: Grading quality of evidence and strength of recommendations. BMJ 328:1490, 2004.

Evaluating and grading the literature involves an appreciation of the various affected variables measured in a study. Additionally, the appraisal of "best evidence" must take into consideration patient population to be relevant to protocol design. Protocol committee members must understand inclusion and exclusion criteria as well as the prevalence and incidence of disease in a particular study. Only after critically analyzing studies in this fashion can practitioners begin to grade the quality of evidence. Quality of evidence traditionally refers to four components: study design, study quality, consistency, and directness.[45]

Study design refers to the basic format and aim of an investigation. Case-control, cohort, and randomized-controlled trials are all examples of study designs. The aim of case-control and cohort studies is to establish an association between some potential risk factor (i.e., hyperglycemia) and morbidity (i.e., infection) or mortality. While cohort studies can be either retrospective or prospective, case-control studies are, by definition, retrospective. RCTs are prospective and aim to identify causality rather than association. For various reasons, RCTs are considered the most decisive test and are frequently deemed definitive.[46] However RCTs are often not feasible and, particularly with regard to rare diseases or outcomes, may not be as applicable as observational studies. Many have in fact challenged the traditional hierarchical study design paradigm that places RCTs at the top and expert opinion and anecdote at the bottom.[47,48] Regardless, study design must be evaluated and graded based on the merit it holds for a specific population and a consideration of a particular outcome.

Table 92-3 Items to Consider in Evaluating Study Quality

Section/Topic	Descriptor
Title/abstract	How participants were allocated to interventions
Introduction/background	Scientific background and explanation of rationale
Methods	
Participants	Eligibility criteria for participants and the settings and locations where the data were collected
Interventions	Precise details of the interventions intended for each group and how and when they were actually administered
Objectives	Specific objectives and hypotheses
Outcomes	Clearly defined primary and secondary outcome measures and, when applicable, any methods used to enhance the quality of measurements
Sample size	How sample size was determined and, when applicable, explanation of any interim analyses and stopping rules
Randomization	
Sequence generation	Method used to generate the random allocation sequence, including details of any restriction (e.g., blocking, stratification)
Allocation concealment	Method used to implement the random allocation sequence clarifying whether the sequence was concealed until interventions were assigned
Implementation	Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups
Blinding (masking)	Whether or not participants, those administering the interventions and those assessing the outcomes were blinded to group assignment; if done, how the success of blinding was evaluated
Statistical methods	Statistical methods used to compare groups for primary outcome(s); methods for additional analyses, such as subgroup analyses and adjusted analyses
Results	
Participant flow	Flow of participants through each stage. Specifically, for each group report the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analyzed for the primary outcome.
Recruitment	Dates defining the periods of recruitment and follow-up
Baseline data	Baseline demographic and clinical characteristics of each group
Numbers analyzed	Number of participants in each group included in each analysis and whether the analysis was by "intention-to-treat"
Outcomes and estimation	For each primary and secondary outcome, a summary of results for each group, and the estimated effect size and its precision (e.g., 95% confidence interval)
Ancillary analyses	Address multiplicity by reporting any other analyses performed, including subgroup analyses and adjusted analyses, indicating those prespecified and those exploratory.
Adverse events	All important adverse events or side effects in each intervention group
Comment	
Interpretation	Interpretation of the results, taking into account study hypotheses, sources of potential bias or imprecision, and the dangers associated with multiplicity of analyses and outcomes
Generalizability	Generalizability (external validity) of the study findings
Overall evidence	General interpretation of the results in the context of current evidence

Reprinted from Moher D, et al: The CONSORT Statement: Revised recommendations for improving the quality of reports of parallel-group randomized trials. JAMA 285:1987-1991, 2001.

Study quality is altogether different from the "quality" referred to earlier. Study quality refers to the methodology and study implementation. Adequacy of blinding, method of randomization, selection of placebo, statistical analysis, and reduction of bias would all be examples of factors to be scrutinized when evaluating study quality. The revised CONSORT statement provides a useful template on which study quality indicators can be measured (Table 92-3).[49] The ability to discern adequacy of quality is neither precise nor has it been shown to be consistent among reviewers.[50] This fact has culminated in a collaborative effort to address these shortcomings and develop a process whereby intraobserver and interobserver variability in evaluation and grading of study quality is reduced.[51] Furthermore, study quality does not necessarily equate with superiority of study design. RCTs, for example, are not necessarily of highest quality. Indeed, RCTs can have significant inherent bias.[52,53] Although bias is difficult to eliminate completely from a study, it must be sufficiently reduced for a study to be of high quality. Jadad and colleagues defined study quality as "the likelihood of the trial design to generate unbiased results."[54] However, as Verhagen and associates indicate, although the reduction of bias enhances the internal validity of a study, study quality must take into account a study's external validity.[55] That is, consideration of the applicability and consequence of a study's result to the population as a whole must be deemed a variable when measuring quality. One of the ways to measure external validity is by examining the consistency and directness of an investigation.

Consistency refers to the reproducibility of results among different investigators. Consistency in the magnitude of effect, the direction of effect, and the statistical and clinical significance of a particular effect must be considered. Major inconsistencies among similar populations, by definition, decrease the quality of evidence and generalizability for a particular outcome and should be considered when grading evidence for protocol implementation. *Heterogeneity* is a statistical term used to measure consistency among studies and is frequently used in meta-analyses.

Traditionally, *Cochran's Q* statistic has been calculated by summing the squared deviations of each study's estimate from the overall meta-analytic estimate.[56] However, because this test has been shown to be poor at detecting significant heterogeneity when the number of studies is small, Higgins and colleagues have devised a more widely applicable test statistic, I^2, that describes the *percentage* of total variation across studies that is due to heterogeneity rather than chance alone.[57,58] Values of I^2 range from 0% (no observed heterogeneity) to 100%. Consideration of this value must be taken into account when designing evidence-based protocols.

Finally, the directness of a study more specifically addresses the generalizability and applicability aspect of external validity. This is an important aspect to consider later in this chapter when considering such protocols as tight glycemic control. Does the reduction of mortality seen in a single-center translate into reduced mortality for all surgical ICU patients, or do the results merely represent the consequences of improved patient care at a single institution? The same can be said of high-volume hemofiltration studies and the incidence of sepsis. It has been said that, "most patients to whom we would like to generalize the results of randomized trials would, for one reason or another, not have been enrolled in the most relevant study."[59] Despite this sentiment, *the data are what the data are*, and it is imperative the intensivist employ methods such as evaluation of directness to make decisions.[60] Evaluation of patient population, diagnostic criteria, and surrogate outcomes all must be scrutinized before application of principles or implementation of protocols based on such evidence.[61]

Protocol design must, in some fashion, address each of the above areas and rank them based on importance of outcome, severity of illness, risks and benefits of implementation, and cost. There are a plethora of systems designed to grade the literature; and most address these issues, in some way or another. A review of over 100 of these systems found that there was no single best scheme but rather that application of the *process* of evidence assessment was what was most important.[62]

Protocol Implementation

Designing a critical care protocol and *implementing* a change in practice are very different. Design is based on data review, judgment of applicability, and ranking the strength of evidence, as reviewed previously. Implementation, however, is *real world* and necessitates communication and collaboration among various members of the ICU team. Some of the more important concepts to be addressed before implementing a new protocol are education, defining targets/goals, data collection, analysis of variance, and measurement of impact.

The importance of thoughtful selection of a multidisciplinary task force to evaluate strategies for critical care protocol development and implementation cannot be understated. Most often, such groups will include both physician and nursing leadership as well as selected ancillary professionals (depending on the protocol), such as respiratory therapists, nutritionists, pharmacists, or physical therapists. Particular to the surgical ICU, physician leadership should involve both members from the critical care team and primary surgical representation.

Passive educational approaches such as didactics and dissemination of protocols have generally been shown to be ineffective implementation strategies.[63-65] Changes in physician behavior require outreach, dialogue, and discussion. Protocols that are integrated within a computerized algorithm such that warnings, reminders, and suggestions are generated when appropriate have been shown to be useful.[64] Education must address key points such as the evidence supporting a change in practice, the advantage of a new practice paradigm, and the compatibility of a novel protocol to the existing practice.

Targets and goals are usually related, although defined differently. *Targets* are frequently measured as continuous data points and often set a limit, outside of which patients are not considered to be "within protocol." *Goals* define a realistic outcome presumably obtainable if targets are met. Examples of *targets* would be maintaining glucose levels less than or equal to 150 mg/dL, elevation of the head of the bed greater than or equal to 30 degrees, administration of antibiotics within 3 hours of presentation, and maintaining inspiratory plateau pressures less than 30 cm H_2O for mechanically ventilated patients. Examples of *goals* may be decreasing sternal wound infection rate, decreasing ventilator-associated pneumonia, decreasing progression of sepsis to septic shock, and decreasing ventilator-associated lung injury. Targets and goals must be defined at the outset so that analysis of protocol compliance and effect can be objectively measured.

ICU Protocols

The focus of this section is on three protocols currently being utilized in critical care units. The purpose is not to define a particular care algorithm but rather to illustrate the process that various groups have gone through to devise best care practices. Each topic presented demonstrates a different facet of protocol development and implementation.

Glycemic Control

Since the publication of the landmark "Leuven" study, literally hundreds of protocols implementing tight glycemic control (TGC) have been published (see Chapter 91).[12] Furthermore, this single study has changed the standard of care in surgical ICUs and TGC has since been adopted by various professional societies.[66,67] How to best achieve euglycemia has been the real debate, and groups must identify, within their own infrastructure, a protocol that will work for them. An illustrative example of rational protocol design can be seen with the Stamford Hospital experience (Fig. 92-1).[68] Although the actual protocol devised by this group may be different from others, the process of design and the steps taken should serve as a model for those wishing to do similar work. The problem (i.e., "hyperglycemia is associated with increased hospital mortality") is stated at the outset. A review of the pertinent literature was undertaken and the problem was confirmed. A system was put in place to accurately quantify the problem at their institution, measure pertinent variables, and evaluate outcome. A multidisciplinary team undertook the task of devising a protocol to rectify the problem. Finally, successful implementation of the protocol was established and a statistical analysis was performed to validate the impact of the protocol.

ICU Protocol for Glycemic Management

Approved by the ICU Committee 2/01/03
Last modified by the ICU Multidisciplinary Committee 9/26/03

Rationale

Hyperglycemia is strongly associated with increased hospital mortality as well as organ system dysfunction among critically ill patients.

Goal

The goal of this protocol is to maintain serum glucose <140 mg/dL

Monitoring

Glucose levels will be evaluated *by blood testing or fingerstick testing,* using the following schedules.

Diet	Frequency of monitoring
NPO	Q8 hours: 6AM, noon, 6PM, midnight
PO diet	1 hour AC and QHS
Tube feedings, TPN	Q6 hours: 6AM, noon, 6PM, midnight

For most patients, the 6AM glucose evaluation will be obtained from the morning BMP. If glucose <140 for two consecutive days without treatment, glucose levels can be checked Q12 hours (6AM, 8PM).

Treatment of Hyperglycemia

Glucose value	Action (subcutaneous insulin dose)
<140	No treatment
140–169	3 units Regular insulin, Recheck glucose value in 3 hours
170–199	4 units Regular insulin, Recheck glucose value in 3 hours
200–249	6 units Regular insulin, Recheck glucose value in 3 hours
250–299	8 units Regular insulin, Recheck glucose value in 3 hours
300+	10 units Regular insulin, Recheck glucose value in 3 hours

*If glucose value exceeds 200 on two successive measurements, a continuous insulin infusion will be initiated. Hourly FSG or blood glucose measurements will be obtained in all patients receiving insulin infusions. The sliding scale noted above is a guideline: it can be modified if the patient requires more or less intensive therapy.

Management of Insulin Infusion

1. Initial infusion rate

Glucose value	Insulin dose
200–249	4 units/hour
250–299	6 units/hour
300–399	8 units/hour
400+	10 units/hour

Important points

*All patients receiving continuous insulin must receive a continuous source of glucose either via IV (D5W or TPN), or enteral feeds.

*The insulin infusion is discontinued if the patient has to leave the ICU for a diagnostic test as well as upon discharge from the ICU.

2. Subsequent management, based on hourly glucose checks

Glucose value	Insulin dose
<140	Stop infusion or continue low dose to avoid "rebound"
140–169	2 units/hour
170–199	3 units/hour
200–249	6 units/hour
350–399	8 units/hour
400+	10 units/hour

If this treatment plan does not lead to a decrease in the patient's glucose values, contact the house officer.

Figure 92-1 Example of rational protocol design. (*Reprinted from Krinsley JS: Effect of an intensive glucose management protocol on the mortality of critically ill adult patients. Mayo Clin Proc 79:992-1000, 2004.*)

Transfusion

It is estimated that as many as one third of patients admitted to an ICU in the United States will receive a blood transfusion (see Chapter 55).[69,70] Although the etiology of anemia in critical care patients is certainly multifactorial and not always obvious, the implications of treatment are becoming evident.[71-73] The risk of transfusion-related infections has decreased but remains. What have become more apparent, however, are the multitude of non-infectious complications associated with allogeneic transfusions, including acute lung injury and immunomodulation.[74,75] Accumulation of these negative data has resulted in the abandonment of the once well-accepted "10/30" rule, first proposed in 1942.[76] How then do intensivists decide on an appropriate transfusion "trigger"?

The best evidence regarding the efficacy of red blood cell transfusion in critically ill patients comes from the Canadian Critical Care Trials Group.[38] Patients who were managed with a restrictive transfusion strategy (maintenance of hemoglobin 7.0-9.0 g/dL, with a transfusion trigger of 7.0 g/dL) had equivalent outcomes (with a trend toward improved outcome) compared with a liberal transfusion strategy (maintenance of hemoglobin 10-12 g/dL, with a transfusion trigger of 10 g/dL). Since that time, there have been two large multicenter studies evaluating the practice of transfusion. The ABC (Anemia and Blood transfusion in Critically ill patients) trial explored the risks and benefits of transfusions in a large European population.[77] The authors were able to show a positive correlation between receipt of any blood transfusion and 28-day mortality (22.7% versus 17.1%, $P = .02$). Furthermore, the mortality risk increased in a dose-related fashion with increased transfusions. A second study, the CRIT trial, performed a similar analysis in the United States.[70] Again, transfusion was independently associated with mortality, and increased blood cell transfusion was associated with increased mortality.

Implementation of a transfusion protocol, however, requires more than a cursory understanding of the literature. As has been reviewed earlier, implementation necessitates an understanding of infrastructure, organization of a multidisciplinary team, a systematic grading of the literature, and a means to measure effect and variability in practice. What one begins to realize when reviewing the literature on this subject is that developing a transfusion "protocol" is meaningless without addressing a comprehensive blood conservation strategy. This is a point not to be overlooked in protocol design. The net effect of protocol implementation may be inconsequential if confounding variables are not addressed. Such variables impacting on the risk of transfusion include, but are not limited to, the following: contribution of phlebotomy,[72,78] inadequate salvage techniques,[79,80] and an inattentiveness to proper pharmacologic hemostatic agents.[81] One of the most cohesive and logical plans to address this topic has been published and should be used as a model for proper protocol implementation.[82]

Ventilator Weaning

There are few process-based interventions that are made in the ICU that have been more rigorously studied than the weaning of mechanical ventilation (see Chapters 91 and 93). Indeed, protocols in this area have been tested and validated, culminating in evidence-based guidelines.[83-88] Given the plethora of data, including three large randomized controlled studies that have demonstrated reduction in duration of mechanical ventilation, intensivists would be remiss if they did not currently have a protocol in place to address this issue.[41,89,90] The reason ventilator weaning protocols are being highlighted, however, is because they illustrate a critical point to understand when designing protocols: regardless of the design and the involvement of personnel, an ICU protocol will ultimately fail if confounding factors are not addressed and included within the protocol. In regard to mechanical ventilation in the ICU, one confounding factor is sedation and analgesia. Without some interface between the timing of ventilator weaning and the interruption of sedation, the compliance and success of the protocol is at jeopardy.[40,91]

The Future of Protocolized Medicine

One of the most frequent barriers to the implementation of established protocols is practitioner compliance. As was reviewed earlier in the chapter, anecdotal experience is often the enemy of evidence-based practice. Some groups have now begun looking at the removal of humans, altogether, from the decision-making process and, instead, relegating the assessments to computers and handheld devices.[86,92-95] What is more important, however, will be physicians' understanding of current technology and of recent literature, an appreciation of their limitations, and the ability to cohesively and continuously review these elements and outcomes in a pragmatic manner aimed at developing best practice guidelines.[96] Several groups have already initiated such reviews in areas such as traumatic brain injury,[97] nutritional support,[98] glycemic control,[99] and sedation/analgesia.[100] The real question that must be answered, however, is whether intensive care has become too complex to rely on a physician's ability to sort through and interpret the thousands of pieces of information that must be addressed each day.

Although protocols inevitably decrease the variability in practice, they do not address the multifaceted approach to ICU care. Some have advocated systematic development of checklists to remind team members of the multitude of goals for every patient, rather than increased protocol generation. An example is the FAST HUG mnemonic developed by Vincent[101]:

F—Feeding
A—Analgesia
S—Sedation
T—Thromboprophylaxis
H—Head of bed elevation
U—Ulcer prophylaxis
G—Glycemic control

Each component of the mnemonic should be addressed with each patient, every day. Whereas protocols may pertain and be applicable to any of the systems, the checklist helps prevent intensivists from oversight.

Conclusion

Protocol development and implementation is a complex and labor-intensive process. A multidisciplinary team is required and a specific educational plan is necessary to properly implement all facets of a protocol. Although evidence-based medicine is at the heart of the process and a detailed analysis of the literature is required, clinical acumens and anecdotes need not be ignored. Protocols are designed for the masses, and it requires a thoughtful and educated intensivist to identify those patients who may not be applicable. Protocols also allow for standardization of research protocols and minimization of confounding variables. The ability to measure the effect of a particular protocol and adapt appropriately is the key to successful protocol application. The future of critical care will certainly see an increase in the number of pro-

tocols based on quality evidence. These protocols will likely interface with various computers and handheld devices to help ensure compliance and more easily interpret the flood of information obtained on a daily basis. Intensivists will need to learn which patients are appropriate for such interventions and, with the help of checklists, ensure comprehensive patient care.

93 Respiratory Care

Key Points

1. Acute respiratory failure requiring ventilatory support occurs if a pathologic process, or a pharmacologic intervention (a) impairs the capacity of the respiratory muscles to generate sufficient Pmus; (b) increases the ventilatory requirements above the muscle capacity; (c) increases the workload associated to the act of breathing.
2. Ventilator-induced lung injury (VILI) acts as the "engine" of multiple organ dysfunction syndrome (MODS).
3. In normal subjects at rest, the end-expiratory lung volume (EELV) closely corresponds to the elastic equilibrium point of the respiratory system (functional residual capacity [FRC]). Whenever the time available for expiration is shorter than the time required for passive emptying back to FRC, air trapping will develop. Consequently, alveolar pressure will remain positive at the end of expiration, which generates a "dynamic hyperinflation," that is, a positive end-expiratory alveolar pressure, called intrinsic PEEP (PEEPi) or auto-PEEP.
4. Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) is characterized by abnormal mechanical properties of the respiratory system with the hallmark features of a reduced FRC and a reduced static compliance of the respiratory system. Measurements of the inspiratory volume-pressure curves of the respiratory system have been used in mechanically ventilated patients with ALI/ARDS as a means of assessing their status and progress and to optimize the use of PEEP and mechanical ventilation.
5. The ARDSNet study was to enroll up to 1000 patients, but accrual was stopped at 861 patients when an interim analysis revealed that the mortality rate in the lung protective group was 22% lower than in the control group. The beneficial results using 6 mL/kg ventilation (predicted body weight) occurred in all patient groups, including septic and nonseptic patients, and those with different degrees of lung dysfunction as assessed by respiratory system compliances.
6. At present the optimal level of PEEP and the best method used to set PEEP have not been definitively established for ARDS and ALI patients. Prone positioning has been demonstrated to improve oxygenation in patients with acute hypoxic respiratory failure but does not improve mortality, so that this therapeutic option might be considered useful only for ARDS patients with refractory hypoxemia. Similarly, inhaled nitric oxide led to improvements in oxygenation in ARDS patients but there was no beneficial effect on mortality. Thus, inhaled nitric oxide cannot be recommended for the routine treatment of ALI/ARDS but it may be useful as a rescue therapy in patients with refractory hypoxemia.
7. Applying noninvasive pressure support ventilation (PSV) (to unload inspiratory muscles and to increase tidal volume [V_T]) and PEEP (to counterbalance the inspiratory threshold load for the inspiratory muscles posed by PEEPi) in the early course of exacerbations of chronic obstructive pulmonary disease (COPD) reduces intubation rates, the frequency of complications, the in-hospital mortality, and the length of stay.
8. Noninvasive techniques, both continuous positive airway pressure (CPAP) and noninvasive positive-pressure ventilation (NIPPV), have been shown to reduce the need of intubation and improve outcomes in patients with acute cardiogenic pulmonary edema (ACPE). Some authors suggest that CPAP should be considered as the first-line treatment in patients with ACPE because it is less expensive and easier to implement and as efficacious as NIPPV. However, it might be better to use NIPPV in hypercapnic patients with ACPE.

Definitions

The target of ventilation is to generate flow and volume to provide adequate alveolar ventilation with the minimal work of breathing. Contraction of the respiratory muscles provides the "power" required for ventilation. The phrenic nerve regulates the timing and the intensity of this power integrating inputs from chemoreceptors, pulmonary stretching receptors, variations in metabolic demands, and so on. During "spontaneous breathing" the respiratory muscles generate a pressure (Pmus) that produces flow against the resistive and volume against the elastic properties of the respiratory system. Under these circumstances, the act of spontaneous breathing can be described at any instant as follows:

$$\text{Pmus} = \text{Pres} + \text{Pel} \quad (1)$$

where Pres represents the resistive pressure and is a function of flow (Pres = flow × resistance) and Pel represents the elastic recoil pressure and is a function of volume (Pel = volume × elastance). Assuming that resistance and elastance are linear, equation 1 becomes:

$$\text{Pmus} = (\text{flow} \cdot \text{ resistance}) + (\text{volume} \cdot \text{ elastance}) \quad (2)$$

Acute respiratory failure requiring ventilatory support occurs if a pathologic process or a pharmacologic intervention (1) impairs the capacity of the respiratory muscles to generate sufficient Pmus; (2) increases the ventilatory requirements above the muscle capacity; or (3) increases the workload associated to the act of breathing. Application of "positive" pressure (i.e., a pressure higher than the atmospheric pressure) to a patient's airway opening during the inspiratory phase is currently the main method to administer "assisted breathing" and restore adequate ventilation. The resulting pressure gradient between a patient's airway opening and alveoli generates a "positive" flow (i.e., directed from the ventilator to the patient). The expiratory phase, which is passive, depends on the end-inspiratory pressure gradient between alveolar pressure (which is positive, due to the elastic recoil pressure stored during the inspiratory phase into the respiratory system) and airway opening pressure. Under these circumstances, the pressure applied at the airway opening of the patient (Pao) includes the pressure generated by the ventilator (Pappl) plus the pressure generated by the contraction of the respiratory muscles according to the following equation:

$$\text{Pmus} + \text{Pappl} = (\text{flow} \cdot \text{ resistance}) + (\text{volume} \cdot \text{ elastance}) \quad (3)$$

Based on the relative contribution of the patient's Pmus to the total pressure applied at the airway opening, modes of mechanical ventilation can be described as "totally" or "partially" ventilator controlled.

- *Total ventilator-controlled ventilatory support:* Patient's own breathing pattern is totally replaced by the ventilator and Pmus is abolished by sedation and respiratory muscle paralysis and the ventilator imposes flow, volume, and/or pressure.
- *Partial patient-controlled ventilatory support:* The ventilator provides a fixed amount of support and the patient's Pmus is preserved. The ventilator delivers a preset VT/inspiratory flow/Pappl in response to the patient's inspiratory effort, and the patient is able to set his or her own respiratory rate and, in some cases, also the duration of inspiratory time and expiratory time and the ratio of inspiratory time to total breath cycle duration.

The capability of restoring gas exchange, unloading respiratory muscles, and relieving a patient's dyspnea with these modes of partial ventilatory support depends on the match between the ventilator settings and the patient's ventilatory demands, that is, on the "patient-ventilator interactions."[1]

Modes of Mechanical Ventilation

Positive-pressure breaths on the ventilator can be categorized by three variables: (1) the *trigger* variable (what initiates the breath), (2) the *limit* variable (what governs the gas delivery), and (3) the *cycle* variable (what terminates the breath). The variables that can regulate the triggering of ventilation include time (during controlled mechanical ventilation) or flow and pressure (during assisted mechanical ventilation). Ventilator gas delivery can be regulated to deliver flow, volume, or pressure. The ventilator can cycle from inspiration to expiration based on a preset time or on a flow/pressure threshold level. These three variables that can be set on the ventilator then affect three physiologic variables involved with breathing: (1) the ventilatory drive, that is, when inspiration starts, (2) ventilatory requirements (how much flow and volume are necessary to satisfy the metabolic demands), and (3) the timing of the integrated circuits generating the respiratory rhythm as measured by the duration and ratio of inspiratory time to the total breath cycle duration.[2]

Total Ventilator-Controlled Ventilatory Support (Controlled Mechanical Ventilation)

The main characteristic of controlled mechanical ventilation is that the variable used by the ventilator (and set by the health care provider) to *trigger* and to *cycle off* the breath is time. The *limit* variable that governs gas delivery during ventilator-controlled ventilatory support is flow and volume (controlled mechanical ventilation [CMV]) or pressure (pressure-controlled ventilation [PCV]) (Fig. 93-1). With the former, the ventilator applies either a constant (square shaped) or nonconstant (in the majority of the cases decelerating) flow to deliver a preset tidal volume (VT). Flow is the independent variable (i.e., the ventilator maintains the predetermined flow pattern whatever the patient's impedance), and the airway opening pressure (Pao) profile during inflation depends on the mechanical characteristics of patient's respiratory system. With the latter, the ventilator applies a preset positive-pressure level (commonly, square shaped) to the patient's airway opening. Pao is therefore the independent variable held constant by the ventilator, whereas delivered VT will depend on the inspiratory time and on the mechanical characteristics of the respiratory system. The inspiratory flow starts with a peak followed by the exponential flow decay and becomes nil as soon as the applied pressure equals alveolar pressure.

The choice between volume- and pressure-cycled modes is not supported by randomized controlled trials. Volume-cycled modes are to be preferred when maintaining minute ventilation is crucial, such as in head-injured patients. Physiologic studies have suggested a more homogeneous distribution of VT when

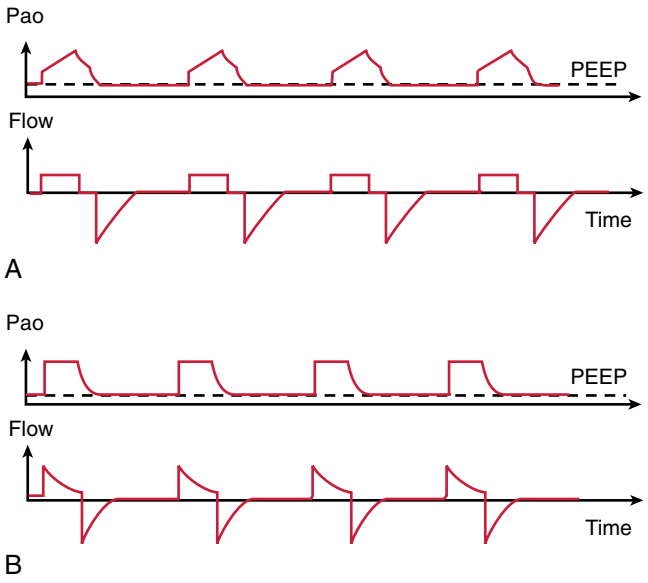

Figure 93-1 Tracings of flow and airway opening pressure (Pao) during the two basic controlled intermittent positive-pressure ventilation (IPPV) modes. Volume-cycled (**A**) and pressure-cycled (**B**) IPPV. PEEP, positive end-expiratory pressure.

ventilating patients with acute respiratory distress syndrome (ARDS) with the pressure-cycled mode.[3]

A controlled mode able to share the theoretical advantages of constant pressure with the guarantee of delivering a preset VT has been recently offered in newer mechanical ventilators ("pressure-regulated volume control" or "volume plus"). It consists of a closed-loop algorithm that, based on the measurement of static compliance of the respiratory system, changes the level of applied pressure on a breath-by-breath basis to match a "target" tidal volume. There are no data documenting superiority of the newer ventilator modalities.

Partial Patient-Controlled Mechanical Support (Assisted Mechanical Ventilation)

Partial ventilatory support techniques are intended to unload the respiratory muscles and relieve dyspnea in patients with impaired neuroventilatory coupling. The main characteristic of assisted mechanical ventilation is that the ventilator provides ventilatory support while the patient's Pmus is preserved. The patient will therefore be able to contribute some degree of ventilator support. The "degree of freedom" gained by the patient may include setting the respiratory rate and establishing the breathing pattern (inspiratory time, expiratory time, duration and ratio of inspiratory time to total breath cycle duration). The capability of restoring gas exchange, unloading respiratory muscles, and relieving a patient's dyspnea with these modes of partial ventilatory support depends on how well there is a match between the ventilator settings and the patient's ventilatory demand.[1,2,4]

The rationale for preserving diaphragmatic activity in the critically ill patient needing ventilatory support is to reduce the need for sedation and paralysis, avoid disuse atrophy of the respiratory muscles, and minimize the cardiovascular side effects of mechanical ventilation.[5] Moreover, as compared with controlled modes, partial ventilatory support has been shown to improve ventilation/perfusion $\left(\dot{V}/\dot{Q}\right)$ mismatch by reaerating dependent lung areas, perhaps through the effects of contraction of the diaphragm. However, if patient-ventilatory asynchrony develops it may even cause harm and delayed weaning from mechanical ventilation or both.

Assist/Controlled Mechanical Ventilation

The patient is allowed to set his or her own respiratory rate by activating the inspiratory trigger function (as a safety measure, if no spontaneous effort occurs, the ventilator will deliver controlled breaths at a preselected backup rate). The variable used by the ventilator to *cycle off* the breath is time. The *limit* variable that governs gas delivery is flow and volume (assisted/controlled mechanical ventilation [A/CMV]) or pressure (assisted pressure controlled ventilation [A/PCV]).

To activate a pressure trigger, the patient needs to decrease pressure in the respiratory circuit at a preset threshold level, whereas with a flow trigger system the patient needs to generate a preset amount of inspiratory flow. The inspiratory effort necessary to trigger a breath has been estimated to be about 17% and about 12% of the total inspiratory effort during pressure and flow triggering, respectively.

Several studies have questioned the ability of A/CMV to meet patient inspiratory demand. Marini and coworkers showed that during patient-triggered breaths, effort does not cease with the onset of gas delivery and that total inspiratory workload during A/CMV may even exceed the work performed during spontaneous breathing.[6] Physiologic studies have shown that patient-ventilator synchrony during A/CMV critically depends on the quality of the trigger mechanism (pressure versus flow-triggers) and on the kind of controlled breath delivered (volume versus pressure-cycled): combining flow-trigger and A/PCV improves patient ventilator interactions owing to the higher inspiratory peak flow as compared with the volume-cycled mode.[7]

However, with A/CMV, by definition, the neuroventilatory coupling is not restored and the amount of work performed by the ventilator will decrease at expense of patient's effort. This ventilatory mode is in general poorly tolerated by awake subjects and may induce respiratory alkalosis and air trapping, particularly in patients with dynamic hyperinflation.

Synchronized Mandatory Ventilation

Synchronized mandatory ventilation (SIMV) allows the patient to breathe spontaneously between a preset number of assist/controlled breaths. Depending on the SIMV modality, controlled breaths may be volume or pressure cycled. Spontaneous breathings may be supported by a variable degree of pressure support (see next section). Varying the rate of mandatory breaths allows either nearly total ventilatory support or fully spontaneous breathing. Regarding patient-ventilator interactions, SIMV shares the same limitations as A/CMV

Pressure Support Ventilation

Pressure support ventilation (PSV) is at present the most popular partial ventilatory support technique either to wean patients from controlled ventilatory modes or to ventilate patients who have acute respiratory failure.[8] During PSV, the patient's spontaneous effort triggers the ventilator and is assisted by a constant positive

pressure (Pappl; see Equation 3). VT depends on the interplay between Pmus, Pappl, and respiratory system impedance (see equations 2 and 3). As a consequence, PSV unloads respiratory muscles and improves the interaction between the patient efforts and VT, in the sense that, for a given inspiratory effort, the patient generates a greater volume than during spontaneous breathing. The ability of PSV to relieve dyspnea, unload the inspiratory muscle effort, and improve gas exchange has been clearly shown.[9] However, the patient is relatively unable to modulate the ventilatory pattern through changes in inspiratory effort while on PSV.[9]

Cycling from the inspiratory to the expiratory phase in PSV occurs when the inspiratory flow rate decreases to a preset level (which, depending on the ventilator, is a fixed or adjustable percentage of peak inspiratory flow). Expiratory sensitivity can be fixed or can vary from 5% to 90% or from 5 to 25 L/m. Modifying the pressure rise time at the beginning of inflation (inspiratory pressure-slope) can influence the expiratory threshold by its effect on the peak inspiratory flow value. There is some evidence that the rapid pressure rise that occurs during PSV might reduce the work of breathing in patients.[10] The decay of inspiratory flow is clearly a surrogate signal to the patient's neural network.[11] If the patient performs weak inspiratory efforts or the applied pressure is relatively high as compared with patient's needs, or both, the ventilator will prolong its inspiratory assistance well beyond the duration of spontaneous inspiration, generating a severe discrepancy between the "neural" and "mechanical" inspiratory time.[12] Adjusting applied pressure to maintain a respiratory rate between 20 and 35 breaths/min and VT between 5 and 8 mL/kg has been recommended as a clinical means to optimize ventilatory support during PSV.[13]

Proportional Assisted Ventilation

During proportional assisted ventilation (PAV), the ventilator amplifies the patient's effort in generating pressure in proportion to the patient's generated flow and volume. What is preset is not a target pressure but the proportion between the patient's inspiratory muscle effort and the ventilator-applied pressure.[9,14]

To realize a proportional assistance, the ventilator measures the spontaneous patient's instantaneous flow and volume through its internal sensors while the intensivist is required to measure and then set the values for elastance and resistance. Knowing all these parameters, the ventilator processor then estimates Pmus (see Equation 2) and assists the patient's effort in a proportional fashion. To do so, the ventilator delivers a pressure assist in proportion to the ongoing administered volume summed with another pressure assist in proportion to the instantaneous inspired flow.

The difference between PAV and PSV is a larger degree of tidal volume variability over time with PAV.[15] A sudden hypercapnic stimulus during PAV triggers a compensatory increase in minute ventilation mostly obtained by an increase in tidal volume, with no change in respiratory rate. In contrast, patients ventilated with PSV react by increasing respiratory rate but are unable to significantly increase VT. Thus, as compared with PSV, PAV better mimics the physiologic response to hypercapnia.[7] PAV has been shown to significantly unload the inspiratory muscles and improve the breathing pattern in patients with chronic obstructive pulmonary disease (COPD).[16]

To correctly set PAV a reliable estimation of elastance and resistance needs to be done (see Equation 2). If the estimate is correct, the pressure generated by the ventilator will be lower than the pressure required to offset the passive properties of the respiratory system: the patient will maintain his or her spontaneous respiratory activity, and the ventilator will continue to work by proportionally amplifying the patient's efforts. Both underestimation and overestimation of elastance and resistance may critically impair these patient/ventilator interactions. If elastance and resistance are *underestimated,* the level of assistance provided by PAV would be insufficient to relieve the patient's dyspnea, while, in contrast, if elastance and resistance are *overestimated,* a positive feedback will develop and the ventilator will continue to deliver flow and volume while the patient stops his or her inspiratory effort (the "*run-away*" phenomenon). The full potential benefits of PAV may be obtained only with a correct estimation of the elastic and resistive properties of the respiratory system and a continuous adaptation of the level of assistance to the changes in respiratory mechanics over time. To ameliorate these problems, PAV plus (PAV+) allows an automatic and noninvasive measure of elastance and resistance through a ventilator's internal sensors, and thus the ventilator continuously adapts the proportional assistance according to these measurements. The noninvasive assessment of the respiratory system mechanics is based on the application of brief (100 to 300 msec) occlusions on airway opening at end inspiration during PAV.[17,18]

Neurally Adjusted Ventilatory Assist

Neurally adjusted ventilatory assist (NAVA) consists of an innovative system able to measure electrical activity of the diaphragm by means of an electrode array inserted into a nasogastric tube that is placed in the lower esophagus and then is able to sense the diaphragmatic activity. This signal from the diaphragm is used both to trigger the ventilator ("neural" trigger function) and to assist the patient's inspiratory effort in proportion to the diaphragmatic electrical activity. With NAVA, the patient's respiratory drive controls the assisted positive breaths in all phases of the ventilatory cycle, from triggering to cycling between the inspiratory and the expiratory phase (Fig. 93-2). Any change in the patient's ventilatory output is matched on a breath-by-breath basis. Although several preclinical and experimental studies documented the potential advantages of NAVA to correctly restore the neuroventilatory coupling,[19,20] this promising technique is not yet available on current ventilators and there are a number of technical issues that have to be resolved before it can be used routinely.

Positive End-Expiratory Pressure/ Continuous Positive Airway Pressure

Positive end-expiratory pressure (PEEP) is the positive pressure applied at the end of expiration during mechanical ventilation. A constant level of positive pressure applied to a spontaneous breathing cycle is named continuous positive airway pressure (CPAP). Physiologic consequences of PEEP/CPAP depend on its effects on gas exchange, pulmonary compliance, and systemic hemodynamics.

Effects on Gas Exchange

PEEP/CPAP may improve arterial oxygenation by reexpanding functionally collapsed alveoli, redistributing lung water, and thereby, reducing $\dot{V}/\dot{Q}$ mismatch.

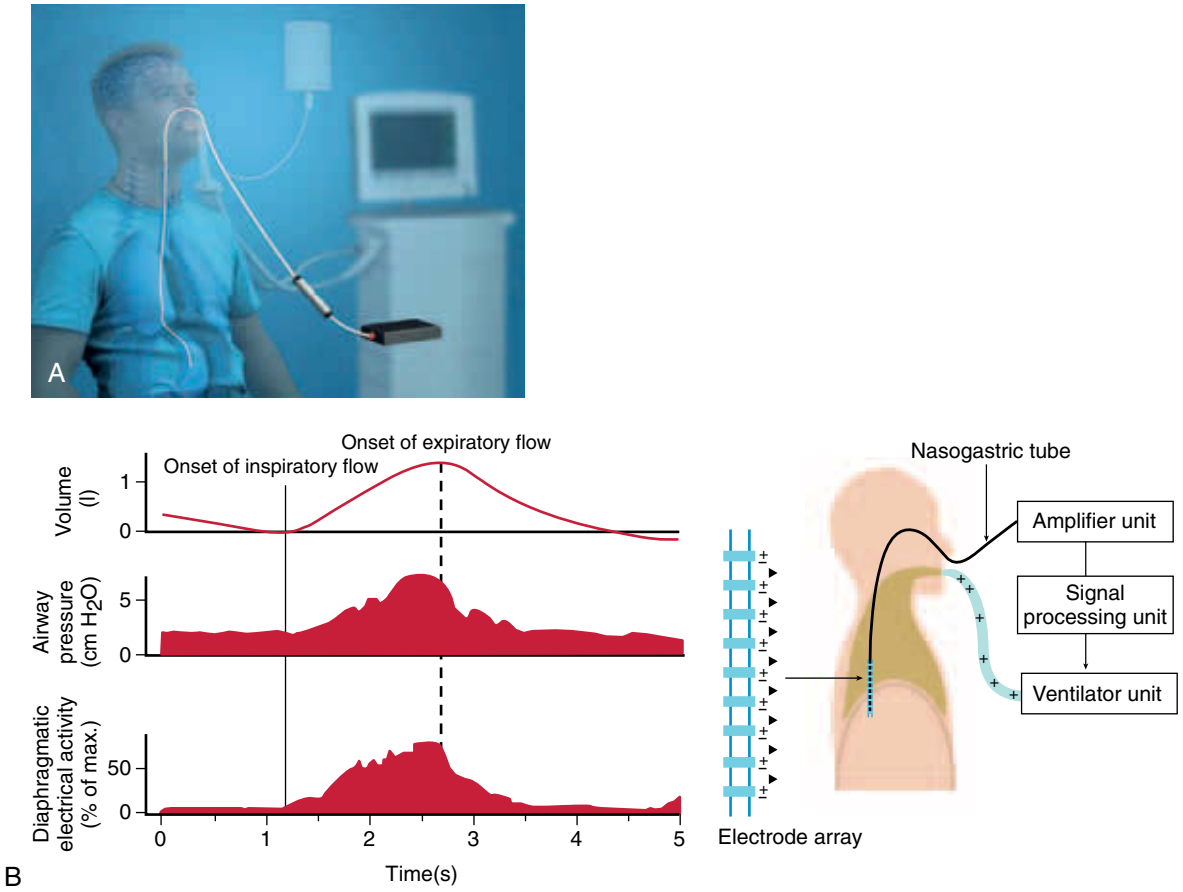

Figure 93-2 **A** and **B,** The neurally adjusted ventilatory assist (NAVA) concept. An electrode array, inserted into a nasogastric tube and placed in the lower esophagus, is able to sense the diaphragmatic activity. This signal is used both to trigger the ventilator ("neural" trigger function) and to assist patient inspiratory effort in proportion to the diaphragmatic electrical activity.

Alveolar recruitment, defined as the amount of noninflated tissue that is reexpanded by a given level of PEEP/CPAP, results in a more homogeneous distribution of the V_T and an increase in the functional residual capacity (FRC). Moreover, the application of PEEP/CPAP leads to the redistribution of lung water from the alveolar space to the perivascular interstitial space and improves $\dot{V}/\dot{Q}$ mismatch by diverting blood flow from shunt regions to normal regions.

All these effects depend on whether the applied PEEP/CPAP recruits previously collapsed alveoli.[21,22] If the applied PEEP/CPAP induces alveolar recruitment, a reduction in shunt with improvement in oxygenation and a reduction in dead space will be seen. On the other hand, if hyperinflation of normal alveoli occurs predominately, a rise in $Paco_2$ due to the increase in dead space will be seen while the Pao_2 could decrease, depending on whether the applied PEEP/CPAP deceased cardiac output.

PEEP/CPAP Effects on Respiratory Mechanics

Compliance of the respiratory system (i.e., $V_T \div$ Ppl − PEEP) represents a good estimate of the elastic properties of the respiratory system. Application of PEEP/CPAP may lead to the following effects on compliance:

- Increase in compliance, suggesting alveolar recruitment
- No change in compliance, indicating that ventilation is occurring on the linear portion of the volume/pressure relationship of the respiratory system
- Decrease in compliance indicating lung overdistention

The interpretation of the effects of PEEP/CPAP on the respiratory system requires assessment of both the lung and chest wall mechanics.

PEEP/CPAP Effects on Hemodynamics

The application of PEEP/CPAP may affect hemodynamics through several different mechanisms: decreased venous return to the right side of the heart, increased right ventricular afterload, decreased ventricular compliance, and decreased ventricular contractility.[23-25] Overall, the hemodynamic consequences of the application of PEEP/CPAP depend on the prior ventricular loading conditions and the ventricular function and on the effect of PEEP/CPAP on lung mechanics.

In patients with normal cardiac function, the main consequence of increased intrathoracic pressure is the reduction of venous return and a reduction of cardiac output. Because the right ventricular preload decreases, an adequate circulating blood volume is required before the application of PEEP/CPAP to

prevent depression of right ventricular output. In patients with poor left ventricular function or congestive heart failure, the increase in intrathoracic pressure reduces the left ventricular transmural pressure, leading to a reduction in left ventricular afterload and an improvement in left ventricular function. In these patients, cardiac output is relatively insensitive to the reduction in venous return because diastolic volume is elevated.[26]

Noninvasive Ventilation

Mechanical ventilation is usually applied through a endotracheal tube or a tracheotomy. An impressive series of studies have demonstrated the efficacy of mechanical ventilation noninvasively applied to patient's mouth or nose to restore respiratory function minimizing the side effects associated with invasive ventilation. Noninvasive ventilation is delivered almost exclusively through partial ventilatory support techniques. Potential advantages of avoiding endotracheal intubation include less patient discomfort, reduced need for sedation, and a lower incidence of ventilator-associated pneumonia and sepsis.[27] Clinical trials have shown that in specific clinical situations there is a significant improvement in patient outcomes when endotracheal intubation can be avoided.[28] However, the success of noninvasive ventilation critically depends on the correct patient selection and on the expertise of the team applying it, because recent data suggest that patients intubated after an unsuccessful trial of noninvasive ventilation can experience a longer duration of invasive mechanical ventilation and a longer intensive care stay.[29]

The established indications for noninvasive ventilation, supported by large randomized controlled trials, are acute COPD exacerbation, acute cardiogenic pulmonary edema, postoperative respiratory failure, and respiratory failure in immunocompromised patients (e.g., solid organ transplant recipients and bone marrow transplant patients; see later).[29]

In other clinical situations, noninvasive ventilation should be applied with caution. Lower intubation rates and shorter hospital lengths of stay were reported in patients with community acquired pneumonia treated with noninvasive ventilation.[30] In experienced centers the application of noninvasive ventilation to ARDS patients as a first-line intervention avoided intubation in approximately 54% of the cases,[31] whereas CPAP was not associated with better survival nor with a decreased length of hospital stay.[32] The use of noninvasive ventilation as a means to accelerate weaning from invasive ventilation has been the object of extensive, although inconclusive, clinical investigations. Its use as a weaning technique in "difficult to wean" COPD patients when the standard criteria for spontaneous breathing were not met was associated with conflicting results on the duration of mechanical ventilation and mortality in two clinical studies.[33,34] Recently, it has been shown that noninvasive ventilation does not prevent reintubation in patients developing acute respiratory failure after extubation.[35] There are too few studies available to establish a place for noninvasive ventilation in acute asthma, upper airway obstruction, and trauma. Other possible fields of application are during fiberoptic bronchoscopy in hypoxemic or hypercapnic patients[36] and as a palliative therapy in patients who are not candidates for invasive ventilation.[37]

Two recent publications evaluated the efficacy on noninvasive ventilation in two large and distinguished hospitals (Massachusetts General Hospital, Boston, and Molinette Hospital, Turin, Italy).[38,39] Both studies indicated that noninvasive ventilation as routine standard medical care resulted in the intubation of a similar percentage of patients with respiratory failure due to cardiogenic pulmonary edema and COPD exacerbation as shown in randomized controlled trials but in a higher percent of patients with hypoxemic respiratory failure than reported in these trials. Failure of noninvasive ventilation was associated with high hospital mortality for patients with hypoxemic respiratory failure.

Predictors of success for noninvasive ventilation include younger age, lower acuity of illness (as quantified by the Acute Physiology and Chronic Health Evaluation II [APACHE II] or SAPS [Simplified Acute Physiology Score] II score), ability of the patient to cooperate, intact dentition, technical ability to minimize air leaks, moderate hypercapnia (i.e., between 45 and 90 mm Hg), and moderate acidosis (i.e., pH between 7.35 and 7.10).[40] A successful trial of noninvasive ventilation should induce a trend toward slower respiratory rates and decrease in $Paco_2$ within 30 to 60 minutes.

The ideal interface for noninvasive ventilation should allow optimal patient comfort and minimal air leaks. Both masks (oronasal or nasal) and helmets are currently available. The oronasal mask induces air leaks in 80% to 100% of the patients, facial skin reddening in 20% to 34%, mask intolerance in 8% to 32%, nasal-mouth dryness and nasal congestion in 10% to 20%, nasal bridge ulceration in 2% to 31%, eye irritation in 16%, gastric distention in 8%, and aspiration in 6% All these side effects may be minimized by using the helmet, but this interface may induce delay in ventilatory assistance with PSV and cause significant acoustic noise.[41]

Patient monitoring during noninvasive ventilation includes frequent checking of the interface to evaluate CO_2 rebreathing, accidental disconnection from the ventilator, air leaks, skin necrosis, and the ability of the patient to clear secretions. Monitoring of physiologic parameters (oximetry, arterial blood gases, exhaled Vt, respiratory rate, use of accessory respiratory muscles, paradoxical abdominal motion, gastric distention, heart rate, and blood pressure) and of subjective parameters (mental alertness, comfort, dyspnea) is of paramount importance for patient safety. It has been estimated that respiratory therapists spent more time with patients treated with noninvasive ventilation when compared with the time they spend with patients who are endotracheally intubated in the first 8 hours, but this trend is reversed in the subsequent 8 hours.[42]

Nonconventional Ventilatory Support

Modalities of ventilatory support described previously are defined as "conventional" because they are based on two principles: (1) they deliver a Vt higher than the dead space volume; and (2) they apply a positive pressure at the airway opening. Hereafter we will describe modalities of ventilatory support that are defined as nonconventional when they are based on the application of a Vt lower than the dead space volume (*high-frequency oscillation*) and on the use of external gas exchangers that bypass the lung and the heart so they provide ventilator support without the need (or with limited need) of positive pressure (*extracorporeal support*).

High-Frequency Oscillation

High-frequency oscillation (HFO) is an open ventilator system that maintains continuous exchange with the atmosphere and

escape of ventilated gases through an open port. A bulk flow provides fresh air to the circuit, and small tidal volumes delivered by the strokes of the device sustain alveolar ventilation. During conventional mechanical ventilation, V_T is higher than alveolar dead space (V_{DS}) and alveolar ventilation can be described by the following equation:

$$f V_A = f (V_T - V_{DS})$$

where V_A is the alveolar volume, V_{DS} the dead space volume, and f the frequency. This equation predicts that the minute alveolar volume is a positive value if V_T is higher than dead space. During HFO a V_T lower than the anatomic dead space (1-3 mL/kg) with a very high frequency is delivered (3-15 Hz).[43]

An important concept during HFO is that it provides an *active* expiration. In other words, during HFO, inspiration and expiration are independent of the level of applied pressure and CO_2 removal and oxygenation are not coupled to the inflation/deflation of the lung. Alveolar gas exchange is therefore entirely due to the bulk flow of fresh air delivered through the circuit through different mechanisms, including (1) direct ventilation by low V_T of those alveoli located more proximally; (2) pendelluft occurring between nearby lung units with different time constants; (3) streaming of inspiratory/expiratory flow in diverging alveolar ducts; and (4) axial convection and lateral mixing.

Extracorporeal Support

Extracorporeal support (ECMO) was proposed to maintain the lung "at rest" while providing adequate gas exchange, but a randomized clinical trial did not show a decrease in mortality.[44] A modified technique (low-frequency positive-pressure ventilation with extracorporeal CO_2 removal [LFPPV-ECCO2R]) was later proposed to inflate the lungs to moderate pressures to maintain FRC while CO_2 removal was ensured by a low flow partial veno-venous bypass. Although the first studies showed promising results, further studies failed to confirm beneficial effects.[45] Consequently, this technique is considered only in patients with severe hypoxemia and hypercapnia unresponsive to optimal management. Results of an ongoing randomized clinical trial comparing patients treated locally with conventional techniques or transported to a center that offers ECMO are expected (www.cesar-trial.org).

Recent advances in technology have proposed new extracorporeal CO_2 removal devices as rescue therapy in severe ARDS to optimize a protective ventilatory strategy. The arteriovenous pumpless devices use the arteriovenous pressure gradient to force blood through a very low-resistance heparinized circuit.[46] The main advantages are lower anticoagulation requirements, small priming volume, little mechanical damage to blood components, and absence of recirculation. On the other hand, it does not offer direct blood flow control, it increases left-to-right shunt, and it could lead to lower-limb ischemia owing to prolonged arterial cannulation. Recently, a new venovenous bypass has been proposed and found to be efficient in removing 20% of CO_2 in the experimental setting.[47]

Monitoring Controlled Mechanical Ventilation

The analysis of the airway opening—time (Pao-t) signal obtained when applying volume-cycled constant-flow ventilation with a brief end-inspiratory pause allows monitoring of the mechanical properties of the respiratory system. The Pao-t during constant flow includes the following information (Fig. 93-3):

- *Resistive pressure increase* (AB tract in Fig. 93-3) represents the step increase in Pao that occurs at the beginning of inspiratory flow delivery. It is not perfectly perpendicular to the time axis but shows a discrete slope owing to the inability of the ventilator to generate a sudden increase in flow and to the inhomogeneities of different lung regions.
- *Elastic pressure increase* (BC tract in Fig. 93-3) represents the increase in Pao generated by the progressive inflation of respiratory system, whose slope depends on the elastic properties of the respiratory system. It is not always linear, because its profile may be curvilinear when the respiratory system compliance varies with lung inflation (see later).
- Pao_{peak} (point C in Fig. 93-3) is the peak in Pao reached at end inspiration. For a given flow rate and inspiratory time, Pao_{peak} expresses both the "resistive" and "elastic" pressure increase. After Pao_{peak}, the Pao-t profile during the end inspiratory pause (when both the inspiratory and the expiratory valves are closed) can be divided into two regions: (1) an immediate pressure drop from Pao_{peak} to $Pao_{occlusion}$ (point D in Fig. 93-3) owing to the interruption of flow that makes the "resistive" pressure nil and (2) a slower decay from $Pao_{occlusion}$ to the end-inspiratory pressure (Pao_{plat}) (point E in Fig. 93-3) that depends on a gas redistribution process between areas with different elastic and resistive characteristics and on the inertial properties of lung tissue. For a given V_T, Pao_{plat} expresses the elastic properties of the respiratory system. After the end-inspiratory pause, the expiratory valve is open while the inspiratory valve is closed and the respiratory system is allowed to passively exhale to the elastic equilibrium point of the respiratory system (EF tract in Fig. 93-3). If an end-expiratory valve is added to the expiratory limb of the ventilatory circuit, the FG tract is equal to the value of the *applied PEEP*.

The rate of change of the airway pressure-time curve during constant flow inflation has been shown to correspond to the rate of change of the compliance of the respiratory system during tidal inflation: a progressive increase in slope of the curve indicates that compliance is progressively increasing, whereas a progressive decrease in slope of the curve indicates that compliance is decreasing with tidal inflation; a linear increase of pressure indicates that compliance is constant throughout inflation.[48,49] Progressive increase or decrease in compliance during inflation is associated with tidal alveolar opening and collapse and tidal alveolar hyperinflation, respectively,[50] that is, with the main mechanisms responsible for mechanical ventilation-induced lung mechanical stress.[51] Hence, by analyzing the Pao-t profile during a period of constant-flow inflation (BC; see Fig. 93-3) the occurrence of tidal alveolar recruitment/de-recruitment or overinflation or both may be detected noninvasively (the *stress index* concept; Fig. 93-4). Recent data indicate that titrating the PEEP level according to the *stress index* analysis can minimize ventilator-induced lung mechanical stress in ARDS patients and suggest that continuous monitoring of the *stress index* may be useful to set up a lung-protective ventilatory strategy.[52]

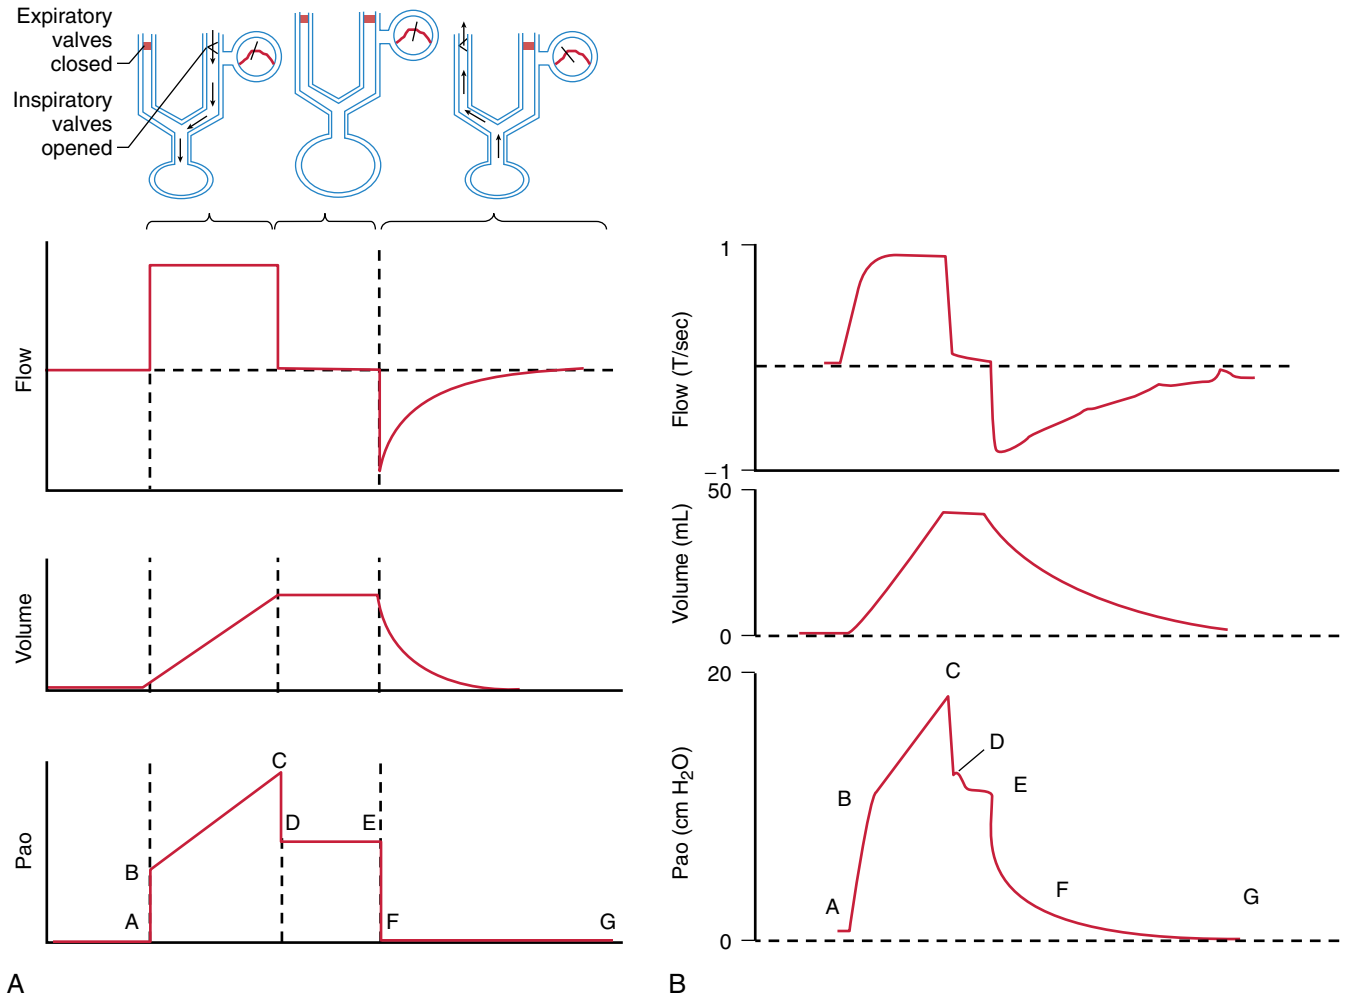

Figure 93-3 Flow, volume, and airway opening pressure (Pao) tracings recorded during controlled constant-flow mechanical ventilation applied. Theoretical traces related to the different phases of the ventilator duty cycle (**A**) and to a monocompartmental lung model (**B**). Mechanical ventilators are not able to generate a perfectly square inspiratory flow tracing such as in the model and the model does not take into account the respiratory system viscoelastic and inertial properties and the inhomogeneities among different lung regions. Accordingly, the AB tract ("resistive" pressure increase) is not perfectly perpendicular to the time axis and a transient phase of pressure slope variation substitutes a discrete B point. The BC elastic pressure increase is not always linear, but its profile may be curvilinear because respiratory system compliance and resistances may be nonlinear in the range of the delivered volume. Finally, after the C point (Pao_{peak}), the Pao-t profile from Pao_{peak} to Pao_{plat} (E) can be divided into two regions: (a) an immediate pressure drop from Pao_{peak} to $Pao_{occlusion}$ and (b) a slower decay from $Pao_{occlusion}$ to Pao_{plat} that take place in 2 to 5 seconds. The latter is principally due to alveolar gas redistribution between areas with different elastic and resistive characteristics (whose pressures at end-inspiration are not in equilibrium). Hence, the $Pao_{occlusion} - Pao_{plat}$ difference is proportional to the inhomogeneities between different lung regions.

Respiratory resistance is the opposition to gas flow through the respiratory system and is quantified as the amount of pressure required to cause a unit rate of gas flow, according to Ohm's law:

$$\text{Resistance} = \text{driving pressure}/\text{flow rate}$$

where driving pressure is the "resistive" pressure applied to generate a given constant laminar flow in the airways. The total resistance of the respiratory system is the sum of pulmonary resistance (airway resistance plus lung tissue resistance) and chest wall resistance (essentially tissue resistances) and is expressed in cm H_2O/L/sec. The total resistance of the respiratory system (*Rmax,rs*) is therefore proportional to the Ppeak-Pplat pressure decay when the constant flow is suddenly interrupted, according to the equation:

$$\text{Rmax,rs} = (\text{Ppeak} - \text{Pplat})/\text{Flow}$$

Rmax,rs may be further partitioned into the airway resistance (Rmin) and additional resistances (ΔR). The immediate drop of pressure from Ppeak to $Pao_{occlusion}$ is proportional to the airway resistances:

$$\text{Rmin} = (\text{Ppeak} - Pao_{occlusion})/\text{Flow}$$

while the slower decay from D to Pplat is proportional to the "additional" resistances:

$$\Delta R = \text{Rmax,rs} - \text{Rmin}$$

In normal subjects during general anesthesia, for a flow of 0.4 L/sec and in the normal VT range, Rmax,rs is 5 to 6 cm H_2O/L/sec and Rmin is 2 to 3 cm H_2O/L/sec.

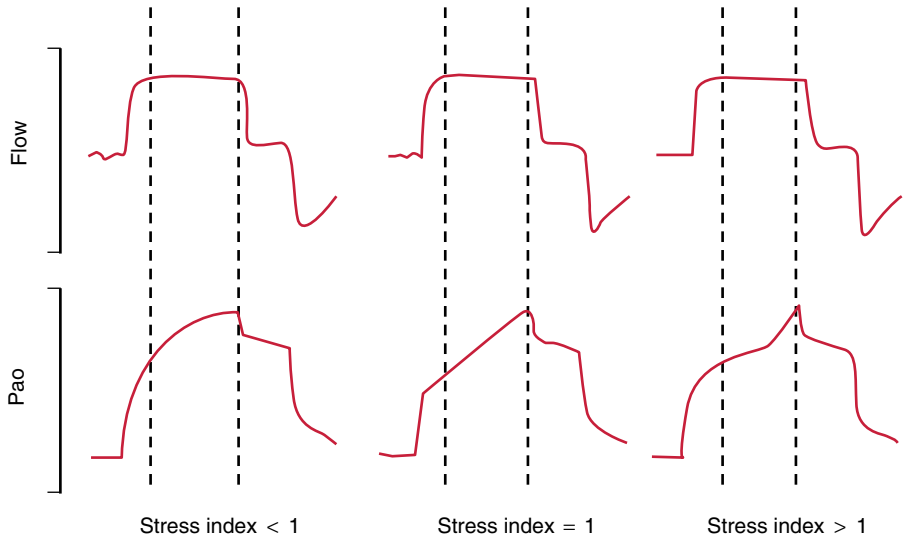

Figure 93-4 The stress index concept. Tidal alveolar recruitment/de-recruitment or overinflation or both may be detected through the analysis of the Pao-t profile during the period of constant flow inflation. A downward Pao-t concavity indicates progressive increase in compliance during tidal inflation, owing to ongoing alveolar recruitment with inflation, whereas an upward Pao-t concavity indicates progressive decreases in compliance during tidal inflation owing to ongoing alveolar overinflation with inflation. To measure the stress index a power equation ($Pao = a \cdot t^b + c$) is fitted on the Pao-time profile. Here, the coefficients a and c are constants and the coefficient b is a dimensionless number that describes the shape of the Pao-t profile (stress index). For a coefficient $b < 1$ the Pao-t profile has a downward concavity (compliance increases with inflation), whereas for a coefficient $b > 1$ the Pao-t profile has an upward concavity (compliance decreases with inflation). Finally, when $b = 1$ the Pao-t profile is straight and compliance remains constant during inflation.

Rmin,rs is increased in pathologic conditions characterized by the increase in airway resistances, such as asthma, acute cardiogenic pulmonary edema, ARDS, and COPD. However, because Rmin,rs is the sum of airway resistances and ventilatory circuit and endotracheal tube resistances, the possibility of an endotracheal tube obstruction should be always considered in the differential diagnosis. Both lung and chest wall inertial properties and lung inhomogeneities (expressed by ΔR) may be increased in some pathologic conditions, such as in patients with severe COPD or in morbidly obese patients.

Measuring PEEPi in passive patients during controlled mechanical ventilation (static intrinsic PEEP, PEEPi,st) is easily accomplished using a 5- to 10-second end-expiratory hold maneuver (during the contemporary closure of both inspiratory and expiratory valves at end-expiration), which allows the ventilator's pressure transducer to read the end-expiratory alveolar pressure (Fig. 93-5). This is the total respiratory system positive end-expiratory pressure (PEEPtot). In patients with dynamic hyperinflation, the value of PEEPtot is higher than the value of the applied PEEP (PEEPext) and PEEPi,st is the difference between PEEPtot and PEEPext.

When using partial ventilatory support techniques, PEEPi needs to be measured in a dynamic fashion (PEEPi,dyn). The gold standard method is based on continuous recording of flow, Pao, esophageal pressure, and eventually gastric pressure (Fig. 93-6).

Static respiratory system compliance (Cst,rs) is defined as the change in respiratory system volume per unit change in applied pressure (expressed in mL/cm H_2O):

$$Cst,rs = V_T / \left(Pao_{plat} - PEEPtot\right)$$

where Pao_{plat} is measured at the end of a 2- to 5-second end-inspiratory pause (point E). Elastance, the mathematical inverse of compliance, is expressed in cm H_2O/mL as:

$$Est,rs = \left(Pao_{plat} - PEEPtot\right) / V_T$$

For a correct calculation of Cst,rs, PEEPtot must be used instead of PEEPext, to discriminate between an increase in Pao_{plat} due to dynamic hyperinflation (where PEEPtot is higher than PEEPext and Cst,rs is not affected) and an increase in Pao_{plat} due to reduction of Cst,rs (where PEEPtot is equal to PEEPext).

Role of Chest Wall Mechanics

Lung and the chest wall are "in series": hence, Cst,rs is the sum of lung and chest wall compliance (respectively, Cst,L and Cst,cw) and Est,rs is the sum of lung and chest wall elastance (respectively, Est,L and Est,cw):

$$1/Cst,rs = 1/Cst,L + 1/Cst,cw$$

and hence

$$Est,rs = Est,L + Est,cw$$

Cst,cw and Est,cw are calculated as:

$$Cst,cw = V_T\left(Pes_{end\text{-}inspiratory} - Pes_{end\text{-}expiratory}\right)$$

and

$$Est,cw = \left(Pes_{end\text{-}inspiratory} - Pes_{end\text{-}expiratory}\right) / V_T$$

From a theoretical point of view, pleural pressure variations should be used instead of esophageal pressure to measure the pressure surrounding the lungs. However, pleural pressure measurements are virtually impossible in clinical practice whereas the esophageal pressure recording is commonly used as a substitute.

Pes is recorded with the patient in a semi-recumbent position through an air balloon–equipped catheter inserted in the

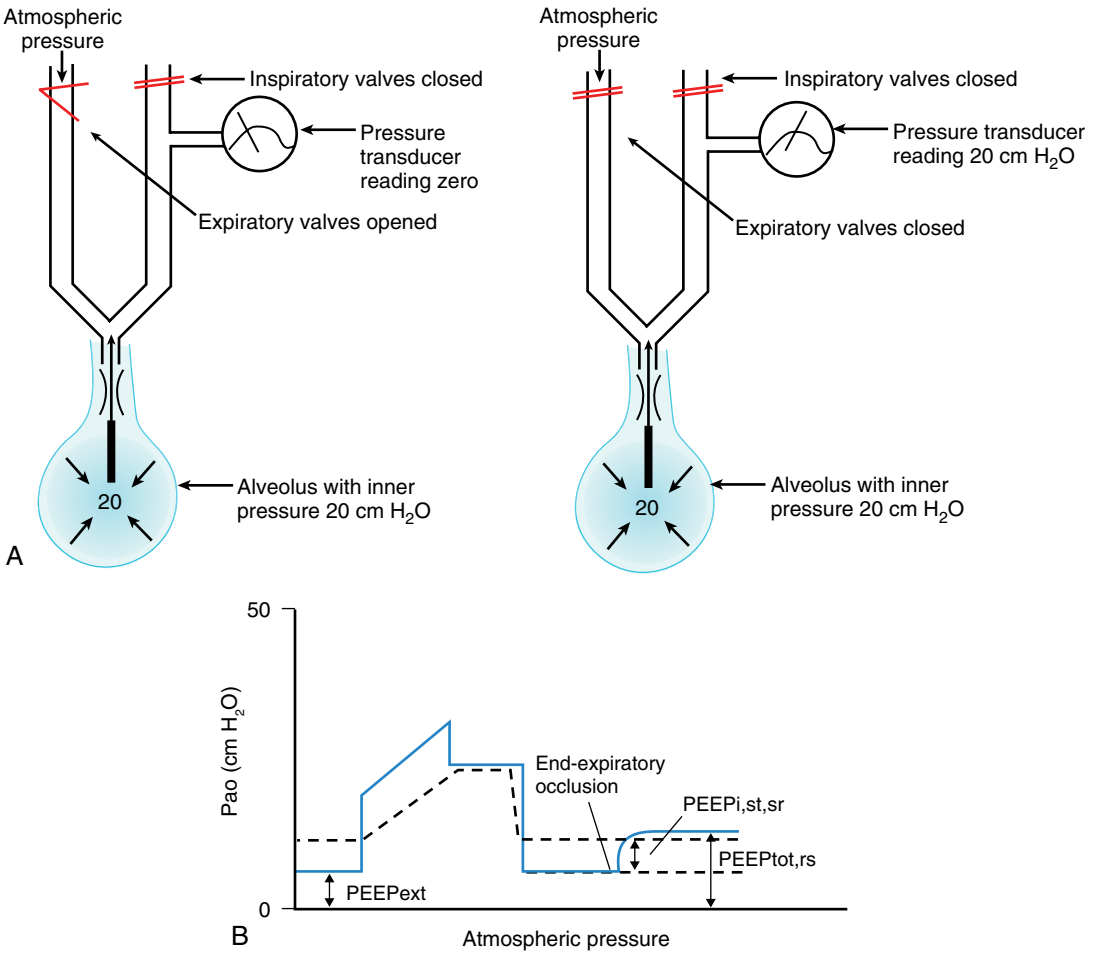

Figure 93-5 Static intrinsic PEEP (PEEPi,st) measurement: schematic representation of the end-expiratory hold maneuver. **A,** Schematic representation of the respiratory system and of a ventilatory circuit. During the expiratory phase, the ventilator opens the expiratory valve while the inspiratory valve is closed. Consequently, the pressure transducer reads atmospheric pressure. When the end-expiratory hold maneuver is performed, both inspiratory and expiratory valves are closed at end expiration. As a consequence, the pressure transducer reads the end-expiratory alveolar pressure. **B,** Recording of the Pao tracing obtained during a cycle of constant-flow mechanical ventilation, followed by an end-expiratory hold maneuver. At the end of the maneuver, the PEEPtot value is obtained. The *dotted line* refers to the theoretical value of alveolar pressure.

lower third of the esophagus and connected to a pressure transducer. Partitioning elastic properties between the lungs and the chest wall may be useful in the differential diagnosis of the decrease in respiratory compliance. Because chest wall and abdomen are coupled through the diaphragm, the increased abdominal pressure is one the most important factors leading to chest wall stiffness. However, patients without increased abdominal pressures may still have chest wall mechanical impairment related to chest wall deformities, fluid overload, or pleural effusions.

Monitoring Assisted Mechanical Ventilation

The main parameters to be clinically monitored during assisted mechanical ventilation include evaluation of patient-ventilator interactions and the occurrence of patient-ventilatory asynchronies.

Inspiratory Trigger Asynchrony

A "phase lag" between the beginning of inspiratory muscle activity and the beginning of mechanical inflation is virtually always present, although its amount is minimized with the neural trigger of NAVA.[53] The presence of PEEPi may complicate patient-ventilator interaction during the triggering phase.[54] Ineffective triggering is due to the inability of the ventilator to detect a patient's request of an assisted breath despite his or her production of a substantial inspiratory effort. This phenomenon usually occurs with high levels of ventilator assistance and short expiratory time. Mechanical characteristics that may facilitate ineffective triggering include low elastance, high resistance, and PEEPi.[55]

Ventilatory Requirement/Gas Delivery Asynchrony

Asynchrony occurs when the ventilator-delivered flow, volume, and pressure are insufficient to meet a patient's ventilatory requirements. Pressure-targeted breathing may better satisfy a patient's ventilatory requirements because the rapid pressuriza-

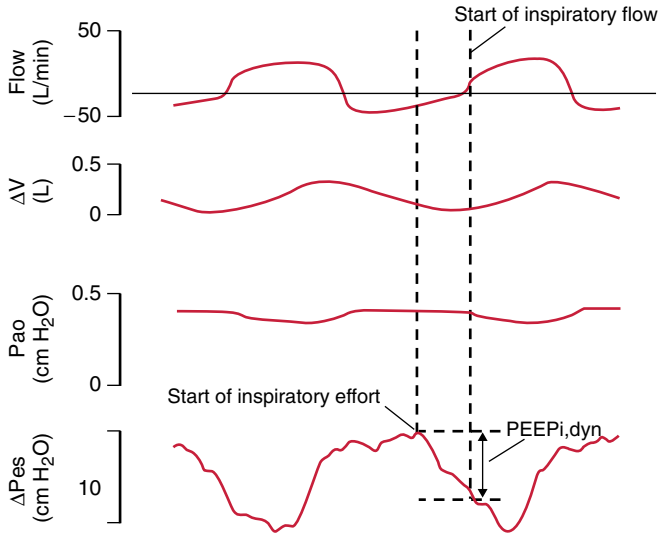

Figure 93-6 Flow, volume Pao, and Pes tracings recorded in a spontaneously breathing patient receiving positive continuous airway pressure. PEEPi,dyn is the value of Pes deflection from the beginning of the inspiratory effort to the point in which a positive inspiratory flow begins. See text for definition of abbreviations.

tion of the airways is coupled with high inspiratory flow just at the beginning of inspiration, reproducing the normal physiologic flow profile.

Cycling Asynchrony

This asynchrony occurs when the patient is trying to exhale but the ventilator continues to deliver gas. Parthasarathy and coworkers demonstrated that prolonging the mechanical inflation during the neural expiration reduces the time available for unopposed exhalation.[56] When PSV is delivered noninvasively, air leaks may cause an abnormal prolongation of the inspiratory time, preventing inspiratory to expiratory cycling off. In this condition, the patient keeps trying to exhale against the ventilator or to inhale without receiving any ventilatory support (inspiratory hang-up).[57]

Work of Breathing

Estimating a patient's work of breathing during partial ventilatory support modes allows the setting of an optimal level of mechanical support in which inspiratory muscles work at a near-normal level, avoiding excessive muscle work or overassistance. Unfortunately, it requires a complex apparatus, continuous measurement of esophageal and gastric pressures, and a great deal of physiologic expertise. As described earlier, the PAV+ algorithm allows a continuous estimate of the work of breathing and the NAVA technology allows a continuous detection of diaphragmatic electrical activity. Although work of breathing may be referred to as a single breath, from a clinical standpoint it is more useful to measure the work of breathing per minute and the work of breathing per liter of minute ventilation (WOB/L = WOB/min ÷ minute ventilation). In a normal subject, the WOB/L at rest is between 0.3 and 0.6 Joules/L, whereas during any available partial ventilatory support technique the patient is subjected to additional "iatrogenic" work to overcome the endotracheal tube and the ventilatory circuit resistances and to trigger the ventilator.[58]

Clinical Problems Associated with Mechanical Ventilation

Elastic Properties of Nonhomogeneous Lung and Ventilator-Induced Lung Injury

Mechanical ventilation is almost invariably used in patients with acute respiratory distress syndrome (ARDS) or acute lung injury (ALI) or to ARDS. In the majority of those patients, once mechanical ventilation is applied, the gas exchange parameters improve as does the overall clinical condition. Unfortunately, since the mid 1980s, a large number of studies have shown that mechanical ventilation can worsen preexisting lung injury (ventilator-induced lung injury [VILI]).[51,59] The main feature of ARDS that predisposes to VILI is the heterogeneous distribution of lung disease. Pivotal computed tomography scan studies have clearly documented that in the ARDS lung normally aerated areas coexist with poorly aerated, consolidated, and hyperinflated areas (Fig. 93-7).[60] A systematic review of the pattern of distribution of these areas allowed classification of the distribution pattern of atelecta-

LIP and UIP both occur within tidal ventilation and indicate the pressure at which recruitment of collapsed alveoli and alveolar hyperinflation start to occur, respectively. See text for definition of abbreviations.

sis into focal (≈36% of patients, where consolidated dependent areas coexisted with normally aerated nondependent areas), diffuse (≈23%, with a generalized opacification of the lung), and patchy (≈41%, where consolidated areas were unevenly distributed in the whole lungs).[60-62] This heterogeneity profoundly affects the mechanical characteristics of the respiratory system, as documented by the shape of the "static" or "quasi-static" inspiratory volume-pressure curve of the respiratory system.[63] When inflating the respiratory system in discrete volume steps, or in a very slow fashion, the increase in airway opening pressure will reflect the variations in elastic properties of the respiratory system. A progressive increase in compliance at the beginning of lung inflation ("lower inflection point" [LIP]) suggests that alveoli collapsed at end expiration are being progressively reopened during inflation (alveolar recruitment), whereas a progressive decrease of compliance toward the end of inflation ("upper inflection point" [UIP]) suggests that a number of alveoli are progressively stretched (hyperinflated) toward the end of inflation. In normal subjects, LIP occurs below the elastic equilibrium point of the respiratory system and UIP occurs at a volume close to total lung capacity. In patients with ARDS, LIP and UIP both occur within tidal ventilation and indicate the pressure at which recruitment of collapsed alveoli and alveolar hyperinflation start to occur, respectively (Fig. 93-8). However, recent studies suggest that lung recruitment along the incremental limb of the volume-pressure curve is a progressive phenomenon and a significant hysteresis between the inspiratory and the expiratory volume-pressure curve has been observed by constructing the decremental (i.e., the expiratory) limb of the volume-pressure curve. This means that, once recruited, atelectatic areas tend to collapse at a lower pressure than the pressure required to open alveoli during inspiration.[64,65]

According to the concept of "baby lung," originally proposed by Gattinoni and colleagues, mechanical ventilation delivering "standard" tidal volumes (i.e., the V_T that "normalizes" arterial P_{CO_2}) will generate cyclic tidal alveolar hyperinflation in the normally aerated areas in ARDS patients.[66] In addition, lung units collapsed at end expiration will reopen during inflation if low levels of PEEP are applied, generating a cyclic tidal alveolar opening and collapse phenomenon (or tidal recruitment). Tidal alveolar recruiting and tidal hyperinflation have been shown to activate proinflammatory intracellular signal pathways in epithelial and endothelial cells of the alveoli and in the lung's resident macrophages. As a consequence, genes responsible for the transcription of proinflammatory and anti-inflammatory mediators are respectively upregulated and downregulated, leading to alveolar inflammation.[67] This ventilator-induced "biotrauma" may arise after even relatively a short period of mechanical ventilation, leading to a local inflammatory response, further amplified by the recruitment of neutrophils, macrophages, and fibroblasts that occurs from the lung injury (Fig. 93-9).[59] In addition, mechanical stimuli posed on the alveolar wall are able to shed thrombomodulin (the surface molecule that proteolytically activates protein C) from the alveolar cell surface, depressing protein C activation at the alveolar level. Therefore, VILI may also exacerbate the intraalveolar procoagulative and antifibrinolytic state.[68] Other expressions of "biotrauma" include impairment of alveolar edema clearance by inactivation of the type I and II alveolar cells Na^+/K^+-ATPase,[69] inhibition of surfactant secretion by epithelial type II cells,[70] and the upregulation of the production of matrix metalloproteinases.[71] All these proposed mechanisms support the idea that VILI could act as the "engine" of multiple organ dysfunction syndrome (MODS), as originally proposed by Slutsky[59] and recently confirmed.[72]

Several "lung protective" ventilatory strategies have been proposed to minimize VILI. Initial studies were based on the measurement of the *inspiratory* volume-pressure curves of the respiratory system. Applying a PEEP level slightly above the LIP to avoid the end-expiratory collapse and a V_T to obtain an end-inspiratory plateau pressure just below the UIP reduced VILI-related lung and systemic inflammatory reactions[73] and VILI-related mortality.[74,75] However, selecting the PEEP level based on the incremental limb of the volume-pressure curve may be misleading, owing to the fact that alveolar recruitment has been shown to increase above the LIP (i.e., a pan-inspiratory phenomenon).[76] Furthermore, in the majority of the ARDS patients there is a significant hysteresis between the incremental and decremental limbs of the pressure-volume curve. Some authors have therefore suggested the selection of the PEEP level based on the *expiratory* limb of the volume-pressure loop. This would be done where a vital capacity maneuver is done to completely recruit the lung, followed by a decremental PEEP trial.[65]

Expiratory Flow Limitation and Intrinsic PEEP (PEEPi)-AUTOPEEP

In normal subjects at rest, the end-expiratory lung volume (EELV) closely corresponds to the elastic equilibrium point of the respiratory system (the FRC). Whenever the time available for expiration is shorter than the time required for passive emptying back to FRC, air trapping will develop. Consequently, alveolar pressure will remain positive at the end of expiration, which generates a "dynamic hyperinflation," that is, a positive end-expiratory alveolar pressure, called intrinsic PEEP (PEEPi) or auto-PEEP.[77,78] The trapped air volume may be assessed by measuring the amount of

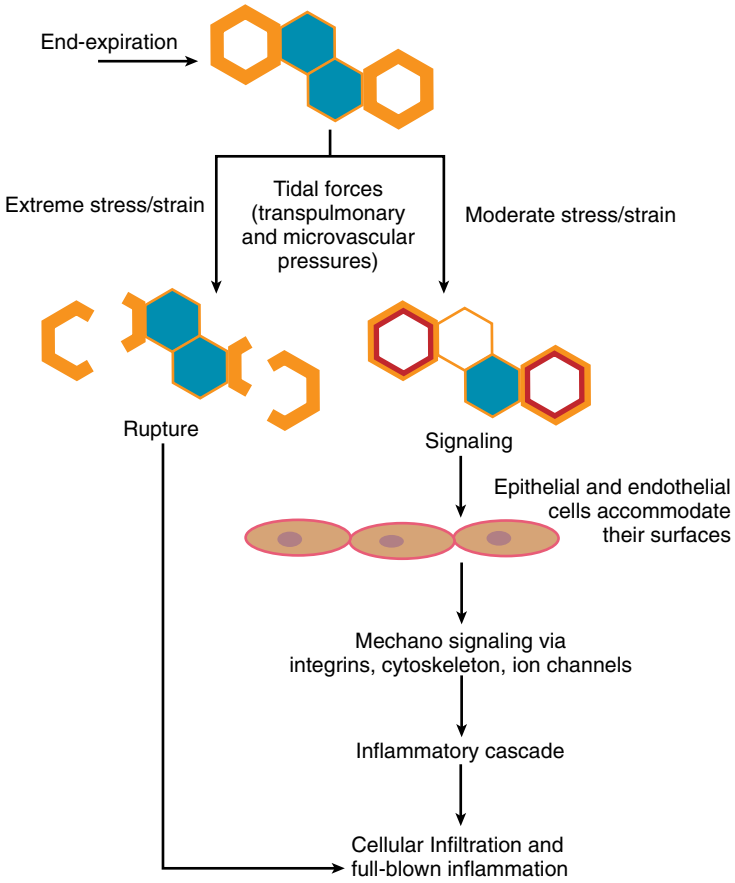

Figure 93-9 The concept of "biotrauma" related to ventilator-induced lung injury. The transduction of a mechanical stimulus posed on the alveolar walls (tidal alveolar opening/collapse and/or tidal alveolar stretch) leads to a biologic signaling that translates into pulmonary inflammation. (*From Marini JJ, Gattinoni L: Ventilatory management of acute respiratory distress syndrome: A consensus of two. Crit Care Med 33:250, 2004.*)

expired volume during a prolonged, passive emptying from EELV to FRC (30-60 sec) (Fig. 93-10).

PEEPi Due to Flow Limitation

Because of the expiratory collapse of distal airways, expiratory flow is severely limited.[79] This condition is peculiar to the patient with COPD, whereas in normal subjects it occurs only during forced maximal expiratory maneuvers. The pathophysiology of expiratory flow limitation has been originally explained by the waterfall model (Fig. 93-11).[80] Accordingly, increasing the pressure downstream from the waterfall by applying an external

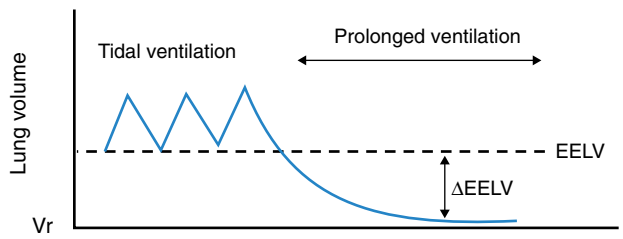

Figure 93-10 Difference (ΔEELV) between the end-expiratory lung volume (EELV) during mechanical ventilation and elastic equilibrium volume of the respiratory system (Vr) in a patient with dynamic hyperinflation. A complete lung emptying is obtained by disconnecting the patient from the ventilator at the end of mechanical expiratory time and allowing a prolonged (15-20 seconds) passive exhalation to atmospheric pressure.

PEEP will have no influence on either the expiratory flow or the pressure upstream of the site of critical airway closure, that is, until the value of external PEEP does not exceed the value of PEEPi.

Acting as an inspiratory threshold load, PEEPi places a burden on the inspiratory muscles, which are forced to develop sufficient force to overcome the opposite recoil pressure before inspiratory flow can begin. The work of breathing necessary to overcome PEEPi to initiate an inspiratory flow may be as high as 40% of total work of breathing in patients with COPD exacerbations[16] and may be significantly reduced by applying an appropriate level of external PEEP.[81] According to the waterfall analogy, the application of an external PEEP in the range of measured levels of PEEPi will decrease the inspiratory work of breathing without inducing further alveolar hyperinflation.[82] However, the waterfall analogy assumes a single value of critical closing pressure for all the distal airways (Pcrit) whereas a significant heterogeneity among regional lung units has been documented.[83] On this basis, the simple waterfall analogy may be not accurate. In terms of mechanically ventilated COPD patients, this implies that the value of external PEEP that can be safely applied without the risk of worsening dynamic hyperinflation should be somewhat less than the measured PEEPi. Experimental data suggest that applying a PEEP level equal to 75% of PEEPi is below Pcrit in the majority of COPD patients.[84]

PEEPi without Flow Limitation

This occurs when the expiratory time is shorter than the time required for passive lung emptying to FRC. The time needed to

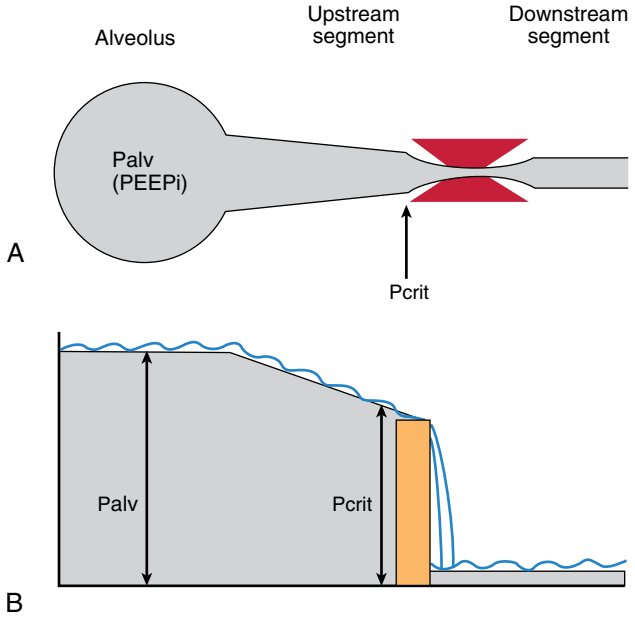

Figure 93-11 The waterfall model. Because of the dynamic expiratory collapse of distal airways, and in COPD patients the expiratory flow is severely limited and at end-expiration, and alveolar pressure (Palv) remains positive, generating intrinsic positive end-expiratory pressure (PEEPi). Because of the dynamic collapse, increasing the pressure in the downstream airway segment will not have influence on the pressure upstream of the site of critical airway closure until the applied pressure exceeds the pressure level in the upstream airway segment (Pcrit).

empty the lung depends on the interplay of several variables: VT, end-inspiratory elastic recoil pressure of the respiratory system, and expiratory resistances. Moreover, in the ventilated patient the resistances of endotracheal tubes, exhalation valves, and PEEP devices must be taken into account. Consequently, under conditions of high minute ventilation, high respiratory system compliance, and high expiratory resistance, the lungs do not have time, during passive deflation, to reach their equilibrium point at FRC. This is different than the problems that occur with flow limitation, because the application of an external PEEP in this condition worsens dynamic hyperinflation, providing a "back pressure" to expiratory airflow.[85]

In the ventilated patient, dynamic hyperinflation may cause severe hemodynamic impairment because it critically impairs venous return and increases right ventricular afterload, leading to a low cardiac output state. This phenomenon, originally described by Pepe and Marini,[86] is more likely to occur when applying controlled mechanical ventilation to patients with COPD or asthma. A rather different scenario occurs in spontaneous breathing patients who develop significant dynamic hyperinflation.[87] PEEPi acts as an inspiratory threshold load in the sense that the patient must create an opposite negative intrathoracic pressure to generate an inspiratory flow. Such a decrease in pleural pressure with no change in lung volume is theoretically similar to a Muller maneuver (Fig. 93-12). When COPD patients experience a severe exacerbation of their disease or when a ventilator-dependent COPD patient is suddenly disconnected from the ventilator, this mechanism has a marked improvement on venous return and cardiac output. Because the pulmonary vascular bed is relatively nonrecruitable in severe COPD, pulmonary artery pressure will increase and right ventricular engorgement ensues. Furthermore, acute right ventricular engorgement has been shown to induce a leftward interventricular septum shift, leading to impairment of left ventricular diastolic relaxation and pulmonary congestion.[88-90] Besides decreasing work of breathing, applying a PEEP/CPAP level lower than Pcrit will limit the hemodynamic consequences of PEEPi in spontaneously breathing patients.[87]

Although PEEPi and dynamic hyperinflation are usually thought to be synonymous, PEEPi does not necessary imply dynamic hyperinflation or air trapping. When expiratory muscles are recruited during expiration, alveolar pressure will be positive at end expiration without dynamic hyperinflation.[91]

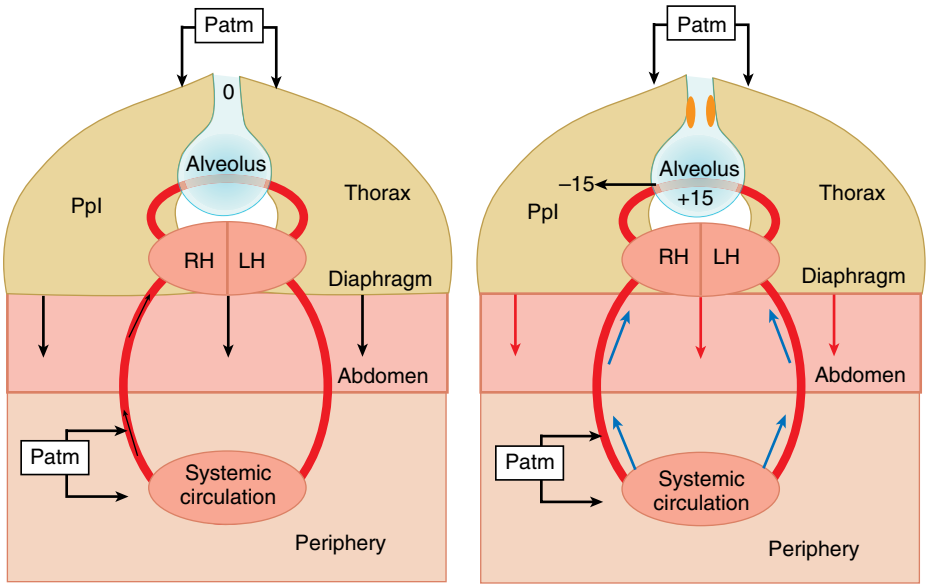

Figure 93-12 Hemodynamic consequences of dynamic hyperinflation and intrinsic PEEP (PEEPi). The physiologic increase in venous return during spontaneous inspiration, due to the generation of a slightly negative pleural pressure (Ppl) as compared with atmospheric pressure (Patm), is pathologically magnified in patients with dynamic hyperinflation. To initiate inspiratory flow (i.e., to generate a negative alveolar pressure), the hyperinflated patient needs to counterbalance PEEPi, generating an opposite negative pleural pressure. This has a marked fostering effect on venous return.

Mechanical Ventilation for Specific Clinical Entities

Acute Respiratory Distress Syndrome

ARDS is an inflammatory response of the lung to both direct and indirect insults defined according to the following criteria: acute onset, presence of bilateral infiltrates on chest radiography consistent with pulmonary edema, pulmonary artery wedge pressure less than 18 mm Hg or clinical absence of left atrial hypertension, and hypoxemia with a Pao_2/Fio_2 ratio less than 200.[92] Patients meeting these criteria but with Pao_2/Fio_2 ratios less than 300 are diagnosed with ALI. Although this definition is simple, limitations have been recently identified: the radiographic criterion has a high interobserver variability among experienced clinicians and no specific radiographic findings are agreed upon,[93] the presence of multiorgan dysfunction is not considered in the definition, and the cause of the lung injury is not identified. Although in the past ARDS was considered rare,[94] a recent population-based study showed an age-adjusted incidence of 86.2 per 100,000 persons/year.[95] Mortality due to ARDS has been reported to decline from 60% to 70% in the late 1980s to 30% to 40% over the past 2 decades with improved management.[96-98] Risk factors linked to increased mortality in ALI/ARDS include advanced age, a low Pao_2/Fio_2 ratio, the presence of septic shock, a high Acute Physiology and Chronic Health Evaluation II (APACHE II) score, a high Sequential Organ Failure Assessment (SOFA) score, a low Glasgow Coma Scale score, and the presence of chronic liver disease.[99] The most common long-term impairments are muscle wasting and weakness, significant neurocognitive and emotional morbidity, and decreased quality of life persisting after 2 years from hospital discharge. This is true despite the fact that pulmonary function generally returns to normal by 6 months, with the exception of a persistent reduction in the carbon monoxide diffusion capacity.[100,101]

The inciting factors for lung injury can be divided into those associated with direct insult to the lungs, such as pneumonia or aspiration, and indirect causes, such as sepsis or severe trauma (Fig. 93-13). This "first hit" to the lungs incites a pulmonary inflammatory response, which may lead to worsening of the pathologic manifestations of ARDS if coupled with injurious mechanical ventilation.[59,67] Clinical studies have suggested that there is an increased mortality in patients who continue to have elevated bronchoalveolar lavage concentrations of interleukin (IL)-6, IL-8, IL-1, and tumor necrosis factor (TNF) cytokine levels during their clinical course, precluding resolution of the pulmonary and systemic inflammatory processes.[96,102,103] An important source of these inflammatory mediators are the neutrophils, which play a pivotal role in the pathogenesis and progression of ALI/ARDS,[104] although it may develop in patients with profound neutropenia, suggesting that several parallel and interacting mechanisms are involved.[105]

ALI/ARDS is characterized by abnormal mechanical properties of the respiratory system with the hallmark features of a reduced FRC and a reduced static compliance of the respiratory system.[106] Measurements of the inspiratory volume-pressure curves of the respiratory system have been used in mechanically ventilated patients with ALI/ARDS as a means of assessing their status and progress and to optimize the use of PEEP and mechanical ventilation.[63]

In the past, mechanical ventilation with a large V_T of 10 to 15 mL/kg was recommended to guarantee a normal pH and $Paco_2$.[107] The use of a large V_T has now been shown to lead to shear stress injury of the lungs, from overdistention and local and systemic inflammatory responses due to this mechanical injury. The multicenter randomized controlled trial carried out by the ARDSNet included 10 academic centers with 75 intensive care units and enrolled patients with ARDS to compare a control ventilatory strategy using a V_T of 12 mL/kg (based on predicted body weight (PBW) versus a lung-protective strategy using a V_T of 6 mL/kg PBW.[96] The study set out to enroll up to 1000 patients, but accrual was stopped at 861 patients when an interim analysis revealed that the mortality rate in the lung-protective group was 22% lower than in the control group. These beneficial results occurred in all patient groups, including septic and nonseptic patients and those with different degrees of lung dysfunction as assessed by respiratory system compliances. The ARDSNet study set PEEP levels and inspired oxygen fractions (Fio_2) according to traditional criteria, using a standardized PEEP-Fio_2 combination table. Moreover, the ARDSNet study aggressively maintained $Paco_2$ close to the normal range, employing higher respiratory rates and a liberal use of bicarbonate. The study is very important from a clinical perspective because it demonstrated that a specific intervention (the reduction of V_T) was able to improve mortality in these patients. Recent investigations testing the effects on mortality of "higher" PEEP titration criteria did not show any

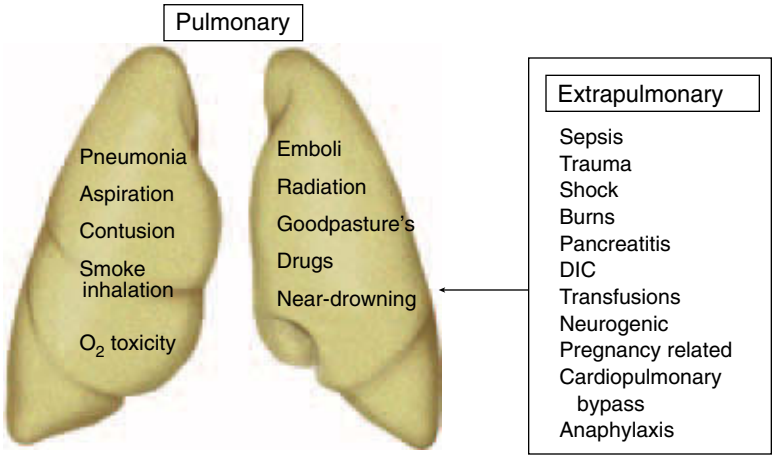

Figure 93-13 Pulmonary (primitive) and extrapulmonary (secondary) triggers of the acute respiratory distress syndrome.

improvement in terms of survival rates,[108-110] although they suggested beneficial effects of higher PEEP in terms of ventilator-free days and need for nonconventional therapy. At present the optimal level of PEEP and best method used to set PEEP has not been definitively established.[22] Prone positioning has been demonstrated to improve oxygenation and to decrease the incidence of ventilator-associated pneumonia in patients with acute hypoxic respiratory failure but does not improve mortality, so that this therapeutic option might be considered useful only for ARDS patients with refractory hypoxemia.[111,112]

Inhaled nitric oxide (iNO) has been shown to be a selective pulmonary vasodilator without systemic effects. It was suggested that this agent might improve gas exchange and reduce pulmonary hypertension, optimizing the $\dot{V}/\dot{Q}$ matching. Nevertheless, despite the improvement in oxygenation, there was no beneficial effect on mortality.[113] Thus, iNO cannot be recommended for the routine treatment of ALI/ARDS but it may be useful as a rescue therapy in patients with refractory hypoxemia.

Chronic Obstructive Pulmonary Disease

COPD is a syndrome of chronic lung inflammation characterized by chronic, not fully reversible, airflow limitation.[114] It is the fourth leading cause of death in the world, and its prevalence has been estimated to be around 9/1000 in men and 7/1000 in women, although recent data indicate that prevalence of the disease in developed countries is similar in the two genders.[115,116] The severe $\dot{V}/\dot{Q}$ mismatch that is associated with the late phase of COPD leads to chronic CO_2 retention, hypoxemia, and compensatory polycythemia. These conditions, together with an extensive destruction and remodeling of pulmonary vasculature, lead to pulmonary hypertension and chronic cor pulmonale.[117] Emphysema critically impairs lung elastic recoil and alters the alveolar attachments to small airways, compromising their stability. Either reduced alveolar driving pressure or susceptibility to dynamic expiratory collapse generates the phenomenon of "expiratory flow-limitation."[78]

Acute exacerbations of COPD are defined as worsening of dyspnea and increase in sputum purulence and volume.[118] Most COPD exacerbations are caused by tracheobronchial infections, exposure to air pollution, or concomitant diseases, although in some instances the cause remains unknown.[119] The exacerbation-induced increase in airways obstruction and worsening of dynamic hyperinflation acutely limits the ability of respiratory muscle to maintain the minute ventilation level. As a consequence, acute-on-chronic hypercapnia, hypoxemia, and hemodynamic impairment develops. Severe, life-threatening COPD exacerbations are characterized by pH below 7.30 and Pa_{O_2} below 60 mm Hg (breathing room air) and require intensive oxygen supplementation and pharmacologic and ventilatory treatment. The target of oxygen supplementation is to maintain Pa_{O_2} slightly above the 60 mm Hg threshold, because a moderate hypoxic stimulus is useful to stimulate the ventilatory drive in the presence of chronic hypercapnia.

Applying noninvasive PSV (to unload inspiratory muscles and to increase V_T) and PEEP (to counterbalance the inspiratory threshold load for the inspiratory muscles posed by intrinsic PEEP) in the early course of COPD exacerbations reduces intubation rates, the frequency of complications, the in-hospital mortality, and the length of stay.[120,121] Experiences with other NIPPV ventilatory modalities (e.g., PAV), although encouraging, are limited to physiologic studies.[122,123] Physiologic studies suggest there are benefits of CPAP in acute COPD exacerbation, but no clear-cut clinical indication for CPAP exists.[124] If controlled mechanical ventilation needs to be used, targeting minute ventilation to the pre-decompensation CO_2 level is important to minimize alveolar hyperinflation and to avoid rebound respiratory acidosis at the reinstitution of spontaneous breathing. In this context, measuring PEEPi and trying to minimize it by selecting the appropriate ventilatory pattern (low VT, low respiratory rate, and high expiratory time) is of paramount importance.[125]

Acute Cardiogenic Pulmonary Edema

ACPE results from any pathologic condition leading to the inability of the left ventricle to handle the pulmonary venous return. The resulting rise in hydrostatic pressure at the capillary level causes a leakage of fluid (with the characteristics of a transudate) in the interstitium and subsequently in the alveolar space. Both interstitial and alveolar edema leads to surfactant inactivation and thickening of small airways walls, resulting in increased lung elastance, resistance (cardiac asthma), and hypoxemia. A positive feedback develops, because hypoxemia and increased work of breathing increase a stress response, which, in turn, increases left ventricular workload and possibly induces left ventricular ischemia, further limiting the ability of the left ventricle to manage venous return.[126] Moreover, the stiffer edematous lung requires the patient to develop larger negative pleural pressure swings, increasing venous return and promoting further capillary fluid leakage. Finally, the more negative the pleural pressure during inspiration, the more transmural left ventricular pressure increases, leading to an increased left ventricular afterload (Fig. 93-14).[26]

Noninvasive techniques, both CPAP and NIPPV, have been shown to reduce the need of intubation and improve outcomes in patients with ACPE.[127-130] Of note, a small clinical trial raised serious warnings on the risk of myocardial ischemic events when ACPE patients are treated with bilevel positive airway pressure

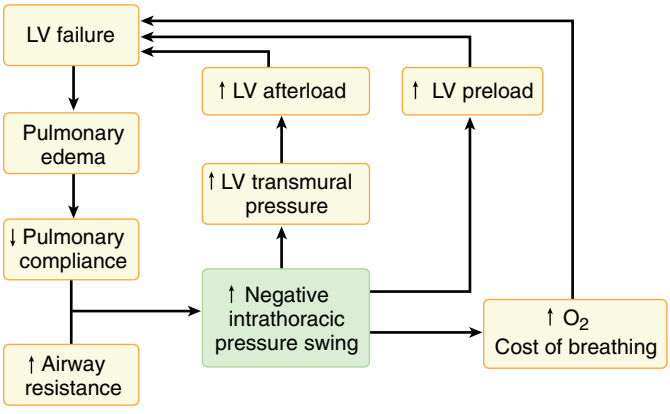

Figure 93-14 The vicious cycle of cardiopulmonary interactions during left ventricular (LV) failure leading to acute cardiogenic pulmonary edema (see text for further details).

(BiPAP, a form of PSV), as compared with CPAP.[131] Recently, two meta-analyses showed that both CPAP and NIPPV significantly reduce the need for intubation but CPAP significantly decreases mortality, whereas NIPPV is associated with a strong but nonsignificant trend toward better survival.[132,133] The same meta-analysis did not show significant differences in myocardial ischemic events between CPAP and NIPPV. Overall, some authors suggest that CPAP should be considered as the first-line treatment in patients with ACPE because it is less expensive and easier to implement and as efficacious as NIPPV.[133]

Several issues regarding noninvasive ventilation in patients with ACPE remain unresolved: Does the mechanism leading to ACPE (systolic versus diastolic heart failure)[134] influence the response to noninvasive ventilation? To what extent is the use of CPAP or NIPPV advisable in patients with acute myocardial infarction? Is there a different indication for CPAP or NIPPV in subgroups of these patients? However, it might be better to use NIPPV in hypercapnic patients with ACPE.[130] Finally, studies investigating the optimal settings of CPAP and NPPV in ACPE patients are needed.

94 Neurocritical Care

Key Points

1. Critical care of the nervous system is based on support of cerebral and spinal cord physiology and the prevention of secondary insult. This, in turn, depends on the comprehensive maintenance of cardiopulmonary, gastrointestinal, renal, and endocrine functional adequacy.
2. Cerebral function is critically dependent on perfusion and oxygenation. Increased intracranial volume beyond the capacity of compensatory mechanism will increase intracranial pressure (ICP) and may diminish perfusion adversely. Resulting cellular energy failure will both initiate and propagate edema and inflammation.
3. The resolution of cerebral edema depends on hydrostatic and osmolar forces applied to the blood-brain barrier. Excesses of perfusion pressure or intravascular hypotonicity will worsen edema and must be avoided. Blood-brain barrier disruption will vary over time and will markedly affect the ability of hypertonic agents to exert an osmotic effect.
4. Fever is frequently overlooked in the neurocritical care unit but significantly affects outcome across a range of pathologic processes.
5. Neurologic monitoring comprises placement of appropriate monitoring devices as well as prompt response and institution of therapy to changes detected. The goal is to optimize the physiologic environment, despite the current lack of level 1 evidence to support the majority of monitors in common use. Clinical examination of neurologic function remains a crucial part of monitoring and care.
6. Incidence of traumatic brain injury has declined but remains a disease of the young, with enormous long-term socioeconomic impact. Prompt surgical appraisal is mandatory; and although hypothermia remains controversial, decompressive craniotomy may be lifesaving in patients with elevated ICP refractory to medical treatment. Corticosteroids are contraindicated.
7. After the initial hemorrhage, mortality and morbidity from subarachnoid hemorrhage (SAH) arise chiefly from subsequent vasospasm. Medical therapy for this complication involves augmentation of perfusion pressure, maintenance of blood volume, and optimization of oxygen delivery. Endovascular therapy with angioplasty with or without chemical vasodilation plays an increasingly important role. SAH may be accompanied by significant pulmonary, cardiovascular, or endocrine effects.
8. Successful therapy for ischemic stroke is contingent on a time window of viability. Urgent appraisal and rapid treatment is crucial to good outcome.
9. Injury to the spinal cord necessitates careful observation of respiratory adequacy, because conditions may deteriorate before any observed improvement. Fatigue is frequently a factor.
10. Infectious disease of the central nervous system demands an aggressive approach to resuscitation, cerebrospinal fluid sampling, and early empirical antibiotic therapy, similar to that in the patient with septic shock.

Critical care of the central nervous system (CNS) involves collaboration between many disciplines—neurosurgery, neuroanesthesia, neurology, neuroradiology, and electrophysiology. Each discipline offers unique contributions, which in partnership, provide optimal care, not only to the injured brain but also to the cardiopulmonary, endocrine, gastrointestinal, and renal systems that support cerebral physiology. Integration of the complex goals of this care relies on the neurocritical care physician, which increasingly is recognized as an important subspecialty.[1]

The use of a neurocritical care team rather than single specialty care has been associated with reduced in-hospital mortality and length of stay.[2] Although the brain has a certain preeminence among the organs of the body, it relies on a stable platform of organ function elsewhere, to enable homeostatic control and mechanisms of repair and recovery to occur. Injury to the brain is associated with and precipitates a wide spectrum of dysfunction of other organ systems (Table 94-1). Although other specialties can train to be neurointensivists, anesthesiolo-

gists with training in neuroanesthesia and critical care are particularly well suited to demonstrate the combination of airway and cardiovascular support skills that, together with understanding of the physiology and pharmacology of the nervous system, may improve outcome.

Intracranial Physiology and Cerebral Autoregulation

The cerebrovascular circulation is constrained by a rigid perimeter of bone. After exhaustion of limited compensatory mechanisms, the bony confines of the skull mandate increasing intracranial pressure (ICP) consequent to increasing intracranial volume. The change in ICP with change in intracranial volume is often referred to as the intracranial compliance curve, but it is more appropriately termed the intracranial elastance curve (Fig. 94-1).

Thus, an increase in elastance implies poor compliance and a small change in volume can lead to an inordinate increase in pressure. These changes in volume arise from increments in intracranial tissue or fluid content, that is, blood, interstitial fluid, or cerebrospinal fluid (CSF). Tissue content is relevant insofar as mass lesions will reduce intracerebral compliance and accentuate the effects of fluid changes.

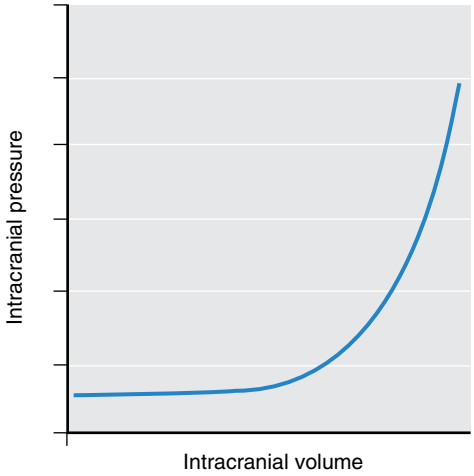

Figure 94-1 Intracranial pressure-volume relationship.

Small increases in volume can be accommodated by an outflow of CSF from the cranial cavity into the spinal canal, producing the exponential pressure-volume relationship (see Fig. 94-1).

The cranial vault is compartmentalized by the falx cerebri and tentorium cerebelli, which creates the possibility of internal pressure gradients (Fig. 94-2). This may induce physical protrusion of brain tissue through the "apertures" of the compartments—herniation. Brain tissue may be injured directly but also indirectly by deforming and compressing vasculature adjacent to the dural margin.[3] This is typically seen in severe lateral herniation—"midline shift"—when the anterior cerebral vasculature may be obstructed, producing frontal lobe infarction.

Pressure gradients are initially hydraulically equilibrated, with CSF moving from the ventricular chambers to the cranial vault. The compensation achieved is limited by the CSF volume available to be displaced; and, ultimately, changes in volume will induce tissue displacement. This displacement may also contribute to impedance of CSF drainage either by occlusion of the foramina of Monro in the case of lateral herniation or by occlusion of the third ventricle and aqueduct by supratentorial herniation through the tentorial gap. This typically gives rise to clinical features of midbrain structures being compressed. Unilateral papillary dilation, ipsilateral or even contralateral paralysis (Kernohan's notch phenomenon), and abnormalities of respiration are apparent in the spontaneously breathing patient. If the herniation continues, it will result in cerebellar descent through the foramen magnum with consequent compression of the brainstem, producing bilateral papillary fixation, either tachycardia or bradycardia, and systemic hypertension.[4] Changes in cerebral mass secondary to increase in venous blood volume will also arise from obstruction to venous drainage by compression of the easily susceptible bridging veins draining from cortex to venous sinuses. Once an individual threshold of compliance is crossed, changes in volume exert a mass effect on the draining veins, which act as Starling resistors. This decreases drainage, which, in turn, amplifies and

Table 94-1 Potential Systemic Complications Associated with Serious Brain Injury

Global	Pyrexia Inflammatory activation
Cardiovascular	Arrhythmia—bradycardia, tachycardia, atrial fibrillation Hypertension Hypotension Left ventricular dysfunction
Respiratory	Apnea Pneumonia—aspiration, hypostatic, ventilator associated Pulmonary edema ARDS
Gastrointestinal	Gastric erosion Ileus Constipation Perforation Malabsorption
Renal	Dehydration Acute renal failure Urinary tract infection
Hematologic	Anemia Leukocytosis Coagulopathy, disseminated intravascular coagulation Deep venous thrombosis, pulmonary embolism
Metabolic/Endocrine	Hyponatremia, hypernatremia Hyperglycemia Hypokalemia, hyperkalemia Hypomagnesemia Hypophosphatemia Catabolic azotemia Rhabdomyolysis

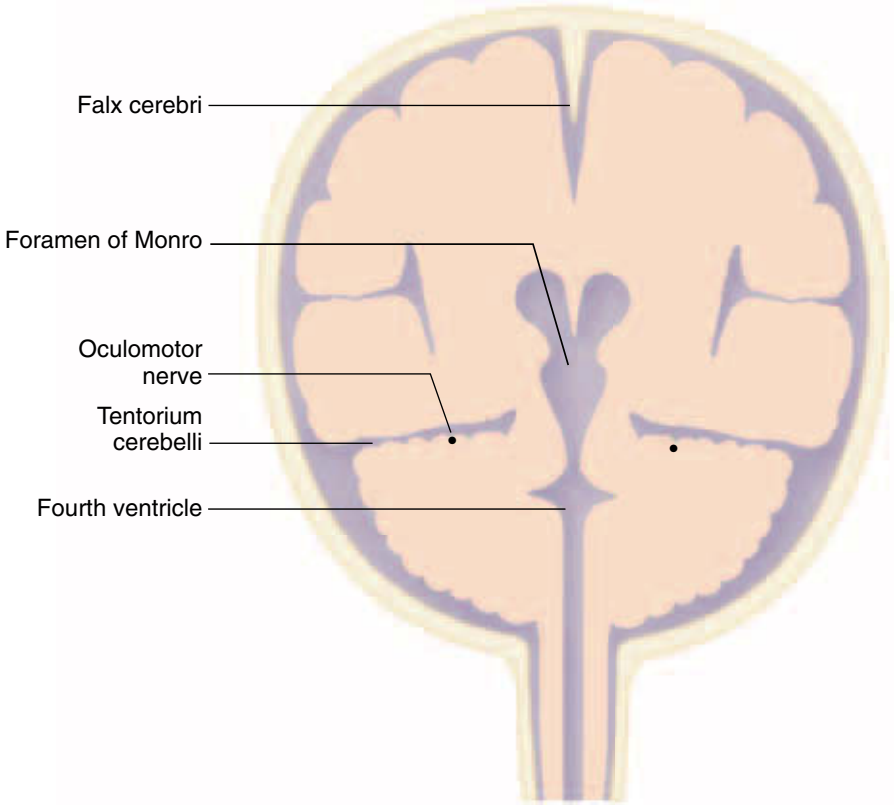

Figure 94-2 Schematic of intracranial compartments—coronal section.

prolongs pressure increases. Blood volume increases may be extravascular (i.e., hemorrhage) or intravascular (i.e., accumulation within a predominantly venous capacitance circulation). (Venous circulation comprises approximately 75% of the cranial blood volume, whereas approximately 25% of vessels are arteries, arterioles, and capillaries.)

The other main fluid mass effect is via edema. This may take the form of cytotoxic or vasogenic edema.[5,6] Cytotoxic edema occurs as a result of hypoxia, with swelling of the intracellular compartment, whereas vasogenic edema in the interstitium usually develops from a breach of the blood-brain barrier, often in response to high blood pressure.[7]

Thus, changes in the control of cerebral blood volume may have significant effects on ICP. Autoregulation of cerebral blood flow (CBF) responds to changes in arterial pressure, arterial P_{CO_2}, or P_{O_2}, by dynamically altering arteriolar caliber so as to maintain a constantly matched cerebral perfusion sufficient to meet metabolic demands (Fig. 94-3). pH, Pa_{CO_2}, potassium, and adenosine are among many purported metabolic mediators of flow.[8]

CBF control may be directly compromised by brain injury or by abnormalities of respiration and blood pressure. In turn, this may increase venous volume by allowing an excessive arterial inflow that venous drainage cannot match, increasing ICP. Consequently, untoward events, including hypotension, airway obstruction, fever, and seizures, produce what is termed a *secondary physiologic insult*. This has been demonstrated to induce further harm to the vulnerable brain and, in so doing, worsen outcome.[6,9]

A reduction in substrate delivery (i.e., oxygen and nutrients) below that threshold necessary to maintain cellular viability

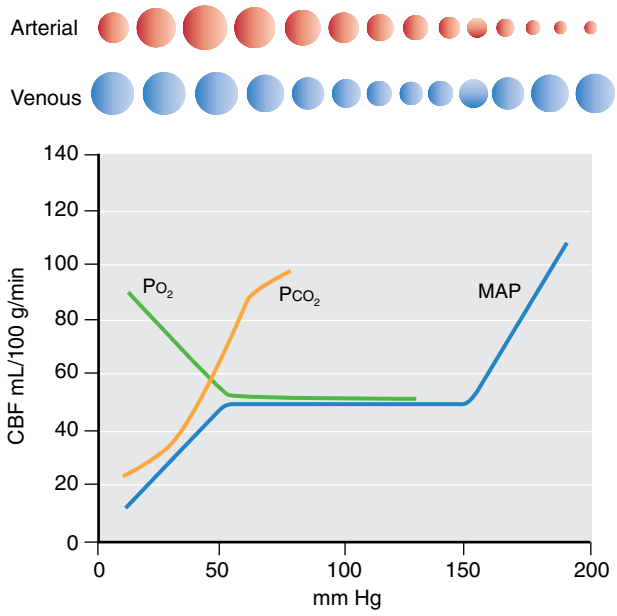

Figure 94-3 Graph of autoregulatory control of cerebral blood flow (CBF) and vascular diameter, in response to changes in mean arterial pressure (MAP), arterial partial pressure of oxygen (P_{O_2}), and arterial partial pressure of carbon dioxide (P_{CO_2}).

produces cell injury with cytokine and chemokine release. This inflammatory amplification expands the injury,[10] disrupts the blood-brain barrier function, and may directly lead to apoptosis. The disruption of the blood-brain barrier creates vasogenic edema and allows serum proteins to cross into brain parenchyma with prolonged effects. This is more evident in the more metabolically gray matter than white matter.[5] Most changes peak in the first 48 hours, but one study identified up to 25% of ICP peak increases occurring after day 5.[11]

General Cardiopulmonary Considerations

Any deterioration in ventilatory efficacy may adversely affect cerebral compliance (elastance) through CO_2-induced vasodilation. There have been concerns on the effect of positive end-expiratory pressure (PEEP) in this situation, but the decreased pulmonary compliance necessitating the PEEP will also limit intrathoracic pressure transmission to the cerebral circulation.[12] The net benefit of improved ventilatory efficacy from PEEP outweighs any mild disadvantages from its use. However, it should be remembered that injudicious PEEP in circumstances of hypovolemia may reduce functional venous return and hence reduce cardiac output with consequent effects on cerebral perfusion.[12]

Reductions in cardiac output can initiate reflex cerebral vasodilation, in an attempt to preserve cerebral blood flow. Hypotension is a well-documented source of worsened morbidity[13,14] whether it occurs by under-resuscitation or iatrogenic mechanisms. This vasodilation will increase venous blood volume and further diminish cerebral perfusion pressure (CPP).[15]

Hypoxemia can cause direct as well as indirect injury to the brain. Hypoxemia below 60 mm Hg is a significant contributor to secondary insult from secondary ICP effects, in addition to the reduction in the oxygen gradient to the cell. The resultant reduction in cerebral perfusion, irrespective of the primary cause, may cause further deterioration by depressing the level of consciousness, in turn leading to airway compromise, hypoventilation, and further decrease in oxygenation (Fig. 94-4). Consequently, pulmonary compromise is often seen in neurologic patients with altered mental status, as a result of impaired airway reflexes and repeated aspiration episodes, culminating in a significant incidence of pneumonia, irrespective of the initiating pathologic process.[16]

Another potential mechanism is the release of cytokines from the brain in response to the inflammatory process triggered by an injury, which may be sufficient to induce acute respiratory distress syndrome (ARDS) and systemic inflammatory response syndrome (SIRS).[17,18] Moreover, the large tidal volume ventilation delivered during initial hyperventilation can enhance the development of ARDS.[19] This may create a therapeutic dilemma in the presence of cerebral pathophysiology. However the "open lung" concept (i.e., small tidal volumes, high frequencies, and high PEEP) developed to minimize alveolar distention and reduce lung injury appears to be feasible in neurosurgical patients despite theoretical concerns for adverse effects on ICP.[20]

The relationship between $Paco_2$ and CBF can be exploited in examining the response of ventilated patients to tests of spontaneous breathing. Normalization of $Paco_2$ may increase ICP, indicating limited craniovascular compliance. Such an insight may guide subsequent therapy and ventilatory strategy, and ICP effects should be considered during any weaning strategy.

Fluids and Electrolytes

Normally, capillary fluid shift is a function of hydrostatic pressure pushing fluid out and the balance of osmotic forces retaining fluid within[21]:

$$Jv = Kf([Pc - Pi] - \sigma[\pi c - \pi i])$$

where Jv is the net fluid movement between compartments, Pc is the capillary hydrostatic pressure, Pi is the interstitial hydrostatic pressure, πc is the capillary osmotic pressure, πi is the interstitial osmotic pressure, Kf is the filtration coefficient (this is a product of surface area and hydraulic conductivity), and σ is the reflection coefficient (the membrane impermeability toward osmotically active particles). In extracranial capillaries, these osmotic forces derive from oncotic pressure, as smaller solutes can cross the capillary basement membrane following concentration gradients and only large protein molecules remain to exert effect.

However, in the brain, because of the presence of "tight junctions" in the endothelium, this intact blood-brain barrier

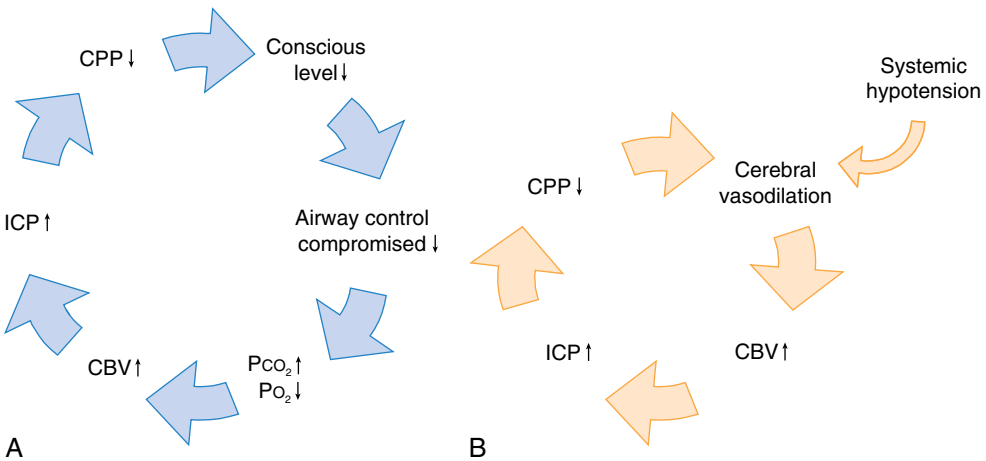

Figure 94-4 A, Ventilatory-neurologic circle of dysfunction. Induced changes in Pco_2 and Po_2 produce changes in cerebral blood volume (CBV), intracranial pressure (ICP), and cerebral perfusion pressure (CPP). This, in turn, impairs ventilatory control. **B,** Hemodynamic-neurologic circle of dysfunction. Similar to the diagram in **A**, systemic hypotension induces cerebral vasodilation, with increased CBV, increased ICP, and reduced CPP, which, in turn, increases vasodilation.

Table 94-2 Sodium Content, Osmolality, and Oncotic Pressure of Commonly Used Intravenous Fluids

Fluid	Osmolality (mOsm/kg)	Oncotic Pressure (mm Hg)	Na^+ (mEq/L)
Plasma*	289	21	141
Crystalloid			
0.9% NS	308	0	154
0.45% NS	154	0	77
3% NS	1030	0	515
Lactated Ringer's	273	0	130
Plasma-Lyte	295	0	140
Mannitol (20%)	1098	0	0
Colloid			
Hetastarch (6%)	310	31	154
Albumin (5%)	290	19	

reflects smaller solutes (e.g., sodium and chloride ions) and this relative impermeability renders cerebral capillary fluid shift a function of hydrostatic and *total* osmolar forces, with the oncotic pressure playing a very small part and the fluid shift most dependent on the osmolar gradient. In the absence of externally administered osmotically active substances (e.g., mannitol), this gradient is largely determined by sodium concentration, as serum osmolality.

$$\text{Serum osmolality} = (\text{serum Na}) \cdot 2 + \text{glucose}/18 + \text{BUN}/2.8$$

Thus, in general, hypotonic solutions should not be used in the neurosurgical patient when edema is a significant consideration. The osmolalities of commonly used solutions are listed in Table 94-2.

At the same time, the tighter endothelial connections and lipid bilayers also serve to reduce water permeability and, hence, the filtration coefficient. This physiologically limits the water shift across the vascular bed in response to changes in tonicity, as otherwise the brain volume would be significantly reduced by the large osmotic forces created by changes of only a few milliosmols per kilogram. Net fluid shift across the blood-brain barrier therefore depends on water permeability, as defined by the filtration coefficient, and the solute permeability, as defined by the reflection coefficient.

This permits osmotic diuresis, in which substances reflected by the blood-brain barrier can exert a significant effect on brain water (e.g., mannitol and hypertonic saline).

Inadequate perfusion and supply of substrate, whether it be relative or absolute, induces energy failure. This translates into real effects on the integrity and function of the blood-brain barrier, which is an energy-dependent physiologic construct as opposed to a purely anatomic structure. Ischemia and rapid reperfusion are associated with the generation of matrix metalloproteinases that directly attack the proteins sealing the connections between the endothelial processes that make up the blood-brain barrier.[22] This creates a loss of integrity and increased porosity of the blood-brain barrier, pathologically affecting the permeability and reflection coefficients. This acute blood-brain barrier disruption may allow solute shifts into the parenchyma and result in brain swelling, the extent of which depends on the "leakiness" of the blood-brain barrier as well as the size and concentration of the osmotically active molecules on either side of the barrier.

Hence, fluid therapy needs to be carefully considered under circumstances of cerebral ischemia and inflammation.

The brain exerts homeostatic control on metabolic and endocrine activity, and neurologic dysfunction can manifest as untoward changes in fluid and electrolyte balance. Diabetes insipidus is a florid example of this with polyuria and subsequent hypovolemia, and, if left untreated, systemic hypotension. Iatrogenic causes may also arise with the use of osmotic diuretics, sedation, and analgesics. Sympathetic denervation as a consequence of brainstem or spinal cord injury may also contribute to reductions in venous return as a result of increased vasodilatation and peripheral venous pooling.[23]

The increased sympathetic discharge commonly accompanying cerebral insults can also manifest as extracerebral stress on the entire body with increased incidence of gastric stress erosion, hypercatabolism, hyperglycemia, and impaired glucose tolerance.[24]

Nutrition requirements are often increased after brain injury, and there is evidence to suggest improved outcome with the early use of enteral nutrition (see Chapter 95).[25]

Hyperglycemia is a potent aggravator of cerebral insult.[26] It remains to be proven whether the widespread use of tight glycemic control with aggressive insulin therapy produces improvements in neurologically compromised patients. There are some suggestions that it may be deleterious.[27]

Fever and Infection

Over 50% of patients in neurologic intensive care units (ICUs) develop fever.[28] This is an often overlooked insult to the compromised brain, increasing oxygen utilization and metabolic stress.[28] Patients within the ICU have multiple risk factors for infection and sepsis, including the presence of a variety of indwelling catheters (e.g., arterial, venous, CSF). Other potential causes of fever include intracranial hemorrhage and idiosyncratic drug effects (e.g., the anticonvulsant phenytoin).[28,29] Fever is associated with a worsened outcome after neurologic injury, including intracranial hemorrhage, subarachnoid hemorrhage (SAH), and stroke. A meta-analysis of available studies demonstrated an increase in neurologic morbidity and mortality associated with fever.[30]

Although hypothermia has not proved to be a successful intervention for patients with traumatic brain injury[31] or SAH,[32] this does not equate to a lack of beneficial effect of normothermia compared with hyperthermia, and many clinicians are increasingly aggressive in preventing and treating fever.[33]

To provide appropriate treatment for fever, it is necessary to perform daily reappraisal to delineate the source of fever, given the large number of potential causes. However, in many cases a cause cannot be determined, and empirical treatment including scheduled administration of acetaminophen, application of cooling blankets, and increasingly, more invasive methods of cooling are required.

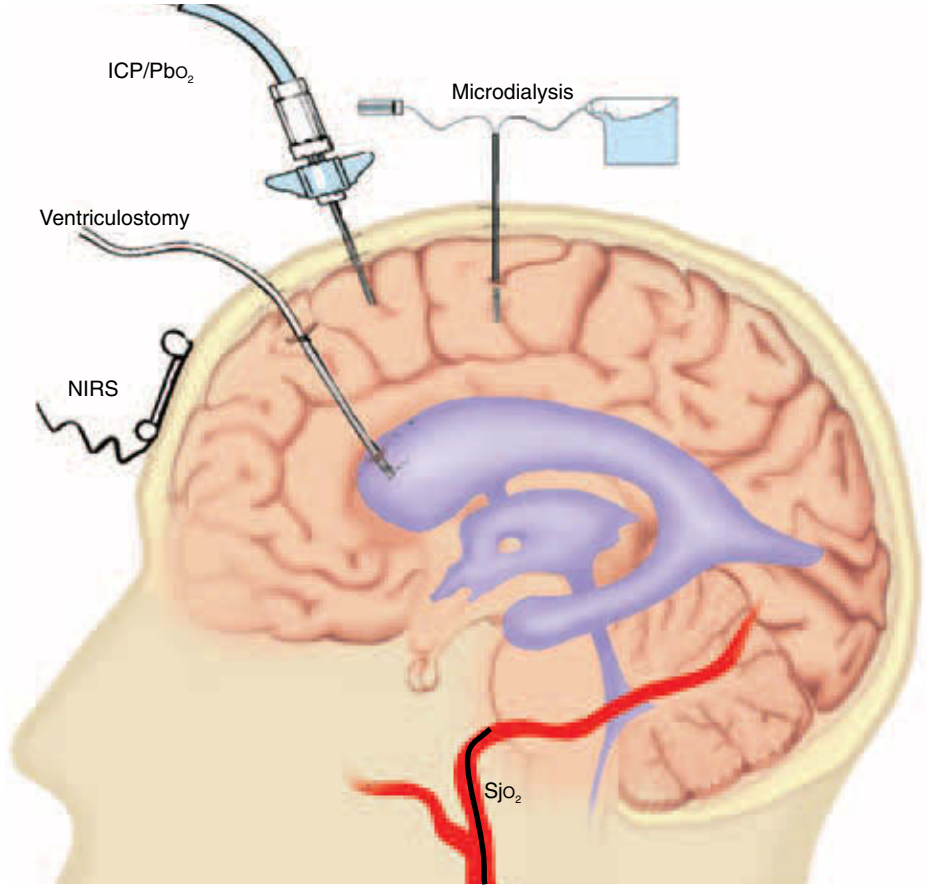

Figure 94-5 Schematic of available intracranial monitoring, with near-infrared oximetry (NIRS), intracranial pressure (ICP, either via ventriculostomy or parenchymal probe), brain tissue oximetry (Pbo_2), microdialysis, and jugular venous oximetry (Sjo_2).

Monitoring

The avoidance or correction of secondary physiologic insults necessitates the aggressive use of physiologic monitors (see Chapter 46 and Fig. 94-5). This does not obviate the need for regular clinical examination of the CNS, because monitors measuring the function of the brain (e.g., processed electrical activity, cerebral oxygenation, and ICP) are merely surrogates and do not integrate the information in a cogent manner. Similarly, attention should be paid to the basics of fluid volume status, respiratory rate, cardiovascular stability, and metabolic consumption.

Intracranial Pressure

ICP monitoring quickly became a standard of care after introduction to clinical use in the 1970s,[34] making subsequent determinations of utility and effectiveness with a randomized controlled clinical trial almost impossible. Noninvasive monitors have not established sufficient reliability to date and remain the subject of research.[35] Despite the broad acceptance of ICP monitoring, some have challenged its use as having no effect on outcome.[36] Nonetheless, the majority of neurosurgical centers insert such devices routinely in the management of traumatic brain injury and SAH, using defined thresholds (e.g., ICP > 25) to trigger treatment interventions, including osmotic agents (e.g., mannitol, or hypertonic saline) or operative treatments (e.g., decompressive craniotomy or CSF drainage).

ICP sensors may only represent the compartment pressure where they were placed (see Fig. 94-2) and may not be sensitive to acute transients in pressure on the other side of the falx or tentorium.[37] Intraparenchymal fiberoptic devices are less invasive and easier to place but may only be calibrated ex vivo and cannot drain CSF. Thus, provided the ventricles are accessible, ventricular catheters remain the gold standard of measurement but at the expense of an increased risk of infection of around 6%.[38]

When the ventricles are small, this becomes technically difficult, and the risks of hemorrhage and contusion are increased.

ICP devices can be quickly placed with a minimum of morbidity in experienced hands and, provided suitable attention is paid to the issue of potential drift from calibration,[39] generally offer useful insights to guide therapeutic interventions.

Observation of their trends reveals characteristic patterns that may have prognostic implications (e.g., the Lundberg "A" or "plateau" ICP wave indicating critical cerebral compliance[40] and impending herniation.

Cerebral Blood Flow

Important threshold values for function were identified by Symon and others (Table 94-3).[41] The initial methods of quantitative CBF measurements were laborious and time consuming and did not offer accurate regional estimates.[42] They were replaced by the use of isotopic tracers that allow basic regional flow measurement

Table 94-3 Functional Thresholds of Cerebral Blood Flow (CBF)

CBF (mL/100 g/min)	Result
50	Normal
20	EEG slowing
15	Isoelectric EEG
6-15	Ischemic penumbra
<6	Neuronal death

EEG, electroencephalogram.

(e.g., inhaled or intravascular xenon-133) or a combination of imaging and qualitative assessment (i.e., single photon-emission computed tomography [SPECT]). Calibrated imaging techniques such as positron emission tomography (PET) and stable xenon or contrast CT perfusion[42] have now become standard in many centers.

Although providing potentially useful information on regional perfusion, these methods often involve transporting the patient outside the ICU, which may be clinically inappropriate in unstable circumstances.

Recently, invasive probes using laser collimated light and the Doppler principle have been introduced to measure the capillary "flux" of red blood cells, providing focal measurements of tissue blood flow. Criticism has centered on their small measurement area, which may not be representative of global conditions.[43]

Thermodilution is a similarly focal technique in which small thermocouples are placed cortically. Blood flow is related to temperature diffusion at the probe.[44] An alternative approach has been to use jugular venous temperature diffusion to assess flow. Whether this reflects CBF reproducibly may depend on the ratio of jugular venous drainage to overall cerebral venous flow.[45] It remains to be seen whether these devices can be developed into reliable and consistent monitoring tools.

Transcranial Doppler Monitoring

Transcranial Doppler monitoring uses the Doppler shift effect to assess flow velocity in insonated arteries.[46] This is often used as a surrogate of flow in examining accessible vessels and in skilled hands offers considerable insights into dynamic flow. This technique has the advantage of being a bedside, relatively speedy and noninvasive monitor of flow within the main components of the circle of Willis via ophthalmic, temporal, and foramen magnum acoustic windows. It has excellent temporal resolution, and, being noninvasive, allows repetitive measurements with little or no risk. In a small proportion of patients, predominantly older women, temporal bone thickness may prevent monitoring.[47] Extrapolation of velocity to flow relies on an assumption of relatively constant diameter of the large conductance vessels. Under different circumstances, changes in velocity can be used to assess alterations of vascular caliber (e.g., arterial vasospasm after subarachnoid hemorrhage)[48] or intracranial stenosis (Fig. 94-6). For the middle cerebral artery, vasospasm can be distinguished from hyperemia by examining the ratio between the intracranial flow velocity to extracranial carotid artery flow velocity (the Lindegaard index). A ratio greater than 3 is generally indicative of vasospasm whereas a ratio less than 3 is consistent with hyperemia.[49]

Autoregulation and Vasomotor Reactivity

Monitors of CBF can assess the response of the cerebral vasculature to changing circumstances of metabolism and blood pressure (i.e., autoregulation).[50,51] Static cerebral autoregulation can be determined with sustained manipulation of blood pressure using either a tilt test or a direct vasopressor as clinically appropriate, whereas dynamic autoregulation can be assessed using rapid deflation of previously inflated thigh cuffs above systolic blood pressure. Alternatively, autoregulation can be assessed by monitoring CBF velocity via TCD in response to spontaneous fluctuation of blood pressure using transfer function analysis, although these are likely to be less reliable than the stimulus-response paradigm.[52] The presence or lack of autoregulation may guide subsequent treatment and prognosis, because frequently the loss of autoregulation is associated with a poor outcome.[53,54] Cerebrovascular reserve or vasomotor reactivity, as determined by CBF response to changes in $Paco_2$, can be assessed either with rebreathing or addition of carbon dioxide to the breathing circuit, or with administration of acetazolamide.[52]

Jugular Bulb Oximetry

The Fick principle may be reversed to examine the venous oxygen saturation that, assuming a constant hematocrit and metabolism, can offer an assessment of the adequacy of CBF and associated oxygen delivery relative to cerebral oxygen consumption—that is,

$$\text{If } AVDo_2 = \left(CMRo_2/CBF\right), \text{ then } Cao_2 - Cjvo_2 = \left(CMRo_2/CBF\right)$$

Ignoring the contribution of dissolved O_2, then

$$\left(Sao_2 - Sjvo_2\right) \times Hgb \times 1.34 = \left(CMRo_2/CBF\right)$$

where $CMRo_2$ is the cerebral oxygen metabolic rate, Cao_2 and $Cjvo_2$ are the arterial and jugular venous oxygen content respectively, Sao_2 and $Sjvo_2$ are the arterial oxygen and jugular venous oxygen saturation respectively, Hgb is the hemoglobin concentration, and 1.34 is the oxygen affinity constant.

In vivo, catheters are placed retrogradely through the internal jugular vein to its jugular bulb at the foramen or even beyond it to the large sinuses (Fig. 94-7).[55,56]

These catheters provide information related to both perfusion and oxygen consumption, in a manner analogous to the use of mixed venous oximetry for shock management. Both desaturation (<50%—suggesting inadequate delivery/excess consumption) and abnormally high saturation (>75%—suggesting hyperemia or stroke) have been associated with poor outcome.[57,58] The derivable arteriovenous oxygen content difference is possibly a more accurate assessment of the adequacy of flow and has been shown to relate to outcome.[59] Jugular venous oximetry has been criticized as being insensitive to focal changes, because it reflects the averaged global cerebral venous oxygen saturation from the confluence of hemispheric venous drainage. Consequently, some authors have suggested using oxygen consumption in combination with the cerebral arteriovenous gradient of lactate to make stoichiometric assessments of aerobic versus anaerobic

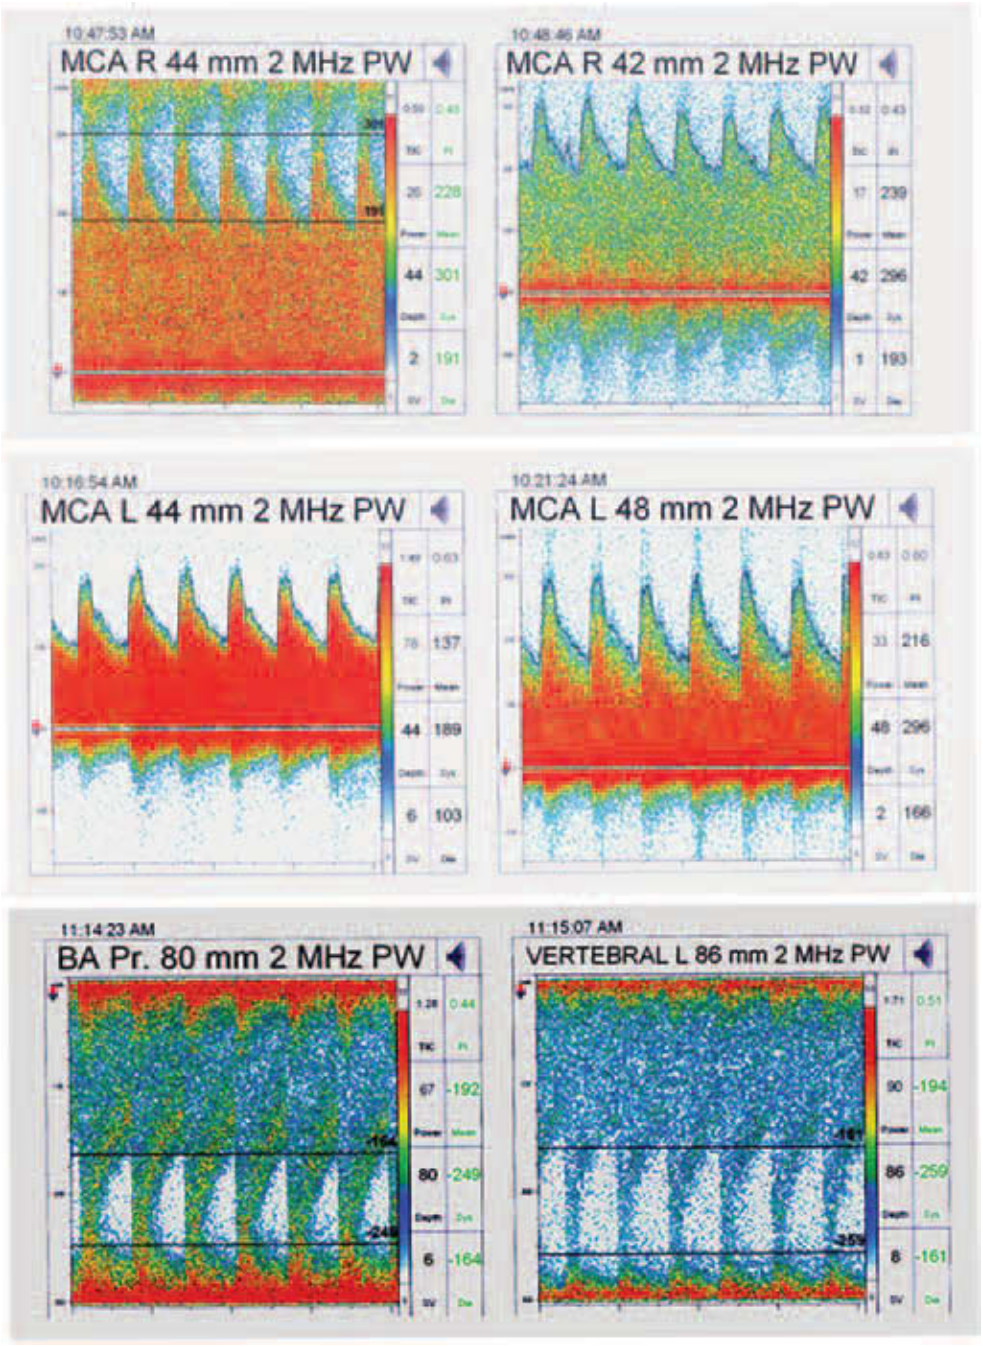

Figure 94-6 Transcranial Doppler images of elevated cerebral blood flow velocities in middle cerebral and vertebrobasilar vessels.

metabolism.[60] They have gone on to suggest metabolically directed management strategies as opposed to management of cerebral hemodynamics,[61] that is, goal-directed therapy based on metabolic indices (jugular venous oxygen saturation), rather than on hemodynamic indices (ICP and CPP).

Brain Tissue Oxygen Tension (Pbo_2)

In conceptually similar assessments of in vivo oxygenation, miniaturized Clark electrodes have been developed and combined with ICP catheters to provide simultaneously estimations of tissue oxygen tension and ICP. Pathologic levels are thought to be below 15 mm Hg with normal values in the 20- to 45-mm Hg range.[62] These Pbo_2 devices have been used in a variety of pathologic conditions, and many authors found them useful in guiding therapy and providing insight into adequacy of cerebral perfusion and have reported improved outcome.[62] However, there is a paucity of adequately powered randomized controlled trials, and many limitations including measurement errors, calibration drifts, and uncertainty of the generalizability of the local measurement remain.[63,64] Nevertheless, in patients without focal lesions, it can provide important physiologic feedback in response to therapeutic manipulations of blood pressure and oxygenation. Thus, a critical component of the utility of Pbo_2 or any of the monitors mentioned here, is a well-thought-out treatment proto-

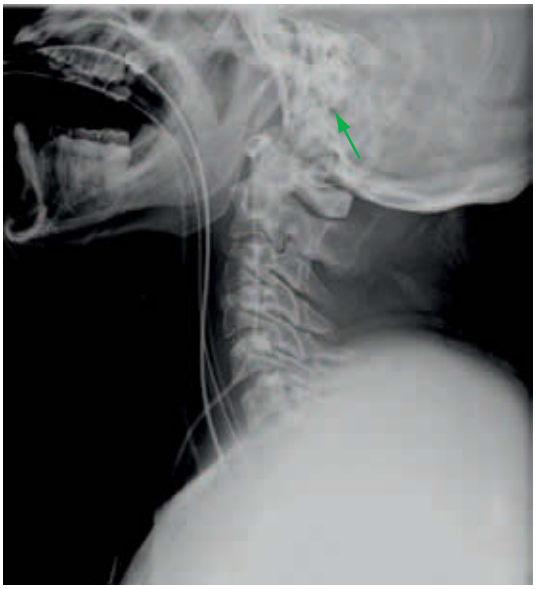

Figure 94-7 Lateral cervical spine radiograph showing appropriate positioning of the SjO_2 catheter above the lower border of the C1 vertebra (*arrow tip* is actually within the jugular foramen).

col with appropriate strategies for intervention guided by information provided by the monitor.[65]

Cerebral Microdialysis

There is significant interest in the use of cerebral microdialysis probes to assess the biochemical milieu of the brain. These probes are placed through a burr hole and cycle small volumes of dialysate through the catheter to an extracranial collection system. Consequently, various substances can diffuse across the semipermeable membrane (e.g., lactate. pyruvate, glucose, glycerol, glutamate)[66] for collection and subsequent analysis using a bedside high-pressure liquid chromatography device. This gives graphical and numerical displays of trended concentrations for the preceding collection interval (usually 1 hour). This then relates to the in vivo biochemistry of the brain. While intuitively attractive, there have been a number of unresolved questions hampering wider implementation, not the least of which is the question on the optimal site of placement, in relation to disease pathology, as well as to anatomic region of gray matter versus white matter.[66]

These issues were recently addressed by a consensus statement on placement of microdialysis catheters, with the aim of improving accuracy in the comparison of results and to allow generalization from accumulated experience.[67] Improvements in membrane technology now permit larger molecules to cross into dialysate, creating the possibility of research into microvascular peptidomics.[66]

Electroencephalography

The EEG records electrical activity generated and detected by appropriately placed electrodes in a radial and axial array, as defined by the 10/20 system, an internationally standardized system of recording. The consequent waveforms are displayed and recorded. The spectrum of component frequencies together with amplitude and power can be quantified and analyzed in a variety of fashions by what are termed processed EEG monitors. These devices can provide important diagnostic information in patients in the neurocritical care unit who cannot be otherwise assessed. The EEG tends to be used in a diagnostic snapshot mode for isolated assessments, and it is underutilized as a continuous monitor within the ICU. This is a function of the difficulty involved in its application and interpretation, which necessitates dedicated equipment and personnel. A 24-hour continuous recording of EEG is, in general, more fruitful than a snapshot recording.

Moreover, both in traumatic brain injury and SAH, there are significant numbers of patients who develop nonconvulsive status epilepticus,[68,69] and this constitutes a regularly overlooked but significant source of morbidity and stress on the brain. Whereas the EEG is a difficult monitor to use, there are definite indications for its deployment and the neurocritical care physician should be familiar with the basic principles of its function and use.

A number of related devices have also been developed from processed EEG to monitor the "depth of anesthesia." Although they have been utilized to monitor the level of sedation in critically ill patients, they are not designed for—and should not be used to—monitor neurologic integrity or seizure activity

Near-Infrared Spectroscopy

The idea of "pulse oximetry for the brain," as conceptualized in the early 1990s, is an attractive one. It relies on the principle of reflectance spectroscopy, in which near-infrared light traverses bone transparently, to be scattered and reflected to a degree inversely proportional to the concentration of light-absorbing materials in tissue (e.g., hemoglobin and other tissue chromophores). The surface detector is constructed and calibrated so as to detect light that has ostensibly traversed down to cerebral cortex and back. An adjacent detector is positioned to detect a signal from superficial tissues and both signals then used in an algorithm to derive an estimated tissue saturation. However, the devices employed have been troubled by issues of reliability, specificity, and cross contamination from other cytochrome-containing tissues.[70,71] There is slightly more enthusiasm for their role as trend monitors of flow, especially in children and patients with extracranial carotid artery disease.[72,73]

Radiologic Imaging

Imaging can be employed as a monitoring technique, albeit on a protracted time scale.[74] The two major modalities are computed tomography (CT) and magnetic resonance imaging (MRI). CT is by far the most useful and commonly used technique, because it is the most efficient method. MRI, although more time consuming, is more sensitive for brainstem lesions as well as for axonal injuries. Both CT and MRI can provide information on the vascular tree, but conventional contrast angiography remains the gold standard. Assessment of intracranial masses, diffuse injury, or hemorrhage can be subsequently used to guide therapy, triage, and prognosis.[75]

Table 94-4 Marshall Scale: Computed Tomography Categories for Head Injury

Category	Definition
Diffuse injury I	No visible intracranial pathologic process
Diffuse injury II	Cisterns are present with midline shift of 0-5 mm and/or lesion densities present; no high or mixed density lesions at ≥25 mL
Diffuse injury III	Cisterns compressed or absent, with midline shift of 0-5 mm; no high or mixed density lesions of ≥25 mL
Diffuse injury IV	Midline shift of >5 mm; no high or mixed density lesion of ≥25 mL
Evacuated mass lesion (V)	Any lesion surgically evacuated
Nonevacuated mass lesion (VI)	High or mixed density lesion of ≥25 mL; not surgically evacuated

To provide meaningful comparison of therapeutic modalities in clinical trials, it is important to standardize and categorize the CT images. The Marshall scale has been used in traumatic brain injury to stratify degrees of hemorrhage within the cranial vault and correlates to outcome (Table 94-4).[76,77] The Fisher scale assesses the volume of subarachnoid blood after a diagnosis of SAH.[78] There again is a strong relationship to outcome regarding the development of vasospasm (Table 94-5).[79] Both scales rely on experienced interpretation for accuracy. A recent paper documenting 18 neurosurgical centers in Italy found inconsistent application of the Marshall scale, suggesting an urgent continued need for standardization.[80]

Clinical Examination

Comprehensive neurocritical care encompasses the ability to perform a competent neurologic examination. Reproducible and objective assessment of neurologic function is just as important a monitor as some of the sophisticated technology mentioned earlier, with the advantage that it offers better insight into global function of the nervous system and allows integration of information in an inherently complex dynamic system. One of the most basic yet important examinations is the pupillary light reflex, the unilateral absence of which may indicate midbrain compression from uncal herniation and neurologic emergency. Bilaterally absent papillary reflexes signify imminent or established cerebellar herniation, but this might be reversible with rapid efficacious treatment.

Table 94-5 Fisher Scale (CT Scan Appearance)

Group 1	No blood detected
Group 2	Diffuse deposition of subarachnoid blood, no clots, and no layers of blood >1 mm
Group 3	Localized clots and/or vertical layers of blood ≥1 mm in thickness
Group 4	Diffuse or no subarachnoid blood, but intracerebral or intraventricular clots are present

Clinical scales have been devised for the common neurologic settings. The Glasgow Coma Scale (GCS) is a well-known, universally if inconstantly applied scale (Table 94-6). It relies on independent assessment of eye opening, speech, and best motor movement in response to progressive trials of command, voice, and noxious stimuli.[81] The Hunt and Hess scale (Table 94-7) when applied to patients with SAH offers classification and prognostication of mortality.[82] The World Federation of Neurologic Surgeons Scale (WFNS) is the preferable rating because it uses the more prevalent GCS but with a modifying component of focal deficit (Table 94-8).[83] Knowing and using these scales are crucial to understanding the terminology and practice of neurocritical care.

Multimodality Monitoring

No single monitor credibly and reliably offers insight into the functioning physiology of the brain. Instead, various surrogates of function are offered. Many criticisms can be directed at each individually, but an interesting concept is that of multimodality monitoring, that is, using a combination of parameters to improve on accuracy of diagnosis and response to management.[84] Although an attractive concept, the precise implementation of this idea is still in its early days, with little methodologic standardization; this may be facilitated by rapidly approaching commercial development.

Common Diseases in the Neurocritical Care Unit

Head Injury

The treatment of traumatic brain injury was one of the initial emphases of neurocritical care. Recent changes in road traffic

Table 94-6 Glasgow Coma Scale

	6	5	4	3	2	1
Eyes	N/A	N/A	Opens eyes spontaneously	Opens eyes in response to voice	Opens eyes in response to noxious stimuli	Does not open eyes
Verbal	N/A	Oriented, converses normally	Confused, disoriented	Utters inappropriate words	Incomprehensible sounds	Makes no sounds
Motor	Obeys commands	Localizes to noxious stimuli	Flexion to noxious stimuli	Abnormal flexion to noxious stimuli	Extends to noxious stimuli	Makes no movements

Table 94-7 Hunt and Hess Grading System

Grade	Clinical Presentation	Survival (%) (approximate)
Grade 1	Asymptomatic or mild headache	70
Grade 2	Moderate to severe headache, nuchal rigidity, and no neurologic deficit other than possible cranial nerve palsy	60
Grade 3	Mild alteration in mental status (confusion, lethargy), mild focal neurologic deficit	50
Grade 4	Stupor and/or hemiparesis	20
Grade 5	Comatose and/or decerebrate rigidity	10

legislation and enhancements in passenger protection have led to a decline in the incidence of traumatic brain injury in the United States, to the degree that motor vehicle accidents have been replaced by falls as the chief cause of injury.[85] These causes, together with assaults and off-road and sporting injuries, still contribute to what is referred to as a "silent epidemic,"[85] accentuated by ongoing military conflicts and their recent hallmark blast injuries[86] and a prevalence consequent on concentration in a predominantly youthful population. Outside of wartime, these causes usually share a common factor in the contribution from alcohol consumption.[87,88]

In all circumstances, brain structure is deformed by the transmission of kinetic energy, severing blood vessels and nerve fibers. The distribution of this damage covers a wide spectrum from localized contusion to diffusely scattered foci, varying with the circumstances of the incident and the architecture of the victim's brain. Typically, cerebral contusions are located at the bony prominences of the skull, at the sphenoid wing and petrous ridge.[89] The variability in inflicted pathology renders some of the broader assumptions about cerebral injury questionable, because a temporal lobe injury may behave very differently from a posterior fossa lesion.

Traumatic brain injury may also be classified according to whether it is blunt or penetrating. Penetrating injury may again have widely varying consequences depending on site, depth, and energy but is generally fatal if it bilaterally traverses the midbrain.[90] While initial mortality from penetrating injury is higher, outcome in survivors is similar to that for nonpenetrating injury.[91]

Vascular injury may affect more superficial arterial blood vessels, as seen in the middle meningeal artery injury typical of pterional fracture. This commonly results in an extradural hematoma.[92] These rapidly expanding collections can result in swift neurologic deterioration and devastating results, if not treated quickly. The mortality is between 15% and 20%.[93] Alternatively, cortical bridging veins between cortex and the dural venous sinuses are often torn by rotational or acceleration/deceleration forces to produce an accumulating subdural hematoma. This may manifest slowly and may even be unaccompanied by signs of external trauma. In the time taken for the venous hematoma to develop, symptoms may be subtle and, unfortunately, may be disregarded. The slow expansion exerts a cumulatively damaging effect, which by the time severe signs eventually manifest, may be just as or even more destructive than a rapidly expansile lesion.[94] This is prevalent in the elderly where the process of senile cerebral atrophy results in greater tension on the bridging veins crossing an increasing distance, consequently rendered all the more susceptible to rupture.

In all these scenarios, the primary pathology is accentuated by secondary features of elevated ICP, diminution of arterial inflow, and consequent reduction in CPP, with resulting tissue hypoxia and cell death, as previously described in the intracranial pressure-volume relationship (see Fig. 94-1).

This can also be modified adversely by loss of autoregulation, which may result in further increases in ICP. This is often seen in diffuse injury, where although individual foci may be small, they additively combine to produce a total burden of inflammatory change sufficient to overwhelm autoregulation.[95]

Traumatic SAH (tSAH) is seen on up to 60% of admissions for traumatic brain injury.[96] There is some variability of detection and reporting, but despite this, tSAH has a substantial effect on outcome.[97] There is an interesting relationship with prolongation of the QTc interval seen in 67% of patients with tSAH.[98] About 20% of patients with tSAH may also develop vasospasm, which can lead to secondary ischemic insult. The diagnosis and management of the vasospasm is facilitated with the use of transcranial Doppler imaging.

A crucial part of the management of traumatic brain injury in the ICU should be a comprehensive examination and assessment utilizing such principles as outlined in Advanced Trauma and Life Support,[99] because it is not unknown for occult injuries to escape initial screening but subsequently exert a delayed physiologic compromise on the arrival of the patient in the ICU, or worse, in the CT scanner. These injuries may accentuate the primary brain injury by contributing to secondary physiologic insult.[14]

Overall, the common goal of treatment of traumatic brain injury is to maintain cerebral perfusion. In patients with mass lesions resulting in anatomic distortion with mass effect, surgical removal is indicated. Although unproven by randomized controlled trial, early decompressive craniectomy for patients with elevated ICP refractory to medical treatment, without or without mass lesions, may improve outcome.

Medical management may be required both before and after surgical intervention or as an alternative in circumstances of diffuse injury. Such treatment strategies within the ICU revolve around the reduction of ICP and the maintenance of cerebral perfusion, which may not be compatible goals. While therapeutic resolution of ICP with osmotic diuresis is a logical approach, it may have unintended consequences on central vascular volume and myocardial function.[100] After an initially beneficial effect in reducing intracerebral volume, mannitol will then go on to leave

Table 94-8 World Federation of Neurologic Surgeons Scale

Grade 1	Glasgow Coma Score (GCS) of 15, motor deficit absent
Grade 2	GCS of 13-14, motor deficit absent
Grade 3	GCS of 13-14, motor deficit present
Grade 4	GCS of 7-12, motor deficit absent or present
Grade 5	GCS of 3-6, motor deficit absent or present

the vasculature via the kidney. This will also reduce the cardiovascular volume, diminishing cardiac output and blood pressure—possibly replacing one physiologic insult for another.

Mannitol has diminished in popularity over recent years to be supplanted by the increasing use of hypertonic saline (HTS).[101] This agent demonstrates a good resuscitation profile, with none of the delayed hypotension observed with mannitol.[102] Some of the same concerns apply to the use of hypertonic saline as exist with the use of mannitol (i.e., diffusion of osmotically active particles into the brain interstitium in circumstances of injury or compromise of the blood-brain barrier).[103] This may create "rebound" effects on reduction of plasma osmolarity as hypertonic saline administration is reduced, with an increase in brain water. This has been observed with differential effects in contused versus noncontused brain.[104] While bolus usage of hypertonic saline has been shown to be useful, it remains to be seen whether sustained infusions or the practice of persistent-induced hypernatremia offer any improvement in outcome.

While the choice of resuscitation fluid has not been shown to have any effect in a large study of trauma victims,[105] a post-hoc analysis of subgroup data demonstrated increased mortality associated with the use of albumin in traumatic brain injury.[106] This is somewhat at odds with the demonstration of potential benefit in stroke[107] and a prospective trial is needed.

Control of the vascular blood volume may also be regulated by manipulation of the Pco_2, which most frequently requires intubation of the trachea and mechanical ventilation.

Controlled hyperventilation is frequently practiced to reduce blood volume, and hence ICP.[108] Recent studies have demonstrated adverse consequences of aggressive hyperventilation, and most authorities agree on limiting the reduction in Pco_2 to avoid ischemia.[109]

The Brain Trauma Foundation publishes guidelines on the management of brain trauma, which are regularly updated. These concentrate on the principles outlined previously, namely reduction of ICP while preserving perfusion pressure.[110] They also provide statements of consensus on the merits of these strategies. They recommend a target Pco_2 of between 30 and 35 mm Hg[108] with a CPP of more than 60 mm Hg. This reflects the perfusion-oriented approach popularized by Rosner and others in which once ICP manipulation has reached its effective limit, mean arterial pressure may be accentuated through the use of fluids and inotropic support to maintain cerebral perfusion at or above 70 mm Hg.[15] This formed the basis of the initial Brain Trauma Foundation recommendations on cerebral perfusion.[111]

However, a subsequent clinical trial optimizing cerebral perfusion could not substantiate improvements in outcome[112] and, coupled with evidence that suggests an excessive CPP may worsen outcome,[113] the current recommendation is for a CPP of 60 to 70 mm Hg.[110]

Hypertension in excess of autoregulatory control can induce both excess blood volume and the formation of vasogenic edema across a compromised blood-brain barrier.[7] This concept underpins the Lund group protocol, which gives priority to limiting the Starling forces across the capillary bed to avoid the formation of edema.[114] These investigators recommend a CPP of 50 mm Hg using β-blockers as required, the reduction of metabolic demand with barbiturates, and intravenous colloid administration.[115]

There are no randomized controlled trials to support one strategy over the other. Nonetheless, a number of case series have now accumulated, offering comparable outcomes to CPP-oriented management.[116,117] There are almost certainly subsets of pathologic processes that may respond to the differing approaches, depending on the precise pathophysiology, determined in part by lesion volume, inflammatory burden, and blood-brain barrier integrity. A challenge lies in identifying which patient would better respond to each therapeutic strategy, perhaps using multimodality monitoring and imaging techniques.

Currently, ICP/Pbo_2 and ventriculostomy are frequently used in the management of patients in severe traumatic brain injury. However, these invasive monitors are contraindicated if coagulopathy is present. The occurrence of coagulopathy in traumatic brain injury is associated with a poor prognosis and should be vigorously treated with clotting factors, fresh frozen plasma, and platelets.

Hyperglycemia has also been reported to be associated with poor outcome in multiple retrospective studies.[26] To date there has been no randomized controlled trial on the influence of tight glycemic control on outcome in patients with traumatic brain injury, although it may be prudent to keep glucose below 140 mg/dL.

Corticosteroids have not been recommended for use in brain injury for some time, and any lingering suggestions that early steroid use may diminish inflammatory consequences of brain injury were finally dismissed by the publication of the CRASH study, which, in a multicenter evaluation of over 10,000 patients, showed an adverse effect of steroids on mortality and morbidity.[118]

Hypothermia, despite its failure to demonstrate a beneficial effect on outcome, may still have a role in the management of patients with traumatic brain injury in which ICP cannot be controlled with conventional means or when decompressive craniectomy is not otherwise available. Moderate hypothermia to 33° to 34°C generally facilitates control of ICP to a manageable level. Rewarming to normal temperature, however, runs the risk of rebound in ICP.

The timing of prophylaxis against deep venous thrombosis (DVT) has been an issue of controversy. There is general agreement on the need for prophylaxis, because up to 25% of patients with isolated traumatic brain injury develop DVT[119] and most clinicians will agree with its implementation 48 hours after injury. There is some evidence to suggest that immediate postoperative use of heparin prophylaxis is safe and does not confer additional risk of bleeding.[120]

Subarachnoid Hemorrhage

In contrast to declining numbers of patients with traumatic brain injury, the incidence of SAH remains consistent at 8 to 10 per 100,000 per year[121] and a major critical care challenge. Ethnic variations on incidence are reported, with the incidence in Finland and Japan being up to three times that in the United States.[121,122] Women have a greater risk than men by a factor of 1.6.[122] A majority of cases of SAH occur in the fourth to sixth decades of life, with a peak at age 55.[123] The majority of cases arise from aneurysms[124] that have a relatively severe morbidity and mortality. Ten percent of patients will die before hospitalization, and 25% will die within the first 48 hours, with initial hemorrhage being the primary cause of death, followed by rebleeding.[125] Subsequent morbidity and death is attributable to neurologic deficits due to ischemia induced by arterial vasospasm.[126]

Significant improvements in mortality and morbidity have occurred in the past 2 decades.[127,128] This suggests that further reductions may be achievable with continued changes in surgical practice and further concentration of expertise in regional centers. Paralleling this has been the development of neuroimaging and endovascular technologies, which have played a large part in improved outcome.[129,130]

Early Versus Late Treatment

Mortality and morbidity from SAH are mostly secondary to rebleeding of unsecured aneurysms and the delayed ischemic deficit or infarction from arterial vasospasm. Rebleeding peaks within the first 24 hours after the initial hemorrhage and declines progressively thereafter, reaching a plateau of 2% by 6 months. In contrast, vasospasm tends to develop by the third day, peaks between 5 and 7 days, and generally wanes by 14 days. This led to some debate on the timing of treatment—where rebleeding may averted by early intervention but at a risk of an increased risk of vasospasm, which may induce devastating neurologic ischemic deficit. Surgically, early treatment is also associated with less optimal brain relaxation conditions. Although no difference in outcome was reported, aggressive vasopressor therapy and endovascular support have tipped the balance in the favor of early clipping in the first 72 hours after bleeding.[131]

In addition to rebleeding and vasospasm, acute hydrocephalus develops in 25% to 30% of patients after SAH, and emergent ventriculostomy may be lifesaving as well as offering a more accurate prognosis.[132]

Antifibrinolytics

Antifibrinolytics to decrease the risk of bleeding increase the risk of stroke[133] and, with the advent of early treatment, are seldom used today. Many clinicians, however, will control blood pressure with the use of vasoactive infusions (e.g., nicardipine) to reduce the risk of rebleeding until the aneurysm is secured.[134]

Vasospasm

Vasospasm is thought to derive from the attenuation of nitric oxide–induced vasodilation, with an associated enhanced production of endothelin production and consequent vasoconstriction. The extravascular heme molecule is the leading candidate in a long list of possible culprits.[135] Seventy percent of patients with SAH develop angiographic vasospasm, although only 30% to 40% of patients will become symptomatic. Patients with a large amount of subarachnoid blood are at higher risk for the development of vasospasm. The Fisher grade is frequently used clinically to prognosticate the risk of vasospasm.[78] A recent meta-analysis of treatment techniques suggests no difference in the incidence of vasospasm between treatments.[136]

Denny-Brown first suggested increasing blood pressure to combat vasospasm in 1951,[137] but it was not until the demonstrated reversal of ischemic deficits with the use of pressors[138] that this approach developed into the subsequent use of what has been termed "triple H" therapy, where induced hypertension (up to and sometimes beyond 180 mm Hg systolic) and aggressive fluid infusion (4-5 L/day) (hypervolemia) could reverse the neurologic deterioration apparent in the patient with severe spasm.[139]

The third "H"—hemodilution to a theoretical optimal hematocrit of 30—is largely a passive result of hypervolemia and is thought to be less important, and possibly even harmful.[140] Despite a significant anecdotal history of effect there has been little evidence of benefit in randomized control trials and meta-analysis.[141,142] Triple H therapy may also be associated with an increased frequency of complications[143] thought to be related to the use of hypervolemia.[142]

There is more evidence to support the effect of hypertension used singly, an effect that can be undermined by the use of additional hypervolemia.[144]

Although hematocrit is considered as less of an issue with triple H therapy, in a retrospective study, it was shown that a higher hemoglobin level is associated with less cerebral infarction and better outcome,[140] and many clinicians will maintain a hematocrit of 30%. Disappointingly, benefit is not seen with deliberate transfusion to increase oxygen delivery. It has, on the contrary, been associated with increased vasospasm and poor outcome.[140,145] The general critical care literature reinforces these deleterious effects of transfusion.[146] A prospective trial is awaited.

The only level 1 evidence from randomized control trials in SAH is regarding the use of nimodipine. This agent, when administered prophylactically from diagnosis for 21 days, offers modest improvement in outcome and incidence of ischemic deficit. Interestingly, it does not have a readily apparent effect on the incidence of angiographic vasospasm.[147]

Other therapeutic approaches to vasospasm include trials on antiplatelet medications,[148] statins, where some small studies have suggested improved neurologic outcome,[149,150] and endothelin antagonists.[151]

Management of vasospasm is facilitated with appropriate use of imaging, including the use of transcranial Doppler monitoring, SPECT, and cerebral angiography when indicated. Institution of triple H therapy necessitates the use of invasive monitoring, including that for arterial blood pressure and central venous pressure (or other indices of preload).

The use of mechanical balloon dilation of blood vessels—angioplasty—has added a major weapon to the armamentarium against vasospasm.[152,153] Angioplasty is limited by the caliber of blood vessels, as well as their accessibility, and carries a risk of catastrophic rupture.[152]

Pharmacologic angioplasty with intra-arterial injection of a vasodilator is gaining in popularity. First established using papaverine, use of calcium channel blockers such as nicardipine and verapamil is being increasingly reported and has fewer adverse effects. All current agents are limited by the transient nature of their effects—less than 24 hours.[154] Vasodilators may be used in vessels too small to be accessible by balloons.

Cardiac Dysfunction

As suggested previously, significant autonomic disturbance may arise in association with SAH, resulting in changes in the electrocardiogram and myocardial performance. Electrocardiographic changes are frequent but do not appear to relate to outcome.[155] However, one series described a 32% incidence of abnormal perfusion scans, independent of the clinical history, electrocardiogram pattern, or neurologic condition.[156]

Abnormal echocardiography has been described in up to 8% of SAH patients, mostly in those with blood in basal cisterns, frequently accompanied by hypotension and pulmonary edema, and is associated with a poor neurologic grade. A typical pattern of symmetric T wave inversion and severe QTc prolongation was described, although multiple electrocardiographic patterns had been observed.[157]

Table 94-9 Suggested Cardiovascular Management Strategies in Subarachnoid Hemorrhage

General

1. Manage hypertension in unsecured aneurysms (with nicardipine titrated to systolic BP < 140 mm Hg.
2. Maintain euvolemia prophylactically; no role for prophylactic hypervolemia.
3. Nimodipine (possibly statins)

Cardiovascular Instability

1. Blood pressure and cardiac output goals will alter as aneurysm is secured.
2. ECG
   If abnormal: QTc prolongation, ST-segment changes; check troponins.
   If troponins elevated: echocardiography.
3. Perform echocardiography if any manifested hypotension or heart failure is suspected.
4. Monitor cardiac output (e.g., LiDCO, PICCO, PABC).
5. Support on dobutamine for cardiac output and norepinephrine for blood pressure.
6. Consider coiling as soon as practicable.
7. Reserve coronary catheterization for isolated wall motion deficit and rising troponins (coil first if possible).
8. Avoid β-blockers unless there is active coronary artery disease.
9. Vasospasm: treat with euvolemia/mild hypervolemia, pressors, and cardiac output monitoring: adjust targets as perfusion tests suggest.
10. Transfusion: maintain hematocrit above 25%. Avoid use of stored blood if possible.

The phenomenon of neurogenic stunned myocardium is a definite clinical entity, with what can be a severe limitation of cardiac contractility. It is, however, a reversible condition, in contrast to myocardial infarction, and has a good recovery profile. Obvious abnormalities of function start to recede within 72 hours; but when stunning is severe, endovascular management rather than surgical treatment may be indicated (if the aneurysm is suitable). Cardiac dysfunction may complicate and limit the active treatment options for vasospasm and render early mechanical angioplasty more appropriate.[158] It has morphologic, epidemiologic, and functional similarities to Tako-tsubo cardiomyopathy, which is an acute transient dysfunction resulting from sympathetic overactivity in postmenopausal women[159] that has also been reported in SAH. Troponins are frequently increased in acute SAH. Whether this release of troponin represents a frank cardiac injury or "myocardial leak" remains unknown, and clinically it does not appear to have prognostic significance.[160] Interestingly, adrenoreceptor polymorphism was implicated in myocardial stunning, in which different receptor genotypes denoted an increased sensitivity to and release of catecholamines, in turn associated with a 3- to 4.8-fold increase in risk of cardiac injury and dysfunction.[161]

A typical strategy for cardiovascular management is given in Table 94-9.

Respiratory Dysfunction

Pulmonary injury is a frequent complication in the clinical course of the patient with SAH, with nearly 17% of patients experiencing severe dysfunction. This is associated with a poor neurologic outcome.[162] Transfusion has been associated with an increased risk of lung injury, which in turn affects mortality.[163] Acute pulmonary edema can also occur in patients in poor grade SAH, and this can be either neurogenic or cardiogenic.

Endocrine and Metabolic Derangements

Hyperglycemia has been identified as a risk factor for poor outcome, especially in SAH.[164,165] However, aggressive glucose control has not been proved to be useful in SAH; and in other critical care settings (e.g., intraoperative control in cardiac patients), this was associated with worse outcome.[166] As in traumatic brain injury, there is also no basis for the use of corticosteroids.[167]

Hyponatremia is observed in 30% to 40% of patients with SAH.[168] The most frequent mechanism is that of cerebral salt-wasting syndrome in which sodium is actively excreted from the body in high concentration and there is an accompanying diuresis despite ongoing hyponatremia.[169]

Berendes and colleagues demonstrated increased brain natriuretic peptide (BNP) release, thought at that time to derive exclusively from the brain.[170] Given the increasing evidence for the ventricle as the main source of production of BNP, it is unclear whether BNP arises from a stressed ventricle at the time of the hemorrhage and associated sympathetic discharge or from a brain experiencing abnormal perfusion states of homeostatic areas. Hyponatremia is also associated with cerebral infarction[171] in keeping with the clinical observation that hyponatremia predicts the onset of vasospasm by around 24 hours.[172]

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been implicated in some cases of hyponatremia, and although the predominant force of opinion is with cerebral salt-wasting syndrome, argument still exists.[173] The distinction is crucial given the very different management. Cerebral salt-wasting syndrome may indicate replacement with sodium and fluids whereas SIADH may indicate fluid restriction, which may aggravate vasospasm. The situation is rendered all the more complex by the consideration that volume loading will itself induce natriuresis.[174] A suggested algorithm for resolving diagnostic uncertainty is given in Figure 94-8.

Feeding and Nutrition

SAH induces a profound stress response, where the hypercatabolic state relates to the severity of neurologic insult. Resting energy expenditure may reach a peak of 172% that of normal on day 10 after hemorrhage. This, coupled with the tendency to suffer from headache, nausea, and vomiting leads to relative hypoalbuminemia that may compound the tendency for hypovolemia.[175]

Ischemic Stroke

Stroke is the third leading cause of death in the United States after heart disease and cancer and a major source of disability, with some 700,000 cases per year.[176]

The deprivation of oxygen and nutrients to the brain beyond the combined thresholds of severity and time will induce cellular death in neuronal tissue. In complete occlusion this will start within minutes. Around the dead tissue, an area of marginally sufficient blood supply exists, where the probability of cell death is related to ischemic time. This is the ischemic penumbra and is potentially salvageable with aggressive intervention. In a similar fashion to the motto of cardiologists "time is muscle," it can also be said that "time is neurons."

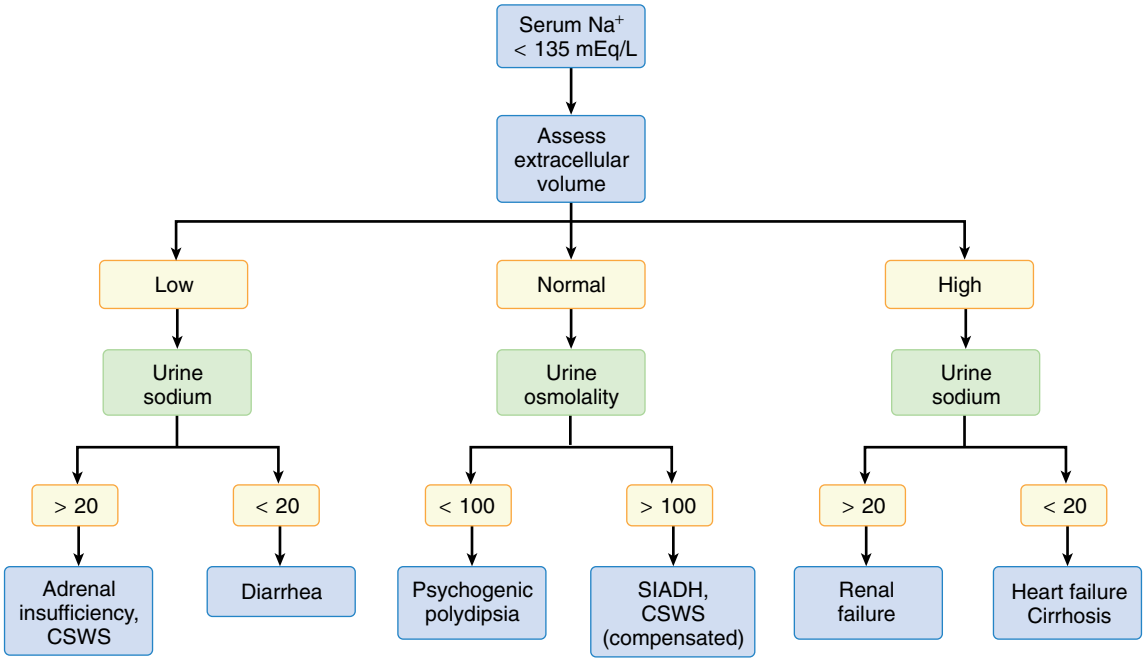

Figure 94-8 Algorithm for the differential diagnosis of hyponatremia in the neurosurgical patient. CSWS, cerebral salt-wasting syndrome; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Thus, the goals of treatment have moved away from physiologic stabilization and risk factor avoidance, toward accelerated reperfusion and retrieval of threatened brain tissue.

This was rendered feasible by the introduction of intravenous thrombolytics, paralleling aggressive cardiac management in threatened infarction. Treatment should start in the emergency department but will continue into the ICU. A window of opportunity of 3 hours has been identified, but this may be adjusted in the light of perfusion- and diffusion-weighted MRI. Intra-arterial thrombolysis is confined to specialist centers, which has limited the acquisition of data on efficacy, but suggestions are that it is effective with a lower incidence of systemic adverse events. It may be particularly advantageous in vertebrobasilar occlusion.[177]

It is crucially important to maintain vigorous perfusion until thrombolysis has been attempted. Consequently, hypertension should not be treated unless it is inducing myocardial damage or where intracerebral hemorrhage has already occurred (hemorrhagic conversion). This latter circumstance would also preclude thrombolysis.

Once thrombolysis has been attempted, this increases the risks of hemorrhage and hypertension should be moderated.[178] Unwanted side effects obviously center around hemorrhage, which is associated with higher thrombolytic doses and later treatment.[179] Keen attention should be paid to postprocedural CT scans and any signs of systemic hemorrhage such as lower abdominal pain, which may indicate retroperitoneal bleeding. Areas of brain that cannot be salvaged will swell, causing compressive ischemia in adjacent regions. Just as the effects of traumatic brain injury and SAH may vary by anatomic site, so, too, will the effects of ischemic stroke vary with the particular vascular area of occlusion.

In addition to control of cerebral volume, recent interest has revived in the early use of decompressive surgery in circumstances of "malignant" swelling. Edema can induce ICPs in excess of 30 mm Hg, with a correspondingly high mortality. Completed studies to date have relatively small sample size, but suggest treatment benefit if decompressive craniectomy is carried out in the first 24 hours after onset of symptoms, with aggressively sized bone flaps.[180] There is a adverse effect of increasing age, but hemispheric dominance seems less important.[177]

In many ways, management is similar to that of mass lesion after traumatic brain injury. Larger studies of efficacy are underway to examine not just mortality but also functional outcome, given a significant body of concern on the possibility of increased survival with increased disability and suffering.

Postoperative Neurosurgical Care

Many neurosurgical procedures are lengthy and involve significant insult to the brain; thus postoperative admission to the ICU for avoidance of secondary insult and a more graduated withdrawal of ventilatory support is common, although objective evidence is lacking. This entails careful control of blood pressure to minimize edema formation, taking account of potential compromise of autoregulation and cerebrovascular compliance. However, the importance of neurologic examination cannot be overemphasized, and early withdrawal or intermittent interruption of sedation to allow appropriate clinical examination is a prudent approach to follow these patients.

Vascular lesions such as arteriovenous malformations and vascular tumors predisposed to the development of hyperemia benefit from careful attention to blood pressure management, as does carotid endarterectomy. In both arteriovenous malformation and carotid disease, areas of the brain adjacent to the malformation or ipsilateral to the tight carotid stenosis may have absent autoregulatory control or autoregulate only at a significantly lower range of blood pressure. Until the autoregulatory

mechanism returns to normal, blood pressure should be carefully and tightly controlled to present what has been termed "normal pressure perfusion breakthrough." This can be accomplished with intravenous nicardipine or esmolol infusion or both, which will allow titratable adjustment of the blood pressure.

Aneursymal clipping does not fall into this category except in cases of vascular graft bypass procedures, where attention should be paid to minimum as well as maximum pressure targets, in what has been termed the *Goldilocks approach*. If pressure is kept too low, then this may risk graft thrombosis. If pressure is too high, then the graft may rupture. Although the range maintained is arbitrary, and there are no supporting data, it is customary to maintain the systolic blood pressure in a narrow range between 100 and 120 mm Hg.

Although not common, patients treated with lumbar CSF drainage may develop central herniation syndrome. The diagnosis is not always apparent, and the sudden decline in mental status, with a history of CSF drainage, should prompt appropriate imaging of the brainstem. Treatment is with fluid hydration and keeping the patient in Trendelenburg position.

Intracerebral Hemorrhage

Nontraumatic intracerebral hemorrhage may arise from ruptured aneurysm, ruptured arteriovenous malformation, hemorrhagic stroke (amyloid angiopathy, hypertension), conversion from ischemic stroke, tumor, substance abuse (alcohol, cocaine, methamphetamines), and the use of warfarin (Coumadin). This wide range of differential diagnoses can swiftly be refined by the CT scan, with accompanying clinical signs aiding localization and the assessment of pathophysiologic effect. Angiography may be required to rule out aneurysmal rupture.

Management is to avoid secondary insult by reducing the incidence of rebleeding, hypoxemia, hypercarbia, or edema.[181,182] Essential care is directed toward the airway and circulation. If the initial CT or MRI appearance is suggestive of arteriovenous malformation, then care should be taken to limit blood pressure to reduce the risk of rebleeding. The addition of ICP monitoring would allow one to set the CPP target and provide a more physiologic approach to the management of systemic blood pressure. If the intracranial hemorrhage is in the posterior fossa or midbrain, consideration should be given to the insertion of a ventriculostomy to reduce the risk of hydrocephalus. Patients with lesions in these regions are prone to airway and respiratory problems and may need early tracheal intubation to protect their airway and prevent aspiration.

Nimodipine does not have an established role in these circumstances. Corticosteroids are also not indicated. If the patient is on warfarin, it should be reversed with fresh frozen plasma and vitamin K.

Most intracranial hematomas expand in volume during the first 24 hours, and the volume of expansion is correlated with outcome. In a dose escalation trial, the use of activated recombinant factor VII led to a reduction in the size of intracranial hemorrhage expansion and an improvement in outcome. However, preliminary results from a phase 3 trial showed that while hemorrhage volume is decreased, outcome is not improved. The role of recombinant factor VIIa in intracranial hemorrhage is therefore uncertain, although it may be useful for rapid reversal of patients on warfarin.

The management of intracranial hemorrhage is generally medical and supportive, with control of blood pressure below 180 mm Hg. Surgery is rarely indicated.[182] However, in patients with cerebellar hemorrhage, and brainstem compression, or in those showing acute neurologic deterioration or obstructive hydrocephalus, surgical evacuation of clots may be indicated.[181,182]

Brain Injury after Cardiac Arrest

Although the therapeutic cerebroprotective value of induced moderate hypothermia has been disappointing in both traumatic brain injury and SAH, its efficacy in improving neurologic outcome has been demonstrated in patients who suffered global hypoxia secondary to ventricular fibrillation. Neurologic morbidity is common in those patients experiencing global cerebral ischemia as a consequence of cardiac arrest and is thought to be related to the generation of free radicals and cellular injury on reperfusion of the ischemic brain.

Two studies reported improved neurologic outcome and reduced mortality in patients with ventricular fibrillation who were resuscitated but remained in coma and immediately treated with mild hypothermia in the 32° to 34°C range.[183,184] These results have been confirmed in a wider population, and 12 to 24 hours of mild hypothermia is now recommended treatment for all post–cardiac arrest patients with neurologic dysfunction.[185]

Whereas initial studies induced hypothermia using cooled intravenous solutions, more sophisticated methods/devices have since been introduced. These include noninvasive methods such as forced air cooling with limb and trunk blankets, topical adhesive cooling pads, as well as invasive methods deploying intravascular heat exchange catheters. Water-cooled adhesive pads connected to heat exchange units are the most commonly used methods at present.

Some clinicians consider the use of somatosensory evoked potentials (particularly the N20 and N70 latencies) to be helpful in the prognosis of coma after cardiac arrest.[186]

Status Epilepticus

This condition has been defined as "repeated seizures occurring frequently without recovery between attacks" and has a significant morbidity and mortality, with around 50,000 deaths per year for an estimated annual incidence of 126,000 to 195,000 cases.[187] Some clinicians have attempted to refine this condition by using a stricter definition of continuous seizure lasting at least 30 minutes. Irrespective of the definition of status epilepticus, prompt treatment of seizure should be instituted, because a seizure lasting beyond 5 minutes is unlikely to stop spontaneously. There are variants of seizure type, but all may present in status, including nonconvulsive types, which present their own particular diagnostic challenges.[188]

Seizure activity may arise from any major insult affecting the cerebral cortex, whether that be infectious, mechanical, metabolic, or toxic. Even mild insults may provoke status where the seizure threshold is reduced by preexisting parenchymal disease or comorbidity (e.g., alcohol withdrawal). Given the previously outlined emphasis on the avoidance and termination of secondary insult to the brain, the metabolic disadvantage of status

epilepticus is readily apparent. Goals of treatment include seizure termination, physiologic support, and prevention of recurrence. This may involve intubation and ventilation, where long-term paralytic agents should not be used for fear of masking ongoing or recurrent seizure. Electroencephalographic control is highly recommended. Preferred anticonvulsants for termination include lorazepam and midazolam, in view of their relatively benign cardiovascular profile. Phenytoin remains a commonly used agent but takes time to administer because it can provoke hypotension and bradycardia if given rapidly. Hypotensive effects may also limit the usefulness of thiopental, pentobarbital, and propofol.[189]

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) occurs at a rate of 1 to 4 cases per 100,000 population per year. The incidence increases with age, and it is one of the most common neurologic causes of admission to critical care units.[190,191]

The classic form of GBS is an acute inflammatory demyelinating polyneuropathy that appears as a progressively ascending muscle weakness. This can manifest as flaccid paralysis and respiratory failure. There are a number of clustered conditions associated with the syndrome, including acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor-sensory axonal neuropathy (AMSAN), and Miller-Fisher syndrome (MFS), with the latter affecting the cranial nerves first. AIDP is the most common variant seen in the United States, and more than 50% of all cases have a recent history of bacterial or viral infection. *Campylobacter jejuni* is the most frequently observed pathogen, along with cytomegalovirus, Epstein-Barr virus, and herpes simplex infections. GBS may display sensory and autonomic features, depending on the subtype, and there is some variation in speed of onset and offset. Commonly, symptoms progress over several days to reach their peak at 2 weeks, with a plateau thereafter. Around 5% of patients will progress more rapidly than that with maximal loss of function within 72 hours of symptom onset. At 4 weeks, the majority of patients will have progressed to the limit of their symptomatology and improvement is observed to start soon thereafter. Recovery, however, may be protracted for up to 6 months. There is some debate as to whether speed of onset relates to a slower rate of recovery and outcome limitation.[190,191]

Loss of ventilatory efficacy is the main reason for admission to the ICU, with a forced vital capacity of less than 20 mL/kg being a sensitive indicator of need for observation, and 15 mL/kg for probable intubation, along with clinical signs of fatigue and airway compromise. Hypercarbia is a relatively late sign, and should not be relied on.

Bulbar dysfunction, while less common, may appear before ventilatory compromise, particularly in patients with the MFS variant.

Dysautonomia is seen in up to 20% of patients and is a source of morbidity.[192] It should be monitored carefully, because there is a significant mortality of arrhythmia in the elderly. It can vary from urinary retention to fixed tachycardia to both severe hypotension and paroxysmal hypertension.

Investigations should include electrocardiography, CSF protein (for acellular protein elevation), electromyography (axonal degeneration is associated with poorer recovery), and antibody status/screening for possible causative pathogens and also prognosis, because GM_1 antibody is associated with worsened recovery whereas MFS is associated with anti-GQ1b antibody.[191]

Particular challenges to management are the problems of deafferentation pain and psychiatric depression. The pain can be severe, is truncal in distribution, and may respond to anticonvulsants more than opiates. It will certainly contribute to the frequently observed depression. This is often worsened by immobility, boredom, and the limited ability of busy staff to actively engage with a (relatively unusual for the neurocritical care unit) cognitively intact patient. Early tracheostomy in identifiably prolonged cases is appropriate.

Both symptom limitation and recovery from GBS have been improved with the use of plasmapheresis or the intravenous administration of gamma globulin. There is no advantage seen by one over the other, nor in combination. However, many physicians will try them sequentially in cases of treatment failure.

Neither interferon nor corticosteroids have been shown to improve outcome, either alone or in combination with immunotherapy.[190]

Spinal Cord Injury

In contrast with GBS, spinal cord injury (SCI) is much more common (11,000 cases/year), is intractable to treatment, and almost inevitably has permanent effects. The number afflicted in the United States in 2006 was 253,000. The degree of dysfunction is similar to GBS in that as the level of injury ascends there is a high level of motor paralysis of the lower limbs, trunk, upper limbs, and diaphragm. Additionally, there is also a traumatic sympathectomy, producing bradycardia, hypotension, and gastrointestinal paralysis. This latter aspect is often overlooked, and subsequent abdominal distention can embarrass an already compromised diaphragm into inefficacy. The cardiovascular effects of sympathectomy, particularly above T5, will manifest as bradycardia and hypotension.[193] This can be supported by fluid and pressor therapy, and the tachycardic effect of dopamine may be a useful attribute. Unopposed vagal stimuli, as well as hypoxia, may induce bradycardia.[193] Resuscitation targets are controversial with recent interest in maintaining spinal perfusion analogous to the CPP of traumatic brain injury. Patients with injuries below T5 may still manifest hypotension but usually only on the provocation of posture, hypovolemia, or comorbidities.

Ventilatory support is dependent on the level of injury. If the injury is below C5, although the diaphragm remains functional, in the acute stage respiratory embarrassment due to abdominal and intercostal paralysis can still occur, because flaccidity in these muscles significantly decreases the functional efficiency of the diaphragmatic contraction. Thus, paradoxical respiration with chest indrawing during inspiration occurs. With complete cervical spinal cord injury, acute respiratory failure is common, secondary to the sudden loss of functional residual capacity and the inability of the sternocleidomastoid muscle to stabilize the chest wall. With time, many patients can regain the ability to breathe spontaneously, except those with high cervical lesions. There is controversy regarding the ventilatory pattern used for spinal patients. Some clinicians suggest that a larger tidal volume should be used, because this might maintain the alveoli open and prevent atelectasis, although this has not been established by a randomized clinical trial.

Lower limb blood flow is reduced with increased arterial and venous pooling. This is associated with a higher incidence of thromboembolic disease, and early prophylaxis with low molecular weight heparin is recommended.

As with GBS, the patient with spinal cord injury is commonly aware, and this constitutes an additional burden of psychological stress. Consequently, the best approach taken is truly a holistic one, tending to psychological needs as well as to cardiopulmonary, gastrointestinal, renal, and integumental support. Significant advances have been made in the critical care and rehabilitation support afforded to these patients, and 2-year survival has increased significantly in the past 3 decades. Unfortunately, this has not translated to increased long-term survival.[194]

Myasthenia Gravis

Although myasthenia gravis is a relatively uncommon disease (prevalence of 10-20 per 100,000), it is relevant to neurocritical care in that patients can present acutely with rapid deterioration of muscle function, predisposing to ventilatory failure—the "myasthenic crisis." Myasthenia itself has a strong association with various autoimmune conditions (e.g., thyroid disease, pernicious anemia, rheumatoid arthritis), as well as being linked to women with certain HLA types.[195,196]

The myasthenic crisis can be precipitated by a progression in severity of the disease state or often by amplification by another factor. This can include infection, recent surgery, or interruption of immunosuppressants. There are a large number of drugs that can exacerbate myasthenic crisis, including aminoglycosides, fluoroquinolones, anticonvulsants (including phenytoin), steroids, β-blockers, calcium antagonists, ketamine, lidocaine, neuromuscular blockers, and anticholinergic agents.[196]

Diagnosis should exclude GBS, brainstem stroke, organophosphate poisoning, and botulism. Tests should include electrophysiology, CSF protein, edrophonium response, and antibodies to acetylcholine and muscle tyrosine kinase receptors.

The presentation is typically that of acutely worsening weakness of either respiratory or pharyngeal muscles, or both. The patient should be observed closely for signs of impending failure. Forced vital capacity is again useful with 15 mL/kg being a useful trigger for intubation.[196]

The other mainstay of therapy is by immunomodulation. Typically, intravenous immunoglobulin or plasmapheresis is started quickly to limit progression of symptoms and avert frank crisis. Corticosteroids do have a role in establishing longer-term control of immunosuppression, because IgG and plasmapheresis have limited duration of efficacy. Corticosteroids alone are associated with a transient worsening of symptoms, before improvement, so are best introduced immediately after plasmapheresis or IgG.[196]

Meningitis

Meningitis is a serious condition producing inflammation of the leptomeninges covering the CNS. The causative pathogens differ among different patient populations. Community infections are frequently caused by *Streptococcus pneumoniae, Haemophilus influenzae, Listeria monocytogenes, Neisseria meningitidis,* and group B streptococci. *N. meningitidis* is particularly evident in teenagers. Since the advent of a childhood vaccination program, *H. influenzae* affects chiefly adults, but the other organisms tend to affect all age groups. Nosocomial infection, on the other hand, predominantly arises in the neurosurgical patient, especially with the use of ventricular devices, and the pathogens here comprise gram-negative rods and staphylococci. Diagnostic features include fever almost invariably with the classic nuchal rigidity and change in mental status; less often, photophobia, papilledema, and new-onset seizures may be seen. A rash is typical of meningococcal infection, whereas arthritis occurs in a significant minority. Tests should include CSF Gram stain and culture by lumbar puncture, but any previous antibiotic dosing can diminish sensitivity. Under this circumstance polymerase chain reaction (PCR) testing is the method of choice, displacing the more variable latex agglutination test. A CT scan should only delay the lumbar puncture when there is history suggesting previous mass lesion, stroke, or focal infection, recent seizures, or immunocompromise. Similarly, signs of papilledema, depressed level of consciousness, or focal deficit indicate a need for a CT examination to avoid herniation. Cerebral edema not infrequently develops in patients with meningitis and can lead to acute deterioration in mental status. ICP monitoring might be indicated.

Treatment should be delivered swiftly, pausing only to get emergent samples for Gram stain and culture. If no identification is possible on Gram stain, empirical antibiotic therapy should be delivered with third-generation cephalosporins (e.g., ceftriaxone or cefotaxime), along with vancomycin until organism and sensitivities are obtained. This will cover the community-acquired pathogens. Nosocomial or trauma-associated infections can be effectively covered with cefepime and vancomycin.

The outcome of meningitis is a function of patient factors, the pathogenicity of the organism, and the time to effective treatment. An interesting study examined admission hypotension, altered mental status, or seizures for an effect on outcome. There was a 9% mortality if one factor was present, increasing to 33% for two factors, and 57% for all three being evident.[197]

Encephalitis

Encephalitis presents with fever, headache, and alteration of consciousness. There may also be delirium, focal deficit, and, commonly, seizures. Nuchal rigidity may be present in a mixed meningoencephalitis picture but should be absent in isolated encephalitis. Accompanying identifiers may be a vesicular rash associated with zoster (although its absence does not remove zoster from suspicion), bilateral paralysis typical of West Nile disease, parotitis if mumps is suspected, and, of course, the hyperactivity, hydrophobia, and pharyngeal spasm of rabies. West Nile disease is swiftly increasing in incidence from 62 cases in 1999 to 4219 in 2006 and seems to be clustering in rural states.[198] There are a large number of both nonviral and noninfectious causes of encephalitis that may confound the diagnosis. These include vasculitis, systemic lupus erythematosus, stroke, rickettsial and parasitic infection, and drug-induced meningitis (e.g., IgG). Careful examination of clinical features, history, and laboratory data are necessary. CSF should be drawn for viral DNA polymerase chain reaction as well as the routine biochemistry, culture, and cell count. MRI is useful in identifying the demyelination and edema that can be difficult to see on CT. Serum serology is helpful for the diagnosis of Epstein-Barr virus, mumps, and West Nile

disease, as sources of encephalitis. Paired samples are to be recommended to allow later comparison if CSF PCR is unhelpful. Brain biopsy was considered the gold standard but is now very much a last option after CSF PCR, culture, and serology have proven negative.

Herpes simplex type 1 carries a very poor outlook if not treated expeditiously, and a course of intravenous acyclovir is recommended as soon as samples are drawn.

The pathogen remains unidentified more often than not, and outcome usually then depends on classification of the clinical features, with intractable seizure and cerebral edema carrying a poor prognosis. Self-limiting seizure usually indicates a swift recovery.

Brain Death

It is crucially important that the physician understand the principles of the diagnosis of brain death and be able to apply them assiduously and without compromise (see Chapter 98). There are many unfortunate instances of poor understanding leading to imperfect examination, misdiagnosis, and considerable distress to all concerned.

Declaration of brain death was originally codified by the Harvard criteria with subsequent modification to allow separation of cerebral death from death of the entire nervous system including spinal cord.[199] This was later expanded to include the diagnosis of brainstem death as equivalent to whole-brain death.[200]

All such diagnoses are built on a solid clinical examination of nervous system function, examining the reflex response of the brain and cranial nerves to varying stimuli of hypercarbia, pain, light, temperature change, attitudinal change of the middle ear, and detection of the blink, cough, and gag reflexes. There should be clear mechanisms for cause of neurologic dysfunction. As with the operation of the GCS scale, the examination has to be done in circumstances of adequate systemic oxygenation and perfusion. Confounders, such as hypothermia, metabolic/endocrine compromise, and persistent sedative or neuromuscular drugs should be avoided, corrected, or removed. There should be two tests done by independent physicians, of whom at least one should have had training in neurology, neurosurgery, or neurocritical care. Time between tests is less important for diagnosis than for the opportunity to start communicating with and preparing the family. One of the tests should include an appropriately conducted apnea trial in the presence of the physician, with confirmation of adequate changes in P_{CO_2}. If for any reason any test cannot be completed in a safe manner, or to the satisfaction of either physician, then a confirmatory test of cerebral blood flow should be performed.

The hospital should have an institutionally approved protocol for the conduct of these tests and mechanisms in place for review and quality improvement.

Ethical Considerations

Ethical issues are frequently encountered in a neurologic ICU setting (see Chapter 9). Unfortunately, as well as the mortality described previously, there is significant life-altering morbidity, to the extent that many patients and families would not desire aggressive therapy.[201] This can be a difficult concept to accept for the physician, whose aim is to heal and preserve life. However, the ethical imperative in Western culture is to preserve the autonomy of the individual (along with the principles of nonmaleficence, beneficence, and justice), and this has been extended to health care decision-making. This may lead to uncomfortable decision-making and communication within the health care team, who may have differing opinions on goals, and from there to the patient and relatives, who, again, may think very differently.

There are a number of strategies that can avoid or minimize these difficulties:

- Prognosis should be made on the basis of the best available evidence. This may involve planning and discussion between the team members in advance of meeting with families. The personal anecdote should be avoided, even if solicited.
- The relationship within the team should be open and collegial, with mutual respect given to the principle of open discussion. This avoids misperception of goals and attitudes and enables more consistent communication with families, who often find dissonance between members of the ICU team disturbing.
- The presence of an advance directive offers major benefits, and the neurocritical care unit should have an admissions protocol that includes asking all competent conscious patients to consider making their attitudes or wishes known.
- Regular family/patient conferences allow communication of prognosis as it is appropriate and offer the opportunity for correction of any misconceptions, as well as progressive education of the family to anticipated problems.
- There should be internal institutional mechanisms for raising concerns and conducting reviews. This is often facilitated by the presence of an institutional ethics committee, who can examine the issues, promote educational discussion, and help achieve a consensus.
- All decision-making should be documented carefully and completely.
- Orders for limitation or withdrawal of care should be written explicitly and institutional protocols used wherever possible.

There are other important areas of possible conflict that it is not possible to address within the confines of this text, but readers are advised to educate themselves on the following:

- The issues surrounding organ donation from the brain dead and the non–heart-beating donor
- Withdrawal of care for the incompetent patient without family
- Hospital bylaws and state legislation on the certification of death, whether that be by neurologic or cardiovascular criteria

Summary

Neurocritical care demands a thorough comprehension of the physiology, pharmacology, and pathology of the nervous system, as well as for the organ systems supporting it. The best care is

provided in circumstances that allow multidisciplinary collaboration and appropriate attention to detail of often complex and demanding pathologic processes, but integrating them optimally under the direction of the critical care physician.

95 Nutrition and Metabolic Control

Key Points

1. Sepsis, trauma, and surgery activate complex metabolic and inflammatory responses that affect all body systems.
2. The metabolic response to stress response is characterized by catabolism, hypermetabolism, hyperglycemia (diabetes of injury), and enhanced lipolysis.
3. The counterregulatory hormones (cortisol, glucagon, catecholamines) along with the cytokines (e.g., IL-1, TNF) are major mediators of this response.
4. Certain intraoperative anesthetic and postoperative analgesic techniques can modulate the stress response.
5. During the acute phase of illness, patients unable to eat should receive parenteral or enteral nutritional support.
6. Nutritional support during the acute phase of critical illness is a supplementary therapy designed to provide patients suffering from underlying metabolic disarray with sufficient nutrients to aid cellular biochemical functions and attenuate further loss of body mass.
7. Only once the ravages of the stress response have abated can lost lean and fat mass be repleted.
8. Overfeeding or aggressive refeeding should be avoided.

The human body is an adaptable organism that has many interrelated mechanisms designed to identify, respond, and neutralize both internal (e.g., infection) and external (e.g., temperature extremes) events that threaten or upset homeostasis (stressors). Anesthesiologists must be knowledgeable about these mechanisms because they routinely care for patients with acute and chronic homeostatic changes. Furthermore, anesthesia and surgery involve much manipulation and disruption of body physiology, anatomy, and biochemistry, leading to the activation of the body's responses to stress.

The stress response evolved as a mechanism for assisting organisms in reacting to immediate danger. The outpouring of catecholamines and other hormones increases the outputs of the respiratory, cardiovascular, and metabolic systems and improves the organism's ability to flee from an enemy and maintain perfusion to vital organs after blood loss. The metabolic alterations caused by change in the hormonal milieu increase the availability of certain substrates and reduce the availability of others. The organism thus attempts to improve conditions for wound healing, blood coagulation, and humoral immunity, a response that is beneficial in acute events such as bleeding and infection. Although once regarded positively as the body's defense mechanism, today the stress response is regarded more equivocally since its physiologic consequences, especially increasing the output of various organ systems, may lead to increased morbidity and mortality by overtaxing already compromised organ systems.[1] For example, among patients with underlying coronary artery disease, the tachycardia and increased myocardial oxygen demand resulting from catecholamine stimulation can cause myocardial ischemia.

The stress response was initially described by Hans Selye as "the nonspecific response of the body to any demand upon it."[2] However, contemporary research demonstrates that the nature of response varies depending on the type and intensity of the stressor and is only nonspecific when the stress is overwhelming.[3,4] Furthermore, chronic activation of the stress response has been implicated as contributing to a variety of conditions, such as atherosclerosis and depression. Although the chronic stress often is not the cause of the disorder it contributes to its pathogenesis, exacerbations, and duration.[5]

Metabolic Control Systems and the Response to Surgical Stress

Living organisms constantly undergo adjustments to adapt to ever-changing internal and external conditions. These natural alterations have been termed *allostasis* and include diurnal variations in temperature and cortisol production, changes in metabolism due to eating and drinking, and the cardiopulmonary responses to exercise.[6] Stress occurs when allostatic mechanisms are insufficient for maintaining homeostasis, thus causing the

organism to significantly alter many of its functions to reduce and contain the stressful threat.[7]

The response to surgical and traumatic injury was classically described by Cuthbertson as having three phases:

1. The ebb phase (<24 hours), also called the resuscitative phase, during which there is tissue hypoperfusion that requires treatment
2. The flow phase (duration depends on injury severity), which has a milieu characterized by catabolism, hypermetabolism, hyperglycemia, and an inflammatory response
3. The anabolic phase (may last for months) when anabolism facilitates the repair of injuries and a return to a normal metabolic environment.

However, the improved survival from major injury, occasioned by modern surgery and critical care, blurs this classic scheme. Today, critically injured patients often undergo multiple surgeries within a few days of their injury and suffer from iatrogenic infections during extended stays in an intensive care unit (ICU). These surgeries and infections add further stresses ("second hit") to an already highly stressed system.[8] The consequences of these second hits are problematic because they perpetuate or intensify metabolic changes that increase the chance of developing multiple organ failure.[9,10]

The Hypothalamus-Pituitary Axis

Many allostatic, as well as homeostatic, changes are controlled by feedback control systems centered on the hypothalamic-pituitary axis. The response to surgical and traumatic stress is triggered by hypothalamic activation secondary to afferent neuronal input from an area of injury or emotional activity centered in the limbic system and humoral factors, such as the inflammatory cytokines tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), and IL-6.[11] Hypothalamic activation increases the activity of the sympathetic nervous system, which increases the output of the cardiovascular system and stimulates the adrenal medulla to secrete epinephrine and the pancreas to secrete glucagon (Fig. 95-1). Hypothalamic activation also stimulates or reduces the secretion of the various hypothalamic releasing factors (e.g., corticotropin-releasing hormone [CRH], growth hormone–releasing hormone [GHRH]). The hypothalamus, the body's thermostat, also controls body temperature. Stimulation by mediators such as IL-1β (endogenous pyrogen) causes fever via a biphasic mechanism; the first phase is mediated by increased intracellular ceramide and the second by cyclooxygenase-2 (COX-2)–mediated prostaglandin E_2.[12,13] CRH is also produced peripherally in the adrenal medulla, gastrointestinal tract, skin, nerve fibers, and immune cells. At inflammatory sites CRH acts as a paracrine/autocrine inflammatory mediator (Fig. 95-2) via peripheral CRH receptors.[14]

During stress, the releasing factors, along with other stimuli, stimulate the posterior pituitary gland (neurohypophysis) to release arginine vasopressin (AVP, antidiuretic hormone [ADH]) and the anterior pituitary (adenohypophysis) to secrete prolactin (PRL) and growth hormone (GH) into the circulation. CRH, acting synergistically with AVP, stimulates secretion of proopiomelanocortin by the anterior pituitary. In the stressed state, IL-6, working through IL-6 receptors present on the pituitary corticotrophic cells, also acts synergistically with CRH. Proopiomelanocortin is cleaved to adrenocorticotropic hormone (ACTH), β-endorphin, and α-melanocyte-stimulating hormone (MSH), thus linking endogenous opioids with the hypothalamic pituitary-adrenal axis. ACTH, in turn, stimulates the zona fasciculata of the adrenal cortex to secrete glucocorticoids. A meta-analysis showed that the cortisol response increases with age and is greater in women than men.[15] Glucocorticoids, including those administered exogenously, constitute a negative feedback system suppressing hypothalamic CRH and AVP secretion. In the unstressed state the hypothalamic-pituitary control mechanism regulates cortisol secretion in a circadian rhythm, with peak concentrations occurring in the early morning and the nadir around 11 PM. In the postoperative stressed state, cortisol secretion increases twofold to threefold with disruption of the circadian rhythm, specifically, longer peak to nadir intervals.[16]

Arginine Vasopressin

AVP is vital for maintaining intravascular homeostasis and is secreted when there is increased osmolality, decreased arterial pressure, and reduced blood volume.[17] It causes vasoconstriction (V1 receptors) and renal water retention (V2 receptors) by stimulating aquaporin-2. Plasma AVP concentrations are elevated after a variety of stresses, including surgery, pneumonia, myocardial infarction with or without left ventricular failure, and electroconvulsive therapy. Plasma AVP concentrations increase after the start of surgery and often remain elevated for days after its completion. The magnitude and duration of the elevated plasma vasopressin concentrations are proportional to the degree of stress. In septic shock there is an initial increase in AVP concentrations followed by a decrease to very low concentrations.[18]

Growth Hormone

Secretion of GH secretion by the anterior pituitary is stimulated by hypothalamic GH-releasing factor and inhibited by somatostatin. GH, vital in the regulation of growth during the prenatal period and childhood, has a biphasic effect when secreted during stress. Initial exposure (2-3 hours) produces insulin-like effects, but longer exposure cause anti-insulin and anabolic effects. The latter results in increased incorporation of amino acids into structural proteins, glucose intolerance due to insulin resistance, and increased lipolysis due to increased sensitivity to the lipolytic effects of catecholamines. GH stimulates the secretion of insulin growth factors 1 (IGF-1) and 2 (IGF-2) by the liver and other peripheral tissues. IGF-1 has insulin-like actions and also mediates the anabolic and skeletal growth–promoting activity effects of GH. IGF-1 facilitates anabolism by directly reducing protein oxidation and enhancing insulin sensitivity so that insulin and GH stimulate protein synthesis.[19] A 5-day infusion of IGF-1 into normal subjects did not change the glucose oxidation rate but increased lipid oxidation, raised resting energy expenditure, and reduced protein oxidation. The six IGF-binding proteins modify the availability and actions of IGF-1. Most circulating IGF-1 is bound to IGFBP-3, whereas IGFBP-1 plays a major role in regulating unbound (free) IGF-1.

Immediately after major traumatic injury, burns, and surgery, GH blood concentrations are elevated, with the increases being roughly proportional to the degree of trauma. However, after a day the preoperative/preinjury GH concentrations start to decline. In severely traumatized patients the pulsatile nature of GH secretion persists but the bursts occur less frequently. IGF-1, IGF-2, and IGFBP-3 are reduced 40% to 60% after trauma and

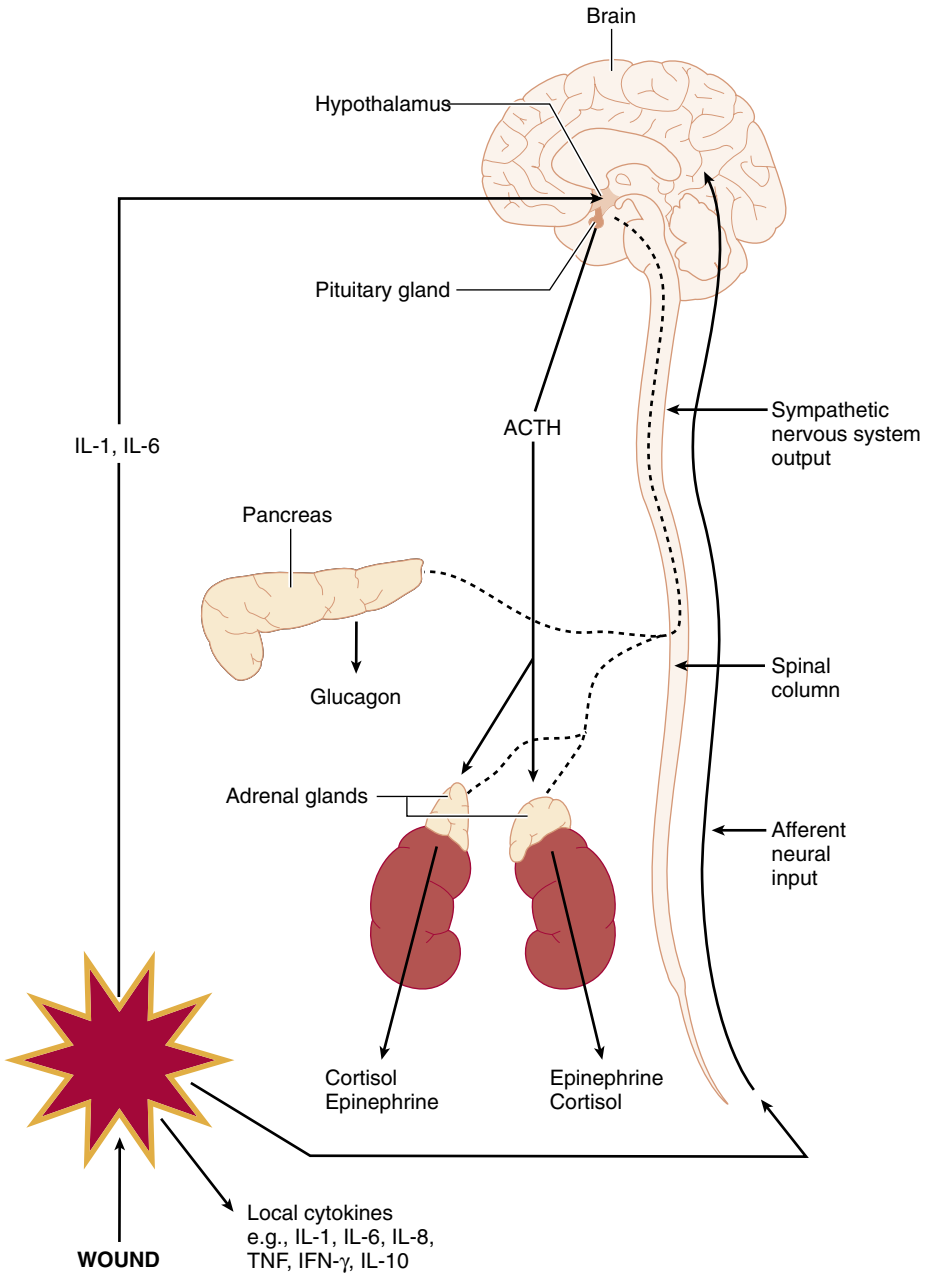

Figure 95-1 Mechanisms that initiate the stress response are shown. Afferent neural input plus cytokines such as IL-6 and IL-1 stimulate the hypothalamic-pituitary axis leading to secretion of adrenocorticotropic hormone (ACTH) (which stimulates the adrenal cortex to release cortisol) and activation of the sympathetic nervous system (which stimulates the pancreatic alpha cells to secrete glucagon and the adrenal medulla to secrete epinephrine). Cytokines and growth factors act locally in the area of the wound and some also have endocrine effects. IL, interleukin; TNF, tumor necrosis factor.

burns, whereas IGFBP-1 and IGFBP-4 are increased. The decreases in GH and IGF-1 concentrations are ascribed to inhibition by interleukin-1β.[20] The consequence of these decreases is protein catabolism.

The Endocrine System

The hypothalamic-pituitary axis is the main controller of the endocrine system, which, in turn, controls much of the body's metabolic functioning (see Fig. 95-1). The endocrine hormones are major mediators of the metabolic response to stress. The hormones glucagon cortisol, and catecholamines oppose the effects of insulin on glucose and lipid metabolism and are thus called the counter-regulatory hormones.

Sympathoadrenergic System

The sympathoadrenergic system, composed of the sympathetic nervous system and adrenal gland, produces and secretes the catecholamines: norepinephrine, epinephrine, and dopamine. Serum concentrations of these hormones increase after stresses such as anxiety, hypotension, hypothermia, surgery, burns, hypercarbia, and accidental injury. In severely burned patients, norepinephrine concentrations increase 2- to 10-fold in parallel with burn size.[21] Concurrent with the activation of the sympathetic system response there is acute suppression of parasympathetic activity. This suppression is important because the parasympathetic nervous system reduces proinflammatory responses.[22]

Epinephrine is secreted into the bloodstream by the adrenal medulla in response to sympathetic nervous system activation, whereas most norepinephrine is released from sympathetic nerve

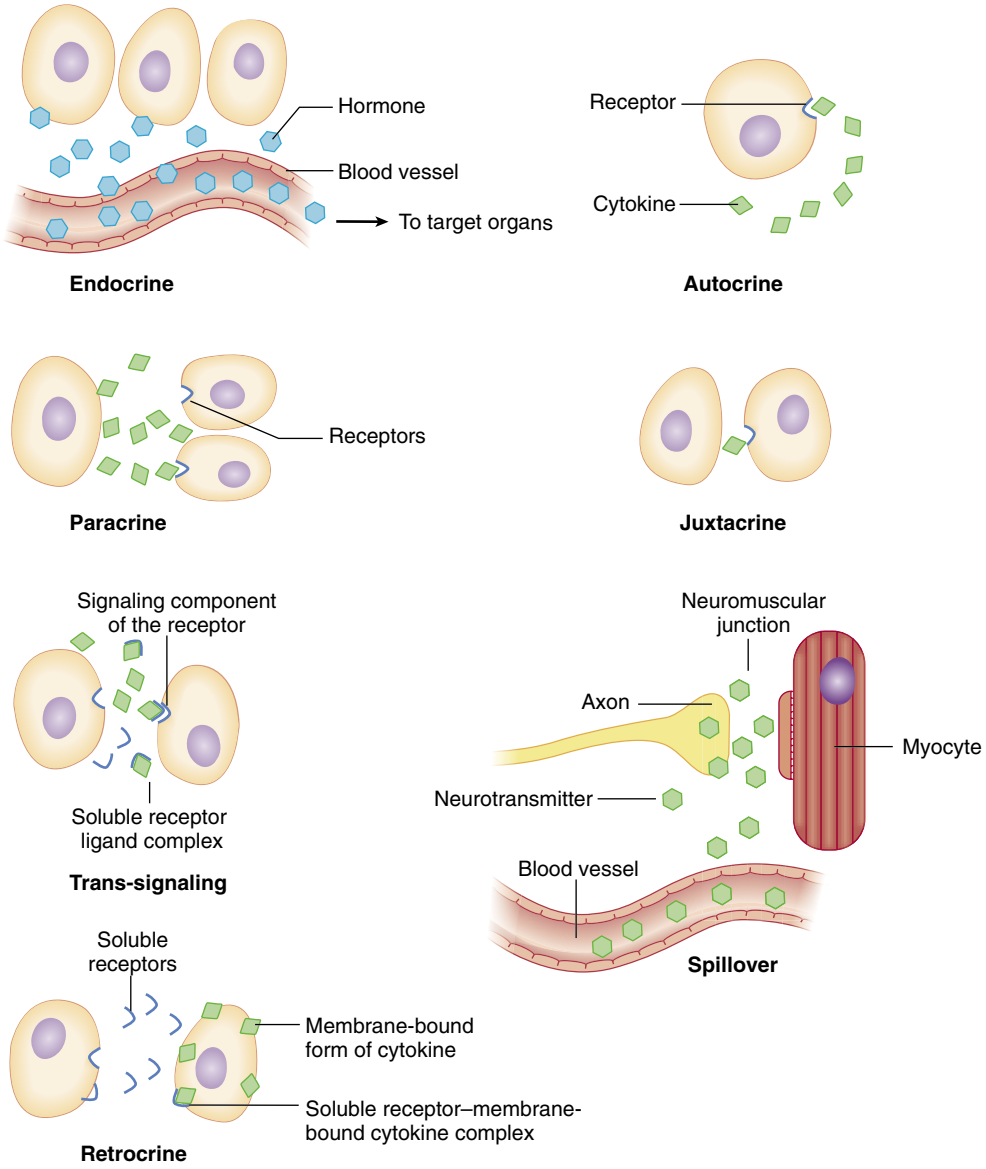

Figure 95-2 Various mechanisms used by hormones, cytokines, and other bioactive substances to affect end-organ function. *Endocrine*—transport to end organs of hormones and other substances via the bloodstream. *Autocrine*—secreted substances affect the cell that produced them. *Paracrine*—mediators act locally within the same tissue bed. *Juxtacrine and cell-to-cell communication*—mediators act on adjacent cells. *Trans-signaling*—a soluble receptor binds in the presence of its ligand to the signaling component of a multimeric receptor complex. *Spillover*—Neurotransmitter not taken up by nerve endings enters blood vessels. *Retrocrine*—soluble receptors interact with membrane-bound forms of cytokines and are used to control cytokine effects.

endings. Therefore, plasma epinephrine concentrations reflect adrenomedullary secretion whereas plasma norepinephrine levels are an index of sympathetic nervous system activity. Plasma concentrations of epinephrine and norepinephrine do not necessarily increase simultaneously. Most norepinephrine released by sympathetic ganglia is removed from the synapse by reuptake into the nerve ending. Therefore, only the norepinephrine that "spills" over into the plasma is assayed (see Fig. 95-2). Plasma norepinephrine concentrations are thus the difference between the spillover and plasma clearance rates. Besides the increased secretion of endogenous catecholamines, many critically ill patients receive vasopressor and inotropic support with infusions of exogenous catecholamine, which can have additive metabolic and other affects. For example, dopamine infusions depress thyroid-stimulating hormone (TSH), prolactin (PRL), and GH secretion.[23]

In addition to their cardiovascular effects, catecholamines have major metabolic effects. Hepatic gluconeogenesis, glycogenolysis, and glucagon release are increased by β_2-adrenergic stimulation, whereas lipolysis is increased by β_2- and β_3-adrenergic stimulation but inhibited by α_2-stimulation.[24] Epinephrine infusion in normal subjects does not affect protein metabolism.[25] The lesser role of the catecholamines, as opposed to glucagon in instigating and maintaining the abnormal glucose metabolism of burn patients, was demonstrated by the failure of propranolol to reduce the rates of glucose production and glucose cycling.

The sympathoadrenal system also affects the immune system. There are neuronal pathways that release neurotransmitter directly into the lymphoid parenchyma so that the lymphocytes and macrophages in these lymphoid regions are directly affected by sympathetic output. In general, this output acts to reduce the proinflammatory response, by decreasing the secretion of proinflammatory cytokines, possibly by a β-receptor–mediated mechanism.[22] However, β-receptor activation by circulating catecholamines seems to increase TNF-α secretion, especially during sepsis. Therefore, the sympathoadrenergic system appears to be both a major mediator of the stress response and also part of its negative feedback arm.

Glucocorticoids

Cortisol is a major stress hormone whose plasma levels are markedly elevated after surgical and traumatic stress. This is mainly due to enhanced secretion by the adrenal cortex. However, in some situations the increased concentrations are also due to reduced renal function and reduced hepatic clearance secondary to decrease hepatic blood flow.[26] In addition, this cortisol production is minimally suppressed by exogenous glucocorticoid administration. This was demonstrated by the inability of 24 mg/day of dexamethasone administered for 2 days after craniotomy to suppress the elevated concentrations of either ACTH or cortisol. Elevated plasma cortisol concentrations stimulate gluconeogenesis, sensitize adipose tissue to the action of lipolytic hormones (GH and catecholamines), and increase proteolysis by blocking the anti-proteolytic actions of insulin.[27] Cortisol is thought to cause insulin resistance by decreasing the rate of insulin activation of the glucose uptake system (inhibiting translocation of glucose tranporter-4 to the cell membrane) and increasing 11β-hydroxysteroid dehydrogenase activity.[23] Additionally, cortisol has anti-inflammatory and immunosuppressive actions. The anti-inflammatory actions include negative feedback to ACTH and proinflammatory cytokine production, as well as stimulation of the secretion of IL-10, an anti-inflammatory cytokine.[28] These anti-inflammatory and immunosuppressive actions are thought to prevent stress-activated defense mechanisms from overshooting and damaging the organism. Unlike elevated concentrations, basal concentrations of cortisol are anti-lipolytic and probably facilitate normal immune responses.

Cortisol is a vital mediator of the stress response because it facilitates catecholamine action and secretion, thus helping to maintain cardiovascular stability during surgical stress. The importance of glucocorticoids is demonstrated by the excessive mortality during stress observed in adrenalectomized animals and patients with Addison's syndrome. Furthermore, increased mortality was observed when etomidate was used to sedate critically ill patients. Etomidate blocks adrenal steroidogenesis by inhibiting 11β-hydroxylation and 17α-hydroxylation. Similarly, patients receiving or having received exogenous steroids within the 6 months before a stressful event should receive steroid replacement therapy to avoid the problems of adrenal insufficiency.

The magnitude and duration of the increases in both intraoperative and postoperative ACTH and cortisol levels correlate well with the degree of surgical trauma. Cortisol concentrations may remain elevated for up to 2 weeks after femoral fractures and burns. The increased ACTH secretion during surgery is often far greater than that required to produce a maximal adrenocortical response, as demonstrated by the observation that administering exogenous ACTH during surgery did not increase plasma cortisol concentrations. In prolonged critical illness (7-10 days), serum ACTH concentrations are low despite elevated cortisol levels, indicating other mechanisms stimulate the adrenal cortex.[29]

Cortisol is 80% bound to cortisol-binding globulin (CBG), which has a high affinity but low capacity for binding cortisol, and 10% to serum albumin, which has a low affinity but a high capacity for this process. The remaining unbound cortisol, referred to as free cortisol, is biologically active.[30] Direct measurement of the free cortisol concentration accounts for the binding effects of albumin, whose concentration is reduced after major surgeries and during sepsis.[31] After major surgery, during sepsis, and after burn injury, free cortisol concentrations are elevated due to both increased total cortisol concentrations and reduced CBG.[32] After major elective surgery, serum total cortisol increased by 55% and CBG decreased by 30%.[33] The reduced CBG is likely caused by inhibition of CBG production by IL-6 and/or increased CBG degradation due to elevated neutrophil-released esterase.

Glucagon and Insulin

Glucagon and insulin are both secreted by the pancreas, the former by alpha cells and the latter by beta cells. These hormones enter the portal vein, exposing the liver to high concentrations of both. The principal action of glucagon is to stimulate hepatic glycogenolysis and gluconeogenesis. Glucagon increases hepatocyte cyclic adenosine monophosphate (cAMP), promoting gluconeogenesis; insulin has the opposite effect: it decreases intracellular cAMP concentrations, preventing gluconeogenesis. Glucagon increases intracellular cAMP via a different receptor–secondary messenger mechanism than used by adrenergic mediators. Glucagon also increases hepatic glycogenolysis and ketogenesis during starvation and diabetic ketoacidosis. There is debate whether glucagon also stimulates lipolysis. In the unstressed state, glucagon secretion is stimulated by hypoglycemia, protein/amino acid intake, endorphins, exercise, GH, epinephrine, and glucocorticoids. Glucagon secretion is suppressed by somatostatin, insulin, and glucose infusion or ingestion.

Insulin is an anabolic hormone with many effects. In addition to increasing glucose transport across the cell membranes of adipocytes and myocytes, it stimulates glycogen production, promotes glucose oxidation, inhibits lipolysis in adipose tissue and skeletal muscle, inhibits net fatty acid oxidation, inhibits hepatic and muscle ketogenesis, and increases the rate of amino acid transport and protein synthesis in muscle, adipose tissue, and liver.[33] The plasma glucagon:insulin ratio is the major determinant of the degree of gluconeogenesis. During fasting and starvation, the ratio is increased secondary to increased glucagon and decreased insulin concentrations. This increased ratio promotes gluconeogenesis and facilitates glycogenolysis. In the fed state the reverse is true, with insulin predominating.

Serum glucagon concentrations rise after most types of major surgery. The glucagon:insulin ratio increases because insulin concentrations decrease during surgery. The decreased insulin concentrations are attributed to suppression of insulin secretion by elevated catecholamine concentrations or increased urinary losses. This suppression can be abrogated by α-adrenergic blockade. The hormonal milieu of low insulin with elevated catecholamines, cortisol, and glucagon stimulates gluconeogenesis. In septic patients this mechanism may fail, resulting in hypoglycemia, a situation associated with very poor survival rates. Postoperatively, insulin concentrations increase because of increases

in both plasma glucose and epinephrine-induced β-adrenergic stimulation. Unlike starvation, the plasma insulin concentrations are often markedly increased above basal values, although they are inappropriately low for the prevailing level of glycemia.

Somatostatin

Somatostatin, a hormone secreted by pancreatic D cells and the hypothalamus, suppresses GH, insulin, and glucagon secretion. When somatostatin was infused into postoperative patients, the rate of glucose production (gluconeogenesis) decreased, as did the rate of glucose clearance. If insulin is infused into patients receiving somatostatin, the rate of glucose clearance returns to basal level, normalizing glucose kinetics. However, there was still increased gluconeogenesis. It thus appears that glucagon is a major mediator of gluconeogenesis.

The Counter-regulatory Hormones

The hormones glucagon, catecholamines, and cortisol are called counter-regulatory hormones because they oppose the effects of insulin and act synergistically to increase hepatic glucose production. Shamoon and associates[34] explored the short-term effects in normal subjects of the combined infusion of hydrocortisone, glucagon, and epinephrine designed to simulate the plasma levels found in moderate injury. They observed increased glucose production (gluconeogenesis) and decreased glucose clearance; the effect was more pronounced when all three hormones were administered together than when they were infused individually or in groups of two, suggesting that they act synergistically.[34] Catecholamines and glucagon act synergistically: when either one is infused into normal subjects, only transient elevations in gluconeogenesis occur; when they are infused simultaneously, gluconeogenesis is more prolonged. A possible reason for this synergism is that glucagon increases intracellular cAMP, especially in the liver, by a non–β-receptor mechanism. This could amplify the actions of epinephrine. Cortisol acts synergistically with epinephrine and other β-adrenergic agonists (an action employed in the treatment of asthma). Proposed mechanisms include cortisol-induced inhibition of catechol-*O*-methyltransferase and blockade of catecholamine reuptake. Glucocorticoids also prevent β_2-adrenergic receptor downreglation by increasing both β_2-receptor expression and increasing β_2-receptor gene transcription.[35] Additionally, glucocorticoids reduce cytokine concentrations, which is important because both IL-1 and TNF can downregulate β-receptors. In addition, prolonged postoperative adrenergic stimulation downregulates and desensitizes β-receptors which is partially reversed by the glucocorticoids.[36] Simultaneous infusion of the three hormones also caused negative nitrogen and potassium balances, glucose intolerance, hyperinsulinemia, insulin resistance, sodium retention, and peripheral leukocytosis. The nitrogen losses appear to be mainly due to cortisol, because nitrogen balance during cortisol infusion was similar to that during the infusion of all three hormones. The nitrogen losses were also not of the magnitude observed after accidental injury. With hormone infusions, there were significant alterations in leucine flux and oxidation but only small increases in 3-methylhistidine excretion, indicating little muscle breakdown. Therefore, other mediators must cause the proteolysis and massive nitrogen loss observed after major injury. Also, the normal subjects were not febrile, failed to increase acute-phase proteins, and did not have decreased serum iron. When the pyrogenic (stimulates IL-1 secretion) steroid etiocholanolone was injected into normal subjects there was fever, leukocytosis, and hypoferremia without elevations in the counter-regulatory hormones, hyperglycemia, or negative nitrogen balance. Infusion of the counter-regulatory hormones plus etiocholanolone simulated more of the features of the response to injury than when they were administered individually. Therefore, both endocrine and inflammatory mediators are active during the response to injury and sepsis.

Reproductive Hormones

The response to surgical and traumatic injury is characterized by hypogonadotropic hypogonadism. The mechanism is reduced response of the pituitary gland to gonadotropin-releasing hormone (Gn-RH) secreted by the hypothalamus, resulting in decreased release of luteinizing (LH) and follicle-stimulating hormone (FSH). Concentrations of FSH and LH change little during surgery but decrease on the first postoperative day. Elevated concentrations of CRH and cortisol may also contribute to the suppressed reproductive function.[37] In males, testosterone concentrations are markedly decreased in direct relationship to illness severity. In burn patients, this was due to lowered biologic activity of LH and suppressed response to the peaks in the pulsatile LH secretion. In males, the adrenal androgens, dehydroepiandrosterone (DHES) and its sulfate (DHEA-S), are suppressed after surgery. In premenopausal women, decreased estrogen concentrations during stress are associated with amenorrhea. However, in postmenopausal women, DHEA and DHEA-S were increased after cholecystectomy. This is an interesting finding because adrenal androgen concentrations are in decline after menopause.

Thyroid Hormones

During postoperative convalescence, after trauma, after extensive burns, and during sepsis (i.e., during nonthyroidal acute illnesses) there are profound alterations in thyroid homeostasis with decreased serum T_3 concentrations, low or normal T4, normal free T_4, increased reverse T_3, and normal TSH. This is often called the "sick-euthyroid syndrome." There is less conversion of T_3 to T_4 because of reduced type-1 deiodinase activity. Although TSH concentrations are within the normal range there are lower nocturnal surges that resemble the pattern found in central hypothyroidism. Additionally, sialylation (by oligosaccharide) of TSH is decreased, possibly explaining the altered TSH bioactivity. The mechanism of sick-euthyroid syndrome development is still unclear, especially in prolonged critical illness in which T_4 concentrations also decrease.[29] Some have pointed to the lack of TSH elevation in the presence of a low serum T_3 concentration and questioned if the problem is too little stimulation by thyroid-releasing hormone (TRH). This view was reinforced by a postmortem study of the paraventricular nuclei of patients with antemortem sick-euthyroid syndrome. There was a positive correlation between low antemortem serum T_3 and TSH concentrations with total postmortem TRH messenger RNA in the nuclei. However, infusion of TRH in stressed patients increased TSH and peripheral thyroid concentrations.[38]

Elevated serum levels of IL-6 are associated with the low serum T_3 concentrations during illness. However, normal subjects infused with endotoxin indicated that TNF does not play a role in endotoxin-induced thyroid hormone changes. Short-term (4-hr) and long-term (42-day) infusions of recombinant IL-6 decrease T_3 but not T_4 concentrations. It is unclear whether elevation of IL-6 is one of the causes of the sick euthyroid syndrome or is just an associated phenomenon. Dopamine infusion

decreases basal TSH concentrations, inhibits the TSH response to TRH, decreases both serum T_4 and T_3 levels, and may aggravate sick-euthyroid syndrome. Cessation of dopamine infusion results in increases in TSH, T_4, and T_3. There has been interest in treating sick-euthyroid syndrome with thyroid hormone and TRH. In a randomized double-blind, placebo-controlled trial of T_3 administration in cardiac surgery patients, although there were lesser decreases in T_3 concentrations during cardiopulmonary bypass, T_3 did not have dramatic effects on hemodynamics.

In the sick-euthyroid syndrome, plasma free-T_4 concentrations remain normal despite reduced total T_4 concentration because of reduced thyroxine-binding globulin (TBG) concentrations. During stress, hepatic synthesis of TBG is reduced and clearance may also be accelerated (protease cleavage). The most intriguing aspect of thyroid metabolism in stressed patients is that they are hypermetabolic despite low T_3 and T_4.

Cytokines

The response to injury and sepsis includes both neuroendocrine and inflammatory/immune responses. Cytokines, the main mediators of the inflammatory response, are produced by cells of the immune system (e.g., lymphocytes, macrophages) and many have multiple functions (Table 95-1). The pattern of cytokine release is genetically and environmentally (type and intensity of the stress) determined. These patterns control the severity of the inflammatory response and the degree of immune response.[39] Some cytokines (e.g., TNF-α, IL-1α/β, IFN-γ, IL-6, IL-8) are proinflammatory (type I), whereas others (e.g., IL-4, IL-10, TGF-β, IL-13) are anti-inflammatory (type II). Some (e.g., IL-12) induce cellular immunity by directing uncommitted helper T cells toward the T_H1 phenotype, whereas others (e.g., IL-10) induce the T_H2 phenotype and enhance humoral immunity. The inflammatory response is controlled by the balance between the proinflammatory and anti-inflammatory cytokines. For example, survival from sepsis was correlated with the recurrent secretion of proinflammatory, rather than anti-inflammatory, cytokines, indicating that the inflammatory response's stimulation of the immune system is necessary to overcome sepsis. Furthermore, after trauma the suppression of proinflammatory cytokines IFN-γ and IL-12 along with elevation of anti-inflammatory cytokine IL-10 was associated with immunosuppression and sepsis.[39]

Cytokines interact closely with the endocrine system, as demonstrated by marked elevations in ACTH and cortisol after IL-6 administration to cancer patients.[40] Alternately, endocrine hormones affect cytokine secretion (e.g., cortisol suppresses the secretion of IL-1 and TNF-α).

Cytokines operate via local paracrine, autocrine, and juxtacrine mechanisms, as well as through endocrine effects (see Fig. 95-2). Therefore, plasma concentrations do not necessarily reflect cytokine activity. Cytokine actions are also modulated by a complex network of receptors, receptor-antagonists, and cytoplasmic signaling molecules. For example, the effects of IL-1 are moderated by the simultaneous secretion of IL-1 receptor antagonist (IL-1ra), which blocks its actions. Furthermore, soluble cytokine receptors are generated by the proteolytic cleavage of membrane-bound receptors or by de-novo production. These circulating soluble receptors bind cytokines and may either neutralize cytokine actions or act as carrier proteins that protect the cytokine from proteolysis. Therefore, they may have either proinflammatory or anti-inflammatory functions.

The local actions of cytokines are demonstrated by the acute wound healing process that occurs in overlapping phases: hemostasis, inflammation, proliferation, angiogenesis, and resolution. The inflammatory phase involves infiltration of neutrophils, macrophages, and lymphocytes that secrete growth factors and cytokines. These mediators, acting locally, are active at all stages of wound healing through chemotactic, mitogenic, and other effects. During the first 24 hours, cytokines in elective incisional hernia repair wound drainage include high concentrations of both proinflammatory (IL-1α, IL-6, and IFN-γ) and anti-inflammatory (IL-10, IL-1ra) cytokines. The concentrations decline over the next few days. It appears that the two types of cytokines balance each other, with the proinflammatory cytokines stimulating immune cells to prevent infection while the anti-inflammatory cytokines modulate their actions and promote healing.[41]

Despite cytokine actions being mainly autocrine, paracrine, and juxtacrine, much research has explored their blood concentrations in stressful situations. In general, the blood concentrations are proportional to the degree of stress. After the moderate stress of total hip replacement surgery, IL-6 was significantly elevated above preoperative levels during the first 6 postoperative hours but began returning toward baseline by the first postoperative day. In contrast, IL-1β, IL-12, IL-10, and IL-8 levels were not elevated.[42]

Many cytokines have multiple functions (see Table 95-1). For example, IL-1 causes fever, induces hepatic acute-phase protein synthesis, upregulates prostanoid synthesis, induces the maturation of B lymphocytes, and activates NK lymphocytes.[41] IL-6 (also called B-cell–stimulating factor and hepatocyte-stimulating factor) has endocrine, as well as local, functions. Many cells produce IL-6, including monocytes, fibroblasts, glial cells, and lymphocytes. Its production is stimulated by endocrine hormones such as catecholamines and suppressed by cortisol and estrogens. The soluble receptors of the IL-6 family (e.g., sIL-6R, sIL-11R) are agonists capable of transmitting signals through interaction with the universal signal-transducing receptor for all IL-6 family cytokines, gp130 (see Fig. 95-2).[43]

TNF-α, a multifunctional proinflammatory cytokine secreted predominantly by monocytes/macrophages, affects lipid metabolism, immunity, hematopoiesis, coagulation, and endothelial function (see Table 95-1). TNF-α has seeming contradictory properties. For example, it induces neutrophil proliferation during inflammation but it can also induce neutrophil apoptosis.[44] Moreover, TNF-α intensifies the inflammatory response by prolonging the survival of inflammatory cells through the suppression of Fas-mediated apoptosis (Fig. 95-3). The multiple roles of TNF are demonstrated by the TNF blockers etanercept, adalimumab, and infliximab, which are used to treat rheumatoid arthritis. However, these drugs increase the risk for developing tuberculosis because TNF plays a crucial role in the body's immune defense against the mycobacteria causing this disease.[45]

Endothelial Cells

Endothelial cells lining blood vessels are metabolically active and play an active role in the stress response by synthesizing a variety of important mediators such as nitric oxide and adhesion molecules (Fig. 95-4).

Table 95-1 Cytokines

Cytokine	Function
TNF-α (tumor necrosis factor, cachectin) Proinflammatory	• Stimulates T and B cells and macrophages • Chemotactic agent for neutrophils • Stimulates neutrophil respiratory burst and proliferation • Stimulates release of tissue factor from endothelium and monocytes • Stimulates monocytes to release other proinflammatory cytokines • Has anti-tumor activity • Mediates cancer and AIDS cachexia • Inhibits synthesis of lipoprotein lipase; suppresses lipogenesis in adipocytes • Stimulates synthesis of acute-phase proteins • Mediates part of the cell-mediated immunity against obligate and facultative bacteria and parasites • Involved in the development of insulin resistance • Decreases erythropoietin production that leads to the anemia of inflammation • Promotes the proliferation of fibroblasts
IL-1 Proinflammatory	• Stimulates myelopoiesis via stimulation of G-CSF and GM-CSF • Endogenous pyrogen • Stimulates T (NK-cells) and B lymphocytes and macrophages • Attenuates anticoagulatory mechanisms and promotes thrombotic processes; induces production of tissue factor • Induces monocytes to release various mediators • Stimulation of T-helper cells, which are induced to secrete IL-2 and to express IL-2 receptors • Promotes the adhesion of neutrophils, monocytes, T cells, and B cells by enhancing the expression of adhesion molecules such as ICAM-1 (intercellular adhesion molecule-1) and ELAM (endothelial leukocyte adhesion molecule) • Mediator of inflammatory reactions. Enhances the metabolism of arachidonic acid (in particular of prostacyclin and PGE_2)
IL-4 Anti-inflammatory	• Inhibits macrophage activity • B-cell proliferation and activation • Enhances Th2 differentiation • Inhibits cell activation of NK cells induced by IL-2
IL-6 Pro- and anti-inflammatory	• Stimulates the acute-phase protein response • Stimulates the hypothalamus to secrete CRF • In sick euthyroid syndrome inhibits 5′-deiodinase, which converts T_4 to T_3 • Stimulates B lymphocytes and is involved in their differentiation into plasma cells • In the presence of IL-2, induces the differentiation of mature and immature T cells into cytotoxic T cells • Stimulates the secretion of antibodies
IL-8 Proinflammatory	• Neutrophil chemotactic agent • Synthesis strongly stimulated by IL-1 and TNF-α • Activates neutrophils; releases enzymes from granules • Chemotactic for all known types of migratory immune cells; enhances the expression of adhesion molecules
IL-10 Anti-inflammatory	• Produced by and downregulates the function of Th1 and Th2 cells • Inhibits antigen-presenting cell activity • Suppresses macrophage activity • Inhibits production of pro-inflammatory cytokines such as IFN-γ, IL-2, and TNF-α in T_H1 T-helper subpopulations • In macrophages stimulated by bacterial lipopolysaccharides, IL-10 inhibits the synthesis of IL-1, IL-6, and TNF-α by promoting the degradation of cytokine mRNA • Prevents the activation of macrophages
IL-13 Anti-inflammatory	• Downregulates macrophage activity, reducing production of proinflammatory cytokines (IL-1, IL-6, IL-8, IL-10, IL-12) and chemokines (MIP-1, MCP) in response to IFN-γ or bacterial lipopolysaccharides • Enhances the production of IL-1ra • Strongly inhibits tissue factor expression induced by bacterial lipopolysaccharides and reduces the pyrogenic effects of IL-1 or TNF, thus protecting endothelial cells and monocytes against inflammatory mediator–induced procoagulant changes
IFN-γ Anti-inflammatory	• IFN-γ has antiviral and antiparasitic activities • Main biologic activity is as an immunomodulator • A major function is to activate macrophages • Influences cell-mediated mechanisms of cytotoxicity • Modulator of T-cell growth and functional differentiation • IFN-γ is the hallmark cytokine of T_H1 cells

IL, interleukin; IFN, interferon.

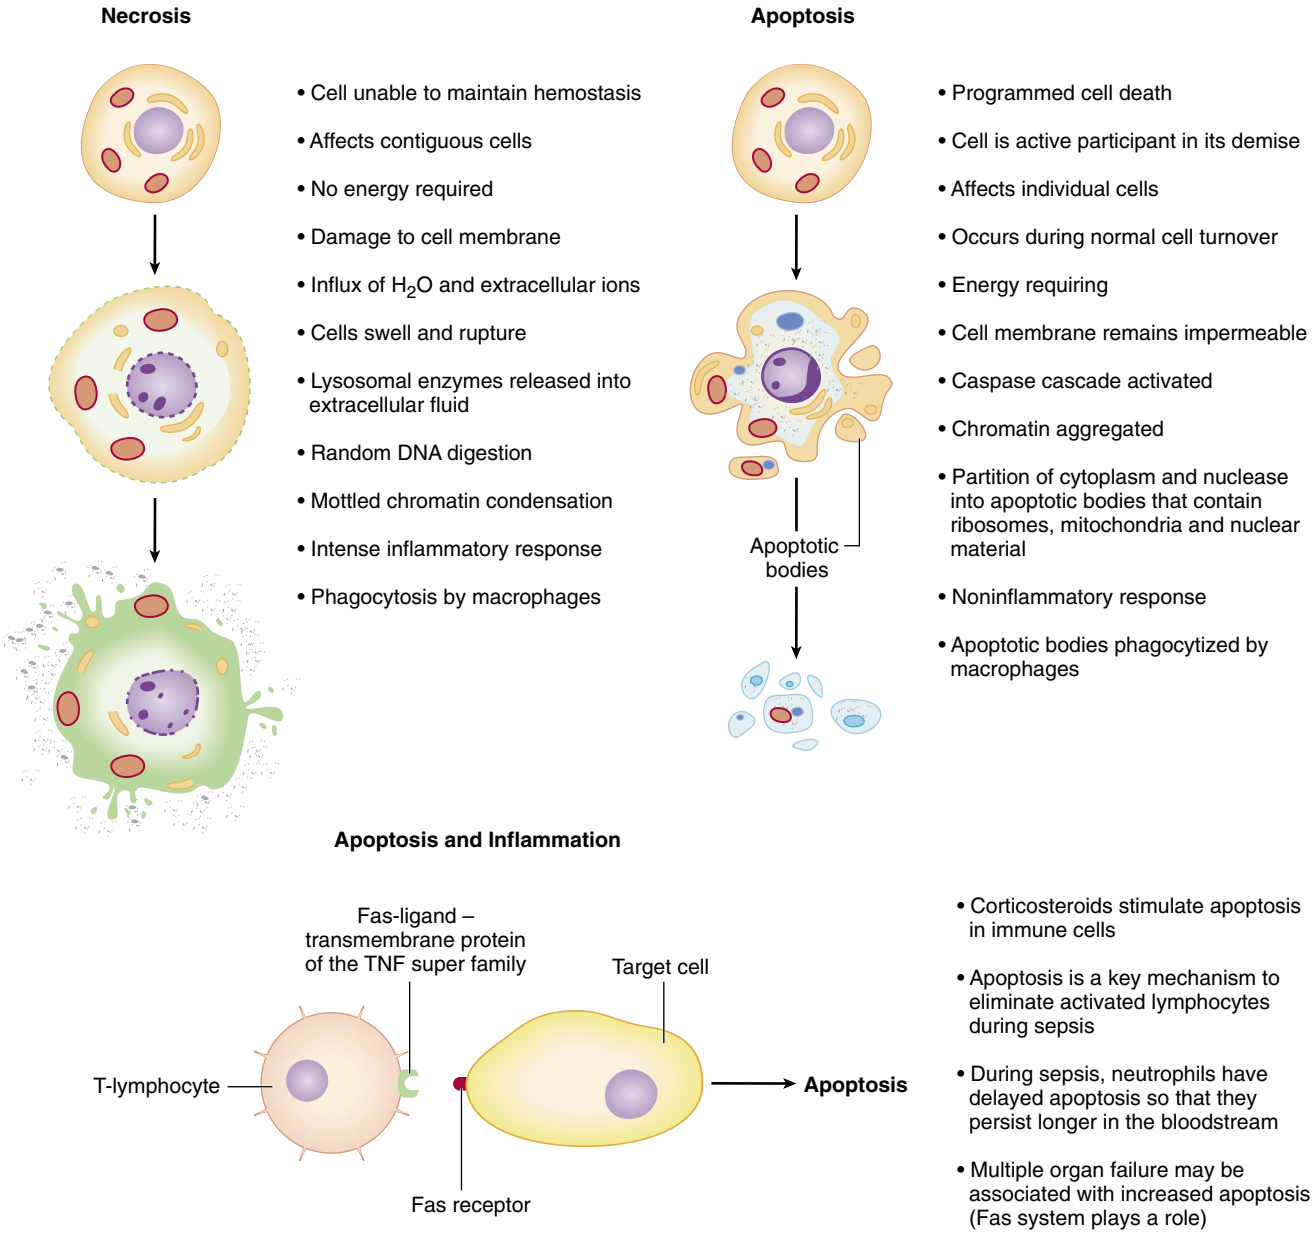

Figure 95-3 The differences between necrosis and apoptosis are shown. The importance of apoptosis during inflammation is also diagrammed.

The Immunologic/Coagulation Connection

Surgical, septic, and traumatic stress produce leukocytosis, thrombocytosis, and anemia. The granulocytosis seen with surgery and infections is mediated by cytokine-induced release of the hematopoietic growth factor granulocyte colony-stimulating factor (G-CSF). G-CSF increases neutrophil, monocyte, and T-lymphocyte production and is elevated above preoperative levels for at least a week after major surgery.[46] Thrombocytosis is induced by thrombopoietin, which increases in concert with IL-6 and acute-phase reactants.[47] Anemia of inflammation occurs during acute and some chronic stressed states. Erythropoiesis is suppressed because of an inability to incorporate iron into erythrocyte precursors despite the presence of adequate bone marrow iron stores. This is secondary to both decreased erythropoietin secretion and reduced sensitivity to its actions.

There is much bidirectional cross-talk between the inflammatory and coagulation systems.[48] During the perioperative period there is marked hypercoagulability secondary to both an increased procoagulant state and reduced fibrinolysis. The former is caused by a combination of decreased antithrombin, tissue factor pathway inhibitor (TFPI), and protein C coupled with increased tissue factor (TF) causing increased thrombin generation and fibrin deposition. This results in microvascular thrombosis. Decreased fibrinolysis is due to reduced t-PA (tissue plasminogen activator) and increased PAI-1 (plasminogen activator inhibitor-1). Cytokines, secreted by immune cells, are the responsible mediators; TNF-α upregulates PAI-I, monocytes express TF, and IL-6 stimulates TF. In addition, especially during

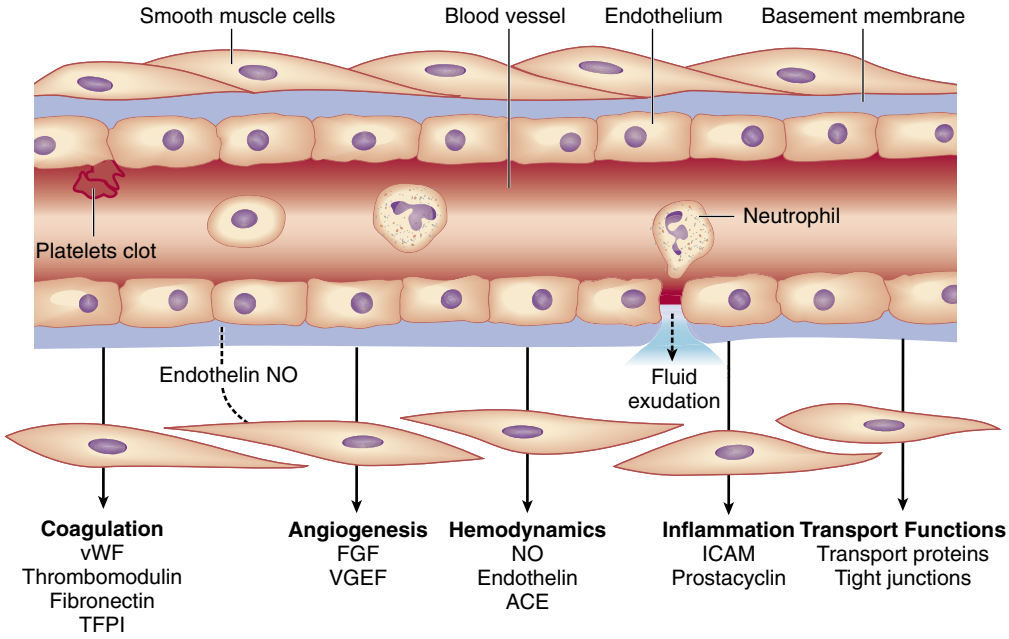

Figure 95-4 Endothelial cells have many functions. Nitric oxide (NO) produced by endothelial cells vasodilates blood vessels by relaxing adjacent myocytes, while endothelin causes vasoconstriction. The NO-endothelin system is the local controller of vascular tone. During sepsis, inflammatory cytokines, such as TNF, upregulate inducible NO synthetase (iNOS), increasing endothelial production of NO and resulting in vasodilation. During sepsis, endothelial disruption occurs because of increased expression of adhesion molecules, resulting in white blood cell attachment and disruption of the basement membrane. This results in exudation of fluid into the extracellular space. Adhesion molecules and selectins recruit leukocytes to enter tissues. vWF, von Willebrand factor; TFPI, tissue factor pathway inhibitor; FGF, fibroblast growth factor; VGEF, vascular endothelial growth factor; ACE, angiotensin-converting enzyme; ICAM, intercellular adhesion molecule; VCAM, vascular cellular adhesion molecule.

sepsis, ex vivo platelet reactivity increases. Acute-phase proteins contribute to the procoagulant state. Fibrinogen concentrations are elevated as are those of α_1-antitrypsin and α_2-macroglobulin, which inhibit protein C. Increased C4 binding protein lowers free protein S, whereas C-reactive protein (CRP) increases the expression of TF by monocytes and neutrophils.[49] The hypercoagulable state is also induced by other factors, including local tissue damage (PAI is secreted by endothelial cells) and materials such as methyl methacrylate monomers and bone marrow debris. During postoperative convalescence (days 3 to 7) hypercoagulability gradually abates. Hypercoagulability is not triggered by the counter-regulatory hormones. Instead, when a cocktail of these hormones plus angiotensin II and vasopressin was infused into normal volunteers, fibrinolytic and anticoagulant activity increased (fibrinogen, t-PA, and protein C concentrations increased, as did platelet activity). These results are reinforced by the anticoagulant effects of an epinephrine infusion begun before an endotoxin infusion in normal subjects.[50]

Regional anesthesia, especially after lower body surgery, causes less hypercoagulability than general anesthesia and is associated with less deep vein thrombosis. Laparoscopic cholecystectomy appears to cause less hypercoagulability than open cholecystectomy and may actually cause hypocoagulability by selectively increasing tPA.

The procoagulant state, in turn, accelerates the inflammatory response. Thrombin, acting through protease-activated receptors, upregulates cytokines (e.g., IL-6, IL-8, monocyte chemotactic protein-1) and increases adhesion molecule expression. The TF/factor VII complex increases inflammatory responses of macrophages and neutrophils, as evidenced by increased plasma concentrations of IL-6 and IL-8 on infusion of recombinant factor VII into normal subjects.[51] Inflammation plus microvascular thrombosis is thought to be a cause of multiple organ system dysfunction and thus is the rationale for activated protein C (APC) treatment in sepsis. APC is approved for treatment of sepsis, whereas trials of TFPI and antithrombin III were unsuccessful.

Fasting and Malnutrition

Fasting results in adaptive responses that permit the body to continue functioning despite a lack of nutrient intake.[52] During the 24 to 48 hours after cessation of nutrient intake glycogen stores are broken down (glycogenolysis) to provide glucose to the tissues. This glucose is vital for the brain, red blood cells, skin, and renal medulla, which have obligatory glucose requirements. Glycogenolysis is mediated by an increased glucagon/insulin ratio (increased glucagon and decreased insulin), which also promotes endogenous glucose production (gluconeogenesis). In addition to the increases in glucagon and decreases in insulin, hypoglycemia is avoided by small increases in catecholamine and cortisol secretion.[53] The increase in catecholamine-induced β-adrenergic stimulation accelerates lipolysis so that triglycerides stored in adipose tissue are broken down to free fatty acids (FFA) and glycerol. Some of the FFA undergo hepatic conversion to ketones (β-hydroxybutyrate and acetoacetate), which are then utilized as an energy source. As glycogen is depleted, glucose is increasingly provided by gluconeogenesis, which provides more than 90% of

the glucose after 42 hours of fasting.[54] Among the substrates for gluconeogenesis are glycerol released during lipolysis and lactate produced by glycolysis.

As starvation continues, skeletal and smooth muscle tissues undergo proteolysis to amino acids. The amino acids alanine and glutamine are transported mainly to the liver but some also to the kidneys, to be used as substrates for gluconeogenesis. This muscle breakdown results in a negative nitrogen balance (catabolism). As starvation progresses, the body adapts by reducing the rate of gluconeogenesis and muscle breakdown, which, along with decreases in free T_3 and catecholamines, reduce resting energy expenditure. This reduced muscle protein breakdown is accompanied by reduced nitrogen losses so that nitrogen balance becomes less negative. The decrease in gluconeogenesis is possible because the brain adapts to using ketones for some of its energy needs.[55] During this time much ATP is produced from fatty acids released by lipolysis.

Prolonged starvation leads to weight loss secondary to major losses of fat and lean (muscle) body mass. Marked weakness and fatigue develop as the result of proteolysis and reduced muscle protein synthesis. Sodium and water retention also occurs. Prolonged starvation reduces immune function and results in increased adherence of gram-negative bacteria to nasopharyngeal and pulmonary endothelial cells. This bacterial adherence along with weakness of the respiratory muscles and immune system makes these patients susceptible to pneumonia, the leading cause of death in starved or severely malnourished patients.

Eating

Eating sets into motion a series of steps that digest, absorb, and metabolize the ingested food. Gut hormones initiate a sequence of systematic events by signaling the body to secrete hormones such as insulin.[56] Ingested carbohydrates are converted to glucose and stimulate insulin secretion, and the glucose not immediately needed for energy is stored as glycogen or converted to fat (lipogenesis). Ingested proteins are digested and broken down into amino acids, used to synthesize proteins, and serve as precursors for neurotransmitters and other substances. Fats are stored and used for energy or as precursors for prostaglandins and other substances. Food ingestion increases metabolic rate—diet-induced thermogenesis or thermogenic effect of food—and contributes 10% to 15% of total daily energy expenditure.[57] Protein ingestion increases metabolic rate more than isoenergetic amounts of carbohydrates or fat.[58] The postprandial rise in energy expenditure lasts for 3 to 4 hours.

The Metabolic Responses to Surgical and Traumatic Injury

The metabolic responses to surgical and traumatic stress differ greatly from the response to starvation. Unlike the adaptive responses aimed at preserving body mass that occur during starvation, the response to stress has been called "auto-cannibalism."[59] This categorization is occasioned by loss of fat and lean body mass caused by an obligate catabolic state with proteolysis, gluconeogenesis, lipolysis, hypermetabolism, and insulin resistance. Autocannibalism is not reduced to any great extent by exogenous nutrients.

The intensity and duration of the metabolic response to surgery and trauma depend on the magnitude of injury, total operating time, amount of intraoperative blood loss, and degree of postoperative pain. The smaller injury of laparoscopic surgery, compared with open surgery, results in lower concentrations of IL-1, IL-6, and the acute-phase reactant CRP.[60] The greatest metabolic responses are observed after severe (>40% body surface area) burn injury with metabolic rates twice normal and catabolism that lasts for many months, leading to immunodepression, recurrent infections, and poor wound healing.[21]

Carbohydrate Metabolism

Surgical and accidental injury increase secretion of the counterregulatory (to insulin) hormones cortisol, catecholamines, and glucagon,[61] resulting in elevated endogenous glucose production secondary to accelerated hepatic gluconeogenesis (Fig. 95-5). This increased glucose production coupled with peripheral tissue resistance to insulin results in reduced glucose utilization and hyperglycemia. Serum insulin concentrations are normal or elevated but are insufficient to prevent hyperglycemia but do prevent ketosis. Hyperglycemia is thought to ensure a ready supply of glucose to predominantly glucose-consuming cells, such as the wound inflammatory cells and immune cells.

Insulin resistance is defined as impaired glucose disposal in the presence of either normal or elevated serum insulin concentrations.[62] This insulin resistance occurs in peripheral tissues, causes a 50% to 70% reduction in insulin sensitivity compared with healthy controls, and is likely due to a postreceptor defect that hinders cellular glucose uptake.[62] This defect is possibly caused by impaired activity of the intracellular glucose transport system or nonoxidative glucose disposal, that is, reduced muscle glycogen synthetase activity.[63] In postoperative patients the magnitude of the insulin resistance is proportional to the magnitude of the surgery. Insulin resistance occurred after both elective open and laparoscopic cholecystectomy and persisted for at least 5 days. In medical ICU patients the severity of insulin resistance was associated with the severity of illness, body mass index, and degree of hypermetabolism.[62]

In stressed patients, the overall amount of glucose oxidized (especially given the overall hypermetabolism) may be decreased despite a glucose oxidization pathway that is intact, because the rate of glucose uptake into the cell is limited by insulin resistance. The incremental response to increases in insulin concentration is maintained, but the ability to reduce blood glucose concentration per insulin concentration is markedly diminished. Despite the insulin resistance, the overall peripheral uptake of glucose is often normal or mildly elevated owing to increased non–insulin-mediated glucose uptake and the large amounts of glucose (due to hyperglycemia) being presented to the resistant insulin pathway. However, relative to the blood glucose concentration and hypermetabolism, the uptake is low.

Glucose can be oxidized to produce ATP, water, and CO_2; converted to glycogen for storage in the liver and muscles; or converted to fat. The latter process is called lipogenesis and occurs in both liver and adipose tissue, although the latter appears to be the main site for lipogenesis. Under normal circumstances carbo-

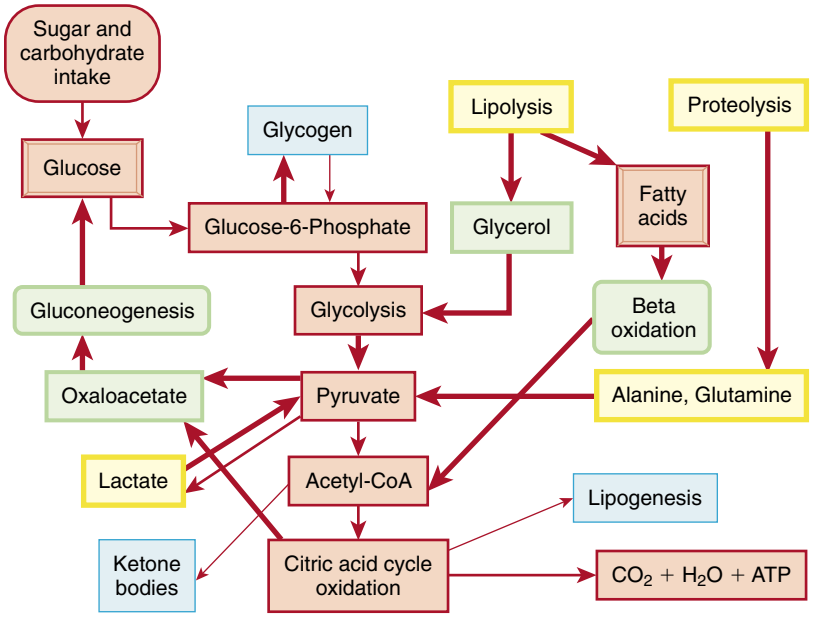

Figure 95-5 The metabolic milieu during stress. The rate of endogenous glucose production (gluconeogenesis) is greatly increased. Glycerol (from lipolysis), alanine (from proteolysis), and lactate (from the wound) are the substrates. Because of insulin resistance less glucose is used to produce energy (ATP) and, thus, β-oxidation of fatty acids becomes the major energy-producing pathway. Exogenous glucose intake does not decrease the rate of gluconeogenesis. The production of ketones is not greatly increased because of normal to elevated concentrations of insulin. Acetyl-CoA, acetyl coenzyme A; ATP, adenosine triphosphate.

hydrate intake inhibits fat oxidation, increases glucose oxidation, and promotes fat storage. Lipogenesis is quantitatively unimportant in humans because the rate of lipogenesis does not exceed the rate of lipid oxidation. Yet, when carbohydrate intake exceeds total energy expenditure, lipogenesis becomes a more important pathway, and respiratory quotients (RQs) may exceed 1.0, indicating net lipogenesis (see Table 95-3). Critically ill patients administered intravenous glucose at 4 mg/kg/min as part of glucose-based total parenteral nutrition (TPN) exhibited some increased hepatic de novo lipogenesis, despite achieving an RQ of only 0.90.[64] This lipogenesis occurred even though lipogenetic capability is thought to be reduced in surgical or septic stress. The reduced lipogenesis is possibly secondary to TNF, which among other things can induce apoptosis of pre-adipocytes and adipocytes. IL1-β may also inhibit lipogenesis in human adipocytes.

Lipid Metabolism

Stressful situations (e.g., injury, sepsis, and congestive heart failure) alter lipid metabolism. The major change is accelerated lipolysis due to increased β_2-adrenergic stimulation.[65] Stimulation of the β_2-receptors increases cAMP concentrations, which, in turn, stimulates the activity of hormone-sensitive lipase (Fig. 95-6). The lipolytic response to β_2 stimulation is greater in lean, than obese, subjects; β_3-adrenergic receptors also appear to play a role in human lipolysis. Elevated concentrations of glucagon, TNF-α, IL-1, interferon-α, and interferon-γ likely have roles in stimulating lipolysis. Insulin resistance contributes to the lipolysis because the anti-lipolytic effect of insulin is attenuated.[62] There are regional variations in the lipolytic rate, with visceral fat cells having the greatest rate due to increased activity of β_2 and β_3 receptors and reduced activity of α_2-adrenergic receptors. Subcutaneous fat has less lipolytic activity due to greater activity of insulin receptors and α_2 adrenoreceptors. The RQ in injured patients is consistently lower than normal subjects for a given level of intake, indicating greater fat oxidation (Table 95-2). Infusion of glucose in amounts that lead to net fat synthesis in normal subjects fails to suppress fat oxidation in injured and septic patients, leading to negative fat balance. Plasma free fatty acid concentrations are high because the lipolytic rate exceeds the rate of fat oxidation.

Rapid glycerol and free fatty acid turnover rates reflect the accelerated lipolysis seen during stress. The increased lipolysis increases the systemic supply of circulating free fatty acids (FFA). However, the turnover rates are greater than those expected from the increases in the plasma concentrations of these substrates. This indicates that there is both increased re-esterification of FFA to triglycerides (TG) and increased lipolysis of TG to FFA. This increased activity of the TG-FFA/glycerol substrate cycle is thought to be one of the causes of the hypermetabolism seen during stress (Fig. 95-7). β-Adrenergic receptor blockade with propranolol decreases lipid oxidation and the resting metabolic rates of burn patients. Glucose infusions further increase lipolysis during abdominal surgery because they increase sympathetic nervous system activity.

In the stressed state the relative contribution of fat oxidation to resting energy expenditure is increased while the contribution of glucose oxidation is decreased. FFA acids released by lipolysis undergo β-oxidation, which in the stressed patient is the predominant ATP-producing pathway (see Figs. 95-5 and 95-6). This situation is reflected in observations made after esophagectomy where there was a gradual decrease in the contribution of fat oxidation to energy production and an increase in the contribution of glucose oxidation as patients convalesced.

Protein Metabolism

One of the hallmarks of the metabolic response to injury and sepsis is catabolism (negative nitrogen balance). Catabolism is caused by accelerated proteolysis of skeletal muscle, which provides some of the substrate for increased hepatic gluconeogenesis (see Fig. 95-5). Reducing the rate of hepatic gluconeogenesis with

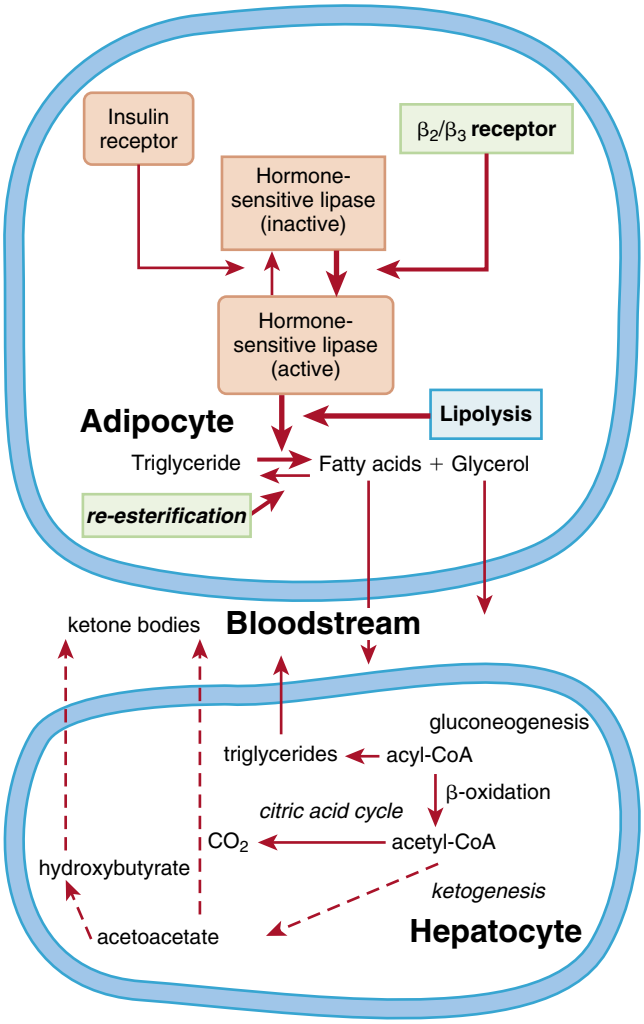

Figure 95-6 Lipid metabolism during the stressed state. Catecholamines stimulate β_2 and β_3 receptors, activating hormone-sensitive lipase, leading to lipolysis. Free fatty acids are transported to the liver where they undergo β-oxidation and are the main source of energy during stress (palmitoyl-CoA yields a net of 130 ATP). Glycerol released by lipolysis is a substrate for gluconeogenesis and is converted to glucose. Because insulin concentrations are elevated, ketone production is not increased. Both lipolysis and re-esterification are increased, leading to a futile cycle.

somatostatin does not decrease the rate of peripheral protein breakdown, demonstrating that the accelerated rate of hepatic glucose production is not linked to increased level of peripheral protein breakdown. The degree of nitrogen loss is proportional to the degree of stress and abates as the patient convalesces. After severe burns, protein breakdown and subsequent amino acid efflux from muscle is increased almost twofold. The increased protein breakdown is thought to be modulated only partially by the endocrine stress hormones, specifically cortisol. Instead, other mediators such as TNF-α, IL-1, IL-6, and interferon-γ mediate catabolic activity. It is the balance between these catabolic mediators and anabolic hormones, such as insulin and insulin-like growth factors, that determine the magnitude of catabolism. A number of metabolic pathways are responsible for skeletal muscle proteolysis including the lysosomal Ca^{2+}-activated, ATP-ubiquitin–dependent proteolytic pathway.[66] The liver also contributes to catabolism through increased clearance of α-amino nitrogen (urea). After surgery the rate of this conversion is doubled. Blockade of glucagon and cortisol secretions with a combination of etomidate, somatostatin, and thoracic epidural anesthesia decreased this clearance, thus indicating roles for glucagon and possibly cortisol and afferent neural reflexes in this process.

There are conflicting data regarding skeletal muscle protein synthetic activity during stress. Some studies indicate reduced (e.g., 31% decrease 24 hours after open cholecystectomy) skeletal muscle protein synthesis whether saline or TPN is infused. Liver biopsies taken during surgery demonstrated depressed hepatic protein synthesis after 20 minutes of surgery that decreased further as surgery progresses.[67] Tissues with rapidly replicating cells, such as enterocytes, immune cells, and keratinocytes, also exhibit reduced protein synthesis. Other investigators claim that the net negative nitrogen balance is due an accelerated rate of protein breakdown that is in excess of an increased protein synthetic rate. Furthermore, the derangement of protein metabolism is profound because administering TPN after open cholecystectomy did not prevent the decline in muscle protein synthesis observed 24 hours after surgery.

The detrimental affects of prolonged bed rest further contribute to the derangements in protein metabolism caused by the stress hormones and cytokines after injury and surgery. In normal volunteers, 28 days of bed rest resulted in a 0.4-kg loss of leg

FUTILE CYCLES

Glucose metabolism

Glycolysis ⟷ Gluconeogenesis

↓

"Wastes" 4 ~P bonds/cycle

Glycolysis

$$\text{Glucose} + 2\ \text{NAD}^+ + 2\ \text{ADP} + 2\ \text{P}_i \rightarrow 2\ \text{Pyruvate} + 2\ \text{NADH} + 2\ \text{ATP}$$

Glycolysis yields 2 ~P bonds of ATP

Gluconeogenesis

$$2\ \text{Pyruvate} + 2\ \text{NADH} + 4\ \text{ATP} + 2\ \text{GTP} \rightarrow \text{Glucose} + 2\ \text{NAD}^+ + 4\ \text{ADP} + 2\ \text{GDP} + 6\ \text{P}_i$$

Gluconeogenesis expends 6 ~P bonds of ATP and GTP

FAT METABOLISM

Lipolysis ⟷ Re-esterification

Re-esterification

Figure 95-7 Two futile cycles that contribute to the hypermetabolism of the stress response. A futile cycle is a set of opposing reactions catalyzed by different enzymes acting simultaneously, with at least one of the reactions driven by adenosine triphosphate (ATP) hydrolysis so that heat is produced. In the lipid metabolism cycle there is net lipolysis whereas in the glucose metabolism cycle there is net gluconeogenesis. ~P, high-energy phosphate bond, generally from ATP.

Table 95-2 Energy Expenditure and Caloric Requirements

Energy Expenditure

Basal energy expenditure (BEE)—also called basal metabolic rate (BMR)—the energy expenditure on awakening from a 12-hour fast measured in a thermoneutral environment (25°C).

Thermogenic effect of food—also called specific dynamic action—the energy expenditure after the ingestion of food. After a meal, energy expenditure may increase 5% to 10%.

Resting energy expenditure (REE)—the energy expenditure while resting in the supine position with eyes open. Includes the thermogenic effect of food if performed within a few hours of a meal or during continuous infusions of nutrients such as during continuous TPN administration. About 10% greater than BEE.

Sleeping energy expenditure (SEE)—the energy expenditure during sleep; it is usually 10% to 15% lower than REE.

Activity energy expenditure (AEE)—the energy expended during physical activity. During maximum exercise it can be 6- to 10-fold greater than the BEE.

Environmental temperature—energy expenditure increases to warm patients placed in a cold environment. Warming occurs through shivering and increased metabolism of brown fat (neonates).

Fever—Fever increases metabolic rate 10% per °C (or 7% per °F).

Total energy expenditure (TEE)—total energy expended over 24 hours: the sum of energy expended during periods of sleep, resting, and activity.

Estimating Resting Energy Expenditure (Harris-Benedict Equation)

Males: eBEE (kcal/day) = 66 + (13.7 • W) + (5 • H) – (6.8 • A)

Females: eBEE (kcal/day) = 655 + (9.6 • W) + (1.7 • H) – (4.7 • A)

eREE = eBEE • stress factor

eTEE = eREE • activity factor

eBEE, estimated basal energy expenditure; W, weight (kg); H, height (cm); A, age (years); eREE, estimated resting energy expenditure; eTEE, estimated total energy expenditure.

Stress Factors

Spontaneously breathing, nonsedated patients:

- Major surgery: 15%-25%
- Infection: 20%
- Long bone fracture: 20%-35%
- Malnutrition: Subtract 10%-15%
- Burns: Up to 120% depending on extent
- Sepsis: 30%-55%
- Major trauma: 20%-35%
- COPD: 10%-15%
- Sedated mechanically ventilated patients: Subtract 10%-15%.

Activity Factors

Sedated mechanically ventilated patients: 0-5%

Bedridden, spontaneously breathing nonsedated patients: 10%-15%

Sitting in chair: 15%-20%

Ambulating patients: 20%-25%

Measuring Energy Expenditure

Indirect calorimetry involves measuring oxygen consumption (Vo_2) and carbon dioxide production (Vco_2). The gas exchange method is used to measure Vo_2 and Vco_2, whereas the Fick method can be used to measure only Vo_2.

Weir equation: EE (kcal/day) = 1.44 (3.9 • Vo_2) + (1.1 • Vco_2)

Measurements made at rest provide the REE. To determine the TEE: REE • activity factor.

Continuous measurement made over 24 hours provides the TEE.

Measuring Nitrogen Balance

N balance = [N intake]–[N output]: Negative balance—catabolism; positive balance—anabolism.

Where [N intake] = all protein/amino acid intake over 24 hours whether enteral or parenteral

[N output] = [UUN + 4 + EL]

UUN, urine urea nitrogen over 24 hours; 4 g average fecal and cutaneous losses; EL, excessive losses, such as protein rich drainages (e.g., pus).

6.25 g protein/amino acids = 1 g nitrogen.

Table 95-2 Energy Expenditure and Caloric Requirements—cont'd

Daily Caloric Requirements	Using Measured or Estimated REE	Using Body Weight
Sedated mechanically ventilated patients	1.0-1.2 • REE	20-24 kcal/kg
Unsedated mechanically ventilated patients	1.2 • REE	22-24 kcal/kg
Spontaneously breathing critically ill patients	1.2-1.3 • REE	24-26 kcal/kg
Spontaneously breathing ward patients (maintenance)	1.3 • REE	24-26 kcal/kg
Spontaneously breathing ward patients (repletion)	1.5-1.7 • REE	25-30 kcal/kg

To gain 1 pound of body weight, one needs an excess above TEE of approximately 3500 kcal.

Respiratory Quotients	Energy (kcal/g)	Respiratory Quotient (RQ)*
Carbohydrate	4.0	1.00
Dextrose (glucose monohydrate)	3.4	1.00
Fat	9.0	0.70
Protein	4.0	0.80
Ethanol	7.0	0.67
Lipogenesis		*8.00*

RQ, ratio of resting CO_2 production to resting O_2 consumption.
*Whole-body RQ is influenced by the relative amounts of carbohydrate, fat, and protein oxidation and lipogenesis. For example, a patient who has received a 5% dextrose infusion of 100 mL/hr (440 kcal/day) for 4 days has a whole-body RQ of 0.77 to 0.80, reflecting the predominance of fat and protein oxidation as the energy source. Whole-body RQ above 1.0 indicates net lipogenesis. In humans, RQs above 1.2 to 1.3 are generally not seen even with very high carbohydrate intakes.

muscle mass and a reduction of 23% in leg extension strength.[68] When hydrocortisone was administered to such bed-rested volunteers, in doses intended to reproduce cortisol concentrations encountered during illness or trauma, there was a threefold greater loss of lean leg mass (1.4 kg), which represents a 6% loss of muscle mass from the legs and a 4-kg loss of whole-body lean mass. There was also a 28% reduction in leg extension strength. The muscle protein synthesis rate was decreased while muscle protein breakdown was unchanged from rates before bed rest.[69] In contrast, blunt trauma patients had a greater mean 6.4 kg loss of whole-body lean mass because they suffered from proteolysis in addition to reduced protein synthesis.[70] Extended periods of immobilization in bed contribute to loss of muscle mass and the weakness suffered by stressed patients. Early mobilization and exercise are thus important aspects of care.

During stress there is increased hepatic synthesis of the acute-phase proteins such as fibrinogen, haptoglobin, complement, immunoglobulins, serum amyloid A, and CRP. The secretion of the acute-phase proteins is stimulated by elevated concentrations of endogenous corticosteroids (which by themselves do not initiate the response) in concert with IL-1β, TNF-α, and IFN-γ. These cytokines induce the secretion of IL-6 by the hepatic Kupffer cells, which also initiates and stimulates the production of acute-phase proteins.[60] Simultaneously, IL-6 and the corticosteroids initiate a negative feedback loop, suppressing IL-1β and TNF-α production by mononuclear phagocytes. Bacterial infections tend to trigger a stronger acute-phase response than viral infections. The increase in the acute-phase proteins leads to greater ability to fight infection, stimulation of the wound healing process, and improved hemostasis. The increase in fibrinogen is responsible for the increased hemostatic ability and also increased plasma viscosity. The latter is the reason the erythrocyte sedimentation rate is used as a nonspecific diagnostic test for disease activity. CRP is often used as a measure of the acute-phase response and the degree of stress because of enormous concentration increases (e.g., on the second day after hip replacement concentrations increased from <6 to >200 mg/L).[42] It is often used as a marker of low-grade inflammation in obesity and cardiac disease because of its proatherosclerotic effects.

Occurring simultaneously with the increased synthesis of acute-phase proteins is reduced synthesis of binding proteins, such as albumin, transthyretin (prealbumin), retinol-binding protein, and transferrin. This reduction in the synthesis and plasma concentrations of binding proteins elevates the plasma concentrations and bioavailability of free hormones and electrolytes. As discussed previously, decreased plasma concentrations of cortisol binding globulin and albumin increase the concentrations of free cortisol. Albumin concentrations (half-life, 21 days) decrease because of reduced synthesis, redistribution in the expanded extracellular fluid, and a greater fractional catabolic rate. Therefore, short-term changes in albumin concentrations do not reflect changes in synthesis. For nutritional evaluation a protein with a short half-life (e.g., transthyretin) is measured. However, it, too, has limitations because concentrations are decreased in hepatic failure and increased in renal failure.

Energy Expenditure

Metabolism consumes fuels, such as glucose and fatty acids, to produce energy-containing compounds (e.g., ATP) for use in many energy-consuming body functions. Among the major func-

tions of eating is replenishing this fuel. The amount of fuel burned is reflected directly by the amount of energy released as heat (direct calorimetry) and indirectly by the amount of O_2 consumed, CO_2 produced, and urine urea nitrogen excreted (indirect calorimetry). The components of the daily total energy expenditure (TEE) are outlined in Table 95-2. Daily caloric intake should be sufficient to meet the daily energy expenditure. Intakes in excess of TEE result in the deposition of fat and weight gain, whereas sustained intakes less than TEE result in weight loss.

In stressed patients the altered metabolic milieu increases resting energy expenditure (REE). Most studies of spontaneously breathing postoperative, trauma, septic, and burn patients have reported that REE is above the estimated resting energy expenditure (eREE) estimated by the Harris-Benedict equation (see Table 95-2). This is in contradistinction to the starved or semi-starved state where the energy expenditure decreases as part of an adaptive response.

Studies performed in spontaneously breathing surgical patients showed that measured (via indirect calorimetry) REE was greater than eREE. The greater REE ranged from 10% to 20% after elective surgery to 20% to 40% during sepsis (although values as high as 80% have been reported after sepsis). Patients with fractures of the long bones tend to have higher REE/eREE than those with similar degrees of injury without fractures. Peak REE occurs about the third postoperative day, and hypermetabolism may last as long as 3 to 4 weeks in critically ill trauma and longer in burn patients. Burn patients can be extremely hypermetabolic (with REE as much as 120% greater than eREE) with the degree of hypermetabolism proportional to the extent and severity of the burns. Elderly patients (>60 years) have less of a hypermetabolic response.[71]

Mechanically ventilated postoperative and trauma patients have lower increases in REE than spontaneously breathing patients because they are receiving sedatives and/or muscle relaxants, which both decrease REE by as much as 20%.[72] In such patients, measured REE is often within ±10% to 16% of the eREE.[73] Another cause of this lack of hypermetabolism is that they have no or minimal work of breathing when ventilation is controlled by the mechanical ventilator. As they begin to breathe spontaneously the REE rises because of increased work of breathing and reduced sedation. During weaning from mechanical ventilation, energy expenditure rises further as the patient sustains more of his or her breathing, sedation is stopped, and anxiety sets it.[74] However, it is important to note that these very ill ICU patients retain much resuscitation fluid ("third space") that increases their body weight by as much as 10% to 12%. Because edema fluid has no metabolic activity, using their current, instead of preinjury, weight in the Harris Benedict equation may overestimate eREE and thus underestimate the degree of hypermetabolism.[75]

The causes of hypermetabolism during stress are multifactorial. Fever results in an increase of 11% in energy expenditure for each degree C increase in body temperature. In addition, the rate of metabolism is increased by the effects of the increase in energy-consuming processes such as gluconeogenesis and ureagenesis. Catecholamines infused into normal subjects increase the metabolic rate. This increase is even greater when cortisol, glucagon, and catecholamines are infused together. The significant hypermetabolism in head-injured patients has been ascribed to major sympathetic nervous system activation. This also occurs with other types of intracranial pathology. For example, for at least 5 days after subarachnoid hemorrhage, REE was 18% above eREE. The increased energy expenditure has also been ascribed to increased protein oxidation and synthesis. Yet this may not always be the case because after elective surgery there was only a modest change in energy expenditure, despite increased protein turnover. Another process that contributes to hypermetabolism is "futile substrate cycling" (see Fig. 95-7). Reducing the rate of the lipolysis/re-esterification futile cycle with β-adrenergic blockade reduced REE in burned children. The teleologic reason for the increase in futile cycling is that it affords patients the flexibility to adapt quickly to changes in energy substrate demands.

Environmental factors may also affect energy expenditure. Elevated ambient temperature (and humidity) has been shown to reduce the REE of burn patients by reducing evaporative losses and, in turn, reducing the need to generate energy to maintain body temperature.[76]

The Metabolic Responses to Sepsis

Unlike elective surgery, with the short-term stress of the surgery followed by a recovery period, sepsis is characterized by an ongoing stressful stimulus with systemic effects that can lead to multiple organ system dysfunction. The basic metabolic response observed during sepsis is similar to that after major surgery, burns, and trauma and in major nonseptic illnesses such as pancreatitis and serious transfusion reactions (e.g., blunting of the inhibitory effects of insulin on lipolysis and gluconeogenesis).[77] However, sepsis is further characterized by the presence of bacteria and bacterial components that initiate and sustain additional metabolic, inflammatory, immunologic, and coagulation responses.[78] This is demonstrated by the greater number of complement and coagulation proteins found in the plasma proteome profile of infected, as opposed to uninfected, critically ill trauma patients.[79] Such biochemical differences are important because they may serve as biomarkers to use in the early detection of active infection and for differentiating between sepsis/septic shock and the systemic inflammatory response syndrome (Table 95-3).

As part of the innate immune host defenses, Toll-like receptors recognize alarmins, either pathogen-associated molecular patterns (PAMP), which are products of bacteria, viruses, fungi, and protozoa, or intracellular proteins (damage-associated molecular patterns [DAMPs]) released by damaged cells.[80] Stimulation of Toll-like receptors (a group of pattern recognition receptors) activates transcription factor NF-κB and JNK (c-*Jun* N-terminal kinase) in immune cells, which initiate transcription of genes encoding proinflammatory cytokines. Interestingly, mice deficient in Toll-like receptors still succumb to sepsis, indicating that multiple pathways are active during sepsis. The type of infection influences the nature of the inflammatory response. Endotoxins (lipopolysaccharide) from gram-negative bacteria induce the production of TNF-α, IL-1, and IL-6, whereas exotoxin from gram-positive organisms increases IL-8 much more than TNF-α, IL-1, and IL-6.[81] Furthermore, septic shock produced a different cytokine profile than severe sepsis.[82] Viral infections produce different profiles from those produced by bacterial ones.

Table 95-3 Criteria for the Systemic Inflammatory Response Syndrome and Sepsis

Systemic Inflammatory Response Syndrome (SIRS)
Two or more of the following are required:
1. Body temperature > 38°C or < 36°C
2. Heart rate > 90 beats/min
3. Respiratory rate > 20 breaths/min or arterial $Paco_2$ < 32 mm Hg
4. WBC > 12,000 mm^3 or < 4000 mm^3 or > 10% immature forms

Sepsis
SIRS plus a documented infection site (documented by positive culture for organisms from that site). Blood cultures do *not* need to be positive. Although SIRS, sepsis, and septic shock are often associated with bacterial infection, bacteremia may not be present.

Severe Sepsis
Sepsis plus associated with organ dysfunction, hypoperfusion abnormalities, *or* hypotension. Hypoperfusion abnormalities include but are not limited to:
- Lactic acidosis
- Oliguria
- Acute alteration in mental status

Septic Shock
Sepsis-induced hypotension despite fluid resuscitation plus hypoperfusion abnormalities

Critical illness–related corticosteroid insufficiency—inadequate serum corticosteroid activity for the severity of illness—is reported to occur with some frequency in septic patients.[83] The cortisol concentration may be in the supranormal range and may or may not increase in response to additional ACTH stimulation. Annane and associates[84] found an incidence of 60% using metyrapone testing in severe sepsis and septic shock. The clinical presentation of this problem is usually reduced responsiveness to fluid and vasopressor therapy. It is also associated with increased mortality.[85] This relative adrenal insufficiency is acute and self-limited because it reverses on resolution of the acute illness. Its etiology is unknown but might be due to decreased ACTH or cortisol secretion and/or reduced end-organ sensitivity to glucocorticoids.[83] Therefore, the challenge is to find ways to easily and rapidly identify patients with this problem and determine whether glucocorticoid replacement improves outcome.[83] In a multicenter, randomized, double-blind, placebo-controlled trial of septic shock patients, 251 patients received 50 mg of intravenous hydrocortisone every 6 hours for 5 days which was then tapered over 5 days and 248 patients received placebo. There was no difference in either group in mortality between those who did and those who did not respond to an ACTH challenge. Although hydrocortisone did reverse shock more quickly than the placebo, it was associated with more episodes of superinfection.[83a] However, hydrocortisone did not improve survival.

Modulation of the Stress Response

Although the stress response evolved as a mechanism for assisting organisms in reacting to immediate danger, its effects may be detrimental to patients undergoing surgery or suffering from sepsis. For example, the hypercoagulable state intended to stem acute bleeding may lead to deep vein thrombosis and pulmonary emboli in immobilized patients. Furthermore, in extended stress situations the prolonged catabolism resulting from cytokine and stress hormone production leads to loss of fat and muscle with ensuing weakness and fatigue. This weakness and fatigue coupled with stress-related disordered immunologic function increases vulnerability to infections.

The detrimental consequences of the stress response have increased interest in aborting its appearance and/or actions. However, it is necessary to consider whether the goal of stress response modulation is full elimination or just attenuation. By eliminating the stress response, its beneficial effects, such as support of blood pressure by catecholamines in the face of hypovolemia or stimulation of cytokine production to enhance immunity, may be lost. Therefore, partial or selective suppression of the response may be more reasonable. In this manner some responses may be partly preserved, for instance the cardiovascular response to hypovolemia. Additional advantages of reducing certain consequences of the stress response include diminishing the degree of catabolism and lipolysis, thus reducing loss of muscle and fat mass. One approach tried in septic patients was selective mediator blockade. A prime example was anti-cytokine therapy (e.g., anti-TNF antibodies, IL-1 receptor antagonists) during sepsis and septic shock. The results of such therapy were disappointing because they not only failed to demonstrate any improvement in survival but, in some instances, even reduced survival. Postulated mechanisms for these failures include the possibility that targeting a single mediator may not be sufficient to block the wide-ranging ongoing biologic cascade. Another possible reason is that cytokines have beneficial immunoenhancing effects that assist the organism in combating infection. Impeding these effects thus leads to decreased immune function, causing increased mortality. Therefore, any attempt at modulating the stress response must be monitored for detrimental effects.

The Preoperative Stress Response

Patients undergoing elective surgery often suffer from preoperative anxiety, a state of psychological stress involving low-level activation of the hypothalamic-pituitary axis and possibly cytokines.[86] Evidence for such early activation comes from the observation that salivary cortisol increases by 50% after receipt of information about surgery.[87] Other studies show that both β-endorphin and epinephrine concentrations increase preoperatively. It is unclear whether this preexisting activation of the stress response has an additive effect on the subsequent stress response induced by surgery.

Preoperative medication is given to temper anxiety, thus attenuating the stress response. Midazolam as a premedication reduces anxiety and limits increases in intraoperative epinephrine and, possibly, norepinephrine and cortisol. Although it is unknown how benzodiazepines exert their activity, patients receiving benzodiazepines produce cortisol in response to exogenous ACTH, supporting the contention that the benzodiazepines exert their effect at a higher level, that is, on the hypothalamus or pituitary. Heavy premedication with a combination of opioid and antihistamine or opioid, anticholinergic agent, and benzodiazepine more successfully blunted serum catecholamine, AVP, ACTH, and cortisol increases than benzodiazepines alone.[88] Nonpharmacologic approaches to anxiety reduction have also been investigated. A number of studies have shown that music

reduces preoperative anxiety and thus may have practical applications.[89]

The Intraoperative Stress Response

Modulating the intraoperative stress response with anesthetics depends on various factors, including the type of anesthesia and surgery. Because it is nearly impossible to separate the effects of the anesthetics themselves from the stress response generated by the surgical injury, studies generally compare the effects of two or more anesthetic regimens on the overall stress response during a specific surgical procedure.

Inhaled Anesthetics

Volatile anesthetics minimally suppress the stress response. There is conflicting evidence as to whether volatile agents prevent surgically induced catecholamine secretion, although, among the volatile agents, enflurane is most capable of blocking intraoperative catecholamine surges. Both in the absence and presence of surgery, halothane and isoflurane failed to affect serum cortisol concentrations. However, sevoflurane attenuated the cortisol and ACTH responses to laparoscopic ovarian cyst removal.[90] During extended (>10 hours) inhaled anesthesia for head and neck surgery there were no differences in plasma cortisol, ACTH, insulin, or glucagon concentrations between isoflurane/nitrous oxide or sevoflurane/nitrous oxide anesthesia, although with sevoflurane, epinephrine and norepinephrine concentrations were attenuated during surgery and rose only after surgery.[91] Volatile anesthetics are generally ineffective in counteracting the metabolic responses (e.g., lipolysis) induced by surgical stimulation.

Intravenous Anesthetics

Some intravenous anesthetics partially modify the endocrine and metabolic components of the stress response. Sodium thiopental (5.0-5.1 mg/kg) does not prevent increases in catecholamine concentrations after intubation. However, many studies show lower epinephrine and norepinephrine concentrations when propofol (2.0-2.2 mg/kg), rather than pentothal, is used for intubation.[92] This finding is attributed to propofol's intrinsic ability to inhibit catecholamine secretion, possibly by decreasing catecholamine release from chromaffin cells. Propofol (1.5-2.5 mg/kg) also decreases cortisol concentrations during intubation. Etomidate does not affect metabolic responses except to decrease hyperglycemia. This is attributed to etomidate suppressing the adrenocortical response by blocking cortisol and aldosterone synthesis.

Compared with benzodiazepines, the α_2-adrenergic agonists clonidine and dexmedetomidine are more successful at blunting the hemodynamic and catecholamine responses to intubation and intraoperative stress. The α_2-agonists blunt the stress response by reducing norepinephrine release from central and peripheral nerve endings.[93] When 4.5 μg/kg of oral clonidine was given preoperatively, intraoperative plasma catecholamine concentrations were reduced. Similar doses reduced not only plasma but also cerebrospinal fluid (CSF) concentrations of TNF-α and norepinephrine.[94] Such doses also attenuated the intraoperative and postoperative hyperglycemic responses to minor surgery. Whether clonidine also attenuates the cortisol response is unclear.[95] Moreover, α_2-agonists, such as dexmedetomidine, do not suppress steroidogenesis.[96]

Opioids

Opioids are capable of blunting the stress response. Fentanyl (50 μg/kg) plus halothane and nitrous oxide abolished the elevations in cortisol, GH, and glucose normally seen during hysterectomy. Morphine (1 mg/kg) reduced GH and cortisol elevations during abdominal surgery. However, other studies show that the same dose of morphine was unable to suppress increased GH secretion during similar surgery. Opiates also decrease cytokine production. Propofol/alfentanil anesthesia when compared with isoflurane anesthesia caused lower IL-6 concentrations. These lower IL-6 concentrations are thought to occur because opioids bind to monocyte receptors and reduce intracellular cAMP concentrations. cAMP is necessary for monocyte secretion of IL-6.[97]

The limitation of the stress-reducing effects of opioids is most evident during cardiac surgery. Although high-dose fentanyl (50-200 μg/kg) and morphine (2-4 mg/kg) prevent pre–cardiopulmonary bypass increases in catecholamines and cortisol, during cardiopulmonary bypass both catecholamine and cortisol concentrations increase. Similarly, high-dose sufentanil (12 μg/kg induction, 3 μg/kg before skin incision, and 5 μg/kg before bypass) limited pre-bypass increases in catecholamines, cortisol, and AVP but failed to attenuate their elevation both during bypass and postoperatively. The reversal of the opioid-related stress-reducing effects by bypass is attributed to nonpulsatile blood flow, artificial surfaces of the bypass circuit, renin and angiotensin release, hypothermia, and dilution of the plasma opioid concentration.[98]

The mechanism by which opiates curb the stress response is unknown. One theory is that this action is mediated through hypothalamic and pituitary opiate receptors. This theory has been questioned because of the similar effects of fentanyl and sufentanil on the stress response despite the much greater affinity of sufentanil for brain opiate receptors. Both intravenous (50 μg then 20 μg every 30 minutes) and intrathecal high-dose (150 μg) sufentanil attenuated the intraoperative epinephrine and norepinephrine responses in patients undergoing general anesthesia for major abdominal surgery. However, only in the intrathecal group were the intraoperative ACTH and cortisol responses attenuated. Therefore, the unique actions of sufentanil may only be apparent on intrathecal administration.[99]

Although general anesthesia undoubtedly prevents an even greater stress response by rendering patients insensate to the discomfort and pain of surgery, it is unable to completely eliminate many manifestations of the stress response. This is ascribed to the inability of anesthesia to diminish or abolish the afferent nervous input from the area of the injury. Additionally, general anesthesia does not alter the effects of cytokines such as IL-6 and TNF, which are produced within the area of the wound.

Neuraxial Anesthesia

Neuraxial anesthesia is more effective than general anesthesia in attenuating the stress response (see Chapter 51). The ability of

such anesthesia to modify the intraoperative stress response depends on the level of the blockade, the location of the surgery, and the drugs used. Lower extremity surgery with epidural anesthesia results in lower intraoperative catecholamine concentrations when compared with general anesthesia.[100] These reductions in catecholamines may be caused by blockade of afferent nerve stimuli, reducing hypothalamic activation of the sympathetic nervous system and adrenal medulla. Further evidence for reduced hypothalamic activation is that epidural anesthesia to a T4 level successfully blunts increases in TSH. Similarly, during vaginal surgery, epidural anesthesia attenuates the usual increases in AVP.

Neuraxial anesthesia for lower abdominal and lower extremity surgery reduces or abolishes the hyperglycemic response to surgery, likely because of the lack of stimulation of hepatic glycogenolysis due to a reduced epinephrine response or blockade of hepatic sympathetic pathways or both. Reduced sympathetic and adrenal activity with epidural blockade also prevents normal intraoperative increases in free fatty acids and glycerol (lipolysis) during lower abdominal surgery. Further evidence that sympathetic blockade reduces intraoperative lipolysis is that during inguinal hernia repair lipolysis was reduced only once spinal anesthesia reached the T1-T3 sensory level. The influence of neuraxial blockade on cortisol secretion is less clear. Although neural blockade during lower abdominal surgery reduces the stress-induced cortisol response, whether the degree of suppression is similar to that of other hormones is still unclear. This may be due to the inability of epidural anesthesia to alter the IL-6 response to abdominal surgery,[101] suggesting that IL-6 secretion is neither mediated by nociceptive stimuli nor affected by sympathetic blockade. IL-6 increases pituitary ACTH secretion and thus stimulates cortisol secretion. Similar attenuation of catecholamine and cortisol secretion occurred when spinal cord–injured patients had surgery below their lesions.[102]

Neuraxial anesthesia more successfully reduces the stress response during lower abdominal than upper abdominal or thoracic surgery. There is a controversy whether T3-T4 epidural blockade can suppress surges in cortisol and catecholamine concentrations during upper abdominal surgery. Epidural blockade as high as C6 does not influence the cortisol response during upper abdominal or thoracic surgery. This was disputed when blockade extending from T3-T4 to L1-L2 significantly reduced the cortisol response during gastrectomies. Similarly, it remains uncertain whether epidural blockade for upper abdominal surgery alters lipid or protein metabolism, although it seems to partially suppress the hyperglycemic response.[103] These studies support the idea that regional anesthesia is unable to suppress the stress responses induced by upper abdominal stimulation. This lack of suppression is attributed to inadequate afferent sympathetic blockade, unblocked vagal afferent pathways, unblocked phrenic afferents, or locally released humoral substances. Others suggested that regional anesthesia that does not completely block afferent stimuli will not affect the hypothalamic-pituitary-adrenal axis because epidurally induced sympathetic block does not completely block neural traffic but just reduces it. Supporting this hypothesis, Tsuji and coworkers[104] found that the combination of epidural and splanchnic blockade (injection of 45 mL of 0.5% bupivacaine directly into the splanchnic plexus) during upper abdominal surgery reduced both the catecholamine response and plasma cortisol concentrations more effectively than epidural alone. Similarly, continuous spinal local anesthetic infusion more successfully attenuated the cortisol and glucose responses to upper abdominal surgery than epidural anesthesia presumably by better blockade of afferent nerves.

Another possible explanation for the inability of epidural anesthesia to attenuate the response to upper abdominal surgery is stimulus transmission through unblocked vagal afferent nerves. However, no attenuation of the stress response is seen after either vagal blockade or surgical vagotomy. Evidence for phrenic nerve involvement comes from Segawa and associates who showed that epidural blockade to the C3-C4 dermatome level during upper abdominal surgery more successfully blunted increases in ACTH and AVP than did C8-T2 blockade.[105]

The drugs used for regional anesthesia also influence the ability to affect the stress response. Epidural opiates are unable to prevent catecholamine surges. Increases in catecholamine concentrations were limited by 2-chloroprocaine and bupivacaine but not by lidocaine. This difference may be due to the central stimulatory effects of lidocaine.

Combined General and Neuraxial Anesthesia

Combined general anesthesia and neuraxial anesthesia should reduce the stress response if the general anesthetic is sufficiently deep to attenuate the stimulation of the endotracheal tube. For example, both desflurane/epidural (sensory block T4-S1 with 10 mL/hr infusion of 0.25% bupivacaine) and desflurane/remifentanil (bolus 1 μg/kg then an infusion of 0.125 μg/kg/min) anesthesia for colorectal surgery resulted in less glucose production and less hyperglycemia compared with desflurane alone.[106]

The effect of combined general and epidural anesthesia in patients undergoing coronary artery bypass grafting has been extensively studied. Patients receiving fentanyl anesthesia plus thoracic epidural bupivacaine (10 mg [5 mg/mL] every 4 hours) during coronary artery bypass grafting have lower epinephrine and norepinephrine levels both intraoperatively (including during bypass) and postoperatively compared with controls receiving only large doses of fentanyl. There are conflicting results as to whether the cortisol response is also reduced, although the cytokine response is not affected. Combined general and epidural anesthesia for cardiac surgery lessened myocardial damage, as evidenced by decreased troponin-T release. This effect may be secondary to the ability of epidural anesthesia to attenuate myocardial sympathetic stimulation, although a meta-analysis did not show fewer myocardial infarctions or lower mortality.[107]

Thermoregulation

Another way of minimizing the stress response is maintaining perioperative normothermia (see Chapter 48). Intraoperative hypothermia followed by postoperative rewarming stimulates the response. Hypothermic patients (35.3°C core temperature) had higher postoperative plasma norepinephrine and epinephrine concentrations than their warmer counterparts.[108] These elevated catecholamine concentrations are partially the result of postoperative rewarming with shivering and vasodilatation that leads to hypotension. Elevated catecholamines have been postulated to be among the reasons for the greater incidence of myocardial

ischemia after vascular surgery in hypothermic patients. There are thus several reasons to maintain intraoperative normothermia.

The Postoperative Period

The intraoperative attenuation of the stress response by anesthesia is often lost on emergence from anesthesia because of pain and awareness coupled with a series of stress-producing events (tracheal extubation, shivering). This postoperative response was demonstrated by extreme elevations in plasma ACTH and cortisol immediately after surgery with isoflurane anesthesia. Likewise, after sevoflurane-nitrous oxide anesthesia, peak cortisol, ACTH, and catecholamine concentrations occurred after tracheal extubation, implicating anesthesia emergence as more stressful than surgery. This phenomenon may be especially marked with sevoflurane anesthesia because of its typical rapid emergence. Associated with these markedly elevated catecholamine concentrations is an increased incidence of myocardial infarction that peaks 24 to 48 hours after surgery.

Like inhaled anesthetic, general anesthesia with intravenous drugs does not prevent the postoperative stress response. Intravenous opioid anesthesia did not blunt the stress response in the late postoperative period (>3 hours). Abrogation of the suppressive effects of anesthesia on the stress response on emergence was further demonstrated when patients were deeply sedated with propofol for 12 hours after cardiac surgery with bypass. This sedation attenuated the rise in cortisol and catecholamines and was associated with less tachycardia and hypertension than in a control group. However, once propofol was discontinued, hormone concentrations rose, indicating that deep sedation only delayed the appearance of the stress response.[109] Therefore, unless therapy that suppresses the stress response is continued during and after emergence and extubation, the postoperative period is marked by full appearance of the stress response.

After lower abdominal surgery, continuous postoperative analgesia via an epidural catheter using local anesthetics reduced the stress response. For example, continuous epidural analgesia (sensory block of T4-S5) for 24 hours after colorectal surgery successfully blunted increases in catecholamine, but not cortisol, concentrations. A similar regimen given for 24 hours after hysterectomy resulted in lower glucose and free fatty acid concentrations than did general anesthesia. Furthermore, better nitrogen economy was seen in hip replacement patients provided with 24 hours of epidural local anesthetics (sensory level: T10), than in patients administered only general anesthesia. This occurred with postoperative local anesthetic doses that provided only analgesia and not anesthesia. Similarly, combined spinal-epidural anesthesia during hip replacement with postoperative epidural analgesia (ropivacaine/sufentanil) resulted in reduced leucine oxidation rate on the first postoperative day while hyperglycemia was prevented only intraoperatively.[110] Attenuating the stress response with continuous postoperative epidural analgesia was more successful in lower than upper abdominal surgery, a finding similar to the observations during intraoperative epidural anesthesia. Yet, there are reports of stress response reduction after upper abdominal surgery. For example, after abdominal aortic surgery epidural morphine reduced the postoperative sympathetic, but not adrenal epinephrine, response, thus reducing the incidence of postoperative hypertension. However, neither epidural ropivacaine nor epidural morphine analgesia suppressed the catabolic response when administered to postoperative colonic surgery patients but ropivacaine did increase the carbohydrate oxidation rate, likely reflecting reduced insulin resistance.[111] The reduced insulin resistance coupled with decreased gluconeogenesis led to less hyperglycemia.[111] Therefore, pain control with epidural opioids or local anesthetics is unable to lessen many of the metabolic changes associated with such surgery.[112] However, combined epidural opioid/local anesthetic analgesia appears more effective in attenuating catabolism.[112a]

Whether modifying the stress response improves outcome is unclear. Ideally, one of desired effects of anesthesia is a "stress free" state, and achieving such an effect has become increasingly important as the stress response is more frequently implicated in the development of postoperative complications, especially among chronically ill and aging patients.[113] However, contemporary anesthesia practice can only partially modify this response and then only under specific conditions. General anesthesia has a very limited ability to attenuate the stress response whereas regional anesthesia is more effective. Therefore, it stands to reason that outcome would improve with regional anesthesia. A meta-analysis showed decreased mortality with regional anesthesia as opposed to general anesthesia in a variety of surgical procedures. However, this analysis has been criticized because it seems that only orthopedic patients had improved outcomes. Furthermore, morbidity studies demonstrated that under some circumstances epidural anesthesia reduces postoperative complications, such as deep vein thrombosis.

Attempts to modulate the perioperative stress response include nonanesthetic approaches (e.g., using β-adrenergic antagonists to block cardiovascular end-organ receptors) and α_2-adrenergic agonists to stimulate central receptors. These approaches have met with some success. Using β-adrenergic antagonists in patients with ischemic heart disease does not reduce the perioperative neuroendocrine or endocrine stress response but just blocks the end-organ response. Such end-organ blockade also has metabolic affects. Administering propranolol to severely burned children decreased their resting energy expenditure, attenuated muscle catabolism, reduced lipolysis, preserved lean body mass, and reduced TNF and IL-1 concentrations without increasing infections.[114] Hepatomegaly due to fatty liver was prevented because reductions in both lipolysis and hepatic blood flow decreased fatty acid delivery to the liver.[115] Mortality was unaffected by propranolol.[114] In severely septic patients selective β_1-adrenergic blockade had no affect on REE or muscle protein kinetics,[116] indicating that attenuation is due mainly to β_2-receptor blockade. However, it is important not to continue the β-blockade into the anabolic period because β-adrenergic activity might be important in muscle tissue restoration.[117]

Another nonanesthetic modulation of the stress response is administering a single preoperative dose of exogenous glucocorticoids. Administration of intravenous methylprednisolone (30 mg/kg) 60 to 90 minutes before the start of major abdominal, hepatic, and esophageal surgery reduced the stress response with lesser increases in IL-6, CRP, norepinephrine, and AVP and increased secretion of IL-10. A meta-analysis of 51 studies in which a single dose of methylprednisolone (15 or 30 mg/kg) was given showed no increase in complication rates.[118] Further study is needed to determine whether this approach significantly affects outcome. Similarly, methylprednisolone treatment before cardiac surgery attenuated cytokine secretion.

The inability of any one modality to reduce the stress response and significantly alter outcome has spawned the "multimodal" approach. The aim is to shorten the convalescence period and reduce the postoperative decline in functional status by improving pain control, early return of gut function, and early mobilization. This approach involves combining some or all of the following: premedication (benzodiazepines, β-blockers, α_2-agonists), preoperative carbohydrate intake, glycemic control, maintenance of normothermia, combining epidural anesthesia/analgesia and nonsteroidal anti-inflammatory drugs, avoiding opioids, early oral feedings or parenteral nutrition, and early mobilization after major abdominal surgery.[119,120] Such a regimen permitted 32 of 60 colorectal resection patients to go home within 48 hours of surgery and in a study of anterior colon resection reduced the hospital length of stay from 10 to 7 days.[121] Radical cystectomy patients anesthetized with general and thoracic epidural anesthesia and postoperative thoracic epidural analgesia and treated with early oral nutrition and forced mobilization had lower urinary catecholamines, less negative nitrogen balance, earlier return of bowel function, and a lower acute-phase response than conventionally treated patients.[119] The multimodal approach to modulating the perioperative stress response has much logic and practicality and, coupled with noninvasive surgery, has the potential to change postoperative care.

Glucose Control

Hyperglycemia appears almost immediately after the start of a major stress secondary to insulin resistance and accelerated endogenous glucose production. Administering exogenous catecholamines and glucocorticoids exacerbates this hyperglycemia. The teleologic explanation for the elevated blood glucose concentration is that it provides the wound and other glucose-dependent tissues with a ready supply of glucose. Experience gained from diabetic care showed the many problems caused by chronic hyperglycemia and the advantages of tightly controlling blood glucose concentrations. This experience was the impetus for exploring whether tight glucose control is also advantageous in the acute hyperglycemia associated with surgical, traumatic, and septic stress.

Acute hyperglycemia is associated with immunosuppression, stimulated sympathoadrenergic activity, increased mortality, increased infections, reduced skin graft success, increased catabolism in burn patients, and osmotic diuresis leading to volume depletion.[121-124] These effects are ascribed to the proinflammatory actions of glucose attributed to increased secretion of TNF-α and IL-1, greater adherence and sequestration of neutrophils in peripheral tissue, impaired microvascular relaxation in the presence of nitric oxide, and decreased monocyte HLA-DR expression reflecting reduced innate immunity.[125] The proinflammatory cytokine response to endotoxin infusion in normal subjects was enhanced by concomitant hyperglycemia.[126] These observations question whether elevated blood glucose concentrations are themselves detrimental or whether hyperglycemia is just a marker of severe stress. Hyperglycemia on hospital admission in trauma victims portends greater mortality, whereas hyperglycemia in both diabetic and nondiabetic cardiac surgery patients is associated with a higher incidence of infections. Moreover, Van den Berghe and associates[122] showed reduced mortality in surgical (mainly cardiac surgical) patients treated with intensive insulin therapy to maintain euglycemia (≤110 mg/dL). Compared with conventional therapy, the aggressive insulin therapy reduced ICU mortality (especially from multiple organ failure) by 43%, sepsis by 46%, and acute renal failure requiring dialysis or hemofiltration by 41%. Also, aggressively treated patients in the ICU for more than 7 days had less critical illness polyneuropathy/myopathy.[127] These results led to the additional question of whether it is the lowering of the blood glucose concentration or the administration of insulin, an anabolic and anti-inflammatory hormone, that reduces morbidity and mortality. Further studies suggest that avoiding hyperglycemia is associated with beneficial effects, since the total amount of insulin administered correlated with increased mortality regardless of the blood glucose concentration.[128] The latter observation indicates that a major determinant of mortality and morbidity is the severity of the critical illness, as demonstrated by the degree of tissue insulin resistance and hence the amount of insulin needed to control blood glucose. Therefore, it is the avoidance of hyperglycemia rather than the insulin administered for its correction that is beneficial.

The beneficial effects of lowering blood glucose concentrations with intensive insulin therapy are ascribed to abrogation of the proinflammatory actions of hyperglycemia (e.g., when somatostatin inhibited insulin release during the infusion of glucose in normal subjects, TNF-α and IL-6 concentrations increased[129]) along with the anti-inflammatory effects of insulin; protection of the mitochondrial compartment and endothelium; lower serum cortisol concentrations; and increased secretion of anti-inflammatory hormones such as IL-4 and IL-10.[130,131] Insulin is also thought to interfere with IL-6 signal transduction. In patients with myocardial infarctions, insulin suppresses the secretion of acute-phase reactants such as serum amyloid A and CRP.[132]

The enthusiasm for tight control of blood glucose in stressed patients must be tempered. There is the possibility of unrecognized hypoglycemia especially in sedated and mechanically ventilated patients. This concern is occasioned by the Van den Berghe study in which 5% of patients suffered a hypoglycemic episode, leading to recommendations that glucose be controlled to higher concentrations (<140 mg/dL).[122] Also, under some circumstances insulin appears to have proinflammatory actions and upregulates NF-κB.[133] The increased insulin doses could also increase resting energy expenditure (REE) further. Another issue is whether all or only specific populations benefit from tight glucose control or from the increased glucose utilization caused by the high insulin doses. In patients staying 3 or more days in a medical ICU, tight control reduced mortality from 53% to 43%.[134] Hyperglycemia is especially problematic in head trauma, and settings of cerebral ischemia. Glucose-insulin treatment might be beneficial in myocardial infarction/ischemia. A meta-analysis incorporating 8432 patients in 29 studies concluded than in critically ill patients, tight glucose control (<110 mg/dL and <150 mg/dL) was not associated with significantly decreased mortality, but increased risk of hypoglycemia.[134a]

Nutritional Support

The Perioperative Period

During the perioperative period there are many nutritional considerations. Patients are routinely fasted for 6 to 8 hours before surgery and thus present to the operating room in a postabsorp-

tive state with decreased insulin/glucagon ratios, utilizing their glycogen stores to provide tissues with glucose. Whether this is an appropriate metabolic milieu to surgically stress an individual has been questioned. Therefore, the utility of providing carbohydrates (50 g) either orally (maltodextrins) or intravenously (glucose) 2 hours before surgery was examined. Such carbohydrate intake increased insulin concentrations to those observed after a meal, reduced postoperative insulin resistance by about 50%, and decreased postoperative gluconeogenesis and nitrogen loss. However, the degree of postoperative hypermetabolism and cytokine activity was unchanged, whereas hospital stay after colorectal and other surgery appeared to be reduced.[135,136]

Immediately after surgery patients traditionally receive infusions of 5% dextrose (glucose monohydrate), which provide 50 g/L dextrose or 170 kcal/L (dextrose provides 3.4 kcal/g). Therefore, patients receiving 2 to 3 L/day of 5% dextrose are essentially being semi-starved. The rationale for infusing small amounts of dextrose is its protein-sparing effects (i.e., reduced gluconeogenesis, which decreases the need for proteolysis, leading to lower urinary nitrogen losses). In normal subjects, nitrogen losses decrease linearly as the amount of dextrose administered increases, up to an intake of 150 g/day. More than 150 g/day of dextrose results in no further protein sparing unless protein and fat are also provided. In addition, small amounts of carbohydrate (100 g/day) prevent ketosis.[55] However, the ability of exogenous glucose to suppress gluconeogenesis is diminished during stress. An infusion of 2 g/kg/min glucose during the first 3 hours of surgery reduced endogenous glucose production by 60%, as opposed to 90% reduction in preoperative patients.[120] In addition, 5% dextrose infusions contribute to hyperglycemia. Dextrose regimens should only be continued for a few days (4-6 days) after surgery, until the patient can resume oral intake. Patients unable to begin oral intake after such time should be evaluated for enteral or parenteral nutritional support.

Efforts have been directed at finding ways to improve the effectiveness of hypocaloric amounts of glucose administered during the postoperative period. When compared with an intravenous pain regimen, the greater pain relief provided after abdominal surgery by continuous intraoperative and postoperative epidural blockade with local anesthetics and opioids (0.1% bupivacaine plus 2 μg/mL fentanyl to a T7-L3 sensory block) further decreased endogenous amino acid oxidation and increased whole-body glucose uptake by decreasing insulin resistance.[137,138] These results are not unexpected because pain itself induces insulin resistance and contributes to the catabolic state after surgery.[139] Furthermore, epidural analgesia reduces the duration of postoperative ileus (thoracic > lumbar, local anesthetics > opioids), allowing earlier resumption of oral intake.[140]

Postoperative protein sparing has been attempted with hypocaloric amino acid infusions. The idea is to provide small amounts of exogenous amino acids as gluconeogenic substrate (1 g produces 0.5 g of glucose) while avoiding the hyperglycemia seen during 5% dextrose infusions. However, there is a limit to how much protein can be used as an energy source and postoperative amino acid infusions decreased gluconeogenesis only slightly (8%-12%), although they suppressed protein breakdown, reduced IGF-1 decreases, and stimulated protein synthesis.[141,142] There appear to be no advantages of administering amino acids instead of 5% dextrose.

Another use of intraoperative amino acid infusions are as thermogenic agents that are started either a few hours before surgery or after anesthesia induction to prevent or attenuate intraoperative hypothermia.[143] During anesthesia, the central thermoregulation is silenced, leading to exaggerated amino acid thermogenesis. Amino acid–induced heat generation during anesthesia occurs mainly in extrasplanchnic tissues, such as skeletal muscle, and is attributed to greater amino acid turnover because both protein breakdown and synthesis are energy-consuming (heat-generating) processes.[144] Such infusions reduced the body temperature decline during spinal anesthesia by 0.5° to 0.8°C.[145,146]

Indications for Nutritional Support

The primary indication for initiating nutritional support is preventing or treating malnutrition among patients unable or unwilling to sustain sufficient oral intake. From 20% to 35% of hospitalized patients suffer from malnutrition on admission or during their stay. Therefore, nutritional assessment and decisions about nutritional support should be a routine part of the ongoing care of all hospitalized patients. A major consideration when contemplating providing nutritional support to an individual patient is whether the nutrition will improve prognosis or the quality of life, since nutritional wasting is the inevitable consequence of many terminal diseases.[147] Another important aspect of providing nutritional support to stressed patients is that their already altered metabolic milieu greatly affects nutrient utilization and metabolism. In addition, critically ill patients with recurrent bouts of sepsis have an ongoing proinflammatory response that contributes to continued catabolism. Therefore, during the acute phase of stressful illness, nutritional support is an adjunctive therapy whose goal is to provide energy substrates to aid cellular functions and attempt to stem losses of lean and fat mass. Repletion of lost fat and muscle tissue must wait until the anabolic phase of the illness.

Preoperative malnutrition is associated with poor surgical outcome owing to a more severe systemic inflammatory response and more postoperative infections.[148] Yet it has been difficult to demonstrate any benefit of preoperative parenteral nutrition in malnourished patients except those severely malnourished, who had fewer noninfectious postoperative complications after 7 to 10 days of preoperative nutritional repletion. In such patients it is also beneficial to continue TPN during and after surgery. A systematic literature review found that the only preoperative TPN that was beneficial was the TPN administered to patients undergoing curative surgery for upper gastrointestinal cancer because it reduced major postoperative complications.[149] Postoperative nutritional support is not indicated unless it is anticipated that patients will be unable to resume adequate oral intake within 7 to 8 days after surgery. Patients not expected to resume adequate oral feedings by this time should begin nutritional support soon (2-4 days) after surgery. Evidence includes a study in which enteral nutrition started within 3 to 4 days of surgery reduced infectious complications after hepatectomy. A meta-analysis of 11 studies of patients after elective gastrointestinal surgery showed that early oral/nasoenteral/jejunostomy feeding started within 24 hours after surgery, compared with no nutrient intake, decreased infection rate and demonstrated a trend to less anastomotic breakdown but an increase in vomiting.[150] Similarly, a systematic literature review concluded that although many patients undergoing pancreaticoduodenectomy are nutritionally depleted before

surgery, routine postoperative TPN is not recommended because of the complication rate. However, postoperative EN is recommended.[151]

Mechanically ventilated ICU patients have a malnutrition rate of 38% to 100%.[141] Therefore, nutritional support guidelines recommend starting enteral nutrition early, that is, within 24 to 48 hours of ICU admission, to reduce infectious complications and duration of hospitalization.[152] Patients unable to tolerate enteral intake should be considered as candidates for TPN.

Parenteral versus Enteral Nutrition

A major decision when designing a nutritional support regimen is the route of administration. If patients are eating on their own, it is necessary to monitor their intake to ascertain its adequacy. Many patients have little appetite and thus may need nutritional supplementation between meals (snacking) to increase their caloric intake. Patients may be unable to feed themselves because of confusion or weakness and may need to be fed. During eating the intake of patients with severe chronic obstructive pulmonary disease (COPD) may be limited by arterial oxygen desaturation, causing fatigue. Such patients may require supplemental oxygen via nasal cannula while eating. Patients who fail to sustain adequate caloric intake by eating require either supplemental enteral or parenteral nutrition.

The enteral route is generally favored over the parenteral one because it is the natural portal of entry for exogenous nutrients. However, current evidence does not fully support this view except that enteral nutrition costs less.[153] The enteral route obviates the need for intravascular access with its attendant risk of infections and sepsis. In addition, the array of nutrients that can be administered via the gastrointestinal tract is greater than what is available for parenteral use, allowing for better tailoring of nutrient intake. Other advantages of enteral nutrition are ease of preparation and maintenance of gut function. The importance of maintaining gut integrity (the gut derives up to 70% of its nutrients from luminal food) is to reduce the translocation of bacteria from the gut. Animal studies showed that translocation of bacteria from intestines with reduced integrity and increased permeability leads to local activation of the gut's immune inflammatory system (Peyer's patches and hepatic Kupffer cells). These cells then release cytokines that intensify the already existing systemic inflammatory response, increasing the risk for multiple organ failure. However, there is no overwhelming evidence of significant translocation in humans.[154] Lack of enteral intake, such as occurs among postoperative and critically ill patients receiving no nutrition or only TPN, is associated with small intestinal villous atrophy, decreased villous cell count, and reduced mucosal thickness. Intestinal permeability, measured using the urinary lactulose-mannitol ratio, is increased. These changes reverse with enteral feeding. Interestingly, there was no evidence of mucosal atrophy among patients who had received 10 days of preoperative parenteral nutrition. It is thought that atrophy itself does not lead to bacterial translocation but that a further insult is needed. One such insult is small intestinal ischemia-reperfusion injury after resuscitation from an episode of shock, which by itself can change gut integrity.[155] This is supported by the observation that the incidence of bacterial growth from surgically removed mesenteric lymph nodes was higher in patients undergoing emergency surgery. Patients with such lymph nodes more commonly had postoperative sepsis.[156] Moreover, in a stressed patient it is possible that constantly proliferating gut epithelial and lymphoid tissues may have an insufficient nutrient supply, further compromising gut integrity. The fear of reduced gut integrity along with studies showing preserved xylose absorption in enterally, but not parenterally, fed neurosurgical patients has been among the reasons for recommending that enteral nutrition begin early even if only very small amounts can be administered. In the latter case, concomitant TPN is indicated to provide adequate caloric intake.[156a]

A major decision with enteral nutrition is the delivery method. Most patients are initially fed via nasoenteric tubes, including large-bore tubes. The advantages of the latter include the ability to quantify residual feedings and quickly reinitiate nasogastric suction. The disadvantages are the potential for pulmonary aspiration occasioned by gastroparesis and incompetence of the gastroesophageal junction due to the diameter of the tube. Additionally, long-term use of large-bore tubes can lead to sinusitis and otitis media. Therefore, the type of feeding tube and the location of its distal end are major issues. For medium and long-term feeding it is best to use a small-bore (8 to 12 Fr), soft (e.g., Silastic), long (to reach the jejunum) feeding tube with a weighted distal end. Such tubes reduce nasal and pharyngeal trauma and minimize gastroesophageal junction incompetence. Gastroparesis is common in critically ill patients so that placing the tube distal to the ligament of Treitz (small intestinal function generally remains intact) prevents pooling of feeds in the stomach with its risk of pulmonary aspiration.[145] Yet, there is controversy as to whether jejunal feeding actually reduces the risk of aspiration. Compared with gastric feedings, jejunal feedings facilitate higher caloric intakes. Passing the tube through the pylorus is often problematic because of gastroparesis and a supine and immobile state. Therefore, if possible, the tube should be passed through the pylorus during abdominal surgery. In nonsurgical situations an attempt may be made to pass a weighted tube through the pylorus by placing the tube in the stomach, turning the patient on the right side, and administering a prokinetic drug (e.g., metoclopramide). If that fails, the tube should be placed endoscopically or fluoroscopically.

Placing a jejunostomy tube during surgery is recommended in patients not expected to eat soon after surgery (e.g., severe trauma, major head injury, and esophageal surgery). Patients fed through nasoenteric tubes who will require prolonged enteral feeding (>4 weeks) should have either gastrostomies or jejunostomies placed surgically or percutaneously with endoscopic assistance. Percutaneous endoscopic gastrostomies (PEG) are commonly performed, and a modification is to place a jejunal tube through the PEG.

Parenteral nutrition is used when the enteral route is unable to provide or sustain sufficient caloric intake. Although it is preferable to use the gut, there are situations where parenteral nutrition is essential. Patients with short bowel syndrome require TPN after surgery and even for life if their residual bowel does not undergo sufficient adaptation to sustain adequate oral intake. Other absolute indications for TPN are small bowel obstruction, active gastrointestinal bleeding, pseudo-obstruction with complete intolerance to food, and high-output enteric-cutaneous fistulas (unless a feeding tube can be passed distal to the fistula). In partial large bowel obstruction it may or may not be possible to feed with a low residue diet. Relative indications for parenteral nutrition include nonhealing moderate-output enteric-cutaneous

fistulas; the need for bowel "rest" such as during inflammatory bowel flare-ups and acute radiation enteritis; marked abdominal distention and ileus due to intra-abdominal sepsis; continued distention after relief of intestinal obstruction; and chylothorax unresponsive to a medium-chain triglyceride diet. TPN is also indicated when the enteral route cannot provide enough nutrition.[157] In ICU patients this occurs because of diarrhea, vomiting, poor stomach emptying, feeding tube displacement, and interruption of feeding for diagnostic tests, procedures, and surgery.[158]

Parenteral nutrition is administered through either central or peripheral venous catheters. Peripheral veins cannot tolerate an osmolarity of more than 750 mOsm/L (the equivalent of 12.5% dextrose) so that the fluid volume that can be tolerated limits the caloric intake. Therefore, this route is used mainly for supplementation or short-term feeding. Central venous catheters are the main route of TPN administration. The preferred entry location is the subclavian vein, which provides a stable site, good patient acceptability, and lower infection rates than either the internal jugular or femoral routes. To minimize insertion and infectious complications a skilled individual should insert subclavian catheters under sterile conditions. The catheter should be a single-lumen catheter used only for TPN. Multiple-lumen catheters and multiple-purpose single-lumen catheters have high infection rates. For long-term use, tunneled Silastic Hickman-Broviac catheters, which have Dacron cuffs located at the proximal end of the tunnel to reduce infections, should be inserted.

Formulations

Glucose and Carbohydrates

In injured and septic patients exogenous glucose and carbohydrates minimally reduce the rates of gluconeogenesis and lipolysis.[159] This differs from refeeding starved patients when carbohydrate administration reduces gluconeogenesis and lipolysis. Despite the reduced glucose utilization, it is still important to administer carbohydrates to stressed patients because some body tissues do not readily use other substrates. Furthermore, glucose and carbohydrate intakes stimulate the secretion of insulin, which has anabolic properties that promote protein synthesis and decrease lipolysis. However, hyperglycemia, even with aggressive insulin treatment, often limits how much glucose and carbohydrate can be administered. The severity of TPN-induced hyperglycemia is directly proportional to the rate of glucose infusion and degree of injury. The elderly are more predisposed to hyperglycemia.

It is important to recognize that patients often receive carbohydrates that are frequently administered from sources other than the glucose in TPN or carbohydrates in enteral nutrition. Patients usually receive 5% dextrose infusions (170 kcal/L) while intravenous lipid emulsions contain at least 22 g/L of glycerol, which enters the gluconeogenic pathway. Overfeeding glucose (>4 mg/kg/min) to acutely stressed patients receiving a total caloric intake greater than REE results in a thermogenic response, further elevation of blood glucose concentrations, and production of additional CO_2. This added CO_2 must be excreted by the lungs and if insufficiently excreted can lead to elevated $Paco_2$. Such overfeeding is not uncommon, as revealed by a survey of U.S. teaching hospitals where many patients are fed with more than 4 mg/kg/min of glucose.[160]

Lipids

Intravenous lipid is usually administered as a long-chain triglyceride (LCT) emulsion. These emulsions contain soybean oil and an emulsifier (egg phospholipid) and are calorically dense (e.g., 10% and 20% solutions contain 1.0 and 2.0 kcal/mL, respectively). Once infused, the lipid emulsion is converted to both triglyceride-rich particles with sizes similar to that of chylomicrons and phospholipid-rich particles produced from the emulsifier called liposomes. The chylomicron-like particles are hydrolyzed by lipoprotein lipase to fatty acids and glycerol. The liposomes stimulate cholesterogenesis, incorporate cholesterol, and accumulate in the blood as the long-lived abnormal lipoprotein-X.[161] To minimize liposome formation, lipid emulsions should be administered slowly. Lipid emulsions are also the vehicle for many lipid-soluble drugs such as propofol, amphotericin B, and etomidate. Therefore, propofol infusion for sedation can provide significant amounts of lipid calories, which should be included when calculating caloric intake.

Exogenous fat is required to prevent essential free fatty acid deficiency, so at a minimum patients receiving TPN should receive lipid emulsion (500 mL of a 10% LCT emulsion) two to three times a week. Lipid emulsion is also utilized for energy because lipid oxidation is the predominant energy-producing pathway during stress. Fat emulsions are well oxidized when administered to septic and trauma patients even when glucose is provided. Even patients with chronic hepatic failure suffering from sepsis and multiple organ dysfunction efficiently metabolize intravenous lipid emulsions. The current practice is to consider lipid emulsions as energy substrates and administer them as 30% to 40% of total TPN calories.

There is concern that lipid emulsions may have immunosuppressive effects. Ex vivo studies showed decreased neutrophil bacterial killing, depressed monokine expression, and other immune-depressant effects. A study of trauma patients attributed increased infections to lipid emulsion administration. However, a meta-analysis found no evidence that LCT lipid emulsions are detrimental to immune function.[162]

The soybean-derived LCT emulsions traditionally used for parenteral nutrition have high proportions of omega-6 polyunsaturated fatty acids, specifically linoleic acid (53%). Linoleic acid is the precursor of thromboxane A_2 and prostaglandin E_1, which cause platelet aggregation and inflammation. Alternatively, fish oils containing omega-3 fatty acids (e.g., eicosapentaenoic and linolenic acids) are precursors of different prostaglandins (e.g., thromboxane A3), which have less platelet aggregating activity and cause less inflammation. Platelets from patients infused for 7 days after surgery with fish oil–enriched lipid emulsions aggregated less than those of patients administered non-enriched emulsions.[163] Also, omega-3 fatty acids decreased the ex vivo production of IL-1, IL-6, and TNF by peripheral blood mononuclear cells. Oral eicosapentaenoic acid intake after surgery improved lymphocyte proliferation and NK cell activity. Enteral nutrition regimens enriched with eicosapentaenoic acid and γ-linolenic acid (which promotes production of anti-inflammatory prostaglandin E_1) have been used in the acute respiratory distress syndrome (ARDS) to reduce pulmonary microvascular permeability and decrease prostaglandin, IL-8, and leukotriene synthesis by alveolar macrophages.[164,165] These formulations are associated with shorter mechanical ventilation, decreased ICU stay, and lower mortality.[166]

The purported limitations of intravenous LCT emulsions has heightened interest in substituting medium-chain triglycer-

ides (MCT) for some of the LCT. MCT do not need carnitine to enter mitochondria and may be advantageous when there is decreased carnitine, such as during sepsis. MCT are essentially an energy substrate, and it is unclear whether they can be stored. MCT appears to have fewer immunosuppressive effects than LCT and do not participate in eicosanoid synthesis.[167] Many commercial enteral formulas contain both MCT and LCT, supposedly because MCT is better absorbed. Intravenous MCT/LCT emulsion is not available in the United States.

Protein and Amino Acid

Amino acids and protein are essential ingredients of nutritional support regimens. TPN contains commercially prepared amino acid mixtures, whereas enteral formulas contain free amino acids, peptides, or whole proteins. The purpose of administering protein or amino acids to stressed patients is to decrease the breakdown of endogenous proteins by providing an alternative source of amino acids for gluconeogenesis and protein synthesis. Unfortunately, in the stressed state, exogenously administered amino acids and protein are not well utilized because proteolysis is relatively unresponsive to the usual negative feedback mechanisms, such as the administration of exogenous glucose, protein, or amino acids. Nitrogen balance remains negative well into the convalescent stage. In the catabolic state an intake of 1.2 to 1.5 g/kg/day of protein/amino acids is recommended because higher amounts do not promote further nitrogen retention and are metabolized to urea, so the blood urea nitrogen may rise. Situations with large external losses of protein, such as extensive burns and large draining abscesses, make it necessary to increase protein/amino acid intake. Adequate nonprotein calories (i.e., glucose and fat) must be administered concomitantly so that the protein/amino acids are not used as an energy source.

The inability of protein/amino acids to significantly attenuate nitrogen losses led investigators to explore ways of decreasing proteolysis and increasing protein synthesis. An initial attempt was to use branched-chain–enriched amino acid solutions as a component of TPN. This resulted in some improvement in nitrogen balance[168] but no improvements in outcome. Some enteral nutrition formulas for highly stressed patients are so enriched.[169] Other attempts focused on administering anabolic substances to reduce protein oxidation and improve protein synthesis. One such substance is insulin, which at lower doses decreases protein breakdown by inhibiting the major catabolic pathway, the ATP-ubiquitin proteasome proteolytic pathway.[170] At higher doses it is thought to also stimulate protein synthesis. Administering small doses of insulin to burn patients increased skeletal muscle protein synthesis and improved wound matrix formation. However, the anabolic effects of insulin on protein metabolism were not observed in enterally fed trauma patients. Therefore, the route of nutrient intake may play a role in insulin's anabolic effects.

To help maintain gut integrity it has been recommended that glutamine be added to both enteral and parenteral nutrition. Glutamine is the most abundant free amino acid in the blood and skeletal muscle and is a primary fuel for rapidly dividing cells such as enterocytes and immunocytes and a precursor of purines, pyrimidines, and nucleotides. It is synthesized primarily in skeletal muscle and is involved in the interorgan transport of nitrogen. Plasma glutamine concentrations decrease during severe stress, probably secondary to decreased glutamine synthesis, providing a possible explanation why alanine is the major interorgan nitrogen transporter. Animal studies indicate that glutamine may become an essential amino acid during catabolic illness when de novo synthesis is insufficient. These studies also show that parenteral and enteral glutamine-supplemented nutrition may prevent gut bacterial translocation, induce neutrophilic phagocytic activity, reduce neutrophil apoptosis, and increase concentrations of the antioxidant glutathione. The data in humans are less compelling.

Glutamine is rather insoluble, so it is difficult to administer. Some success was achieved by infusing it as the L-amino acid, glutamine dipeptides, α-ketoglutarate, or alanyl-glutamate. TPN solutions enriched with glutamate, arginine, and aspartate increased glutamine concentrations. After elective abdominal surgery, TPN with added glutamine dipeptide reduces infections and shortens hospital stays.[171] A systematic review found a trend that TPN and enteral nutrition supplemented with glutamine reduce mortality, infections, and organ failure in critical illness. However, the evidence was of limited quality.[172]

Nutritional regimens require many ingredients (see Tables 95-2 and 95-4). Choosing the route of administration is the key decision, because the type and composition of the formula are wholly dependent on the route. With use of the parenteral route, protein intake is limited to commercial mixtures of amino acids, carbohydrate to glucose, and lipids to the available emulsions. With enteral nutrition, more options are available because a variety of commercial formulas exist. It is possible to supplement enteral formulas with modular protein, lipid, and carbohydrate products. Caloric intake may be determined by either measuring REE using indirect calorimetry or estimating requirements (see Table 95-2).

Complications

Complications of nutritional support can result from problems with the delivery system or the nutrition itself. Morbidity related to the delivery system or the nutrients occurs more often with enteral nutrition than with parenteral nutrition. However, infectious complications are more frequent greater with parenteral nutrition.

Complications of central venous catheterization occur with parenteral nutrition. These complications include pneumothorax secondary to subclavian or internal jugular vein catheterization. The pneumothorax rate for subclavian catheterization is 1% to 5% but is lower if performed by an experienced operator. Other complications include hemorrhage causing hemothorax, brachial plexus injury, and catheter misplacement in the azygos vein, right ventricle, or retrograde into the jugular vein. Peripherally inserted (via an arm vein) central venous catheters (PICC) have the advantage of obviating pneumothoraces but are more difficult to place and have a higher incidence of poor position and skin site irritation. Catheter tips should be above the left atrium and confirmed by chest radiography before starting nutrition. Peripheral venous access whether via a short peripheral venous catheter or a PICC line can result in thrombophlebitis. With short catheters the osmolarity of the solution must be limited to less than 750 mOsm to prevent phlebitis. To further prevent phlebitis, some clinicians add heparin and hydrocortisone to the solution, whereas others place a nitroglycerin patch over the catheter site. It is imperative that peripheral parenteral nutrition catheter sites be inspected regularly and catheters changed when evidence of phlebitis develops.

Table 95-4 Considerations When Designing Nutritional Support Regimens

Considerations	Requirements	Issues
Route of administration	Enteral vs. parenteral or both	
Caloric requirements	Measure REE with indirect calorimetry Estimate REE with established equations Use weight-based formula	See Table 95-3
Protein/amino acids	Evaluate degree of stress, measure nitrogen balance Parenteral nutrition—amino acid solutions Enteral nutrition—standard or high-protein formulas; amino acids (elemental diet) vs. peptides vs. protein hydrolysates. If protein losses are excessive, then need increased protein intake.	Unstressed patients: 0.8-1.2 g/kg/day protein Stressed patients: 1.0-1.5 g/kg/day protein
Calorie/protein ratio	Expressed as calorie/nitrogen ratio	Standard formulas: 150:1 Stress formulas: 125-100:1
Carbohydrates	Parenteral nutrition: glucose is only available nutrient Enteral nutrition: oligosaccharides and starches	Glucose intake not to exceed 4 mg/kg/min during stress.
Lipid	Parenteral nutrition: LCT emulsions (in some countries LCT/MCT emulsions are available) Enteral formulas: contain LCTs or LCTs/MCTs; some enriched with omega-3 fatty acids	Sufficient LCT to prevent fatty acid deficiency
Lipid/carbohydrate (CHO) ratio	Parenteral nutrition: lipid/CHO ratio 30:70 to 60:40 Enteral nutrition: depends on formula. Calorie-dense formulas (1.5-2.0 kcal/mL) have higher lipid/CHO ratios.	
Electrolytes	Parenteral nutrition: sodium (NaCl, Na acetate), Potassium (KCl, K acetate), PO_4 (KPO_4, $NaPO_4$) $MgSO_4$, calcium (Cagluconate) Enteral nutrition: as per formulation; may add electrolytes, if needed	Potassium: 1-1.2 mEq/kg/day Magnesium: 8-20 mEq/day Calcium: 10-15 mEq/day Phosphate: 20-30 mmol/day
Trace elements	Parenteral nutrition: copper, molybdenum, selenium, zinc, manganese, chromium Enteral nutrition: also contain iron, iodine	
Vitamins	Parenteral nutrition: commercial multivitamin preparations contain all vitamins (some do not include vitamin K). Enteral nutrition: contains all vitamins including vitamin K; the volume of formula that provides the recommended daily requirements depends on the formula. Fat-soluble vitamins: A, D, E, K Water-soluble: B_1 (thiamine), B_2 (riboflavin), B_3 (niacin), B_5 (pantothenic acid), B_6 (pyridoxine), folate, B_{12}, C	Need to monitor prothrombin time weekly and give vitamin K, if indicated. Vitamin C: increased requirements for wound repair
Water	Parenteral nutrition: dilute vs. concentrated formulas Enteral nutrition: standard (1.0 kcal/mL) vs. calorie-dense (2.0 kcal/mL)	Dilute for peripheral vein administration. Concentrated for fluid restriction or high caloric intakes
Disease-specific considerations	Renal failure Hepatic failure Pulmonary disease Burns Diabetes	See “Special Considerations” in text. See “Special Considerations” in text. Reduce absolute carbohydrate intake; substitute lipid for carbohydrates with high total caloric intake See “Special Considerations” section Control blood glucose and monitor serum triglycerides.
Congestive heart failure	Concentrated formulas, low sodium intake	

LCT, long-chain triglyceride; MCT, medium-chain triglyceride.

Catheter-related infections are the major venous access complication encountered with TPN. Microbial colonization and bacteremia result from the interaction of four factors: (1) the hydrophobicity and exopolysaccharide production of the microbe, (2) the amount of fibrin and fibronectin attached to the catheter surface, (3) the catheter material (hydrophobicity, surface charge, thrombogenicity), and (4) iatrogenic factors such as sterile technique and immunocompetence. Infections are uncommon during the first 72 hours after insertion but then increase in incidence. The incidence of central venous catheter–related bloodstream infections ranges from 0.3 to 30 per 1000 catheter-days and are most often caused by *Staphylococcus epidermidis* or *Staphylococcus aureus* or *Candida* species. Mortality attributed to catheter-related infections is as high as 25%. A major part of TPN care is aimed at reducing infections. Therefore, solutions are prepared under laminar flow hoods. Once they are prepared, nothing may be added to the solution, they must be refrigerated until use, any manipulation of the catheter or line must be performed using sterile procedures, manipulation of the line should be kept to a minimum, and the site must be examined regularly for signs of erythema and infection.

Inserting nasoenteric tubes for enteral nutrition can result in complications because such tubes can enter the pulmonary airways, can coil and knot in the stomach, and fail to enter the stomach and thus remain in the esophagus. Therefore, it is vital to confirm the feeding tube location with chest and/or abdominal radiographs before starting the feeding. Nasoenteric tubes can be withdrawn into the stomach (in case of jejunal feeding) or the esophagus, increasing the risk for aspiration. Such tube misplacement occurs because of patients pulling on the tube and during suctioning of the mouth. Therefore, the tube should be securely fastened to the nose and if any dislodgment is suspected, a radiograph should be obtained. The major problem with enteral nutrition is frequent decreases or discontinuations of the intake, which prevent administering of all the daily caloric requirements. These decreases and discontinuations have been ascribed to high gastric residuals, mechanical problems with the feeding tubes (e.g., dislodgment into the esophagus and obstruction), medical or surgical procedures, sepsis, and vomiting. As many as a third of patients receiving enteral nutrition are unable to achieve a target intake of 25 kcal/kg/day. Therefore, it is important to closely monitor the actual enteral nutrition intake so that measures can be taken to ensure adequate caloric intake. These include establishing more secure access to obviate or prevent tube dislodgment (e.g., placing a PEG) and placing the tube tip distal to the ligament of Treitz to avoid gastric residuals. In cases in which the enteral intake remains inadequate, supplementing with parenteral nutrients should be considered.[173] A cumulative caloric debt may occur in patients not fed early and adequately. Therefore, it is important to monitor caloric intake and try to avoid caloric deficits.[153]

In general, surgically placed needle jejunostomies provide safe and effective access for postoperative enteral feeding. However, complications may occur, including tube dislodgment, local cellulitis, and obstruction. Obstruction can be avoided by frequent flushing and limiting the viscosity of the feeds. Major complications were seen in 4% of 220 trauma patients who had jejunostomies placed during laparotomy. These complications included small bowel perforations, small bowel volvuli with infarction, intraperitoneal leaks, and small bowel necrosis.[174,175] Small bowel necrosis has a mortality rate approaching 100%.[176] These complications occurred more often with larger diameter tubes than needle jejunostomies.[174] Others have reported intra-abdominal and subcutaneous abscesses and small bowel obstruction. Other complications include catheters breaking especially at the hub and jejunocutaneous fistulas on removal.

Metabolic Complications

Nutrition support should be initiated slowly and increased only if the patient tolerates the feeding. Because metabolic complications of nutritional support occur frequently, it is important to monitor electrolytes and glucose daily in acutely ill patients, particularly when starting the nutrition. If necessary, adjustments should be made in the formulation. Hyperglycemia is a common problem, especially with severe stress, steroid use, and diabetes mellitus requiring treatment with insulin. It is preferable to administer insulin than to reduce the glucose intake unless there is excessive hyperglycemia (>250 mg/dL) despite high insulin doses. Insulin treatment can reduce serum potassium and phosphate concentrations, which require repletion. Importantly, as the stress response abates, the degree of glucose intolerance lessens and insulin requirements drop. Therefore, it is imperative to monitor blood glucose closely to prevent hypoglycemia.

Hypoglycemia can occur on the abrupt discontinuation of continuous feedings containing significant amounts of carbohydrate. Continuous feedings result in high blood insulin concentrations so that hypoglycemia intervenes when the carbohydrate intake stops. Therefore, when stopping continuous parenteral and enteral nutrition, any concomitant insulin infusion must be stopped, intravenous glucose should be infused, and blood glucose monitored frequently. The practice of using TPN solutions containing lower glucose:lipid ratios (70:30 to 50:50) has reduced the incidence of hypoglycemia after abrupt discontinuation. TPN should be continued during surgery, whereas enteral nutrition should be discontinued 8 hours before surgery and a glucose infusion begun to prevent hypoglycemia.

Refeeding

Refeeding nutritionally depleted patients (≥10% loss of body weight over ≤6 months) must be done carefully so as not to overload a metabolic system that has adapted to minimal or no food intake. Feeding such patients must begin with balanced diets of carbohydrates, fats, and proteins at intakes below REE. The intake should be increased stepwise over a week to 10 days. Intake must be monitored to prevent overindulgence because these patients may be hyperphagic. Patients must be monitored for signs of fluid overload, pulmonary edema, and electrolyte disturbances. Hypophosphatemia occurs when tissues begin to rebuild and is especially problematic if inadequate phosphate intake is provided ("the refeeding syndrome"). Hypophosphatemia may lead to major muscle (including respiratory muscle) weakness and glucose intolerance because phosphate is a vital component of tissue membranes, enzymes, and nucleosides, especially ATP. Concurrent hypomagnesemia, hypocalcemia, and hypokalemia may exacerbate the muscle weakness. Thirty-four percent of 62 patients who had not received nutritional intake for at least 48 hours after ICU admission developed hypophosphatemia (serum levels < 0.65 mmol/L or a drop of 0.16 mmol/L) on refeeding. Chronic alcoholics are especially prone to hypophosphatemia.

Nitrogen balance may take a while to turn positive because of the need to gradually increase protein intake and because glu-

coneogenesis continues for some time after the beginning of refeeding. Generally, nutritionally depleted individuals efficiently replete fat and glycogen stores and rebuild muscle tissue. To rebuild muscles requires exercise so that it is virtually impossible to rebuild the muscles of bedridden or immobile patients.

Overfeeding

Overfeeding stressed patients has many consequences (Table 95-5).

Table 95-5 Consequences of Overfeeding in Parenteral and Enteral Nutrition

Caloric Intake	Substrate in excess of energy needs and synthetic function
>1.5-1.7 REE in stressed patients	Increased fat storage, CO_2 production, urea production and thermogenic effects
Carbohydrates	
>4.5 mg/kg/min	*Lungs:* Increased CO_2 production leads to: Increased $\dot{V}_E$, which may lead to breathlessness. If increase in $\dot{V}_E$ insufficient, then increased $Paco_2$. *Liver:* Fatty liver: increased AST, ALT, and alkaline phosphatase, hepatomegaly *Hyperglycemia*: may lead to osmotic diuresis and prerenal azotemia *Increased intracellular potassium*: decreased serum potassium *Increased intracellular phosphate*: decreased serum phosphate *Increased REE* due to increased thermogenesis caused by increased catecholamine secretions
Lipids	
>2 g/kg/day	*Liver:* cholestasis, fatty liver *Increased congestion of RES with fat* *Increased serum triglycerides*
Protein	
>2 g/kg/day	*Kidneys:* Increased ureagenesis With decreased renal function BUN increases. With normal renal function, diuresis may occur due to increased BUN secretion. This may lead to prerenal azotemia. *Lungs:* Amino acids/proteins increase respiratory drive and might cause breathlessness.
Fluid Intake	If excessive may lead to fluid overload; is especially problematic with reduced cardiac or renal function.

AST, aspartate aminotransferase; ALT, alanine aminotransferase; REE, resting energy expenditure RES; reticuloendothelial system; BUN, blood urea nitrogen; $\dot{V}_E$, minute ventilation.

Gastrointestinal System Complications

Parenteral nutrition is associated with hepatobiliary complications whose causes are often multifactorial. Factors related to their development include underlying diseases and their severity, intercurrent sepsis, and drugs. The role of TPN may be additive, if not primary. Large glucose loads (>4 mg/kg/min) can result in hepatic steatosis and steatohepatitis with "portal triaditis" on biopsy. The latter is accompanied by elevations in γ-glutamyl transpeptidase, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase. Intrahepatic cholestasis with elevated alkaline phosphatase and bilirubin may occur 3 to 6 weeks after TPN is started. Large lipid loads (≥2 g/day) administered for prolonged periods may also cause cholestasis.

Enteral nutrition is frequently associated with gastrointestinal tract dysfunction. There is delayed gastric emptying in about 50% of mechanically ventilated patients. Therefore, feeds are usually administered continuously and gastric residuals are measured at frequent intervals. Among patients fed intragastrically, gastric residuals, vomiting, and regurgitation occur more frequently than among those being fed into the small intestines. In a multicenter prospective study of 400 ICU patients fed mainly via nasogastric tubes, gastrointestinal complications occurred in 62.8% and were due to diarrhea (14.7%), constipation (15.7%), high gastric residuals (39%), abdominal distention (13.2%), vomiting (12.2%), and regurgitation (5.5%). Enteral nutrition was withdrawn in 15% of patients because of gastrointestinal complications.[176] With gastroparesis and large volume (150-220 mL) residuals, prokinetic agents (e.g., metoclopramide) should be considered. In a randomized study, intravenous erythromycin was more effective than metoclopramide (improvement 87% versus 62%) but the effectiveness of both treatments declined over time. Rescue therapy using both drugs was effective.[177] To decrease aspiration, patients should be fed in the semi-recumbent position and promotility agents used if residual gastric volumes are high. It is yet unclear whether postpyloric feeding reduces aspiration.[152] With enteral nutrition it is important to be aware that drug-nutrient interactions can occur.

Diarrhea is a particularly unpleasant (for patient and staff) complication of enteral nutrition. Its reported incidence, depending on its definition, ranges from 2% to 53% of patients and 38% of feeding-days. The definition of diarrhea used is important because many enteral products are "low residual," that is, they do not contain fiber and may not cause formed stools. Formula-related causes of diarrhea include hyperosmolar feedings, too rapid administration, and contamination of feedings with toxigenic or pathogenic organisms. Therefore, feeds should be sterile and not be allowed to hang for more than 8 hours. Non–formula-related causes include concomitant administration of drugs constituted in sorbitol elixirs, mannitol, or polyethylene glycol; *Clostridium difficile* enterocolitis; intra-abdominal infection; receipt of broad-spectrum antibiotics; and hypoalbuminemia. Hypoalbuminemia-associated diarrhea has been attributed to small bowel wall edema, leading to malabsorption. Yet, diarrhea-free feeding has been achieved in hypoalbuminemic patients by using elemental and peptide diets. Fiber-containing formulations might reduce diarrhea, but not consistently.[178] Most enteral formulas are lactose free, eliminating lactose intolerance as a problem. In patients without infectious diarrhea, pectin and anti-motility drugs may reduce the diarrhea. However, such patients must be monitored for the development

of constipation. Hepatobiliary complications of enteral nutrition are rare (<5%).

Special Considerations

Burns

Burn patients present special problems because of their very high energy expenditures, transcutaneous losses of protein, and great fluid requirements. If patients are unable to eat, enteral nutrition is the preferred modality. A number of trials indicate that enteral nutrition started within a few hours of admission reduces the magnitude of the stress response to burns. Therefore, it is common practice with significant burns (>20%) to begin nutrition early, that is, within less than 16 hours of admission. However, on systemic review there was insufficient evidence to show the advantage of early versus late enteral nutrition or that enteral nutrition reduces the stress response.[179] To ensure successful administration of many calories of a high-protein diet, nasoenteric feeding tubes should be placed into the jejunum. Caloric intake must be closely monitored in burn patients. If inadequate calories are being ingested, then supplementation is needed. In patients who are eating, this may be in the form of nutritional supplements ingested between meals. In enterally fed patients, supplementation can be provided with parenteral nutrition.

Hepatic Dysfunction

Hepatic dysfunction, especially cirrhosis, with intercurrent acute illness presents a complex metabolic scenario (see Chapters 66 and 67). Patients with cirrhosis are frequently nutritionally depleted secondary to anorexia, large loses of protein into ascites, and hypermetabolism. They have hyperinsulinemia, insulin resistance, accelerated gluconeogenesis, increased lipid oxidation, and, possibly, reduced glycogenesis. Essential fatty acid, zinc, and selenium deficiencies also occur. After liver transplantation, glucose clearance improves owing to correction of the hyperinsulinemia and insulin resistance. However, patients receiving corticosteroids as part of their immunosuppressive therapy continue to have abnormal glucose metabolism.

Because of their depleted state, cirrhotic patients would appear to be candidates for nutritional repletion. Yet, because of their poor prognosis, especially when complicated by serious illness, enteral nutritional support of seriously ill hospitalized cirrhotic patients was associated with reduced survival. However, the success of liver transplantation renewed interest in nutritionally supporting transplant candidates. These patients require fluid and sodium restriction and diuretics to control their fluid overload. They need increased protein/amino acid intakes (1.2-1.5 g/kg/day) to replace the losses due to ascites formation and high caloric intake to account for hypermetabolism (25-40 kcal/day).[180] Some cirrhotic patients develop hepatic encephalopathy, which limits protein intake. If patients develop encephalopathy while receiving a standard protein intake of 0.8 g/day plus lactulose, then branched-chain amino acid–enriched solutions and feedings should be considered. In cirrhosis, the plasma concentrations of these amino acids are low. Furthermore, they are not metabolized in the liver so are available for protein synthesis. When administered intravenously they are thought to counter the effects of intracerebral aromatic amino acids, which are involved in hepatic encephalopathy.[181] A Cochrane review showed a decreased rate of hepatic encephalopathy without reduction in mortality rate or adverse events.[182]

Renal Dysfunction

Preexisting chronic renal disease and newly developed acute renal failure present special nutritional challenges (see Chapters 65 to 67). Acute renal failure is especially problematic in the surgical arena because of its association with shock and sepsis. Such patients are insulin resistant, catabolic, and hypermetabolic, like other stressed patients. However, uremia exacerbates catabolism because it exacerbates insulin resistance, metabolic acidosis, and circulating proteases. The kidney interconverts various amino acids and also degrades specific peptides so that there also are major abnormalities in protein/amino acid handling. Cytokines liberated during hemodialysis may further aggravate the catabolic state. Renal failure patients are intolerant of large fluid loads, especially when oliguric, are unable to self-regulate electrolyte concentrations, and are unable to tolerate large protein/amino acid loads because of an inability to excrete urea. Because these patients require about 30 kcal/kg/day and 1.0 to 1.5 g/kg/day of protein, frequent dialysis is needed to remove wastes and excess fluid. The protein/amino acid intake may need to be increased because of dialysis-related loss of amino acids. In the past, essential amino acid–enriched solutions were used to reduce the urea production. However, current recommendations are to provide a combination of essential and nonessential amino acids based on the theory that normally nonessential amino acids may become essential in diseased states.[183]

Hemodialysis, continuous venovenous (and arteriovenous) hemodiafiltration (CVVHD), and peritoneal dialysis facilitate enteral nutrition and parenteral nutrition by removing excess fluid and urea, as well as balancing electrolyte concentrations, thus permitting patients to receive a full complement of calories and amino acids/protein. However, these therapies result in the loss of amino acids (10-15 g/d) unrelated to amino acid intake but related to plasma amino acid concentrations, volume of dialysate effluent, and filter efficiency. The concentrations of most amino acids are equal in plasma and dialysate. Therefore, the amino acid/protein content of the nutritional support should be increased. With aggressive CVVHD, patients required as much as 2.5 g/kg/day of protein to achieve positive nitrogen balance.[184] Dialysis also results in losses of peptides, proteins (with peritoneal dialysis), and water-soluble vitamins. Therefore, some renal enteral nutrition formulations have added B vitamins.

Peritoneal dialysis and CVVHD solutions usually contain 1.5% glucose, although concentrations as high as 4.25% are used. Up to 35% to 45% of this glucose can be absorbed and is a source of carbohydrate calories. With peritoneal dialysis, as much as 500 g/day of dextrose may be absorbed. Similarly, glucose-containing solutions used as replacement solutions during hemofiltration can be a source of glucose calories, in one study providing 300 g/day of glucose. This glucose load must be considered when

designing nutritional regimens and glucose/carbohydrate contents reduced accordingly. Additionally, glucose concentrations need to be monitored because of both the profound stress state and dialysis-associated glucose absorption. Insulin therapy may be needed to reduce the hyperglycemia. However, renal failure patients may be especially sensitive to insulin.

Generally, nutritional regimens for renal failure patients should not contain phosphate, potassium, or magnesium because concentrations of these electrolytes are already elevated. Calcium intake may need to be increased, whereas sodium content should be nearly isotonic because of an inability to regulate serum sodium concentrations. During dialysis, serum electrolytes must be closely monitored and deficiencies corrected as indicated.

Pancreatitis

Traditional treatment of acute pancreatitis and of acute exacerbations of chronic pancreatitis is to exclude all oral intake, institute nasogastric suction, and deliver all nutritional support parenterally. However, contemporary practice is to begin enteral nutrition early (within 48-72 hours) in the course of the disease. A meta-analysis of seven trials showed that compared with TPN, enteral nutrition is associated with less infectious morbidity, shorter hospital lengths of stay, and less organ failure, with no effect on mortality.[185] In addition, another meta-analysis reported that compared with TPN, enteral nutrition caused less hyperglycemia and reduced insulin requirements in acute pancreatitis.[186] Therefore, enteral nutrition is the preferred route of nutritional support in patients with acute pancreatitis and TPN should be used only when enteral nutrition is not tolerated.[187]

Conclusion

A key question is whether nutritional support improves patient outcome, that is, whether it lowers mortality and mobility and reduces ICU and hospital lengths of stay. Although no definitive large prospective multicenter studies have examined this issue, a few meta-analyses and large studies examined selected aspects of nutritional support. Some studies concluded that starting enteral nutrition within 3 days of ICU admission reduces the duration of mechanical ventilation and improves outcome and is superior to parenteral nutrition. A meta-analysis of 13 studies in critically ill patients showed lower infectious complications with enteral nutrition versus parenteral nutrition, but no difference in mortality.[188] However, more recent meta-analyses suggest that the benefits of enteral nutrition may not be so pronounced and that TPN actually improves survival when compared with delayed (>5 days) enteral nutrition despite a higher infection rate among patients receiving TPN.[189,190] The recent evidence for equal or better survival with TPN versus early enteral nutrition might be due to better glucose control and the ability to reach caloric goals more readily with TPN.[189] This is in contradistinction to an earlier meta-analysis that examined the relationship between TPN and standard care (usual oral diet plus intravenous dextrose) where TPN had no effect on mortality but lowered complication rates in malnourished patients.[191] Complication rates, but not mortality, were lower among patients who did not receive intravenous lipids. Another meta-analysis of 27 randomized trials in surgical patients showed that TPN did not affect mortality and possibly reduced complication rates.[192] This and other analyses did not show any detrimental effects of intravenously administered lipids.[162,192] The five-center prospective SUPPORT study of 6298 seriously ill patients showed that nutritional support was not associated with improved survival in any group (COPD, acute respiratory failure, multiple system organ failure, cirrhosis) except those in coma.[193] Moreover, a systematic review of 11 trials showed better outcomes in terms of survival and disability in head-injured patients fed early versus late (enteral nutrition or TPN) after the injury.[194] Delayed feeding was associated with poorer outcomes and the advantages of TPN disappear when feeding was delayed. Contemporary practice is to begin enteral nutrition (when not contraindicated) within 1 to 3 days of ICU admission while monitoring caloric intake and institute TPN if the enteral nutritional caloric intake is insufficient. However, beginning TPN early to provide sufficient calories while simultaneously beginning enteral nutrition is also supported by evidence.[195]

Caring for surgical and critically ill patients requires that clinicians consider the consequences of the metabolic and inflammatory responses to injury and sepsis. This translates into practical actions such as modulating the response itself (e.g., with epidural anesthesia), modifying end-organ responses (e.g., β-adrenergic blockade), and treating its consequences (e.g., blood glucose control, nutritional support). The aims of these interventions are to improve patient outcome by decreasing the deleterious (e.g., increased nitric oxide production) effects of the response without reducing its beneficial (e.g., immune enhancing) actions. Yet, further basic and clinical research is needed to further examine the stress response and its modulation. This will involve using system biology incorporating genomic, transcriptomic (mRNA), proteomic, and metabolomic information to better understand the complexity of this response. The importance of genomics is underlined by research that reveals that the secretion of cytokines and end-organ responses due to activation of Toll-like receptors during sepsis differ depending on an individual's genetics.[196] Similarly, gender plays a role in the response. For example, young girls with burns have less hypermetabolism and higher anabolic hormone concentrations than boys, whereas healthy adult women appear to have lower susceptibility to sepsis than men, possibly because of more pronounced proinflammatory innate immunity and a lesser decrease in norepinephrine sensitivity when exposed to endotoxin.[197] Therefore, future clinical approaches to stressful situations could involve genetic and proteomic screening (e.g., with microarrays) to better tailor treatment.

96 Renal Replacement Therapies

Key Points

1. The removal of sodium and water cannot be dissociated when using diuretics or in certain renal replacement techniques. Diuretics lead to a natriuresis, whereas dialysis may result in hypotonia or hypertonia, depending on the effect of dialysis on the diffusion and on the removal of molecules, including urea and other electrolytes.
2. Slow continuous ultrafiltration (SCUF) produces an ultrafiltration (UF) that varies from plasma water minimally due to Donnan effects. The UF from SCUF is iso-osmotic and isonatremic because sodium elimination is linked to the sodium concentration in plasma.
3. The ultrafiltrate composition produced from continuous venovenous hemofiltration (CVVH) and from hemofiltration in general is similar to plasma water, but the sodium concentration in the UF can be significantly affected by the sodium concentration in the replacement solution.
4. Sodium removal can be dissociated from water removal in CVVH, thus obtaining a real change of the sodium pool in the body. This effect on sodium cannot be achieved with any other technique.
5. The best evidence to date supports a renal replacement therapy dose of at least 35 mL/kg/hr—spKt/V 1.4—for CVVH, continuous venovenous hemodiafiltration (CVVHDF), or daily intermittent hemodialysis (IHD).
6. There is evidence that, when the circuit set-up is perfectly optimized, anticoagulants are only a relatively minor component of circuit patency: in fact, when patients have bleeding disorders (i.e., prolonged clotting times, thrombocytopenia), renal replacement therapy can be safely performed without the utilization of any anticoagulant.
7. The UNLOAD trial is the first randomized comparison of intravenous diuretic therapy alone against an alternative therapy, ultrafiltration, in hypervolemic patients. The principal findings of this trial were (a) in hypervolemic patients with congestive heart failure (CHF), ultrafiltration led to greater weight and fluid loss than intravenous diuretics at the doses used in this trial; (b) volume removal with ultrafiltration at the index hospitalization was associated with significant reductions in the rate and durations of subsequent hospitalizations and fewer unscheduled medical visits for CHF; and (c) the benefits from the short-term use of ultrafiltration over 90 days was achieved without significant adverse effects.
8. It is now possible to generate ultrapure replacement fluid and administer it in the intensive care unit (ICU) with a lower cost than continuous renal replacement therapy (CRRT), in greater amounts and for shorter periods of time. The choices are now almost limitless; 3 or 4 hours of IHD with standard settings or CRRT at 35 mL/kg/hr of effluent flow rate can be selected. Slow low-efficiency extended daily dialysis (SLEDD) at blood and dialysate flow rates of 150 mL/min for 8 hours during the day or SLEDD for 12 hours overnight can be considered as an alternative.

Acute kidney injury (AKI) is a complex disorder without a clear-cut, universally accepted definition.[1,2] Renal replacement therapy (RRT) is the fundamental part of AKI management. Although there are a number of different strategies of extracorporeal renal support that are available, a definite standard has not been defined and there is no evidence regarding the superiority of one technique over another in obtaining superior efficacy or outcomes. The best time to initiate and stop RRT is controversial. In this chapter we review AKI and provide theoretical and practical bases for RRT prescription with the goal of helping anesthesiologists and intensive care unit (ICU) clinicians to understand critical care nephrology.

Epidemiology of Acute Kidney Injury

A recent multinational, multicenter, prospective, epidemiologic survey of AKI was conducted in ICU patients[3] who were either

treated with RRT or fulfilled at least one predefined criteria for AKI, either oliguria (urine output < 200 mL/12 hr) or marked azotemia (blood urea nitrogen [BUN] level > 30 mmol/L). The data were collected at 54 hospitals in 23 countries. Of 29,269 critically ill patients admitted during the study period, 1,738 (5.7%) had AKI during their ICU stay, including 1,260 (4.3%) who were treated with RRT. Overall hospital mortality was 60.3%. The most common contributing factor to AKI was septic shock (47.5%). Approximately 30% of patients had preadmission renal dysfunction. At hospital discharge, 86.2% survivors were independent from dialysis. Independent risk factors for hospital mortality included the use of vasopressors, mechanical ventilation, septic shock, cardiogenic shock, and hepatorenal syndrome.

Crude mortality assessment shows that the overall hospital outcome of patients with AKI has remained high, and it has not changed in the past 30 years. The explanation for this finding is that patients with AKI 30 years ago were mostly treated outside the ICU and did not require or receive mechanical ventilation or vasopressor drugs, and they were 20 to 30 years younger. Their outcomes were typically assessed retrospectively, and these patients were only in academic centers. More recent data document that patients have much higher scores for severity of illnesses and yet the mortality of AKI has not increased and may have even decreased slightly. Also, the duration of treatment has clearly decreased in terms of need for dialysis, length of stay in the ICU, and length of stay in the hospital. The techniques for artificial renal support have also changed markedly.[4] Despite these advances, there remains a 50% to 60% crude mortality rate associated with AKI, suggesting that the present therapy is still inadequate.

In modern health care systems, patients with AKI are able to obtain acute RRT. It has been estimated that the incidence of AKI needing extracorporeal support is approximately 11 per 100,000 population/year. The annual mortality rate is 7.3 per 100,000 patients, with the highest rates in males older than age 65 years. Renal recovery occurs in 78% (68/87) of survivors at 1 year; although a great number of patients with severe AKI will die, most survivors will become independent from RRT within a year.[5] The increasing number of acute dialytic treatments in the ICU has led to the development of a new specialized branch of nephrology in the past 10 years: critical care nephrology. AKI requires a multidisciplinary approach with intensivists and nephrologists sharing their respective knowledge. Fluid balance, vasopressor dosage, mechanical ventilation support, and arterial blood gas exchange including Pao_2/Fio_2 ratio need to be linked to RRT prescription, dialysis dose, ultrafiltration (UF) requirement, and anticoagulation strategy The theoretical and technical aspects of critical care nephrology are also necessary parts of an intensivist's curriculum.

History of Renal Replacement Therapy

From the initial description of continuous arteriovenous hemofiltration (CAVH) in 1977 by Peter Kramer and colleagues,[6] RRT has progressively evolved in the ICU from a therapy of desperation for AKI to a standardized, widely used, fully independent form of artificial kidney support in critically ill patients. Older CAVH machines had the blood flow depend on the patient's spontaneous arteriovenous pressure gradient. Therefore, the UF was totally dependent on the generated transmembrane pressure (TMP) gradient. If a patient had a low mean arterial pressure or the intrinsic resistance of the circuit was elevated, there was very little UF formed. Nonetheless, often CAVH provided a very slow, continuous fluid removal and did maintain a steady solute concentration so that there were no peaks of waste products. The increased utilization of CAVH led to fully staffed, independent teams that functioned in ICUs without the usual staff of dialysis units.

CAVH was useful in that it did not generate the same problems associated with hemodialysis, including hypotension, rapid fluid shifts, increased cerebral edema, or rapid reductions in plasma osmolality. However, the limitations of CAVH included the requirement for both arterial and venous access. Solute clearance in CAVH is limited by the low UF rates and the pure convective nature of this treatment. Thus, the patients with the lowest mean arterial pressures would have the lowest clearances and early clotting of the circuit. CAVH can maximally achieve approximately 20 mL/min of clearance, which is insufficient to meet the needs of severely catabolic patients.

To overcome these technical limitations associated with CAVH, new filters were designed with increased cross-sectional area and inner hollow fiber diameter that reduced unit length so that there was a lower resistance to blood flow. These improvements optimized the UF that could be achieved with this technique. Highly biocompatible membranes mounted on parallel plate devices were also utilized because they had lower intrinsic resistance (ensuring higher extracorporeal blood flows at a given arteriovenous pressure gradient) and they were equipped with a second port in the filtrate compartment to achieve counter-current dialysis (CAVHD), rather than just convective filtration.

However, the most important innovation was the addition of a peristaltic pump to the extracorporeal circuit. This innovation, the addition of a pump to the CVVH circuit, basically created a dialysis machine in the ICU, without importing the expertise of the dialysis team. Blood flow is now programmed and delivered with reasonable precision. The new continuous venovenous therapies require negative pressure measurement and alarms in the arterial line before the pump, as well as positive-pressure measurements and alarms in the venous return line. A bubble trap is required In the venous return line to prevent air embolism (this was not necessary in CAVH where positive pressure existed in the entire length of the circuit). The higher blood flows induced by the addition of the peristaltic pumps led to higher filtration and higher clearances. It also became necessary to add roller pumps to the fluid replacement section of the circuit, and external scales had to be utilized to provide accurate estimates of fluid balance during treatment. It soon became evident that an ideal extracorporeal circuit should have incorporated continuous pressure measurements of inlet and outlet lumens of the catheter inlet and outlet of the filter and ultrafiltrate and dialysate ports. This information is now integrated with adequate alarms to allow the ICU staff to maintain filter efficiency and circuit patency, to detect potential sources of clotting, and to ensure patient safety.[7]

Other innovations that have helped establish CVVH as the RRT for the ICU is the creation of standardized dialysates for the ICU and double-lumen catheters that can be placed in single

veins, thus decreasing the high rate of complications associated with the placement of large arterial cannulas.

Indications to Start and Stop Renal Replacement Therapies

There is no consensus as to the indications for the initiation of RRT. Some of the indications espoused by various authors include azotemia, anuria, and complications of AKI, including pulmonary edema, severe fluid overload, hyperkalemia, and uncontrolled metabolic acidosis. An algorithm for RRT indication has been suggested (Table 96-1).[8] Unfortunately, once RRT has started there is no generally accepted biochemical or clinical marker that is achieved by the therapy. A routine clinical practice is to "adequately" control fluid balance and to maintain a serum urea concentration below 30 mg/dL, a serum creatinine value below 2 mg/dL, and normal electrolytes values.

Techniques and timing of weaning patients from RRT are poorly described in the literature. We recommend that, when the patient has reached hemodynamic stability or the need for vasopressors has been reduced or the severity of illness has decreased, the need for RRT can be ascertained. This process can be accelerated when urine output increases and fluid balance becomes manageable without RRT.

Techniques and Modalities

All renal replacement therapies consist of blood purification by having the blood flow though semi-permeable membranes. Blood flows into hollow fibers composed by porous biocompatible synthetic materials. A wide range of substances (water, urea, and low- middle-, and high-molecular-weight solutes) allow the blood across such membranes, by diffusion (solutes) and by convection (water and solutes) (Fig. 96-1).

During *diffusion,* solutes move from blood across the membrane in an attempt to reach the same concentration on each side of the membrane; this leads to the passage of solutes from the compartment with the highest concentration to the compartment with the lowest concentration. Other components of the semipermeable membrane that affect the rate of diffusion include the thickness and surface of the membrane, temperature of the blood, and diffusion coefficient. *Dialysis* occurs when a solution flows through a semi-permeable conduit counter current to the blood, allowing maximal solute diffusion, because the solute concentration is lower in the solution than in the blood.

Table 96-1 Indications for Renal Replacement Therapy*

- Anuria-oliguria (diuresis ≤ 200 mL in 12 hr)
- Severe metabolic acidosis (pH < 7.10)
- Hyperazotemia (BUN ≥ 80 mg/dL) or creatinine > 4 mg/dL
- Hyperkalemia (K^+ ≥ 6.5 mEq/L)
- Clinical signs of uremic toxicity
- Severe dysnatremia (Na^+ ≤ 115 or ≥ 160 mEq/L)
- Hyperthermia (temperature > 40°C without response to medical therapy)
- Anasarca or severe fluid overload
- Multiple organ failure with renal dysfunction and/or systemic inflammatory response syndrome, sepsis, or septic shock with renal dysfunction

*The presence of one indication suggests, two indications strongly suggest, and three indications mandate initiation of renal replacement therapy.

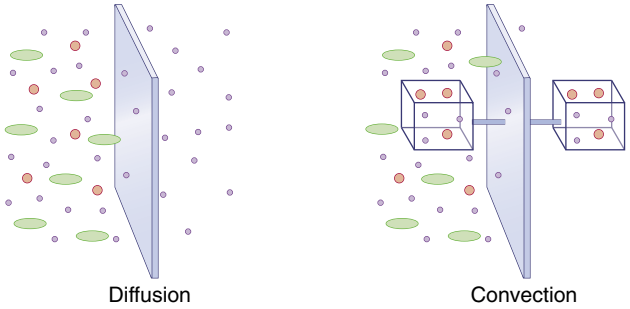

Figure 96-1 Diffusion and convection are schematically represented. During diffusion, solutes flux (Jx) is a function of solutes concentration gradient (dc) between the two sides of the semipermeable membrane, temperature (T), diffusivity coefficient (D), membrane thickness (dx), and surface area (A) according to the following equation:

$$Jx = D \cdot T \cdot A\,(dc/dx)$$

Convective flux of solutes (Jf) requires instead a pressure gradient between the two sides of the membrane (transmembrane pressure [TMP]) that moves a fluid (plasma water) with its "crystalloid" content (a process called ultrafiltration, whose entity is also dependent on membrane permeability coefficient [Kf]). Colloids and cells will not cross the semi-permeable membrane, depending on the size of the pores:

$$Jf = Kf \cdot TMP$$

where TMP = Pb – Pd – π, with Pb, blood hydrostatic pressure, Pd, hydrostatic pressure on ultrafiltrate side of the membrane, and π, blood oncotic pressure.

During *convection,* the movement of solute across a semi-permeable membrane takes place in conjunction with significant amounts of *ultrafiltration* (water transferring across the membrane). In other words, as the solvent (water in plasma) is pushed across the membrane in response to the TMP by UF, solutes are carried with it, as long as the porosity of the membrane allows the molecules to be sieved from blood. The process of UF is governed by the UF rate (Qf), the membrane UF coefficient (Km), and the TMP gradient generated by the pressures on both sides of the hollow fiber, according to the following formula:

$$Qf = Km \cdot TMP$$

The hydrostatic pressure in the blood compartment is dependent on blood flow (Qb). The greater the Qb, the greater the TMP. In modern RRT machines, UF is maximized by applying a pump, which generates control of the UF rate. As blood is processed, the membrane fibers can become soiled, and a negative pressure becomes necessary to maintain a constant Qf. Molecules cleared during convection are physically dragged to the UF side, but this function is seriously limited by a protein layer that progressively develops and closes fiber pores during convective treatments.[9] Membrane capacity, or a defined adsorption, has been shown to have a major role in the clearance of higher-molecular-weight toxins.[10] Membrane adsorptive capacity is generally saturated in the first hours of RRT treatment. Therefore, diffusion and convection are very important for the efficacy of RRT.[11]

As UF proceeds over time, plasma water and solutes are filtered from the blood, hydrostatic pressure within the filter is lost, and oncotic pressure is gained because blood concentrates

and the hematocrit increases. The fraction of plasma water that is removed from blood during UF is called the filtration fraction. The filtration fraction should be kept in the range of 20% to 25% to prevent excessive hemoconcentration within the filtering membrane and to avoid a critical point where oncotic pressure is equal to TMP and where filtration/pressure equilibrium is reached. Finally, replacing plasma water with a substitute solution completes the *hemofiltration* (HF) process and returns the now purified blood to the patient. The replacement fluid can be administered after the filter, with a process called postdilution HF. Otherwise, the solution can be infused before the filter to obtain predilution HF. Although postdilution HF allows a urea clearance equivalent to therapy delivery (i.e., 2000 mL/hr, see later), the administration of the solution before dilution leads to a prolonged circuit lifespan by reducing hemoconcentration and the protein caking effects described earlier. Conventional HF is performed with a highly permeable membrane with a surface area of about 1 m^2, steam sterilized, with a cut-off point of 30 kD. The difference between the volume of ultrafiltered plasma water and reinfused substitution solution gives the net UF, which is the fluid that is eventually removed from the patient. Prescriptions for net UF are based on the individual patient needs and can range from more than 1 L/hr (pulmonary edema in a patient with congestive heart failure who is resistant to diuretics) to zero (sepsis with catabolic state with increased creatinine levels). A net UF rate must be added to dialysis to achieve fluid balance during diffusion that does not allow water movements.

Dose and Prescriptions for Renal Replacement Therapies

Like any other therapy administered in the ICU, dialysis should be administered in an appropriate amount. Nephrologists estimate an appropriate RRT dose by measuring the elimination of a representative marker solute, such as creatinine. This estimate has two major flaws. First, the marker solute cannot and does not represent all the solutes that accumulate during AKI because kinetics and volume of distribution are different for each solute. Therefore, the removal of creatinine during RRT is not necessarily representative of the removal of other solutes. This is true both for patients who have end-stage renal failure and patients with AKI. Nevertheless, despite all of these limitations, a significant body of data[12] suggests that single solute marker assessment of dose of dialysis appears to have a clinically meaningful relationship with patient outcomes and, therefore, is of clinical utility.

During RRT, clearance of creatinine and urea depends on circuit blood flow (Qb), hemofiltration (Qf) or dialysis (Qd) flow, solutes' molecular weights, and hemodialyzer type and size. Qb, as a variable in delivering the RRT, is mainly dependent on vascular access and the operational characteristics of the machines utilized in the ICU. Qf is strictly linked to Qb, during convective techniques, by filtration fraction. Filtration fraction does not limit Qd, but when the Qd/Qb ratio exceeds 0.3 it can be estimated that dialysate will not be completely saturated by blood diffusing solutes. During UF, the driving pressure jams solutes, such as urea and creatinine, against the membrane and into the pores, depending on membrane sieving coefficient (SC) for that molecule. SC expresses a dimensionless value and is estimated by the ratio of the concentration of the solutes in the filtrate divided by that in the plasma water, or blood. An SC of 1.0, as is the case for urea and creatinine, demonstrates complete permeability, and a value of 0 reflects complete rejection. Molecular size over approximately 12 kD and filter porosity are the major determinants of SC. The clearance (K) during convection is measured by the product of Qf times the SC. Thus, differently from diffusion, there is a linear relationship between K and Qf, the SC being the changing variable for different solutes. During diffusion, the linear relationship is lost when Qd exceeds about a third of Qb. As a rough estimate, we can consider that during continuous slow efficiency treatments, RRT dose is a direct expression of Qf or Qd, independently of which solute must be removed from blood.

During continuous treatment in the ICU, the goal is to deliver at a minimum, a urea clearance of 2 L/hr. There is some evidence that 35 mL/kg/hr might be better (i.e., about 2.8 L/hr in a 70-kg patient (see later). Evaluations of chronic dialysis in end-stage renal disease patients have been described by the fractional clearance of a given solute, Kt/V, where K is dialysis clearance, t is the time of dialysis administration, and V is the solute marker volume of distribution. Kt/V is an established marker of adequacy of dialysis for small solutes correlating with medium-term (several years) survival in chronic hemodialysis patients.[13,14] Urea is typically used as a marker molecule in end-stage kidney disease to guide treatment dose, and a Kt/V_{UREA} of at least 1.2 is currently recommended. As an example, we can consider the case of a 70-kg patient who is treated 20 hours per day with a postfilter hemofiltration of 2.8 L/hr at a zero balance: his K_{UREA} will be 47 mL/min (2.8 L/hr = 2800 mL/60 min) because we know that during postfilter hemofiltration ultrafiltered water from plasma will drag all the urea across the membrane, making its clearance identical to UF flow. This treatment time (t) will be 1200 minutes (60 minutes for 20 hours). His urea volume of distribution will be approximately 42,000 mL (60% of 70 kg, 42 L = 42,000 mL), which is roughly equal to total body water. Simplifying our patient's Kt/V_{UREA} we will have $47 \times 1{,}200/42{,}000 = 1.34$.

Application of Kt/V_{UREA} to patients with AKI has not been rigorously validated.[15] In fact, although the application of Kt/V to the assessment of dose in AKI is theoretically intriguing, many concerns have been raised because problems intrinsic to AKI can hinder accuracy. These problems include the lack of a metabolic steady state, uncertainty about the volume of distribution of urea (V_{UREA}), a high protein catabolic rate, labile fluid volumes, and possible residual renal function, which changes dynamically during the course of RRT in the ICU. Finally, hypotension and vasopressors requirements can be responsible for solute disequilibrium within tissues and organs.

These observations highlight the current inadequacies of applying the paradigms utilized in end-stage renal failure patients to patients with AKI in the ICU. They also indicate that, unlike the field of chronic hemodialysis, only major changes in dose (e.g., changing from second daily to daily dialysis) can truly deliver a "different" therapy in the setting of AKI. More subtle adjustments such as prescribing a calculated Kt/V of 1.0 versus 1.2 can easily be criticized as being within the calculation error around each prescription in these patients and not necessarily representing a reliable change in dose delivery.

The therapeutic needs in the patients with AKI that can be or need to be affected by the "dose" of RRT are not only the simple control of small solutes as represented by urea. The features that can be affected include control of acid-base balance, tonicity, potassium, magnesium, calcium, phosphate, intravascular volume,

Table 96-2 Algorithm for Renal Replacement Therapy

Clinical Variables	Operational Variables	Setting
Fluid balance	Net ultrafiltration	A continuous management of negative balance (100-300 mL/hr) is preferred in hemodynamically unstable patients. Complete monitoring (CVC, S-G, arterial line, ECG, pulse oximeter) is recommended.
Adequacy and dose	Clearance/modality	2000-3000 mL/hr (or 35 mL/kg/hr) for CRRT; consider first CVVHDF. If IHD is selected, an every-day/4 hr prescription is recommended. Prescribe a Kt/V > 1.2.
Acid-base	Solution buffer	Bicarbonate-buffered solutions are preferable to lactate-buffered solutions in case of lactic acidosis or hepatic failure or both.
Electrolyte	Dialysate/replacement	Consider solutions without K^+ in case of severe hyperkalemia. Manage accurately with $MgPO_4$.
Timing	Schedule	Early and intense renal replacement therapy is suggested.
Protocol	Staff/machine	Well-trained staff should routinely utilize renal replacement therapy monitors according to predefined institutional protocols.

CVC, central venous catheter; S-G, Swan-Ganz catheter; ECG, electrocardiogram; CRRT, continuous renal replacement therapy; CVVHDF, continuous venovenous hemodiafiltration; IHD, intermittent hemodialysis.

extravascular volume, and temperature and the avoidance of unwanted side effects associated with the delivery of solute control. Examples of these issues include the use of RRT in the setting of coagulopathic bleeding after cardiac surgery or in liver failure. RRT will allow the administration of large volumes of fresh frozen plasma, cryoprecipitate, and platelets to be administered rapidly without inducing fluid overload because 1.0 to 1.5 L of ultrafiltrate is removed in 1 hour. Another example is a patient with right ventricular failure, AKI, and ARDS who is receiving lung-protective ventilation with permissive hypercapnia and has acidemia. RRT will allow acid-base control and normalization of pH 24 hours per day, which will improve lung function and right- and left-sided heart function by maintaining a normal volume status and possibly decreasing pulmonary arterial pressures. Other examples include the use of RRT for potassium control in patients with rhabdomyolysis. Clearly, RRT is utilized for more than clearance of any one solute.

Tables 96-2 and 96-3 show potential flow charts that could be followed each time an RRT prescription is indicated.

Does Receipt of More Dialysis Improve Patient Outcomes?

The hypothesis that higher doses of dialysis may be beneficial in critically ill patients with AKI has been investigated by several authors. Brause and coworkers[16] used continuous venovenous hemofiltration (CVVH) and found that higher Kt/V values (0.8 versus 0.53) correlated with improved uremic control and acid-base balance. No other clinically important outcome was affected by this change. Investigators from the Cleveland Clinic[17] retrospectively evaluated 844 patients with AKI requiring continuous renal replacement therapy (CRRT) or intermittent hemodialysis (IHD) over a 7-year period. They found that when patients were stratified for severity of disease, the dose of dialysis did not affect the outcomes of patients with very high or with very low scores but was associated with improved survival in patients with intermediate degrees of illness. A mean Kt/V greater than 1.0 was associated with increased survival. This study was retrospective

Table 96-3 Example of Possible Prescription for Continuous Treatment in a 70-kg Patient (V_{UREA} = 42 L) during an Ideal Session of 24 Hours (t = 1440 min)

	Estimated Urea Clearance (K_{CALC})*	Notes	Value of Q to Obtain 35 mL/kg/hr	Value of Q to Obtain a Kt/V of 1
CVVH postdilution	K_{CALC} = Qrep	Always keep filtration fraction < 20% (Qb must be 5 times Qrep)	Qrep: 41 mL/min or 2450 mL/hr	Qrep: 29 mL/min or 1750 mL/hr
CVVH predilution	K_{CALC} = Quf/(1 +[Qrep/Qb])	Filtration fraction computation changes (keep < 20%)	For a Qb of 200 mL/min: Qrep: 53 mL/min or 3200 mL/hr	For a Qb of 200 mL/min: Qrep: 35 mL/min or 2100 mL/hr
CVVHD	K_{CALC} = Qdo	Keep Qb at least thrice Qd	Qdo: 41 mL/min or 2450 mL/hr	Qdo: 29 mL/min or 1750 mL/hr
CVVHDF postdilution (50% convective and diffusive K)	K_{CALC} = Qrep + Qdo	Consider both notes of CVVH and CVVHD	Qrep: 20 mL/min + Qdo: 21 mL/min	Qrep: 14 mL/min replacement solution + Qdo: 15 mL/min

*Net ultrafiltration (patient fluid loss) is considered zero in K_{CALC} for simplicity.
Urea volume of distribution: V (L) = patient's body weight (kg) × 0.6.
Estimated fractional clearance: $Kt/V_{CALC} = K_{CALC}$ (mL/min) × prescribed treatment time (min)/V (mL).
35 mL/kg/hr roughly corresponds to a Kt/V of 1.4. A Kt/V of 1 approximately corresponds to 25 mL/kg/hr.
Filtration fraction calculation (postdilution): Qrep/Qb × 100.
Filtration fraction calculation (predilution): Qrep/Qb + Qrep × 100.
Qb, blood flow rate; Qrep, replacement solution flow rate; Quf, ultrafiltration flow rate (Quf: Qrep + Qnet); Qnet, patient's net fluid loss; Qdo, dialysate solution flow rate.

so there was a post-hoc selection bias. The validity of these observations remains controversial.

Daily IHD compared with alternate-day dialysis also seems to be associated with improved outcomes in another recent trial.[18] Daily hemodialysis resulted in significantly improved survival (72% versus 54%, $P = .01$), better control of uremia, fewer hypotensive episodes, and more rapid resolution of AKI. However, several limitations affected this study: sicker, hemodynamically unstable patients were excluded and underwent CRRT instead. Furthermore, it appears that patients receiving conventional IHD were underdialyzed. Finally, second daily dialysis was associated with significant differences in fluid removal and dialysis-associated hypotension, suggesting that other aspects of "dose" beyond solute control (inadequate and episodic volume control) might have explained the findings. These observations suggest that further studies should be undertaken to assess the effect of dose of IHD on outcomes.

In a randomized controlled trial of different doses of CRRT in 425 critically ill patients with AKI, those who either received CVVH at 35 mL/hr/kg or at 45 mL/hr/kg were found to have improved survival compared with the patients who received CVVH at 20 mL/hr/kg.[19] Many technical and/or clinical problems, however, make it difficult to apply the exact protocol utilized in this investigation. A survey of several ICUs worldwide found that very few units deliver this intensive CRRT regimen. Uchino and coworkers found that median unadjusted CRRT dose was 2000 mL/hr and the corrected dose was 20.4 mL/hr/kg. Only 11.7% of patients are being treated with a corrected dose of more than 35 mL/kg/hr.[20]

In a study conducted by Ronco and associates, the technique of CRRT was CVVH with postdilution, whereas current practice includes other techniques, including continuous venovenous hemodialysis (CVVHD) and continuous venovenous hemodiafiltration (CVVHDF). Also, Ronco and associates' study was conducted over 6 years in a single center, uremic control was not reported, the study was unblinded, and the incidence of sepsis was low compared with other incidences in the literature.[3] Therefore, confirmatory studies are needed.

Another prospective randomized trial conducted by Bouman and colleagues[21] assigned patients to three different groups: early high volume hemofiltration (72 to 96 L/24 hr), early low volume hemofiltration (24 to 36 L/24 hr), and late low volume hemofiltration (24 to 36 L/24 hr). These investigators found no difference in terms of renal recovery or 28-day mortality. Unfortunately, prescribed doses were not standardized by weight, making the potential variability in RRT dose large. Furthermore, the number of patients studied was small, making the study insufficiently powered. Finally, the incidence of sepsis in the patients studied was low compared with other populations with AKI.

Recently, Saudan and coworkers[22] enrolled 371 patients with AKI (102 to CVVH and 104 to CVVHDF) and prescribed 25 mL/hr/kg UF in the CVVH group and 24 mL/hr/kg in the CVVHDF group. Patients receiving CVVHDF were prescribed an adjunctive mean dialysis dose of 18 mL/hr/kg. The CVVHDF patients had significant reductions in their creatinine and urea within 48 hr of the initiation of continuous RRT compared with the patients who received CVVH alone (50% versus 40%, $P < .009$ and 46% versus 38%, $P < 0.014$, respectively). Survival rates at 28 days and at 90 days were higher in the patients who had received CVVHDF than in the patients who received CVVH. Criticisms include that the study was underpowered. Also, the investigators compared a modality with dialysis to one without dialysis. Nevertheless, pooled results from the last four studies[19-22] seem to indicate a significant effect on survival in patients who receive more dialysis.[23] Although these data may still not be definitive, the best evidence to date supports the use of a minimum of 35 mL/hr/kg for CVVH, CVVHDF, or 1.2 Kt/V daily IHD.

Treatment interruptions due to patient need for surgery or other diagnostic procedures affect the results of CRRT. In a prospective observational trial,[24] it was shown that "down" time (amount of hours spent off an active treatment) adversely affected control of azotemia. There was a significant correlation between down time and creatinine concentrations ($P < .0001$). According to these authors, the down time should be less than 8 hours per day to maintain creatinine and urea concentrations (2 L/hr of UF). For example, if one prescribed a UF rate of 35 mL/hr/kg, only 23 mL/hr/kg would actually be delivered when there was a down time of 8 hr/day.

Evanson and coworkers[25] found other factors that diminished IHD administration, including high patient weights, male sex, and low blood flow, limited IHD administration and that about 70% of dialysis delivered a Kt/V of less than 1.2. A retrospective study by Venkatarman and associates[26] also showed that patients receive only 67% of prescribed CRRT therapy due to all these factors. Of note, in the CVVH dose trial,[19] only patients who achieved more than 85% of the prescribed dose were included in the analysis. To obtain this goal, compensation for interruptions in CRRT treatments due to ICU procedures were made by increasing effluent flow rates in the subsequent hours. A recent observational trial, where the CRRT prescribed/delivered ratio was monitored, an average 10.7% ($P < .05$) reduction of therapy delivery was found when compared with the prescribed dose.[15] This delivery reduction was sometimes due to the estimation error brought by the use of dose calculator software but more often was due to the short operative treatment time. Therefore, if at all possible, interruptions in CRRT should be minimized.

Continuous Versus Intermittent CRRT

When the critical parameter of dialysis efficacy is metabolic control, an acceptable mean BUN concentration of 60 mg/dL can be reached only after days of 2 L/hr CVVH in a 100-kg patient. Computer-based simulation documents that this goal is difficult to achieve even with intensive IHD regimens.[27] In the Surviving Sepsis Campaign guidelines for management of severe sepsis and septic shock,[28] it is suggested that based on the present scientific evidence continuous RRT is equivalent to IHD for treatment of AKI. In a large comparative trial randomizing 166 critically ill patients with AKI to either CRRT or IHD,[29] the authors found that the CRRT population, despite randomization, had significantly greater severity of illness scores. This could in part explain why, despite better control of azotemia and a greater likelihood of achieving the desired fluid balance, patients receiving the CRRT had an increased mortality. Vinsonneau and colleagues[30] recently conducted a large, prospective, randomized multicenter study in 21 ICUs over a 3.5-year period. The primary end point was the 60-day mortality after the randomization of 360 patients with ARF to either CVVHDF or IHD in centers that were familiar with both techniques. The eligibility criteria changed after 8 months owing to the poor recruitment rate. No difference in 28-, 60- (CVVHDF 33%; IHD 32%), or 90-day mortality rates was

found between the two groups. The study was well conducted, and, at the moment, it is the best example of a randomized controlled study comparing effectively the two techniques. Nonetheless, the study was started more than 7 years ago, during which time the practices in both CVVHDF and IHD have changed considerably. As stated by Vinsonneau and colleagues, this may have led to changes in investigator practices during the study period, particularly with respect to the delivered dose of renal support. This possibility, however, is hard to ascertain given that the investigators, by protocol, started therapy with "initial standardized settings" and then adapted these settings to meet individual patient requirements to obtain the metabolic control objectives. Interestingly, the mortality decreased in the IHD arm of the study over the time of recruitment, which reflected a change in practice toward an increased dialysis prescription. Given the lack of control regarding the dosage in both arms of the study, definitive conclusions cannot be made. As remarked in the accompanying editorial,[31] the question of which treatment is better is influenced by the nature of the task. CRRT might be better in terms of total water and solute removal over 24 hours and for hemodynamically unstable patients, but IHD can remove much more water and solute per hour and does not require continuous anticoagulation or complete patient immobilization.

Other investigators have drawn similar conclusions.[32,33] Over the past 2 decades, technical advances in the delivery of IHD have dramatically decreased the propensity of IHD to cause intradialytic hypotension. These advances include the introduction of volume-controlled dialysis machines, the routine use of biocompatible synthetic dialysis membranes, the use of bicarbonate-based dialysate, and the delivery of higher doses of dialysis. Schortgen and coworkers demonstrated that there was a lower rate of hemodynamic instability and better outcomes after implementation of a clinical practice algorithm designed to improve hemodynamic tolerance to IHD.[34] Recommendations included priming the dialysis circuit with isotonic saline, setting dialysate sodium concentration at above 145 mmol/L, discontinuing vasodilator therapy, and setting dialysate temperature to below 37°C. These changes may have made IHD as good if not better than forms of CRRT.

Randomizing patients to receive one therapy or the other regardless of the conditions might yield results that are difficult to generalize to clinical practice. About 10 years ago, a similar passionate debate on ventilation weaning strategies (pressure support ventilation versus T-piece spontaneous ventilation versus continuous pressure airway pressure versus synchronized intermittent mandatory ventilation) was ongoing. The scientific community finally agreed that it is difficult to select one method over the other and that the *manner* in which the mode of weaning is applied may have a greater effect on the likelihood of weaning than the *mode* itself.[35]

Hybrid techniques are now available. These include slow low-efficiency extended daily dialysis (SLEDD),[36] prolonged daily intermittent RRT (PDIRRT),[37] extended daily dialysis (EDD),[38] or simply extended dialysis,[39] depending on variations in schedule and type of solute removal (convective or diffusive). These therapies were developed to offer the best aspects of both CRRT and IHD, including efficient solute removal with minimum solute disequilibrium, reduced UF rate with hemodynamic stability, optimized delivered to prescribed ratio, low anticoagulant needs, diminished cost of therapy delivery, efficiency of resource use, and improved patient mobility. Initial case reports have shown that these hybrid approaches are feasible and they do have high clearances. A single short-term single center trial compared these hybrid therapies to CRRT and showed that the dose delivery and hemodynamic stability were acceptable.[39] Recently, Baldwin and coworkers randomized 16 patients to 3 consecutive days of treatment with either CVVH (8 patients) or extended daily dialysis with filtration (EDDf) (8 patients) and compared small solute, electrolyte, and acid-base control.[40] They did not find a significant difference between these two techniques in urea or creatinine concentrations over 3 days. All electrolyte derangements before treatment were corrected by either treatment, except for 1 patient in the CVVH group who developed hypophosphatemia (0.54 mmol/L) at 72 hours. After 3 days of treatment, there was a mild but persistent metabolic acidosis in the EDDf group compared with the CVVH group.

It is now possible to generate ultrapure replacement fluid and administer it in the ICU with a lower cost than CRRT, in greater amounts and for shorter periods of time. The choices are now almost limitless; 3 or 4 hours of IHD with standard settings or CRRT at 35 mL/kg/hr of effluent flow rate can be selected. SLEDD at blood and dialysate flow rates of 150 mL/min for 8 hours during the day or SLEDD for 12 hours overnight can be considered as an alternative.[41-47]

The Role of Renal Replacement Therapies in Different Clinical Conditions

Sepsis and Multiple Organ Dysfunction Syndrome

Extracorporeal blood purification therapies (EBPT) have been proposed as adjuvant therapies for sepsis and multiple organ dysfunction syndrome (MODS) (see Chapters 91 and 92). RRT has been the most frequently utilized type of therapy. There are some animal and patient data that show that RRT has some benefit in this clinical setting. Animal models of severe sepsis[47-49] demonstrated a beneficial effect of high-volume hemofiltration (HVHF) on hemodynamics, proportional to the intensity of UF that was used. The benefit found in the animal experiments has led to the use of HVHF as a "ideal model of therapy to be started when endotoxemia is present or suspected, or even before it" in patients. HVHF protocols have been developed by different authors: 4 to 10 L/hr UF sessions in most of cases lasting only 4 to 8 hours and followed by traditional CVVH have been suggested.

The first reports of using HVHF for the treatment of patients with septic shock and MODS have just appeared: Lonnemann[50] demonstrated that the use of HVHF led to improved macrophage function in that macrophages regained their ability to produce tumor necrosis factor-α (TNF-α) in response to endotoxin exposure. Oudemans-van Straaten and colleagues[51] conducted a prospective cohort analysis in 306 patients who received HVHF at a mean UF rate of 4 L/hr. They found improvements in hemodynamics, including cardiac index, blood pressure, and stroke volume in patients who had presented with abnormal parameters. They also documented an increase in patients' systemic vascular resistance that allowed a decrease in the doses of

dopamine administered to these patients. Honore and coworkers[52] evaluated the effects of short-term high-volume hemofiltration (STHVH) in 20 patients. In this investigation, STHVH lasted 4 hours and the 9-L/hr sessions were followed by conventional CVVH in these patients with severe septic shock. Eleven of the 20 patients responded to the therapy, because they had increases in cardiac index, mixed venous saturation, and arterial pH and reductions in their doses of epinephrine. The study also documented that the rate of survival to 28 days in the patients who responded was significantly higher (9 of 11) than in the patients who did not respond to this treatment. Because all the patients received STHVH, it is not clear what the mechanism was for the response and why some of the patients responded and others did not.

Cole and coworkers[53] measured hemodynamics, serum cytokines, and complement concentrations in 11 patients with septic shock and MODS. These patients were randomly assigned to HVHF (8 hr; 6 L/hr) or to standard CVVH. The decrease in vasopressors requirement was significantly higher in the patients who received HVHF. Cole noted that the patients in the HVHF group had insignificant concentrations of the measured soluble mediators in the ultrafiltrate, suggesting the filter may have adsorbed some of the mediators.

These studies are limited because they enrolled small numbers of patients.[53,54] The results show that HVHF techniques can be utilized in these unstable, critically ill patients and that some of the patients appear to derive benefit from the therapy. Larger randomized trials are needed before the routine use of these therapies in septic patients.[54-58]

Coupled plasma filtration adsorption (CPFA)[59,60] separates plasma from blood using a plasma filter and then the plasma is passed through a synthetic resin cartridge and returned to the blood. A second blood filter is used to remove excess fluid and small-molecular-weight toxins. The resin was chosen based on its adsorption capacity for important inflammatory mediators, low levels of extractable toxins, and an acceptable pressure flow performance profile. In a randomized clinical trial, this technique removed almost 100% of the circulating concentrations of TNF-α and interleukin-β (IL-β), allowing significant reductions of vasopressor drugs in the intervention patients compared with the patients who received CVVH. Therefore, more research is necessary to evaluate similar techniques in patients with septic shock.

Ultrafiltration During Cardiopulmonary Bypass

Ultrafiltration has been used for many years in pediatric cardiac patients in an effort to attenuate the effects of hemodilution that occur after cardiopulmonary bypass (CPB) (see Chapter 60). Reported benefits of UF include decreased total body water, higher systemic arterial blood pressure, decreased duration of postoperative inotropic support, improved preload, recruitable stroke work, improved oxygenation, better pulmonary compliance, decreased duration of ventilatory support, higher postoperative hematocrit value, lower postoperative blood loss and requirement for blood transfusion, higher concentrations of plasma proteins and fibrinogen, less production of thromboxane B_2 and less activation of complement, decreased pleural effusions, and shorter duration of hospitalization. Other studies have documented removal of vasoactive substances and inflammatory cytokines in the UF effluent.

There have been nine studies that have, in various manners, evaluated UF in perioperative pediatric cardiac patients.[57-66] Four studies evaluated the concentrations of inflammatory markers with UF; three found a postoperative reduction in the concentration of inflammatory markers including IL-8 and IL-6 in patients who received UF, and one study found no differences in the concentrations. Three other studies evaluated postoperative bleeding, and two found a reduction in postoperative bleeding with UF and one study found no difference. Three studies reported improved hemodynamics after UF, including improved cardiac index and blood pressure. Five studies found improved hematocrits and reduced patient weights after hemofiltration. Individual studies also found an increased variability in heparin concentration but no change in aprotinin concentrations. These studies included very few patients and so the effects of UF on mortality or morbidity cannot be assessed.

There have been two basic approaches to UF in pediatric cardiac patients. First, conventional ultrafiltration (CUF) performs UF during the rewarming phase of CPB. Because the patient is still on CPB, the volume of fluid removed with CUF is limited by the volume of the CPB circuit and the requirements of the venous reservoir for adequate arterial inflow. Modified ultrafiltration (MUF) is performed after the discontinuation of CPB and is, therefore, independent of the circuit volume. To perform MUF the patient is weaned off bypass and then the hemofilter pressure is maintained by the difference in pressure between the arterial inflow and the right atrial outflow. Because of this technical difference, more fluid can be removed with MUF than with CUF, assuming that no or minimal additional volume is added to the circuit during CUF. This difference may translate into greater efficacy in attenuating the deleterious effects of hemodilution and systemic inflammatory reaction. Although a number of studies have investigated the potential advantages of MUF, the issue of whether MUF has any intrinsic benefit over CUF aside from the potentially greater volume of fluid removed has yet to be investigated.[67,68]

A third approach is a combination of the CUF and MUF, which starts CUF as soon as 3 to 5 minutes after the discontinuation of bypass. After the complete weaning from bypass, UF is switched to the modified method. During the MUF period blood from the venous reservoir is transfused to compensate for the lost water, keeping the arterial blood pressure above 60 mm Hg.[69] This aggressive strategy was evaluated and found to decrease inflammatory mediators (IL-6, endothelin-1, thromboxane B_2), attenuate lung edema and inflammatory pulmonary injury, and improve pulmonary function.

Journois and coworkers conducted a randomized, controlled study of zero-balanced high volume UF in 20 children (UF rate equivalent to 7 to 9 L/hr in a 70-kg adult) undergoing cardiac surgery.[70] The study documented a significant reduction in postoperative blood loss and time to extubation and improved alveolar-arterial oxygen gradient.

Congestive Heart Failure

Fluid overload occurs in patients with congestive heart failure (CHF) and is usually treated with diuretics and, if necessary, inotropic support. Extracorporeal UF is a possible solution to

help restore fluid balance close to normal. Several new technologies have made UF available today in all centers and easy to be instituted. The largest study on the use of ultrafiltration in patients with CHF was the prospective, randomized, multicenter trial UNLOAD (UF versus intravenous diuretics for acute decompensated CHF). Two hundred patients were recruited and randomized to receive UF or diuretics.[71] Inclusion criteria required the presence of at least two signs of fluid overload defined by a standard physical examination or simple diagnostic tests: distended neck veins, edema or ascites, pulmonary congestion on a chest radiograph or on chest auscultation, a history of paroxysmal nocturnal dyspnea, or hepatomegaly. Those randomized to the UF arm did not receive any diuretics within the first 48 hours of randomization. Those randomized to standard therapy were on loop diuretics at a dose level that was at least twice that of their daily diuretic dose. The duration and rate of UF were not predefined and were carried out based on the clinical judgment of an investigator. The UNLOAD trial is the first randomized comparison of intravenous diuretic therapy alone against an alternative therapy, UF, in hypervolemic patients. The principal findings of this trial were (1) in hypervolemic patients with CHF, ultrafiltration led to greater weight and fluid loss than intravenous diuretics at the doses used in this trial; (2) volume removal with ultrafiltration at the index hospitalization was associated with significant reductions in the rate and durations of subsequent hospitalizations and fewer unscheduled medical visits for CHF; and (3) the benefits from the use of short-term UF over 90 days was achieved without significant adverse effects.

The removal of sodium and water cannot be dissociated when using diuretics or in certain renal replacement techniques. Diuretics lead to a natriuresis, whereas dialysis may result in hypotonia or hypertonia, depending on the effect of dialysis on the diffusion and on the removal of molecules, including urea and other electrolytes. Therefore, water removal is always associated with the removal of other solutes and the amount of solutes lost depends on the technique used. Slow continuous UF (SCUF) produces an UF that varies from plasma water minimally due to Donnan effects. The UF from SCUF is iso-osmotic and isonatremic because sodium elimination is linked to the sodium concentration in plasma. In contrast, the ultrafiltrate composition produced from CVVH and from hemofiltration in general is similar to plasma water but the sodium concentration in the UF can be significantly affected by the sodium concentration in the replacement solution. Sodium removal can be dissociated from water removal in CVVH, thus obtaining a real change of the sodium pool in the body. This effect on sodium cannot be achieved with any other technique. The advantage is that not only plasma concentrations can be normalized but also the electrolyte content in the extracellular and possibly intracellular volume are changed by this technique.[72]

Technical Notes

Nomenclature

- *Intermittent hemodialysis (IHD):* The most common technique utilized for chronic renal failure. A diffusive treatment in which blood and dialysate are circulated in countercurrent manner and usually a low permeability, cellulose-based membrane is employed. Dialysate must be pyrogen free but not necessarily sterile, because dialysate-blood contact does not occur. The UF rate is equal to the scheduled weight loss. This treatment can be typically performed 4 hours thrice weekly or daily. Qb: 150-300 mL/min; Qd: 300-500 mL/min.
- *Peritoneal dialysis (PD):* A diffusive treatment in which blood, circulating along the capillaries of the peritoneal membrane, is exposed to a dialysate. Access is obtained by the insertion of a peritoneal catheter, which allows the abdominal instillation of dialysate. Solute and water movement is achieved by the means of variable concentration and tonicity gradients generated by the dialysate. This treatment can be performed continuously or intermittently.
- *Slow continuous ultrafiltration (SCUF):* A technique in which blood is driven through a highly permeable filter via an extracorporeal circuit in a venovenous mode. The ultrafiltrate produced during membrane transit is not replaced so it corresponds to the weight loss. It is used only for fluid control in overloaded patients (i.e., CHF patients who do not respond to diuretic therapy). Qb: 100-250 mL/min; Quf: 5-15 mL/min (Fig. 96-2).
- *Continuous venovenous hemofiltration (CVVH):* A technique in which blood is driven through a highly permeable filter via an extracorporeal circuit in venovenous mode. The ultrafiltrate produced during membrane transit is replaced in part or completely to achieve blood purification and volume control. If the replacement fluid is delivered after the filter, the technique is defined as postdilution hemofiltration. If the replacement fluid is delivered before the filter, the technique is defined as predilution hemofiltration. The replacement fluid can be delivered both pre and post filter. Clearance for all solutes is convective and equals UF rate. Qb: 100-250 mL/min; Quf: 15-60 mL/min (see Fig. 96-2).

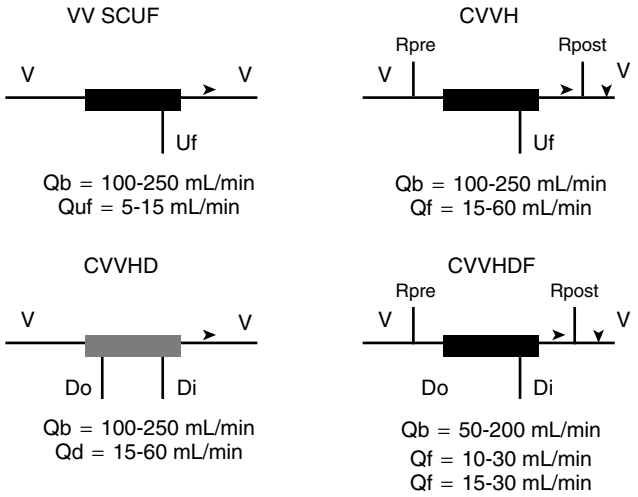

Figure 96-2 Schematic representation of most common continuous renal replacement therapy setups. *Black triangles* represent blood flow direction. VV, venovenous; Uf, ultrafiltration; Rpre, replacement solution prefilter; Rpost, replacement solution postfilter; Do, dialysate out; Di, dialysate in; Qb, blood flow; Quf, ultrafiltration flow; Qf, replacement solution flow; Qd, dialysate solution flow.

- *Continuous venovenous hemodialysis (CVVHD):* A technique in which blood is driven through a low permeability dialyzer via an extracorporeal circuit in venovenous mode and a countercurrent flow of dialysate is delivered in the dialysate compartment. The ultrafiltrate produced during membrane transit corresponds to the weight loss. Solute clearance is mainly diffusive and efficiency is limited to small solutes only. Qb: 100-250 mL/min; Qd: 15-60 mL/min (see Fig. 96-2).
- *Continuous venovenous hemodiafiltration (CVVHDF):* A technique in which blood is driven through a highly permeable dialyzer via an extracorporeal circuit in venovenous mode and a countercurrent flow of dialysate is delivered in the dialysate compartment. The ultrafiltrate produced during membrane transit is in excess of the patient's desired weight loss. A replacement solution is needed to maintain fluid balance. Solute clearance is both convective and diffusive. Qb: 100-250 mL/min; Qd: 15-60 mL/min; Qf: 15-60 mL/min (see Fig. 96-2).
- *Hemoperfusion (HP):* The patient's blood is circulated on a bed of coated charcoal powder to remove solutes by adsorption. The technique is specifically indicated in cases of poisoning or intoxication with agents that can be effectively removed by charcoal. This treatment may cause platelet and protein depletion.
- *Plasmapheresis (PP):* A treatment that uses specific plasma filters. The molecular weight cut-off of the membrane is much higher than that of hemofilters (100,000-1 million kD): thus, plasma as a whole is filtered and blood is reconstituted by the infusion of plasma products such as frozen plasma or albumin. This technique is performed to remove proteins or protein-bound solutes.
- *High-flux dialysis (HFD):* A treatment that utilizes highly permeable membranes in conjunction with a UF control system. Because of the characteristics of the membrane, UF occurs in the proximal part of the filter that is counterbalanced by a positive pressure applied to the dialysate compartment. This causes a phenomenon called backfiltration in the distal part of the filter from convective passage of the dialysate into the blood. Diffusion and convection are combined, but the necessity of a pyrogen-free dialysate replacement is avoided.
- *High-volume hemofiltration (HVHF):* A treatment that utilizes highly permeable membranes and hemofiltration with a high-volume setting: Qb > 200 mL/min; Qf > 45 mL/kg/hr.[41]
- *High-permeability hemofiltration (HPHF):* A treatment that utilizes high cut-off (60 kD) permeable membranes and hemofiltration. High treatment flows are not necessary, but a strict control of bigger molecules, like albumin, is recommended.[42]

Anticoagulation

The need for anticoagulation of the CRRT circuit is due to the contact between blood and the tubing of the circuit and the membrane of the filter. This contact induces activation of the coagulation cascade. This activation inevitably results in clotting of the filter or circuit. The quantity and duration of anticoagulation changes depending on the schedule of RRT; anticoagulation is necessary for continuous treatments, where the blood-artificial surface interaction is maximal.

Circuit Set-up Optimization

Several technical features of each RRT circuit affect the need for anticoagulation. Vascular access has to be of adequate size, kinking of the circuit tubing needs to be avoided, and the blood flow rate should exceed 100 mL/min, Pump flow fluctuations are mainly due to increased resistances in the circuit. The venous bubble trap is where air/blood contact occurs and so must be monitored. The plasma filtration fraction should be kept as far as possible below 20% and, when possible or considered correct, predilutional hemofiltration should be utilized. There is evidence that, when the circuit set-up is perfectly optimized, anticoagulants are only a relatively minor component of circuit patency: in fact, when patients have bleeding disorders (i.e., prolonged clotting times, thrombocytopenia) RRT can be safely performed without the utilization of any anticoagulant.[43]

Unfractioned Heparin

Unfractioned heparin (UFH) is the most widely used anticoagulant. It is easy to use and an antidote is available (protamine). Heparin doses range from 5 to 10 IU/kg/hr. In patients who require limited RRT, it can also be used in combination with protamine (regional heparinization) with a 1:1 ratio (150 IU of UFH per milligram of protamine), monitoring activated prothrombin time (aPTT). The problems with the use of UFH include its unpredictable bioavailability, the necessity for antithrombin III (ATIII) levels for optimal use, and the occurrence of heparin-induced thrombocytopenia (HIT).

Low-Molecular-Weight Heparins

Some centers now utilize low-molecular-weight heparins (LMWH) for RRT. Prospective studies have not yet shown LMWH to be superior in prolonging the life of RRT circuits. LMWH have better bioavailability than UFH and a lower incidence of HIT and they cost about 10% more than UFH.

Prostacyclin (PGI_2)

This agent is a potentially useful drug for anticoagulation for RRT, because it is the most potent inhibitor of platelet aggregation with a short half-life. PGI_2 is infused at a dose of 4 to 8 ng/kg/hr with or without the addition of low-dose UFH. Hypotension might be induced by higher doses of PGI_2. Some studies have demonstrated PGI_2 efficacy, but its high cost and harmful side effects might limit the use of this agent.[44]

Citrate

Citrate chelates calcium, which prevents clot formation. A calcium-free sodium citrate containing replacement solution or dialysate solution or both is prepared and is administered at the appropriate rate to achieve the desired aPTT (60 to 90 seconds). Calcium chloride is then administered to replace the chelated/dialyzed calcium and maintain normocalcemia. This approach is effective in maintaining excellent filter patency and compares favorably with heparin. It also avoids the risk for HIT and does not lead to systemic anticoagulation. The drawbacks of this anticoagulation management include the risks of hypocalcemia, metabolic alkalosis, and the cumbersome preparation of the replacement/dialysate fluid.[45,46]

Table 96-4 Anticoagulation Strategies

Drug	Pro	Con
No anticoagulation	High risk of bleeding patients	Relative shorter circuit lifespan
Unfractionated heparin	Routine	HIT
Low-molecular-weight heparin	Routine (alternative to UH)	HIT
Prostacyclin	Very short circuit lifespan	Hypotension
Citrate	Routine/very short circuit lifespan	Hypocalcemia
Danaparoid	HIT	Insufficient data available
Argatroban	HIT	Insufficient data available
Irudine	HIT	Insufficient data available
Nafamostat mesylate	HIT	Insufficient data available
Heparin-coated circuits	Routine	Insufficient data available

UH, unfractionated heparin; HIT, heparin-induced thrombocytopenia.

Other Strategies

Alternatives to the techniques presented here are listed in Table 96-4 for completeness.

Vascular Access

The fundamental role played by vascular access must be emphasized. Circuit failure is more often due to inadequacy of the vascular access than to insufficient anticoagulation. Thus, the optimal dialysis catheter can save the patient from an inappropriate increase in anticoagulation. Venovenous RRT relies on the use of a temporary double-lumen catheter. Such catheters are inserted in a central vein and available in various shapes and sizes. The site chosen for insertion of the double-lumen catheter should be done on the basis of clinical expertise, the body habitus of the patient, and the presence of other intravenous catheters that can be exchanged for the dialysis catheter. Cannulation of the right internal jugular vein, with the tip of the catheter reaching the right atrium, is associated with circuit blood flow rates of up to 300 mL/min. Catheter size for adult patients ranges from 12 to 14 French and the lengths from 16 to 25 cm. A 20-cm long catheter is used for the femoral vein location and has its tip positioned close to the inferior vena cava, allowing optimal flows within the circuit. When an inadequate blood flow in a catheter is suspected, venous and arterial lumens should be flushed with saline with the goal of testing resistance to injection. Limb clotting of the line versus kinking due to patient's position must be distinguished. Administration of heparin or urokinase into the catheters can be tried for a few hours to de-clot the catheter. The catheter can also be exchanged for a new catheter.

Summary

The mechanisms involved in RRT are founded on the principles of water and solute transport via diffusion and convection. These mechanisms have been applied and lead to different techniques (intermittent, extended, or continuous RRT) and modalities (hemofiltration, hemodialysis, hemodiafiltration, plasma filtration, hemoperfusion, coupled plasma filtration and adsorption). A precise understanding of technical and clinical implications of such therapies is important to achieve the desired results. Different RRT prescriptions, modalities, and schedules can be administered to critically ill patients with AKI. Clinical effects on critically ill patients depend on the selected RRT strategy and on the severity/complexity of the patients' clinical picture. A specific dose of RRT has not been adopted in clinical practice owing to a lack of enough clinical evidence. The best evidence to date supports an RRT dose of at least 35 mL/kg/hr—spKt/V 1.4—for CVVH, CVVHDF, or daily IHD.

97 Cardiopulmonary Resuscitation: Basic and Advanced Life Support

Key Points

1. Chest compressions performed with minimal interruption are critically important in improving the chance of survival from sudden cardiac arrest.
2. Thirty chest compressions followed by two rescue breaths is the recommended ratio for single rescuers resuscitating children and adults.
3. Chest compressions should be performed at a rate of 100/min for children and adults.
4. The American Heart Association 2005 guidelines recommend that a single shock be delivered when a shockable dysrhythmia exists, followed by resumption of chest compressions as soon as the shock is delivered. Two minutes of chest compressions and ventilation should be performed before reassessing the underlying cardiac rhythm.
5. Automated external defibrillators (AEDs) may follow an outdated defibrillation protocol (e.g., three defibrillation shocks before resumption of cardiopulmonary resuscitation [CPR]). In this circumstance, the rescuer should allow the AED to function as programmed until a manual defibrillator becomes available.
6. When a rescuer is unfamiliar with the type of manual defibrillator used during resuscitation, a default energy of 200 J is a reasonable energy level for defibrillation.
7. In an unwitnessed cardiac arrest or in situations in which initiation of CPR has been delayed, 2 minutes of CPR before the first defibrillation has been shown to have survival benefit.
8. Hyperventilation during resuscitation increases intrathoracic pressure, impairs venous return to the heart, and has a negative impact on survival from cardiac arrest. The resuscitation team leader must ensure that only 8 to 10 breaths per minute are being delivered during resuscitation attempts.
9. Therapeutic hypothermia has demonstrated benefit in improving the neurologic outcomes of victims resuscitated from out-of-hospital ventricular fibrillation who remain comatose on hospital admission. This therapeutic intervention should be considered for victims of in-hospital ventricular fibrillation cardiac arrest with decreased neurologic function after resuscitation.
10. Resuscitation knowledge declines rapidly, even in anesthesia providers. Review of advanced cardiac life support (ACLS) resuscitation protocols may be necessary in the interim between ACLS certification. ACLS protocols should be made available on resuscitation carts to ensure that more uniform and accepted resuscitation interventions are followed during resuscitation attempts.

Although the history of resuscitation can be traced to at least biblical times,[1] contemporary approaches to cardiopulmonary resuscitation (CPR) date back to 1966, when a National Academy of Sciences National Research Council conference generated consensus standards for the performance of CPR.[2] Since that time, successive conferences have reviewed the practice of CPR in the light of available experimental and clinical data and have prepared revisions of previous standards.[3-9] The most recent recommendations, the "2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care" (Guidelines 2005), represent the second internationally recognized resuscitation guidelines developed by experts from the American Heart Association (AHA) and the European Resuscitation Council; accordingly, these guidelines represent a variety of countries, cultures, and medical specialties. Each intervention included in the new guidelines has undergone comprehensive evidence-based evaluation of the scientific information available supporting its uses in emergency cardiovascular care and resuscitation, as well as a structured and transparent process for managing potential conflicts of interest. Both basic life support (BLS) and advanced cardiac life support (ACLS) are established on credible foundations and have enjoyed widespread acceptance in the emergency cardiovascular care community. Indicative of this acceptance is the widespread popularity of the AHA BLS and ACLS training programs and related training materials. The intent of this chapter is to review the premise, rationale, and techniques

for the performance of both BLS and ACLS in light of current understanding and as published in AHA textbooks on BLS[10] and ACLS.[11] It is not the intent of this chapter to restate the performance of all BLS CPR procedures, which can be reviewed in the guidelines and also in the AHA BLS text.[10] Rather, both BLS and ACLS are reviewed within the context of their application by anesthesiologists in operating rooms, intensive care units (ICUs), and other patient care environments.

Basic Life Support

BLS involves early recognition of medical emergencies, activation of an emergency response system (e.g., dialing 911 in the United States), and interventions made in response to sudden cardiac arrest (SCA), heart attack, stroke, and airway obstruction by a foreign body. Airway, breathing, and circulation are BLS assessments readily performed without equipment. Rescue breathing, the Heimlich maneuver, CPR, and the application-use of an automated external defibrillator (AED) are BLS interventions. All BLS interventions are time sensitive for preventing SCA, terminating SCA, or supporting the circulation until restoration of spontaneous circulation occurs after SCA. For those performing BLS interventions, particularly CPR, the importance of prompt initiation and expert performance of these skills cannot be overemphasized. AEDs are included in BLS interventions because of their widespread availability in public spaces (i.e., airports, schools, shopping centers, hospitals, casinos, sporting arenas), their uncomplicated application, and automated analysis of cardiac rhythm and administered shocks (if indicated based on analysis of cardiac rhythm by the AED). The interdependency of BLS components will be reviewed in light of current understanding and the 2005 AHA recommendations.

Cardiopulmonary Resuscitation

SCA is a complex and dynamic process. Antegrade systemic arterial blood flow continues after cardiac arrest until the pressure gradient between the aorta and right heart structures reach equilibrium. A similar process occurs during cardiac arrest with antegrade pulmonary blood flow between the pulmonary artery and the left atrium.[12-14] As the arterial-venous pressure gradients dissipate, the left heart becomes less filled, the right heart becomes more filled, and the venous capacitance vessels become increasingly distended (Fig. 97-1). When arterial and venous pressure equilibrates (approximately 5 minutes after cardiac arrest), coronary perfusion and cerebral blood flow stop.

In the absence of native cardiac function and systemic circulation, CPR is performed until return of spontaneous circulation occurs, the patient is pronounced dead, or in some special circumstances, the patient is placed on extracorporeal circulation and membrane oxygenation (ECMO). Although CPR is far less efficient than the native circulation, when properly performed, it can provide coronary circulation and cerebral blood flow sufficient to afford full recovery in many cases if return of spontaneous circulation can be reestablished.

"Push hard and push fast" are the recommendations for chest compressions during CPR from the 2005 International Consensus conference.[15] Although there is insufficient evidence from human studies to identify an ideal chest compression rate, chest compressions performed at a rate of 100/min and with enough force to generate a palpable carotid or femoral pulse are considered ideal. Chest compressions are frequently interrupted during resuscitation attempts.[16-18] These interruptions have a negative impact on coronary and cerebral perfusion, as well as on return of spontaneous circulation.[14,19] Current recommendations for CPR reflect these observations by placing increased emphasis on limiting interruptions in chest compressions, even for other resuscitative measures (i.e., rescue breaths, attempts at defibrillation, tracheal intubation). During single- and two-person CPR, Guidelines 2005 recommends compression-ventilation ratios of 30:2 in both scenarios with minimal interruption in chest compressions for rescue breaths.

Physiologic Considerations

Since the early 1960s, when CPR became a widespread clinical technique, it has been assumed that blood is ejected as a direct result of actual compression of the heart between the sternum and the vertebral column. This is commonly referred to as the "*cardiac pump mechanism*." Transesophageal echocardiography during CPR in humans provides an opportunity to assess changes in cardiac dimensions and valve positions during chest compressions, as well as the direction of blood flow. Observations made with echocardiography during CPR describe a reduction in left and right ventricular volume, closure of the tricuspid and mitral valves during chest compression, and ejection of blood into the arterial system, all of which are consistent with the cardiac pump mechanism (Fig. 97-2).[20-23]

Repeated, forceful coughing (cough CPR) can sustain consciousness during ventricular fibrillation (VF) for as long as 100 seconds when the arrhythmia (or any arrhythmia capable of rapidly compromising cardiac output) is immediately recognized and the patient can respond to verbal prompts to cough. This observation suggests that mechanisms other than direct cardiac compression may account for forward blood flow during cardiac arrest.[24] Vigorous coughing produces an arterial pressure pulse associated with forward blood flow that opens the aortic valve during the generation of pressure and flow.[25] These findings

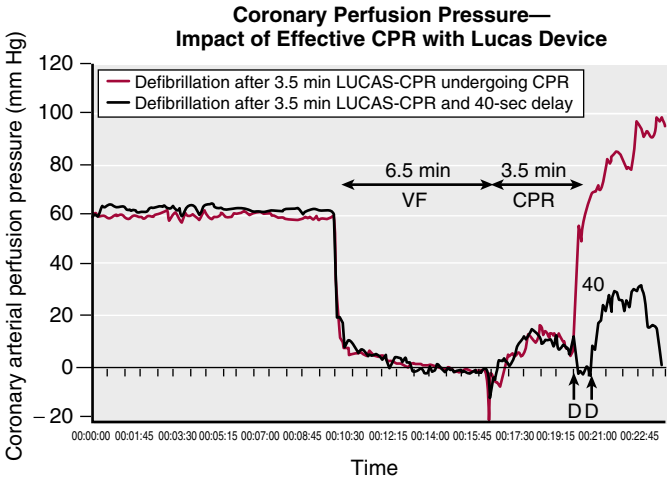

Figure 97-1 Effect of ventricular fibrillation on coronary perfusion pressure followed by CPR and defibrillation. CPR, cardiopulmonary resuscitation; D, defibrillation; VF, ventricular fibrillation. *(From Steen S, Liao Q, Pierre L, et al: The critical importance of minimal delay between chest compressions and subsequent defibrillation: A haemodynamic explanation. Resuscitation 58:249, 2003.)*

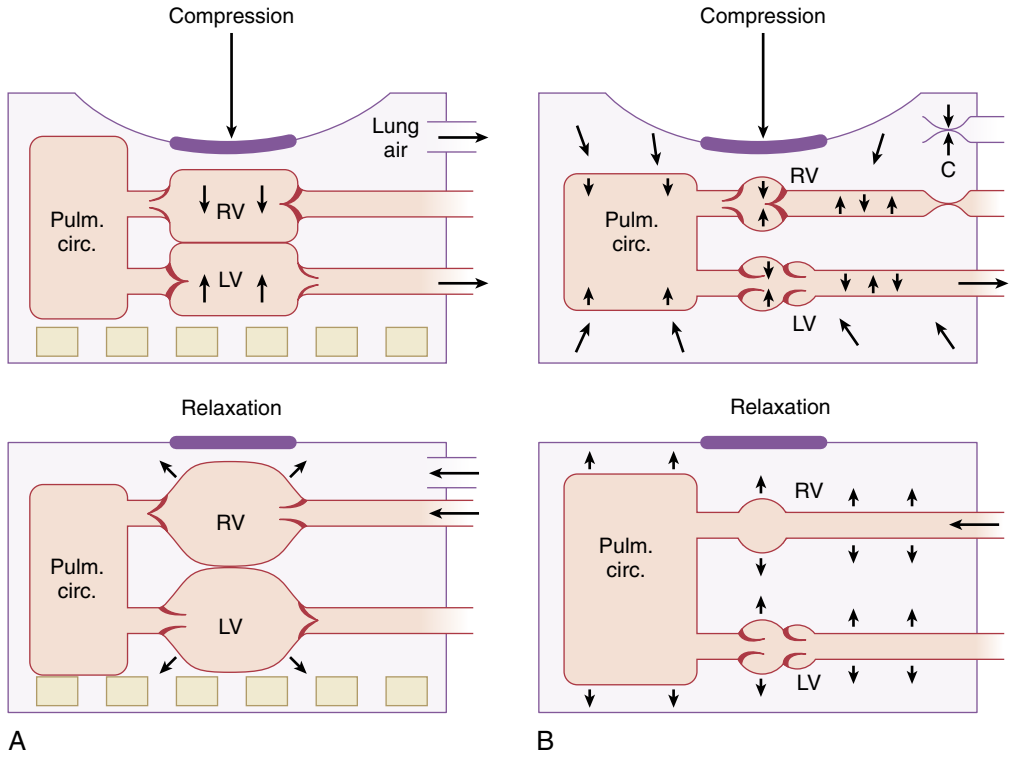

Figure 97-2 **A,** Schematic representation of the cardiac compression pump. **B,** The intrathoracic pressure pump. C, in panel **B** represents collapse of airways and venous structures. LV, left ventricle; RV, right ventricle. *(Redrawn with modification from Halperin HR: Mechanisms of forward flow during external chest compression.* In *Paradis NA, Halperin HR, Nowak RM [eds]: Cardiac Arrest: The Science and Practice of Resuscitation Medicine. Baltimore, Williams & Wilkins, 1995, p 252.)*

support the proposal that increases in intrathoracic pressure generate forward blood flow,[26] which is commonly referred to as the "*thoracic pump mechanism*" (see Fig. 97-2). The increasing intrathoracic pressure during chest compression equalizes intravascular pressure within the thorax. On the venous side, valve and venous collapse at the thoracic inlet limits the transmission of retrograde pressure or flow. The arterial system, which is relatively resistant to collapse, transmits pressure and flow into the extrathoracic arterial tree. A peripheral arteriovenous pressure difference is thus established that permits blood to flow forward in the extrathoracic vascular system. Some studies suggest that during compression or vigorous coughing the left side of the heart may act as a passive conduit for transfer of pulmonary venous blood out into the peripheral arterial circulation. During compression, blood flows from the lungs through the left ventricle toward the periphery. The pulmonary valve is closed and the mitral and aortic valves are open during periods of high intrathoracic pressure when the chest is compressed.[27]

There is evidence that both cardiac pump and thoracic pump mechanisms exist at times during resuscitation attempts. Echocardiographic evidence clearly demonstrates findings consistent with the cardiac pump theory. Cough CPR is effective in maintaining consciousness, at least in the early period after the onset of lethal arrhythmia, consistent with the thoracic pump theory. Chest compressions during cardiac arrest may initially promote a cardiac pump mechanism as a result of the presence of blood in the left heart. As pressure gradients between the arterial and venous systems equilibrate during prolonged resuscitation, pulmonary blood volume increases and probably supports a thoracic pump mechanism.

Systemic, coronary, and cerebral blood flow during CPR is dependent on effective chest compressions, as well as on return of venous blood to the heart. At chest compression rates of 80 to 100/min, the compression-relaxation ratio approaches 50:50. The time available for return of blood to the thorax is limited. Venous blood returns to the thorax at very low pressure during cardiac arrest. Modest increases in intrathoracic pressure will impair return of venous blood and have a negative impact on systemic, coronary, and cerebral perfusion, in addition to reducing the chance of spontaneous circulation.[28]

Cardiac output during CPR with effective, uninterrupted chest compression is 25% to 30% of the normal spontaneous circulation. Systemic and pulmonary perfusion during CPR reflects the decreased cardiac output as demonstrated by weak carotid pulses with compression and low carbon dioxide excretion (as will be addressed later). In cardiac arrest without a hypoxic etiology (e.g., drowning, suffocation), oxygen content in the lungs at the time of cardiac arrest is usually sufficient for maintaining an acceptable arterial oxygen content during the first several minutes of CPR. Rescue breaths are less important than initiating chest compressions immediately after the onset of SCA. Blood flow rather than arterial oxygen content is the limiting factor for delivery of oxygen to the coronary, cerebral, and systemic circulation during CPR. Multiple modifications to standard CPR exist, as well as mechanical adjuncts to improve circulation during CPR. A few will be reviewed here in light of current understanding.

Interposed abdominal compression (IAC) is a form of CPR in which the abdomen is compressed midway between the xiphoid process and the umbilicus during the upstroke of the chest com-

pression phase in an attempt to sustain aortic diastolic pressure and thus improve coronary perfusion pressure, a critical determinant of successful restoration of spontaneous circulation. Experimental evidence has shown that carotid blood flow[29] and end-diastolic arteriovenous pressure differences,[30] indexes of coronary perfusion pressure, are increased with IAC-CPR. In a recent evidence-based review of IAC-CPR, Babbs[31] reported evidence of improved immediate resuscitation when this technique was applied to in-hospital cardiac arrest victims based on the results of three randomized human studies. Though accepted by the AHA as an satisfactory adjunct to standard CPR, this intervention is rarely used despite recognition of its benefits, minimal risk, and easy application. When sufficient personnel trained in the technique are available, AIC-CPR can be considered a reasonable alternative to standard CPR.

Active compression-decompression CPR (ACD-CPR) accomplishes compression and active decompression of the thorax by means of a device containing a suction header, bellows, and a compression area within the bellows. Preliminary data in arrested humans comparing ACD-CPR with standard CPR have provided evidence of hemodynamic benefit, with higher systolic arterial pressure and end-tidal carbon dioxide pressure (P_{ETCO_2}) and echocardiographic demonstration of an increased velocity-time integral, an analog of cardiac output. In humans studied during implantation of cardioverter-defibrillators, ACD-CPR increased systemic arterial pressure, coronary perfusion pressure, and minute ventilation when compared with standard CPR.[32] Although these observations provided clinical support for experimental studies indicating improved hemodynamic (and perhaps ventilatory) function with ACD-CPR versus standard CPR, still lacking was evidence of benefit on patient outcome.

Several studies of ACD-CPR have been performed in patients after out-of-hospital cardiac arrest,[33-35] but none have demonstrated an improvement in patient outcome in terms of hospital discharge when ACD-CPR was compared with standard CPR. The largest study comparing ACD-CPR with standard CPR included 1784 adults after in-hospital and prehospital cardiac arrest. This study, like its predecessors, concluded that ACD-CPR does not improve survival or neurologic outcomes.[36] Thus, despite the earlier experimental and clinical evidence that ACD-CPR may confer benefit to victims of cardiac arrest by virtue of enhanced hemodynamic variables, no evidence supports the hypothesis that ACD-CPR improves outcomes after cardiac arrest in humans when compared with standard manual CPR. The ACD-CPR device may also expose patients to harm.[37] Currently, no ACD-CPR devices are approved by the Food and Drug Administration for sale in the United States.

The impedance threshold device (ITD) limits entry of air into the lungs during the recoil phase after chest compression, thereby creating greater negative intrathoracic pressure and drawing greater blood volume into the chest than with standard CPR. What results appears to be greater coronary blood flow (occurring during the diastole/chest recoil phase of chest compressions), greater cerebral blood flow, and improved hemodynamics in comparison to standard CPR. The results of animal and clinical studies endorse the benefits of this device, which include improved resuscitation and short-term survival when compared with standard CPR.[38-40] Although this device is most effective with endotracheal tubes, if a rescuer can maintain a good seal with a facemask, the ITD can be used. Even though long-term survival has not been documented after use of the ITD during resuscitation, if the device is available, there are no compelling reasons to not consider using this technology.

Circumferential compression of the chest with a load-distributing band (LDB) has been described as a mechanism for generating fluctuations in intrathoracic pressure and thereby improving blood flow by exploiting the thoracic pump mechanism beyond that possible with standard CPR.[41,42] This device wraps circumferentially around the patient's torso, is closed with Velcro, and then automatically adjusts the length of the belt to fit snuggly around the patient's chest. Repetitive shortening of the belt compresses the chest and generates forward blood flow. Chest recoil occurs as the belt relaxes. As with the other devices already mentioned, the LDB has been shown in a preliminary study to increase both aortic and coronary perfusion pressure in animals, which has resulted in improved survival and neurologic outcome.[43,44] However, a recent multicenter, randomized prehospital clinical trial to evaluate the effectiveness of an LDB was halted early because of markedly reduced neurologic recovery in cardiac arrest victims on whom the LDB was used when compared with cardiac arrest victims who received standard CPR.[45] The authors speculate that application of the device probably delayed or interrupted CPR and also noted that the time to first defibrillation in the LDB group occurred on average 2.1 minutes after the standard CPR group.

Although the devices mentioned here all demonstrate improved circulation and blood flow in comparison to standard CPR during cardiac arrest in humans, none of the devices demonstrate improved hospital discharge rates after resuscitation from cardiac arrest. What is certain is that CPR, regardless of the mechanism of blood flow and technique, is only a temporizing procedure in need of rapid supplementation with ACLS, most critically, rapid defibrillation of the fibrillating heart.

Monitoring Performance of Cardiopulmonary Resuscitation

Until recently, palpation of the carotid or femoral pulse and observation of pupillary size were the standard and very indirect measures for assessing the apparent adequacy of CPR. Obviously, a palpable large-artery pulse indicates only the transmission of a pressure wave into the arterial tree during chest compression and provides no objective evidence of the effectiveness of cardiac output. Initial *pupillary* size and changes during CPR are of some prognostic value.[46] Pupils that are persistently contracted or initially dilated but subsequently contracting are associated with a greater likelihood of successful resuscitation and neurologic recovery than persistently dilated or subsequently dilating pupils are.[47]

Monitoring systemic arterial pressure directly, as can usually be accomplished during in-hospital CPR, is helpful in optimizing the rate and depth of chest compressions.[48] Aortic diastolic pressure in particular, an index of coronary perfusion pressure, should be monitored whenever possible and optimized with appropriate changes in manual compression technique and early and repeated injection of epinephrine and vasopressin before restoration of spontaneous circulation.

In 1978, Kalenda[49] described the use of capnography as a guide to the effectiveness of external chest compressions. He demonstrated the value of monitoring P_{ETCO_2} in three patients in cardiac arrest and confirmed changes in P_{ETCO_2} with restoration of spontaneous circulation. Kalenda proposed that when ventilation is constant, as during controlled mechanical ventila-

tion, "the expired CO_2 is a precise and continuous mirror of lung perfusion and hence of cardiac output."[49]

Despite the potential clinical importance of Kalenda's well-documented observations and conclusion, it was several years before monitoring of P_{ETCO_2} during cardiac arrest and CPR was explored further. In 1984, using a porcine model of cardiac arrest, Grundler and colleagues[50] demonstrated a rapid decrease in P_{ETCO_2} with the onset of arrest and its immediate increase with resuscitation. Based on these preliminary experimental observations, this group suggested that P_{ETCO_2} monitoring may be a relatively simple and noninvasive guide to advanced life support interventions during CPR.[50,51] Severe reductions in pulmonary blood flow during cardiac arrest and CPR and therefore an acute failure of delivery of O_2 to the lungs explained the very low P_{ETCO_2} and increased venous CO_2 pressure (P_{VCO_2}) observed (see the discussion of sodium bicarbonate).[52] Subsequent studies in dogs provided confirmation of the possible utility of P_{ETCO_2} in that expired P_{VCO_2} correlated very closely with coronary perfusion pressure, which itself was shown to be a determinant of survival from cardiac arrest in this model.[53,54] In a porcine model of VF, the onset of VF was associated with a rapid decline in P_{ETCO_2} from a mean (±SEM) of 4.0% ± 0.2% to less than 0.7% ± 0.2%.[55] With external chest compression and constant-volume mechanical ventilation, P_{ETCO_2} increased to 1.9% ± 0.3%, with an immediate increase to 4.9% ± 0.3% after successful defibrillation and 12 minutes of CPR. Close correlation was found between changes in cardiac output and P_{ETCO_2} during both closed-chest and open-chest CPR.[55]

P_{ETCO_2} monitoring has been reported in arrested humans undergoing CPR.[56-59] In a study of 10 patients in whom spontaneous circulation returned, P_{ETCO_2} increased immediately on restoration of spontaneous circulation from a mean (±SD) of 1.7% ± 0.6% to 4.6% ± 1.4%.[56] The rapid increase in P_{ETCO_2} was often the first clinical evidence of resumption of spontaneous circulation.

In 10 critically ill patients, 9 of whom were in septic or cardiogenic shock at the onset of cardiac arrest, P_{ETCO_2} decreased from a mean (±SD) of 1.7% ± 0.9% to 0.4% ± 0.4% shortly after the onset of cardiac arrest.[59] The very low pre-arrest value is indicative of low cardiac output and therefore low pulmonary blood flow. During external chest compression, this value increased to 1.0% ± 0.5%. In seven patients in whom circulation was restored, P_{ETCO_2} rapidly increased from 1.3% ± 0.5% to 3.7% ± 2.1% and then declined to a stable volume of 2.4% ± 1.8% 4 minutes after resumption of spontaneous circulation. In patients with whom resuscitation failed to restore spontaneous circulation, P_{ETCO_2} remained at 0.7% ± 0.4%.[59]

Evidence is increasing that P_{ETCO_2} measurements obtained during cardiac arrest and CPR may have predictive value relative to the likelihood that spontaneous circulation will be restored. In one study, patients who later had a pulse had a mean P_{ETCO_2} of 19 ± 14 (SD) mm Hg at the beginning of resuscitation, whereas those who never regained a spontaneous pulse had a mean P_{ETCO_2} of 5 ± 4 mm Hg ($P < .0001$).[58] Other investigations have observed similar significant differences in P_{ETCO_2} during CPR between patients in whom spontaneous circulation develops and those in whom it does not.[60-62] Two of these studies were conducted in patients after out-of-hospital cardiac arrest.[61,62] P_{ETCO_2} was significantly higher during CPR in patients who subsequently regained spontaneous circulation than in those who did not. For example, 1 minute after the initiation of measurement, P_{ETCO_2} was 23.0 ± 17.4 mm Hg in those who regained pulses and 13.2 ± 14.7 mm Hg in those who did not ($P = .0002$) (Table 97-1). Differences of similar magnitude were noted at 2 minutes, as well as differences in the maximum value observed during resuscitation.[61] Although more such data are needed to quantitate the predictive power of these differences, it seems certain that P_{ETCO_2} measurements during cardiac arrest and CPR will become an objective index to predict the likelihood that persistent resuscitative effort will result in restoration of spontaneous circulation.

The major determinants of P_{ETCO_2} are CO_2 production, alveolar ventilation, and pulmonary blood flow.[63-66] In the presence of constant-volume ventilation and apparently unchanged CO_2 production immediately after cardiac arrest, the changes in P_{ETCO_2} observed both experimentally and clinically during cardiac arrest and CPR and during resumption of spontaneous circulation indicate that P_{ETCO_2} reflects pulmonary blood flow and therefore cardiac output.[56-60] Monitoring of both systemic arterial pressure by arterial catheter and P_{ETCO_2} with controlled ventilation should provide optimal hemodynamic assessment of the adequacy of the resuscitative effort and response to interven-

tions such as changes in depth, rate, and location of manual chest compressions, as well as response to drugs such as epinephrine and vasopressin.[48]

Compelling evidence confirms major deficiencies in the provision of CPR, particularly by trained health care professionals, in both out-of-hospital and in-hospital settings.[16,17,67,68] Long pauses without chest compressions and compressions that are suboptimal in both rate and depth are frequent in both settings and result in decreased blood flow. Animal studies have shown that inadequate blood flow from poorly performed CPR during cardiac arrest has a negative impact on both restoration of spontaneous circulation and survival.[14,69,70] Clinical evidence also suggests that excessive ventilation occurs during resuscitation attempts and likewise has a negative impact on resuscitation outcomes.[28] In light of these observations, the major focus in Guidelines 2005 simplified CPR for the purpose of prolonging uninterrupted chest compression.

Airway Control and Ventilation

Ventilation is critical for restoration of spontaneous circulation and organ preservation during cardiac arrest. The AHA ACLS training program has effectively conveyed this treatment priority.[9] The techniques used for providing ventilation are obviously dependent on the clinical situation. The head tilt–chin lift maneuver is recommended for initial airway control.[9,71,72] The epiglottis rather than the tongue is the major cause of upper airway obstruction in unconscious humans.[73] Because of its ligamentous attachments to the hyoid bone, the epiglottis can be lifted by manual maneuvers that displace the hyoid bone anteriorly. These observations provide anatomic confirmation of the efficacy of the head tilt–chin lift technique for opening an obstructed airway. The head tilt–jaw thrust maneuver accomplishes the same purpose in restoring airway patency.[74]

When rescue breathing is indicated for a nontracheally intubated cardiac arrest victim, two 1-second breaths are delivered after the 30th compression during both one- and two-person CPR.[9] Rescue breaths should provide only enough force and volume to cause chest rise. Excessive ventilation force or tidal volumes run the risk of overcoming esophageal opening pressure and thereby contributing to gastric inflation[75] and its consequences.[76,77] Once a tracheal tube is in place, ventilation can occur at a rate of 8 to 10 breaths per minute independent of chest compressions.[9] Ventilation should minimally disrupt chest compressions.

During the first few minutes after the onset of cardiac arrest, chest compressions are more important than rescue breathing (provided that the cardiac arrest is not secondary to asphyxiation, as with drowning or suffocation). Delivery of oxygen to tissues with CPR is limited more by blood flow and low cardiac output than by arterial content.[9] The low cardiac output associated with CPR results in low oxygen uptake from the lungs, which in turn reduces the need to ventilate the patient during this low-flow state.[78] In view of this information, uninterrupted chest compressions must be given the highest priority early in resuscitation efforts.

Anesthesiologists use advanced life support procedures and devices early in resuscitation, whether in the operating room or elsewhere; these procedures are reviewed here within the context of early control of the airway and ventilation. In the traditional BLS/ACLS format, these procedures are all considered ACLS techniques and adjuncts.

Endotracheal intubation is the usual and expected standard of airway control in the critical care setting.[79] Alternative airways that may be useful in gaining rapid control of the airway and ventilation while reducing the risk of pulmonary aspiration of gastric contents in situations in which tracheal intubation is not possible include the laryngeal mask airway (LMA) and the esophageal-tracheal Combitube[80-82] (also see Chapter 50). These devices are classified in Guidelines 2005 as acceptable and possibly helpful, especially when the rescuer is inexperienced in placing tracheal tubes.[9] Although they may be helpful as temporizing devices, endotracheal intubation remains the optimal technique for controlling the airway and ventilating the lungs during CPR. Regardless of the device used, once an advanced airway is inserted and placement confirmed, ventilation can be provided at a rate of 8 to 10/min without interruption of chest compressions.

Confirmation of proper placement of an endotracheal tube can be difficult in a patient who has undergone cardiac arrest. Observation of the rise and fall of the thorax and auscultation of lung fields in this situation can be misleading. Likewise, because of the very low pulmonary blood flow during CPR, P_{ETCO_2} detection devices may not readily distinguish tracheal from esophageal intubation. For these reasons, esophageal detector devices based on the description by Wee[83] have been introduced and advocated for use in emergency situations such as cardiac arrest. Both a syringe and a self-inflating bulb have been used. The efficacy of these devices in distinguishing esophageal from tracheal intubation is based on the principle that the trachea remains patent during aspiration of air whereas the esophagus collapses because of its fibromuscular structure. The effectiveness of the self-inflating bulb in distinguishing esophageal from tracheal tube position[41,42,84] and in confirming proper position of the esophageal-tracheal tube has been documented.[85] In an emergency patient population, an esophageal detector device as described by Wee was observed to be more accurate than detection of P_{ETCO_2} because of its greater accuracy in patients in cardiorespiratory arrest.[83] False-negative results with the self-inflating bulb occur more frequently in emergency intubations than in anesthetized patients undergoing elective procedures. Causes include partial tube obstruction with secretions, atelectasis, bronchospasm, and endobronchial intubation.[86] A high incidence of false-negative results was observed in morbidly obese patients.[87] In these patients, reduced functional reserve capacity and large-airway collapse secondary to invagination of the membranous posterior tracheal wall after the application of subatmospheric pressure with the self-inflating bulb were identified as the cause of the false-negative results.[87] With these limitations in mind, the self-inflating bulb or syringe-type esophageal detector is useful in emergency situations such as cardiac arrest, particularly when used in combination with P_{ETCO_2} detection.

Despite extensive experience with the LMA in fasted patients undergoing general anesthesia, its role during CPR remains somewhat controversial.[88-92] In anesthetized patients, positive-pressure ventilation with the LMA is safe and effective, but concern was expressed that gastric inflation could be a problem in the presence of increased inflation pressure.[93] This problem, of course, is common in patients who sustain cardiorespiratory arrest because they typically have a full stomach and frequently require high inflation pressure during ventilation. The

LMA has been used successfully in arrested patients who have no evidence of regurgitation or aspiration.[94] In patients in whom endotracheal intubation is not possible, the LMA is more secure than a facemask and offers an alternative to control the airway and ventilate the patient.[90,95] Importantly, placement of an LMA by an inexperienced provider cannot result in unrecognized esophageal intubation in a patient requiring emergency airway management.

The esophageal-tracheal Combitube is an acceptable alternative airway device for use in cardiac arrest. The Combitube is a double-lumen device with proximal pharyngeal and distal inflatable cuffs that is introduced blindly into the airway. One lumen of the device has a closed distal lumen and ventilation holes at the level of the hypopharynx. The second lumen is open ended with a balloon cuff at its distal end. Both lumens of the airway can accommodate ventilation. Once inserted and followed by inflation of the pharyngeal and distal cuffs, confirmation of the proper ventilation port is mandatory. Auscultation and P_{ETCO_2} detection must demonstrate that tracheal rather than esophageal ventilation has been achieved.[96] When the esophageal-tracheal Combitube is properly placed, the airway is isolated and the risk for aspiration of gastric contents is reduced.

If these devices and techniques are unsuccessful in securing an airway, immediate cricothyroidotomy may be necessary. A 12-, 13- or 14-gauge catheter-over-needle device can be inserted quickly into the trachea through the cricothyroid membrane. Equipment permitting transtracheal jet ventilation from a 50-psi oxygen source through such a catheter should be available in the operating room and ICU.[97,98] Benumof and Scheller[98] provided specific guidelines for acceptable transtracheal jet ventilation systems. These guidelines should be considered for the implementation of an effective jet ventilation system in operating rooms or ICUs. Ventilation of an arrested patient can be accomplished with a variety of devices, including anesthesia bags, self-inflating bags, oxygen-powered, manually cycled demand valves with peak flow rates of 40 L/min, and time cycled, constant inspiratory flow rate generators known as automatic transport ventilators.

Increasingly, airway management and ventilation conducted in the setting of resuscitation has come under scrutiny.[16,17,67,68] Clinical studies support the concept that circulation, not ventilation, has the greatest impact on survivability after cardiac arrest.[67,99,100] Yet chest compressions are frequently interrupted for prolonged periods to allow either ventilation or placement of an advanced airway in both the in-hospital[16] and prehospital environments.[17] Ventilation during resuscitation, with or without the advanced airway in place, is often excessive and associated with increased intrathoracic pressure, lower coronary perfusion pressure, impaired venous return, and ultimately, decreased survival.[28,101] The team leader must be attentive to the rate and vigor of ventilation performed during resuscitation attempts, in addition to other components of therapy.

Automated External Defibrillators and Manual Defibrillation

The most frequent cardiac rhythm responsible for witnessed cardiac arrest in adults is VF. CPR prolongs the duration of VF but cannot convert the arrhythmia to an organized rhythm. Successful termination of this arrhythmia requires prompt electrical defibrillation, not medications. The most recent AHA guidelines include early defibrillation with an AED as part of BLS training and the concept of public-access defibrillation, which endorses the policy of making defibrillation available to victims of cardiac arrest through nonconventional providers (e.g., police, security guards, and others).[9] The AED, when applied to a patient, is capable of analyzing cardiac rhythm, detecting VF and rapid ventricular tachycardia (VT), and then delivering a defibrillatory shock. A trained rescuer's role is to apply the defibrillator pads to the patient's chest, activate the AED, and if the device indicates that a shock is indicated, deliver the shock by pushing a button when prompted to do so by the AED.

Previous guidelines addressing AED use in cardiac arrest recommended administering up to three consecutive uninterrupted shocks if needed to terminate VF. Chest compressions were not performed during the shock sequence. Current experimental and clinical evidence suggests that success in defibrillation and survival are negatively influenced by frequent or prolonged interruptions in chest compressions during cardiac arrest.[14] In light of this most recent information, Guidelines 2005 recommends a single shock from an AED followed immediately by a 2-minute period of CPR, the equivalent of five cycles of 30:2 chest compression-ventilation, before reanalysis of the cardiac rhythm. Chest compressions are continued until the AED is charged and ready to deliver the shock. In most instances, the heart is at least transiently "stunned" by defibrillation shocks and is benefited by a period of coronary blood flow with chest compressions. For the exceptional patient with invasive monitoring present at the time of cardiac arrest, if an organized cardiac rhythm with a perfusing arterial waveform follows defibrillation, chest compressions may not be indicated.[70] The recommended sequence of actions to minimize interruptions in CPR during treatment of cardiac arrest with AED technology is shown in Figure 97-3.

VF is a highly metabolically active state of the myocardium. In the presence of VF, myocardial stores of oxygen and metabolic

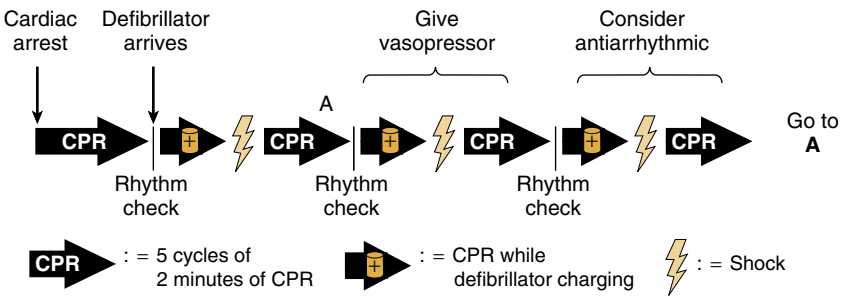

Figure 97-3 Pulseless arrest: treatment sequences. CPR, cardiopulmonary resuscitation. *(From CPR and ECC Guidelines 2005. Handbook of Emergency Cardiovascular Care for Healthcare Providers. Dallas, American Heart Association, 2006, p 8.)*

substrates are depleted rapidly. Chest compressions deliver oxygen and energy substrates to the myocardium, thus making defibrillation more likely. Experimental animal[102] and prehospital evidence from Seattle[103] and Oslo[104] demonstrate increased defibrillatory success when CPR is provided before defibrillation, particularly if the cardiac arrest was unwitnessed or if the time between cardiac arrest and arrival of rescuers exceeds 4 minutes. Guidelines 2005 recommends 2 minutes of CPR (five cycles of 30:2 compression-ventilation) before the first rhythm analysis of the cardiac arrest in the setting of unwitnessed cardiac arrest or delays in initiation of CPR. In settings in which defibrillation technology (manual defibrillator or AED) is immediately available (i.e., <3 minutes), rescuers should begin CPR and then defibrillate as soon as possible.[9]

The first AED was introduced in 1979.[105] In 1986, the first microprocessor-based AED was introduced; this AED used three successive, nonescalating, 180-J monophasic damped waveform shocks. Advances in defibrillator technology, including conversion from monophasic to biphasic defibrillator waveforms, resulted in smaller, lighter units with more accurate rhythm analysis. Impedance-compensated, nonescalating low-energy biphasic waveforms (150 J) were first introduced in 1996 and have been shown to achieve success in terminating VF in comparison to traditional, escalating-energy monophasic waveforms (200 to 300 J) in the controlled setting of an electrophysiology laboratory.[106-108] Biphasic waveforms deliver energy first in one direction and then reversed for the duration of the impulse. One of two biphasic waveforms is used in modern AEDs and defibrillators: biphasic truncated and rectilinear biphasic. Both waveforms have proved effective in terminating VF, with the energy levels used being specific to each waveform. Impedance compensation allows the defibrillator to change waveform morphology based on the impedance measured during delivery of a shock (typically 70 to 80 Ω) to generate transthoracic current capable of defibrillation. Biphasic defibrillation waveforms and impedance compensation together allow effective defibrillation at lower energies than with monophasic, non–impedance-compensated monophasic waveforms.[109-112] Defibrillation success is defined as termination of VF into an organized rhythm or asystole 5 seconds after shock, regardless of the hemodynamic response.[113]

Guidelines 2005 recommends a single AED shock (as determined by the AED), followed immediately by CPR for 2 minutes as part of BLS with the availability of an AED.[9] An issue probably faced by trained rescuers is the wide variability of AED devices encountered in both health care facilities and public-access defibrillation settings. Given the cost, longevity, and low-maintenance nature of AEDs, replacement of previous-generation devices programmed with outdated defibrillation protocols will probably have low priority by those responsible for managing the devices. As a result, a rescuer applying an AED may find an outdated rhythm analysis (i.e., prolonged interruption of chest compressions) and defibrillation protocol (i.e., three stacked shocks). At this time, deferring to the AED protocol, even if outdated, is probably more helpful than attempting to circumvent the protocol and "trick" the AED into following a current protocol. Effort should be made to obtain a manual defibrillator at the earliest opportunity if an outdated AED protocol interferes with the resuscitation attempt.

In circumstances in which standard defibrillators rather than AEDs are used for resuscitation, the rescuer must recognize the technology inherent in the defibrillator. When a manual defibrillator is activated, the rhythm screen typically identifies the defibrillation technology as either monophasic or biphasic. The manual defibrillator should be managed with a protocol identical to current AED protocols: an emphasis on delivering uninterrupted chest compressions while the defibrillator pads are being applied and for periods when rhythm analysis is not occurring, resumption of chest compressions immediately after delivery of a shock, reanalysis of cardiac rhythm as indicated after 2 minutes of chest compressions and rescue breathing, and an attempt at defibrillation for only VF and rapid VT. If a monophasic defibrillator is available, defibrillation energy should begin at high energy (300 to 360 J).[9] Prospective human clinical studies have failed to identify the optimal biphasic energy levels for first or subsequent defibrillation attempts.[112,114,115] Although first-shock energies specific to the defibrillation waveform have been recommended (150 to 200 J with a biphasic truncated exponential waveform, 120 J with a rectilinear biphasic waveform), a rescuer encountering an unfamiliar device should choose an energy setting of 200 J for the first shock and may increase the energy as needed for subsequent shocks when indicated.[116] In addition, when biphasic waveform defibrillation is used, the body weight of the patient does not influence the energy delivered because the waveforms compensate for transthoracic impedance to allow uniform delivery of energy and thus obviate the need to vary from the recommended defibrillation energy. This concept has been demonstrated in a study by White and colleagues.[117] Time to the first shock remains the most important factor influencing successful resuscitation.

Additional discussion related to cardioversion and defibrillation is included in the treatment algorithms for specific arrhythmias presented later.

Advanced Cardiac Life Support

Although it is commonly understood and accepted that all physicians, regardless of specialty, should be able to perform CPR, it must be emphasized that CPR almost invariably necessitates rapid interventional follow-up care with ACLS procedures. Anesthesiologists should be capable of rendering such definitive follow-up intervention, whether in the operating room, ICU, emergency department, delivery room, or hospital ward. In the operating room, cardiac arrest is rare. In two studies, cardiac arrests occurring within 12 hours[118] and 24 hours[119] of induction of anesthesia were reviewed to evaluate the role that anesthesia may have contributed to the cardiac event. The somewhat reassuring observation that intraoperative cardiac arrests are rare (1.1/10,000 and 1.4/10,000 in the aforementioned two studies) does not dismiss the need for anesthesiologists to be thoroughly acquainted with ACLS equipment and interventions because when these methods are needed, they must be executed skillfully and decisively. The need for skillful and knowledgeable ACLS intervention in intraoperative cardiac arrest is recognized.[120] Failure to intervene rapidly with ACLS pharmacologic therapy was identified as a major cause of poor outcome in other reports of intraoperative cardiac arrest.[120,121] It is evident that ACLS is a body of knowledge and skill with which anesthesiologists must be thoroughly familiar.

In a study using a computer program that simulates critical patient incidents such as cardiac arrest, it was observed that only 30% of participants, who consisted of anesthesiology residents,

faculty, and private practitioners, managed a simulated cardiac arrest in accordance with the AHA ACLS guidelines.[122] Timing since the last ACLS training was noted to be an important predictor of proper management of simulated cardiac arrest. Of those trained in ACLS within 6 months preceding the assessment, 71% managed cardiac arrests successfully, whereas successful management decreased to about 30% in those whose ACLS training occurred 6 months to 2 years earlier. No participant who had been trained in ACLS longer than 2 years before the assessment used ACLS guidelines correctly in the simulated cardiac arrest management.[122] These findings are consistent with a recent report assessing anesthesiologists' retention of resuscitation skills and knowledge after ACLS training.[123] These authors found a significant decline in skill (i.e., time to first defibrillation, defibrillation sequence, administration of medicine, tracheal intubation) and knowledge by 6 months. These findings support the position that some form of periodic training and retraining in ACLS is necessary for maintaining the level of knowledge and skills essential for management of cardiorespiratory arrest in accord with contemporary principles as incorporated in the ACLS training program.

Monitoring and Recognition of Arrhythmia

Prompt recognition and treatment of potentially life-threatening (pre-arrest) cardiac arrhythmias are essential components of ACLS.[124] Early recognition and immediate pharmacologic intervention necessitate the full application of BLS and ACLS and can frequently prevent the onset of fatal arrhythmias. In this context, supraventricular arrhythmias that may cause hemodynamic compromise are discussed first, followed by recognition and management of those that are ventricular in origin.

Supraventricular Bradyarrhythmia

Supraventricular bradyarrhythmias may be sinus or junctional in origin, or they may be caused by second-degree (types I and II) or third-degree atrioventricular (AV) block. Sinus (or junctional) bradycardia and type I (AV nodal) second-degree block are usually manifestations of increased vagal tone. Sinus bradycardia and type I second-degree AV block (Wenckebach phenomenon) may be observed during high-dose narcotic anesthesia. During spinal anesthesia, reduced venous return and unopposed vagal tone may produce bradycardia and hypotension of sufficient severity to progress to cardiac arrest.[125] Treatment is indicated whenever the bradycardia, regardless of type, leads to a significant decrease in systemic arterial pressure, produces clinical signs of reduced cardiac output (or a decrease in measured output), or is accompanied by ventricular ectopic depolarization. Any of these signs should be taken as evidence of hemodynamic or electrophysiologic deterioration with the propensity to progress to lethal arrhythmias, either asystole or VF. Initial treatment is atropine, 0.5 to 1.0 mg intravenously and repeated as needed at 3- to 5-minute intervals up to 0.04 mg/kg.[126] If such treatment is ineffective in producing an increase in heart rate and hemodynamic (increased systemic pressure, cardiac output, or both) or electrophysiologic (elimination of ventricular ectopy) improvement, alternatives include external or transvenous pacing or, during spinal anesthesia, low-dose (0.2 mg) intravenous epinephrine.[127] The availability of intraoperative cardiac pacing equipment and techniques has diminished the need for isoproterenol for the treatment of bradyarrhythmias. The increase in myocardial oxygen demand imposed by isoproterenol makes its use potentially hazardous in the presence of acute myocardial ischemia. If transvenous or transcutaneous pacing is not available for treating atropine-refractory bradyarrhythmias, an infusion of dopamine (5 to 20 μg/kg/min) or epinephrine (2 to 10 μg/min) would be a better choice than isoproterenol.

Pulmonary artery catheters that permit the insertion of atrial or ventricular pacing probes are available (also see Chapter 40). If such a catheter is in place, emergency pacing can be instituted rapidly. Pacing probes can be advanced into position quickly to permit rapid control of the cardiac rate by ventricular, atrial, or AV sequential pacing. Atrial pacing wires require an intact AV nodal conduction system. Ventricular pacing is indicated when AV nodal conduction is disrupted.

External transcutaneous pacing can be used to rapidly treat atropine-resistant bradyarrhythmias. These devices have been described as safe and effective, and intraoperative experience has been favorable.[128,129] They should be readily available for emergency use along with a defibrillator. External pacing is not beneficial in bradyasystolic arrest.

Transesophageal atrial pacing has been effective in treating intraoperative supraventricular bradyarrhythmias such as sinus or junctional bradycardia.[130,131] In its present configuration, however, it cannot be used to pace the ventricles and therefore is not useful in the management of any form of bradycardia caused by AV conduction disturbances.

Supraventricular Tachyarrhythmia

Supraventricular tachyarrhythmias include atrial flutter, atrial fibrillation, AV junctional tachycardia, multifocal atrial tachycardia, paroxysmal reentrant tachycardia, and other much less frequent arrhythmias. Paroxysmal supraventricular tachycardia (PSVT), atrial fibrillation (or flutter) with rapid ventricular rates, and multifocal atrial tachycardia are discussed here because not only can they produce hemodynamic compromise, they can also present diagnostic and therapeutic challenges.

An example of PSVT is shown in Figure 97-4. If such a tachyarrhythmia produces hemodynamic deterioration, cardioversion is the treatment of choice. The recommended initial dose for cardioversion of atrial tachyarrhythmias is 100 to 200 J if a monophasic defibrillator is used or 100 to 120 J with a biphasic device. Energy can be increased as needed if the arrhythmia is resistant to therapy. If the patient is hemodynamically stable, vagal maneuvers can be attempted (e.g., Valsalva maneuver in awake patients) before initiating pharmacologic interventions. Vagal maneuvers alone will terminate about 20% to 25% of reentry supraventricular tachyarrhythmias.[132] If vagal maneuvers are unsuccessful, adenosine is the drug of choice for termination of organized rapid supraventricular arrhythmias.[133-135] Adenosine slows sinoatrial and AV nodal conduction and prolongs refractoriness, which is very effective in terminating PSVT, the most common cause of which is reentry within the AV node.[136-138] The drug is of diagnostic usefulness in revealing the underlying mechanism in tachyarrhythmias of uncertain origin (e.g., atrial fibrillation, atrial flutter) by inducing transient block of AV nodal conduction (see Fig. 96-4).[139-141] Because of rapid cellular uptake and metabolism, adenosine must be injected rapidly into a venous catheter proximal enough to the heart to ensure delivery of a sufficient concentration of the drug at the AV node to induce an AV nodal conduction block. Adenosine can be used initially in a

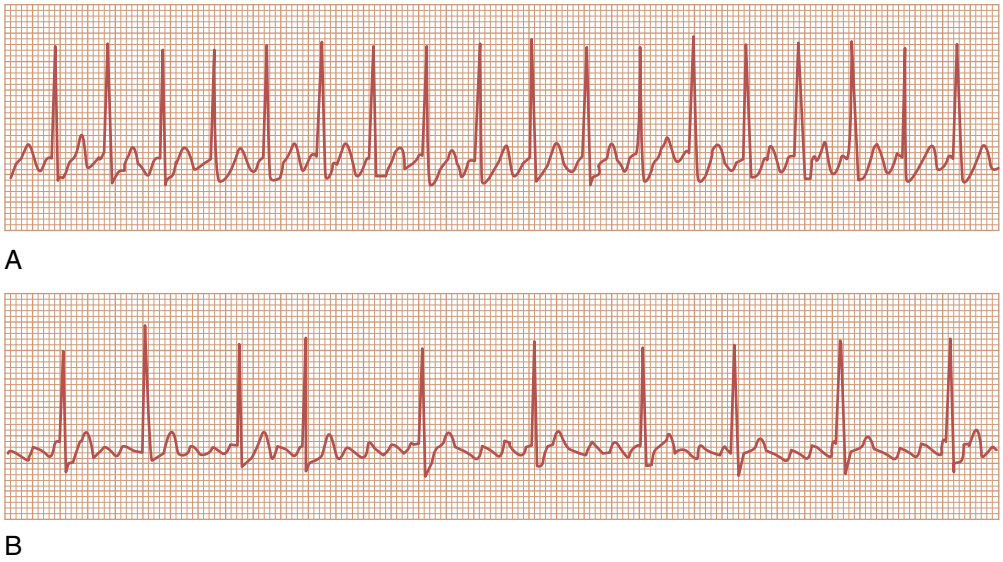

Figure 97-4 **A,** A supraventricular tachycardia at a rate of 180 beats/min is present; the origin of the tachycardia is not evident. **B,** After injection of 6 mg adenosine, atrial flutter waves are clearly visible, thus establishing the diagnosis.

dose of 6 mg, and if necessary, a second dose of 12 mg can be given in 1 to 2 minutes. If a central venous catheter is used, these doses can be reduced to 3 and 6 mg, respectively.[142] If the drug is injected more distally and slowly (e.g., into a small-bore catheter in a dorsal hand vein), not only may therapeutic failure result, but transient acceleration of the tachyarrhythmia may occur as well (Fig. 97-5).[143] This paradoxical acceleration of the rate is a manifestation of the increase in sympathetic nervous system traffic induced by adenosine in the presence of inadequate AV nodal blockade. Likewise, conversion of 2:1 or 1:1 conduction in atrial flutter has been observed.[144-146] This adverse effect indicates that an attempt to establish the diagnosis of atrial flutter should be made electrophysiologically, with vagal maneuvers used if necessary to unmask the flutter waves. Rate acceleration has also been observed after the administration of adenosine to patients with atrial fibrillation and preexcitation (Wolff-Parkinson-White syndrome).[147] As with verapamil in this setting, the acceleration in rate is a result of the AV nodal block with diversion of fibrillation wave fronts through the accessory connection. Even though the short half-life of adenosine may reduce this hazard, it seems prudent to avoid adenosine, as well as other AV node–blocking drugs, in patients with atrial fibrillation and preexcitation.

Adenosine's very short half-life (<5 seconds) is both advantageous and disadvantageous: side effects such as flushing,

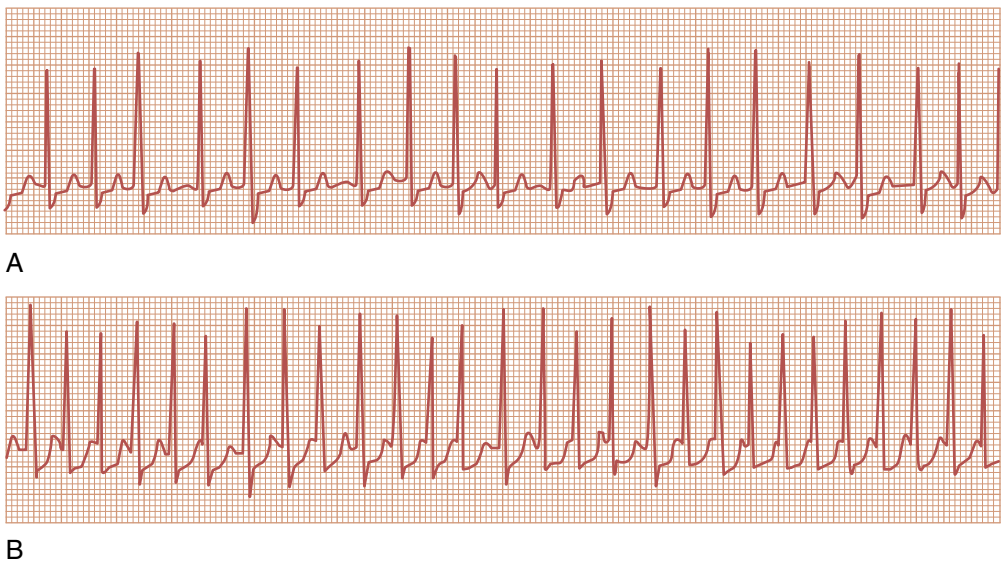

Figure 97-5 **A,** Atrial fibrillation with a ventricular response of 190 beats/min. **B,** After injection of 6 mg adenosine, the ventricular response increased to 240 beats/min. *(From White RD: Acceleration of the ventricular response in paroxysmal lone atrial fibrillation following the injection of adenosine. Am J Emerg Med 11:245, 1993.)*

Table 97-2 Administration of Adenosine*

Peripheral (antecubital)	6 mg, then 12 mg if needed
Central	3 mg, then 6 mg if needed

If taking dipyridamole	2 mg peripherally, 1 mg centrally

*Use with caution in asthmatic patients and those taking carbamazepine.

dyspnea, and chest pain are short lived, but the tachyarrhythmia may recur and necessitate the use of another drug. The AV nodal–blocking action of adenosine is antagonized by theophylline or related methylxanthines and is potentiated by dipyridamole and carbamazepine.[133-135,148,149] A suggested scheme for the use of adenosine, including dosing adjustments, is presented in Table 97-2.

Bronchospasm has also been described after the injection of adenosine, including intraoperatively.[150-153] This complication has occurred in patients with bronchial asthma or chronic obstructive pulmonary disease (COPD). The mechanism is unknown, but the bronchospasm may result from stimulation of bronchial smooth muscle adenosine receptors or stimulation of mast cell–derived mediators of bronchoconstriction. Aminophylline, an adenosine receptor antagonist, has been used successfully intraoperatively to treat adenosine-induced bronchospasm.[153] In light of this experience, adenosine should not be used or should be used with caution in patients with a history of bronchial asthma or COPD with a bronchospastic component.

If the PSVT does not respond to adenosine or if it recurs, verapamil is the drug of choice. A dose of 5 mg produces a more sustained block of AV nodal conduction. Verapamil can also be used to slow the ventricular response in atrial fibrillation or flutter.[154] However, it should not be used in patients with Wolff-Parkinson-White syndrome in whom atrial fibrillation or flutter develops. In this setting, verapamil-induced increases in conduction over the accessory pathway may produce alarming acceleration of the ventricular rate or VF.[155-157] If atrial flutter or fibrillation results in hemodynamic deterioration because of the rapid ventricular response, cardioversion is the treatment of choice. Atrial flutter can be terminated with low-energy synchronized shocks.

Atrial flutter or fibrillation with a rapid ventricular response can cause rate-related hemodynamic compromise manifested perioperatively as hypotension, decreased cardiac output, or both. In hemodynamically unstable patients, cardioversion should be used. Recent-onset atrial flutter is typically very sensitive to low-energy shocks (e.g., 50 J, monophasic or biphasic waveforms) (Fig. 97-6). Atrial flutter can also be terminated by overdrive pacing with external generators that have this capability. For atrial fibrillation, the initial dose for cardioversion is 100 to 200 J with monophasic waveforms or 100 J to 120 J with biphasic waveforms. Escalation of energy doses for the second and subsequent doses is indicated.[9]

In hemodynamically stable patients with rapid ventricular rates secondary to atrial fibrillation or flutter, treatment is pharmacologic. With acute onset of these tachyarrhythmias, ibutilide given intravenously has the most rapid onset of effect in restoring sinus rhythm.[158,159] Ibutilide is a class III antiarrhythmic drug that prolongs the action potential duration and effective refractory period without effects on action potential upstroke. The dose is 1 mg given over a 10-minute period. A second dose can be administered 10 minutes after the first, if necessary. Conversion to sinus rhythm is more frequent with atrial flutter than with atrial fibrillation (63% versus 31%) and more frequent with atrial fibrillation of shorter duration.[158] Prolongation of the QT interval reflects the pharmacologic action of the drug; polymorphic ventricular tachycardia (PVT) accompanied by increases in the QT interval has been reported in 8.3% of patients receiving ibutilide, so clinicians should be prepared to manage this arrhythmia[158] (see discussion of ventricular tachyarrhythmias).

Alternative options for the treatment of supraventricular arrhythmias include diltiazem, verapamil, β-blocking medications, procainamide, and amiodarone. By slowing conduction and increasing refractoriness in the AV node, calcium channel–blocking agents result in control of the ventricular rate in patients with atrial flutter, atrial fibrillation, and multifocal atrial tachycardia. Diltiazem is given in an initial dose of 0.25 mg/kg over a 2-minute period, followed, if needed, in 10 to 15 minutes by 0.35 mg/kg. An infusion at a rate of 5 to 15 mg/hr can be used to maintain rate control. If verapamil is used, 5 mg can be given initially and then 5 to 10 mg in 15 to 30 minutes if needed. β-Adrenergic–blocking drugs are helpful in controlling the ventricular rate when no contraindications to use are present. Amiodarone is a complex agent with antiadrenergic effects in the presence of supraventricular arrhythmias and tachycardias resulting from accessory pathways or rapid AV node transmission of atrial impulses and in situations in which other agents have failed to control the heart rate. It is given as a 150-mg intravenous bolus over a 10-minute period, followed by a 1-mg/min infusion for 6 hours to a maximum daily dose of 2 g.

Multifocal (multiform) atrial tachycardia is a quite common tachyarrhythmia that is often misdiagnosed as atrial fibrillation.[160-162] Increased automaticity in multiple atrial foci results in a need for therapy different from that for reentrant supraventricular arrhythmias (atrial flutter, atrial fibrillation, PSVT). Multifocal atrial tachycardia is diagnosed by observing the presence of at least three morphologically different P waves in the same lead of a 12-lead electrocardiogram (ECG) and a ventricular rate more rapid than 100/min (Fig. 97-7). It is usually described as occurring in patients with COPD, especially during exacerbations, and ICU management is necessary. However, it occurs in other settings as well, such as hypokalemia, catecholamine administration, and acute myocardial ischemia.[163,164] Treatment of underlying conditions probably contributing to myocardial irritability is important. Digitalization and cardioversion, sometimes helpful in other supraventricular arrhythmias, are ineffective in multifocal atrial tachycardia. Digitalis toxicity or repeated and futile attempts at cardioversion can follow misdiagnosis. Acceptable rate control treatment in patients with preserved ventricular function includes calcium channel blockers, β-adrenergic blockers, and amiodarone. In the presence of impaired ventricular function, diltiazem and amiodarone may be useful.

Ventricular Bradyarrhythmia

In the setting of emergency cardiovascular care, the bradyarrhythmia arising within the ventricles that is in need of urgent treatment is complete heart block with a very slow idioventricular escape rhythm (e.g., 15 to 30 beats/min) (Fig. 97-8). In this situation, atropine can be tried, but the treatment of choice is external or transvenous pacing as soon as it can be accomplished. If an external pacemaker is available, pacing should be instituted quickly.

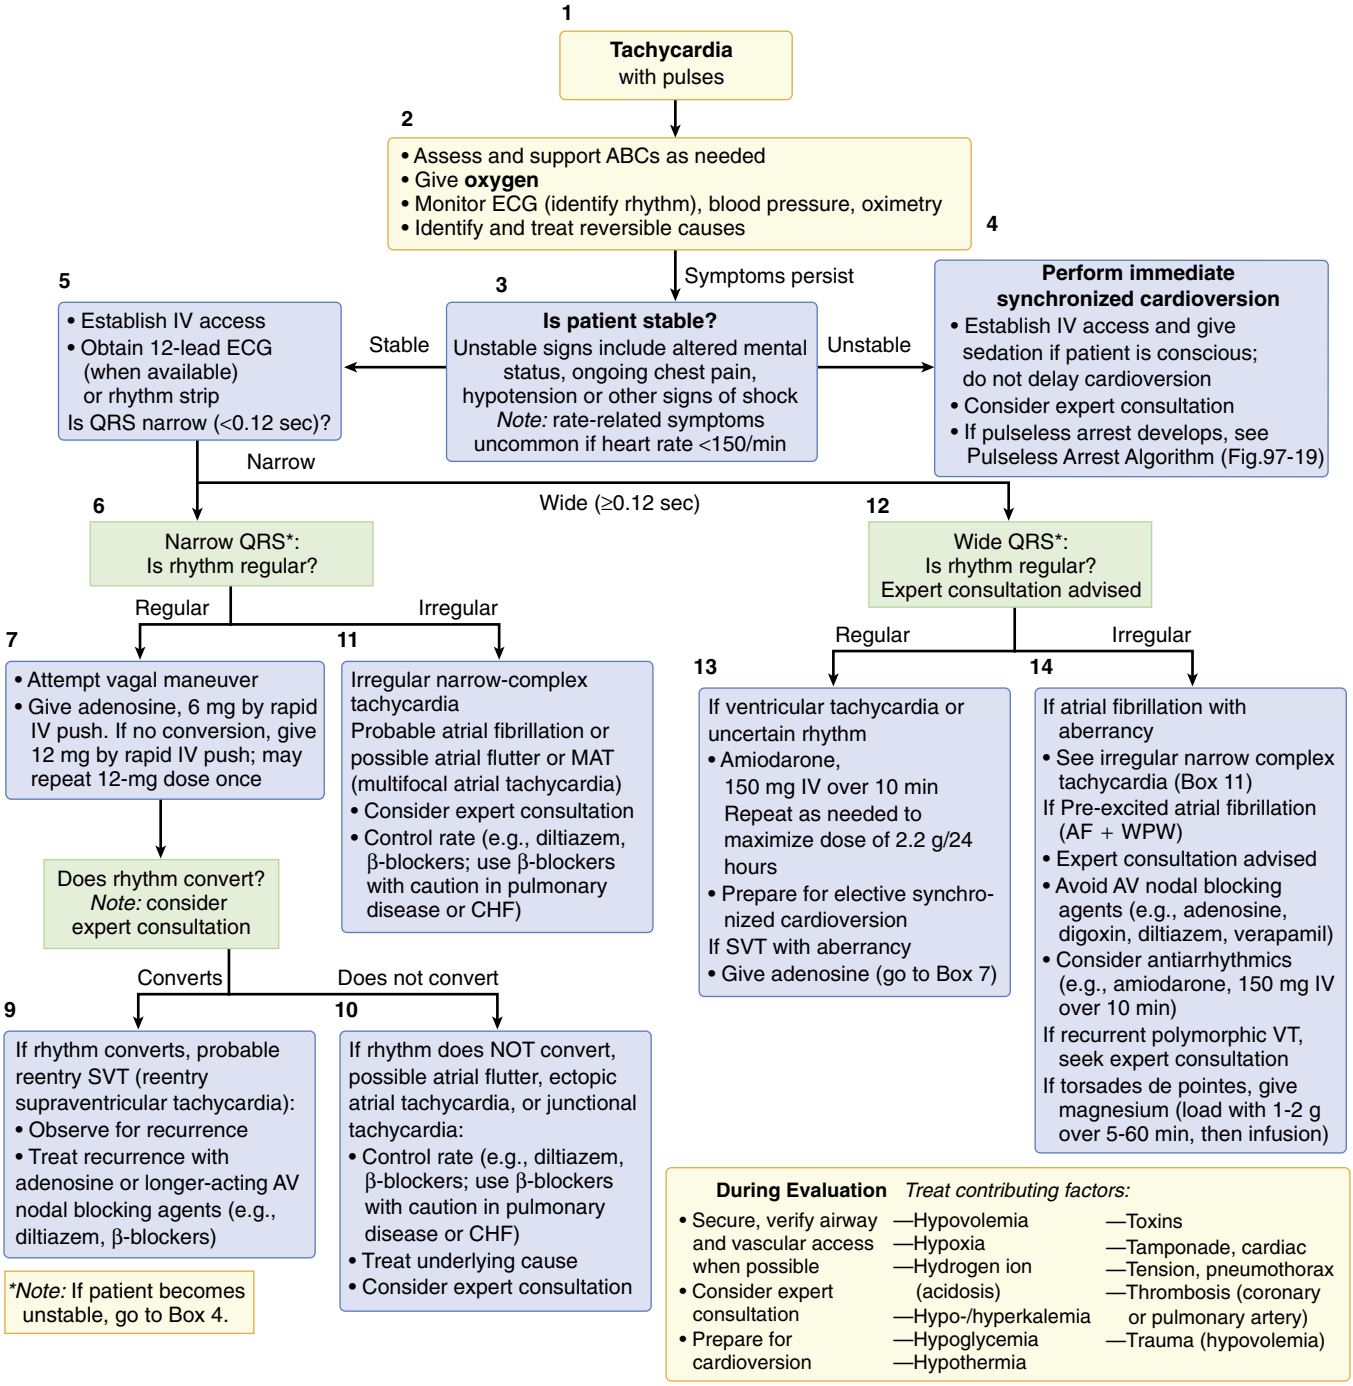

Figure 97-6 Advanced cardiac life support algorithm for tachycardia. ABC, airway, breathing, circulation; AV, atrioventricular; CHF, congestive heart failure; ECG, electrocardiogram; IV, intravenous; SVT, supraventricular tachycardia; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White syndrome. *(From 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 112:IV-70, 2005.)*

Ventricular Tachyarrhythmia

In the category of potentially life-threatening and sometimes pre-arrest arrhythmias, VT (Fig. 97-9) is commonly in need of urgent intervention. VT that produces cardiac arrest (pulseless VT) is discussed with VF. Treatable causes of VT should always be sought before or during pharmacologic or electrical interventions. Hypoxemia, hypercapnia, hypokalemia or hypomagnesemia (or both), digitalis toxicity, and acid-base derangements are obvious considerations.

Treatment of VT is dependent on the degree of hemodynamic compromise induced by the tachycardia. If the patient remains stable and ventricular function is preserved (no evidence of pulmonary edema or a known history of left ventricular function), procainamide and synchronized cardioversion are the treat-

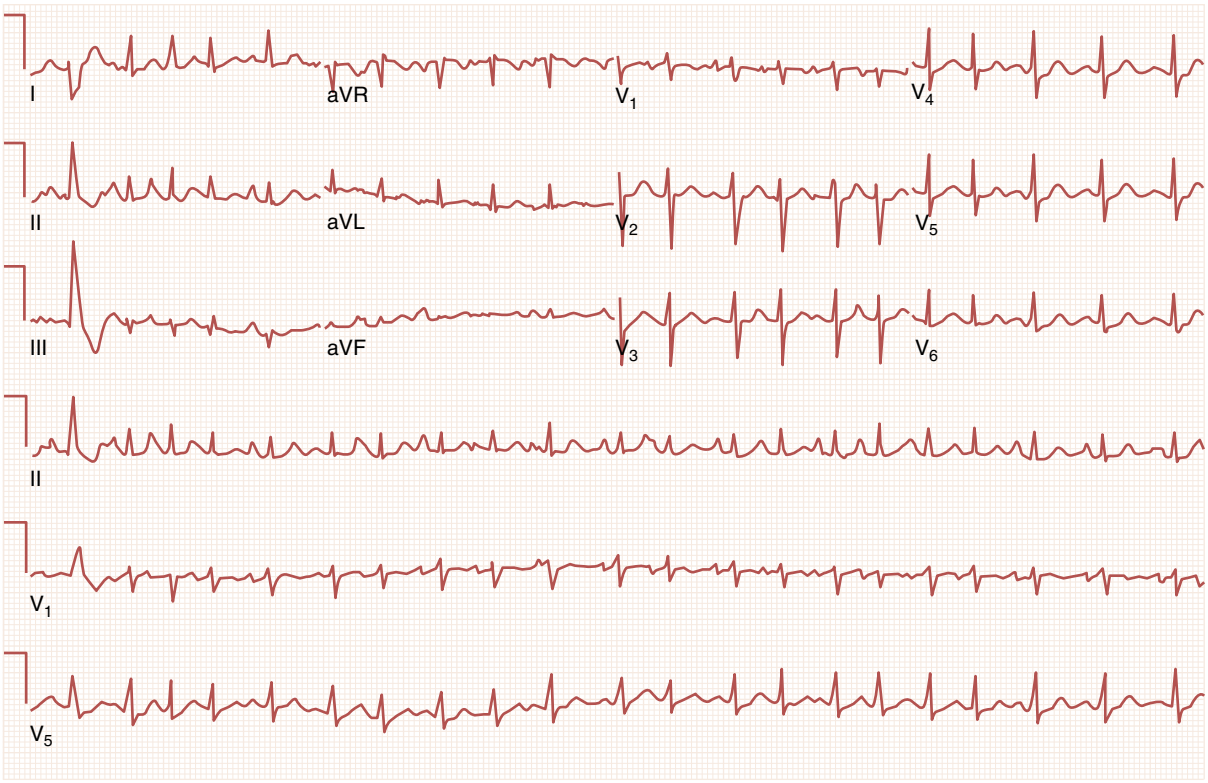

Figure 97-7 Multifocal atrial tachycardia. P-wave morphology varies across the tracing. Each QRS complex is preceded by a single P wave.

ment choices. If cardioversion is chosen, the energy levels are identical to those used in unstable patients. If procainamide is chosen, a loading dose of 20 mg/min until the tachycardia is controlled or a total of 17 mg/kg has been injected. Systemic hypotension and QRS widening by more than 50% of control values are therapeutic end points. If procainamide fails to control the arrhythmia, amiodarone should be administered. In patients with evidence of or known impaired left ventricular function, amiodarone is the drug of choice. Amiodarone, 150 mg in 100 mL of sterile water injected over a 10-minute period, followed by a loading infusion of 1 mg/min for 6 hours and then a 0.5-mg/min maintenance infusion over an 18-hour period, may be effective.[165-168] The mechanism of action of amiodarone is unclear, but it probably includes antisympathetic and calcium channel–blocking actions. It exerts antiarrhythmic action within an hour of intravenous administration. If breakthrough VT/VF occurs, supplemental 150-mg infusions over a period of 10 minutes can be given. The major adverse effects of amiodarone are hypotension and bradycardia, both of which can be prevented by slowing the rate of infusion.

In unstable patients (e.g., in the presence of systemic hypotension, pulmonary edema, or clinical or electrocardiographic signs of acute myocardial ischemia or infarction), synchronized cardioversion is the treatment of choice with either monophasic energy doses of 360 J or biphasic, nonescalating, impedance-compensated energy doses of 120 J. An algorithm for cardioversion of a variety of tachyarrhythmias, including VT, is shown in Figure 97-6.

An atypical form of VT known as *torsades de pointes* ("twisting of the points") that was originally described in 1966 is characterized by twisting of the QRS axis around the baseline and a polymorphic appearance.[169-173] The underlying electrophysiologic derangement in this arrhythmia is a marked and nonuniform delay in repolarization manifested by a prolonged QT interval on the ECG. It typically begins with a characteristic long-short initiating sequence (Fig. 97-10). It can be induced by drugs such as quinidine, procainamide, disopyramide, and phenothiazine, as well as by bradycardia, hypokalemia, hypomagnesemia, or acute ischemia or infarction.[174] Even though amiodarone produces marked prolongation of repolarization, it rarely causes torsades de pointes, possibly because the drug-induced prolonged repolarization is uniform (nondispersed), in contrast to the repolarization abnormality induced by other drugs.[175] Closely related

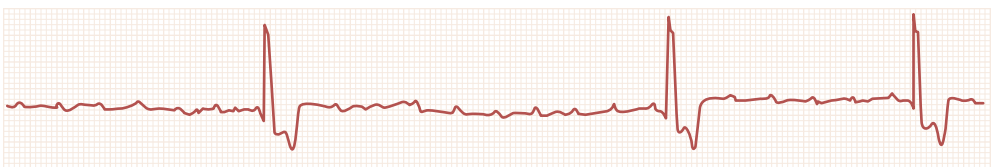

Figure 97-8 Slow (14 beats/min) idioventricular escape rhythm in a patient with carotid sinus hypersensitivity. External or transvenous pacing is the treatment of choice for bradyarrhythmias such as this.

Figure 97-9 Ventricular tachycardia. The rate is 280 beats/min, the QRS width is 160 msec, and three consecutive capture/fusion beats are seen.

to torsades de pointes is PVT (Fig. 97-11). Description of the tachycardia as PVT rather than torsades de pointes implies that there is no evident cause of prolonged repolarization and the QT interval is not prolonged.[176-179] Because both PVT and torsades de pointes can be life threatening, a correct diagnosis is required. The critical therapeutic distinction is based on the presence or absence of prolongation of the QT interval. If QT prolongation is present, therapy is directed toward shortening the repolarization time (after withdrawal of the offending drugs listed earlier or correction of abnormalities such as hypokalemia). In the past, drugs such as isoproterenol were used for this purpose, but definitive short-term therapy is overdrive ventricular or atrial pacing, preferably the latter, if AV conduction is intact. Magnesium sulfate has also been used successfully in the treatment of torsades de pointes, and some clinicians recommend it as the first line of emergency treatment.[180-183]

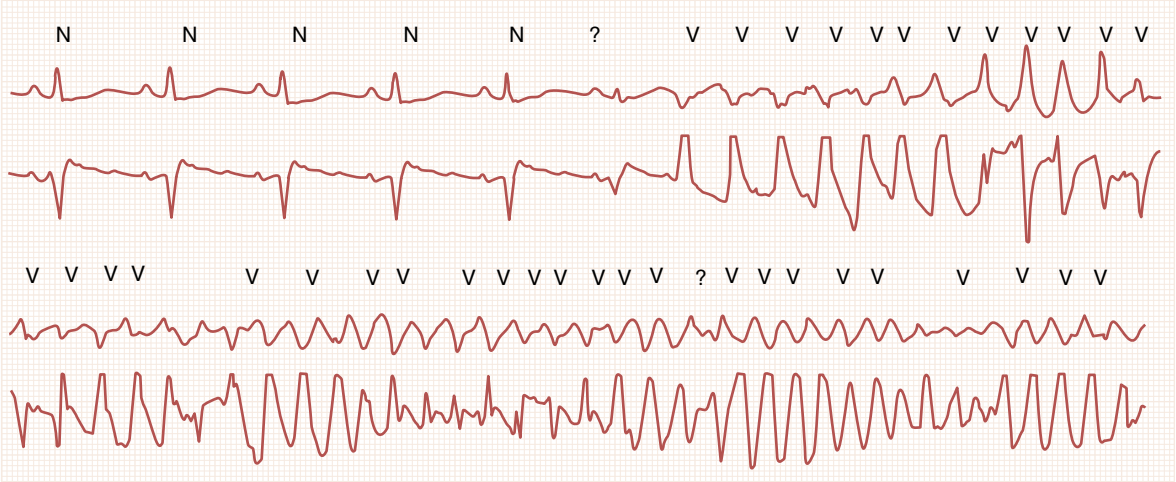

Figure 97-10 Polymorphic ventricular tachycardia. A prolonged QT interval during sinus rhythm suggests that the arrhythmia is torsades de pointes. This arrhythmia occurred in a patient after resuscitation from cardiac arrest.

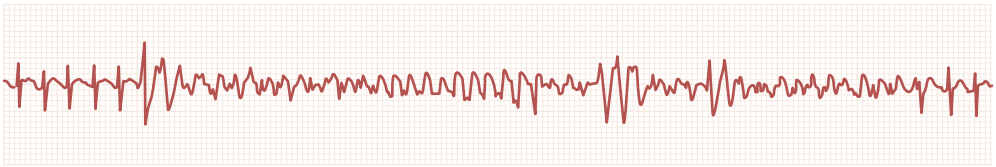

Figure 97-11 Polymorphic ventricular tachycardia. The QRS complexes have varying morphology, but without the "twisting of the points" torsades morphology seen in Fig. 97-10. The tachycardia terminated spontaneously. *(From White RD, Wood DL: Out-of-hospital pleomorphic ventricular tachycardia and resuscitation: Association with acute myocardial ischemia and infarction. Ann Emerg Med 21:1282, 1992.)*

If PVT is present (i.e., without evident QT prolongation), standard antiarrhythmic therapy as outlined earlier for VT can be tried, although magnesium sulfate should be considered early in the treatment of this form of PVT as well, particularly if torsades de pointes is suspected by history but QT prolongation cannot be confirmed on the ECG. In fact, a 12-lead ECG is often needed to identify QT lengthening. If hemodynamic deterioration occurs with PVT, defibrillation should be used as the initial treatment.

An algorithm for the treatment of tachyarrhythmias that encompasses those of both supraventricular and ventricular origin is shown in Figure 97-6. This algorithm makes provision for intervention in patients with wide–QRS complex tachycardia (Fig. 97-12) of indeterminate origin based on the patient's hemodynamic stability. In a hemodynamically stable patient, Guidelines 2005 emphasizes making a specific diagnosis and identifying the presence of a clinically significant reduction in ventricular function rather than attempting a diagnosis based on response to antiarrhythmic mediations.[9]

Verapamil should be avoided in any wide–QRS complex tachycardia unless it is known with certainty that the tachycardia is supraventricular in origin; if VT is present, verapamil can induce severe hypotension or cardiovascular collapse in as many as 87% of such misdiagnosed episodes (Fig. 97-13). Any wide-complex tachycardia of uncertain origin (despite careful scrutiny of the ECG for all helpful clues) should be assumed to be VT and be treated accordingly. If the patient is hemodynamically deteriorating, cardioversion should be used initially without a preceding trial of drug therapy.

Management of Cardiac Arrest

This section reviews the interventions, both electrical and pharmacologic, used for treatment of the various forms of cardiorespiratory arrest. Included is a discussion of the major beneficial and adverse actions of the drugs used in ACLS. The clinical applications of some of these drugs have already been presented in the review of recognition and management of "pre-arrest" or potentially life-threatening events.

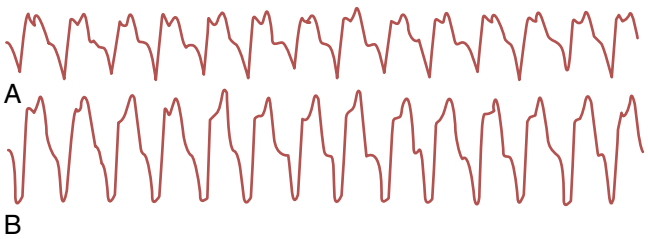

Figure 97-12 Wide–QRS complex tachycardia at a rate of 160 beats/min. **A,** Precordial lead 5. **B,** Lead 2. Atrioventricular dissociation is present, as evident by the P wave preceding the third QRS complex, thus confirming this to be ventricular tachycardia.

Pulseless Ventricular Tachycardia or Ventricular Fibrillation

For therapeutic purposes, pulseless VT and VF should be considered the same entity in need of the same interventions. It is fortunate that this is the most common form of cardiac arrest because it is the most treatable and it is the arrhythmia that yields the greatest likelihood of immediate and long-term survival, both in the hospital and out of the hospital.[184] This finding has accelerated the extension of early intervention in VF to levels of out-of-hospital emergency care lower than emergency medical technicians, even to first responders with minimal training. The likelihood of significant salvage by early defibrillation also accounts for the growing interest in and distribution of AEDs in public places and the rapid increase in implantation of cardioverter-defibrillators[185-190] in patients at risk for cardiac arrest from VF. It is obvious that physicians involved in caring for patients in the hospital are assumed to know now to intervene in the event of cardiac arrest, how to operate defibrillators, and how to administer drugs rationally, especially in the presence of VT/VF, when survival is likely with rapid and correct treatment. Unfortunately, retention of the knowledge and skills in resuscitative interventions learned in ACLS courses declines rapidly.[123] Periodic ACLS review courses may be indicated in the intervals between ACLS certification to ensure that current ACLS therapies and interventions are used. Making ACLS handbooks available to resuscitation teams may also improve performance of resuscitation events.

Despite rare reports of apparently spontaneous termination of VF, the required and definitive intervention is rapid defibrillation. Two practical and important considerations enter into every attempt to defibrillate patients in VF. The first is the energy output of the defibrillator.[191] Termination of VF is critically dependent on the amount of energy available from a defibrillator, and it is therefore necessary that output be checked at regular intervals. Guidelines for proper maintenance of defibrillators are available.[192]

The second practical consideration is resistance to flow of current during delivery of the shock. Current flow is inversely related to resistance; excessive resistance because of poor technique can impede the transthoracic flow of current adequate to induce defibrillation.[191] Guidelines 2005 recommends the use of self-adhesive defibrillation pads rather than paddles because the pads can be placed before cardiac arrest in patients at risk.[9] Preapplied electrode pads are particularly advantageous in the operating room when patient position precludes rapid access to the chest for standard paddle placement. Finally, defibrillation should

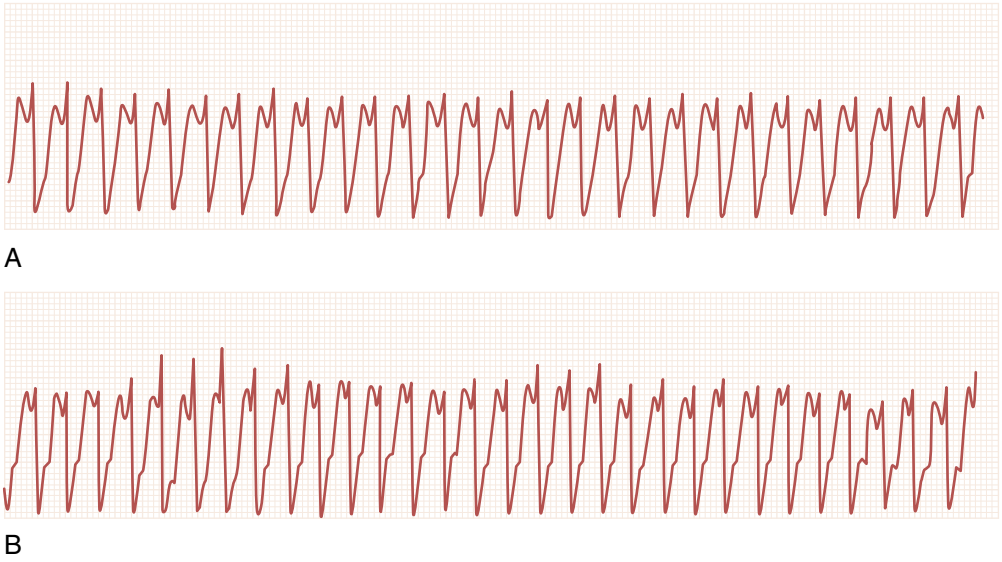

Figure 97-13 Adverse response to verapamil. Tachycardia thought to be atrial flutter was present initially (**A**). After injection of 5 mg verapamil, the rate accelerated and the patient became unresponsive, thus necessitating cardioversion (**B**). The first rhythm was ventricular tachycardia. Cardiovascular collapse is a potential complication of verapamil injection when the tachycardia is ventricular in origin.

occur at the end of expiration during rescue breathing to minimize impedance.

In the operating room or ICU, when cardiac arrest is witnessed and a monitor reveals the mechanism to be pulseless VT or VF, defibrillation should be performed immediately. If a monophasic defibrillator is available, 360 J should be delivered. Energy settings for biphasic defibrillators depend on the waveform. Biphasic truncated exponential waveforms should use 150 to 200 J for the first shock. Energy settings for rectilinear biphasic waveforms should use 120 J for the initial shock. If the rescuer is unfamiliar with the waveform used, 200 J should be used as a default energy.[9] All biphasic defibrillators available today are impedance compensated and adjust the delivered dose of energy in response to the impedance measured with each shock. If VF recurs, either the same or an escalating dose of energy can be used. At this time there is insufficient evidence that escalation of energy is superior to nonescalating energy shocks in terminating recurrent VF. In circumstances in which a cardiac arrest is witnessed but access to a defibrillator is delayed, chest compressions should be initiated immediately and continued until the defibrillator is available and charged. If at any time VF recurs after successful conversion, defibrillation should be repeated at the most recent successful energy level. If VF persists despite this initial treatment, pharmacologic therapy becomes necessary. It is assumed that the anesthesiologist has already controlled the airway and ventilation by endotracheal intubation and ventilation with 100% oxygen. In situations in which endotracheal intubation is not in place at the time of cardiac arrest, defibrillation takes precedence over endotracheal intubation if the defibrillator is immediately available.

If return of spontaneous circulation has not occurred after an initial attempt at defibrillation, five cycles of CPR consisting of 30 compressions to 2 ventilations, and then a second defibrillatory shock, pharmacologic interventions should accompany the resuscitative efforts. Currently, only two medications are recommended for use in cardiac arrest: epinephrine and vasopressin.[9] A peripheral intravenous line is recommended for resuscitation attempts because placement of a peripheral catheter does not interrupt chest compressions. Assuming that a peripheral intravenous line is present, initial drug injections can be given by this route, followed by a fluid bolus to propel the drug into the circulation. Peripherally administered drugs typically require 1 to 2 minutes to reach the central circulation in the setting of cardiac arrest. Two minutes of CPR should be performed after drug administration and before defibrillation is attempted. If peripheral venous access cannot be established, intraosseous or central venous cannulation should be considered.[9] Intraosseous cannulation will not interrupt chest compressions and will yield blood concentrations of drugs equivalent to those administered through a central line. In most circumstances a central line is not necessary for most resuscitation attempts and should not be pursued before peripheral or intraosseous attempts. Because of evidence that glucose administration during global cerebral ischemia can worsen neurologic outcome in survivors,[193-196] lactated Ringer's solution or normal saline should be used instead of glucose-containing solutions.

Previous clinical impressions regarding the beneficial effects of epinephrine during cardiac arrest, regardless of the underlying rhythm, have been substantiated.[197-201] The drug increases both cerebral and myocardial blood flow in experimental cardiac arrest.[197-199] The mechanisms responsible for enhanced cerebral and myocardial blood flow appear to be based on prevention of arterial collapse and intense vasoconstriction in other vascular beds, thus preventing runoff of blood into noncritical tissues and preferentially increasing cerebral and myocardial perfusion pressure and flow.[197] In human victims of cardiac arrest, epinephrine has been shown to produce increases in both peak aortic and coronary perfusion pressure, further attesting to its vasoconstrictive properties in a clinical setting.[202] The recommended dose of epinephrine is 1.0 mg (10 mL of a 1:10,000 solution). This dose should be repeated every 3 to 5 minutes as long as cardiac arrest persists to ensure sustained blood flow benefit.

If for some reason an intravenous line is not present or cannot be inserted promptly, endotracheal or intraosseous delivery of medication should be considered. Epinephrine can be injected into the tracheobronchial tree, a site from which it is rapidly absorbed to produce a prompt pharmacologic effect.[203-205] If this route is used, a dose of 2 to 2.5 times the intravenous dose is recommended.[126]

Because of the critical role of potent vasoconstriction in the beneficial action of epinephrine, phenylephrine has been studied as well.[198,206,207] Comparison of phenylephrine and epinephrine in experimental cardiac arrest has shown no evident benefit gained from using phenylephrine in terms of changes in blood flow,[197,207] somatosensory evoked potentials,[197] or neurologic or cardiovascular outcome.[199] Thus, epinephrine remains the drug of choice.

Based on experimental observations of apparent hemodynamic benefit from large doses of epinephrine (up to 0.2 mg/kg),[208,209] numerous clinical reports and studies have assessed the impact of high-dose epinephrine on such end points as restoration of spontaneous circulation and discharge from the hospital.[210-216] Although some investigators have observed an increased frequency of restoration of spontaneous circulation after high-dose epinephrine versus standard 1-mg doses,[214] most have not, and no study has yet confirmed benefit in terms of discharge and survival. Given the lack of conclusive evidence demonstrating benefit from high-dose epinephrine treatment, it is no longer accepted therapy for cardiac arrest.

Vasopressin was added to the treatment algorithm of VF and pulseless VT based on experimental and clinical data suggesting that it has beneficial effects on perfusion of vital organs during cardiac arrest.[217,218] Endogenous plasma vasopressin levels were noted to be significantly higher in patients successfully resuscitated from out-of-hospital cardiac arrest than in those who died, thus suggesting that the human body discharges this hormone under circumstances of physiologic stress.[219,220] Vasopressin acts by direct stimulation of smooth muscle V_1 receptors, and such stimulation results in prolonged smooth muscle constriction even in the presence of severe acidosis, which might maintain coronary perfusion pressure and contribute to improved success with resuscitation.[221,222] In one study, vasopressin administered to patients with refractory cardiac arrest led to increased blood pressure and, in some, return of spontaneous circulation.[223] However promising these results are in suggesting a potential benefit of vasopressin in cardiac arrest, no study has demonstrated significant benefit resulting in hospital discharge. In Guidelines 2005, the use of vasopressin is endorsed as an alternative to one dose of epinephrine during refractory VF.[9] Because of its long half-life (10 to 20 minutes) compared with that of epinephrine (3 to 5 minutes), vasopressin is administered in a one-time dose of 40 units intravenously or intraosseously.

If VF persists after initial defibrillation or injection of epinephrine or vasopressin (or both), a repeated defibrillation attempt at the maximal energy available for the device used should be initiated. If VF persists thereafter, mediations with antifibrillatory effects should be chosen. Amiodarone and lidocaine are acceptable choices. Lidocaine has not been shown in an evidence-based evaluation to have any demonstrable short-term or long-term benefit in patients with VF or pulseless VT. Amiodarone is the preferred antiarrhythmic agent in the presence of persistent VF. An initial amiodarone dose of 300 mg via the intravenous or intraosseous routes can be followed by a single dose of 150 mg.

Amiodarone produces prolongation of action potentials and refractoriness in all cardiac tissue. These effects may contribute to its potential use for refractory VF. In the study Amiodarone in Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachycardia (ARREST), Kudenchuk and colleagues[224] reported the results of a randomized, prospective study in which amiodarone, 300 mg intravenously, or placebo was administered to victims of out-of-hospital cardiac arrest with persistent VF after three attempts at defibrillation and 1 mg of intravenous epinephrine. The study demonstrated significant increases in survival to hospital admission in the amiodarone-treated group but was not able to demonstrate any difference in hospital discharge rates. In the study Amiodarone versus Lidocaine in Pre-hospital Ventricular Fibrillation Evaluation (ALIVE), Dorian and colleagues[225] reported the results of a double-blind, controlled clinical trial comparing amiodarone with lidocaine in patients experiencing out-of-hospital cardiac arrest in Toronto, Canada. Their results demonstrated that amiodarone was superior to lidocaine in terminating persistent VF in the out-of-hospital setting. Like the ARREST study, the ALIVE study was able to demonstrate the improvement induced by amiodarone only in survival to hospital admission, not to discharge, when compared with control or lidocaine therapy. Based on these studies, greater consideration for the use of amiodarone rather than lidocaine seems prudent in the management of patients experiencing persistent VF. However, given the current lack of evidence that survival to hospital discharge is improved with amiodarone versus lidocaine, there is no advantage in the use of either drug in the setting of refractory or persistent VF.

In cardiac arrest that does not respond to initial measures (intubation, ventilation with 100% oxygen, defibrillation, epinephrine, and antiarrhythmic drugs), sodium bicarbonate can be considered if specific conditions are present, such as preexisting metabolic acidosis, severe metabolic acidosis documented during resuscitation attempts, overdoses of tricyclic antidepressants, and hyperkalemia. If hyperkalemia is known or suspected to be present, sodium bicarbonate should be administered promptly (Fig. 97-14). Despite its long history of early and frequent administration in cardiac arrest, there is still no convincing evidence that it confers any benefit in survival from VF.[226,227] By contrast, its adverse effects are well documented, including severe plasma hyperosmolality,[228,229] paradoxical cerebrospinal fluid acidosis,[230] and generation of CO_2.[228,231] It is this last effect that has been primarily responsible for its infrequent role in cardiac arrest treatment algorithms.

During cardiac arrest with severely reduced pulmonary blood flow and therefore CO_2 transport and elimination, CO_2 is retained in mixed-venous blood and tissues, and a disparity between pH and P_{CO_2} in arterial and mixed-venous blood is produced.[231] Sodium bicarbonate is a rapid and potent generator of CO_2, which can be observed in arterial blood, as well as in expired air, after intravenous injection. Sodium bicarbonate would only add to the CO_2 load and could worsen mixed-venous (and presumably tissue) acidosis. Myocardial hypercapnic acidosis has been confirmed to exist during experimental cardiac arrest and resuscitation,[232] and it is not reversed with sodium bicarbonate or other buffer agents.[233] At least with regard to the heart, increases in tissue P_{CO_2} produce progressive decreases in the performance of ischemic myocardium. Clinically, one may infer that intractable pulseless electrical activity (PEA) could be a consequence, even if VF were eliminated. Myocardial hypercapnic

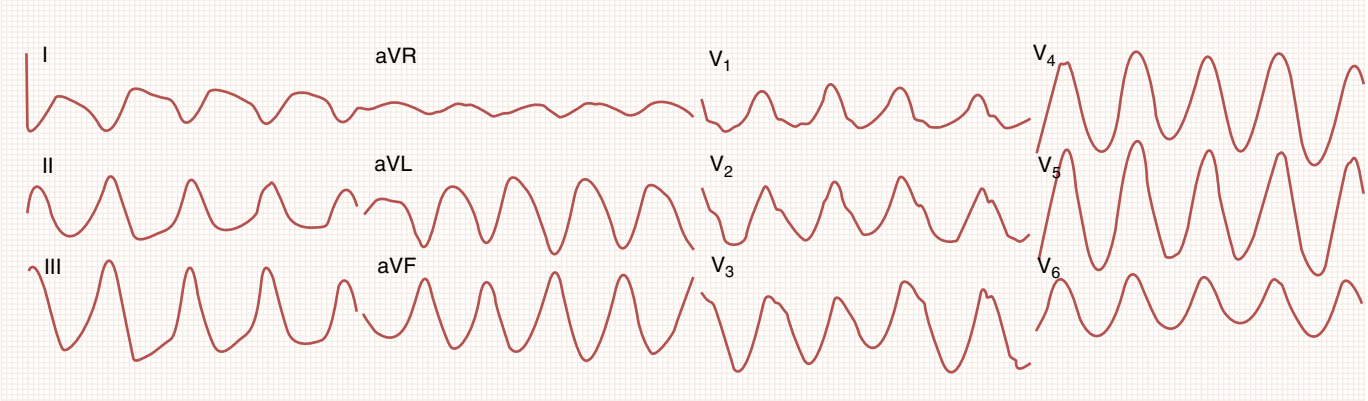

Figure 97-14 Hyperkalemic ventricular tachycardia with a sine-wave morphologic pattern.

acidosis decreases the success of restoration of spontaneous circulation and survival.[234]

In view of all these observations, sodium bicarbonate should not be used routinely in the treatment of cardiac arrest. It can be considered after the forgoing electrical and pharmacologic measures have been instituted, if preexisting metabolic acidosis is present, or if severe documented metabolic acidosis develops during the arrest.[235] A review of acid-base derangements during cardiac arrest[236,237] suggests that sodium bicarbonate may be beneficial in restoring spontaneous circulation after prolonged (15 minutes) VF cardiac arrest based on experimental observations. Clinically, if this drug is used, an initial dose of 1 mEq/kg can be given. When possible, bicarbonate therapy should be guided by bicarbonate concentrations or base deficits measured by blood gas analysis.

Pulseless Electrical Activity

PEA refers to a heterogeneous group of cardiac rhythm disorders, all characterized by pulselessness in the presence of some type of electrical activity other than VT or VF. Thus, included in this designation are traditional electromechanical dissociation, in which pulseless but organized electrical activity is present, idioventricular rhythms, ventricular escape rhythms, post-defibrillation idioventricular rhythms, and bradyasystole.

High priority must be given to identification of a possibly correctable cause of any form of PEA. For example, in a traumatized patient, hypovolemia, cardiac tamponade, and tension pneumothorax with hypoxemia are possible causes. Intraoperatively or postoperatively, acute massive pulmonary thromboembolism should be considered. Idioventricular rhythms may accompany such derangements as severe hyperkalemia, acidosis, hypothermia, or overdose with drugs such as digitalis, β-blockers, calcium channel blockers, and tricyclic antidepressants. In any of these forms of PEA, the most important point is that although initial temporizing measures such as injection of epinephrine or pacing may be needed to "tide the patient over," immediate diagnostic assessment and redirection of treatment in a disorder-specific direction may permit salvage of any patient with PEA. Figure 97-15 provides the PEA treatment algorithm with potentially reversible causes contributing to the condition.

Asystole

Complete and sustained absence of electrical activity is most often an irreversible and therefore terminal event caused by derangements such as uncorrected persistent hypoxia, severe hyperkalemia, massive drug overdose, myocardial infarction, or hypothermia. In most of these conditions, the asystole is irreversible and terminal, but at least a brief trial of interventions may be warranted in some patients. In specific instances such as hyperkalemia, known metabolic acidosis, or tricyclic antidepressant overdose, sodium bicarbonate should be administered early in the effort. Neither defibrillation nor pacing is indicated for the treatment of asystolic cardiac arrest.

Post–Cardiac Arrest–Induced Hypothermia

Therapeutic hypothermia is a new and significant intervention included in the Guidelines 2005 recommendations for patients who have experienced an out-of-hospital VF cardiac arrest, have been resuscitated, and are hemodynamically stable but unresponsive on hospital admission.[9,238,239] Hypothermia (32°C to 34°C) induced and maintained by external cooling techniques (cooling blankets, ice pack application) for 12 to 24 hours after resuscitation appears to be beneficial to neurologic outcome with minimal complications when compared with similar patients who were not cooled.[240] For patients with non-VF or in-hospital cardiac arrests, therapeutic hypothermia has not been studied. However, therapeutic hypothermia after resuscitation from cardiac arrest is given a class IIb recommendation, thus affording physicians the opportunity to use this intervention in the management of non-VF or in-hospital cardiac arrest occurring after resuscitation.

Outcome after In-Hospital Resuscitation

Discharge survival rates after in-hospital cardiac arrest and resuscitation range from 8% to 21%, with most reports demonstrating an average survival rate of approximately 14%.[241-251] These reports usually include cardiac arrests in both ICUs and general wards. In a retrospective review of 668 cardiac arrests over a 3-year period, the discharge survival rate was 3.3% in ICU patients and 14.0% in non-ICU patients.[249] In a small retrospective study of 24 consecutive patients who had an intraoperative cardiac arrest between 1986 and 1994, the survival rate was 38%.[252] A primary cardiac event was presumed to be causative in 50%. An accompanying invited commentary pointed out that much of the credit for these favorable outcomes is attributable to advances in intraoperative management by anesthesiologists. In any case, it is certain that anesthesiologists well trained in resuscitation can play a decisive role in the management of patients after intraoperative cardiac arrest.

The most favorable outcome, as in out-of-hospital cardiac arrest, is observed with VF or VT.[241,243,244,246-248] In a study compar-

ing CPR techniques in 143 hospitalized patients experiencing asystolic or PEA arrest, no patients survived to hospital discharge with intact neurologic function.[253] The duration of resuscitative attempts is a determinant of survival.[254-259] In one study, none of 179 patients in whom resuscitative effort lasted longer than 30 minutes survived to be discharged.[246] Other variables that limit survival from in-hospital cardiac arrest include unwitnessed arrest,[249] sepsis,[249] cancer,[246,249] renal failure,[246] and pre-arrest hypotension.[241,246] Age is a major determinant of outcome.[249] In one study no patients 70 years or older who experienced cardiac arrest and resuscitative attempts survived to discharge.[249] These data were obtained in a hospitalized population of relatively sick, aged male patients, and it is not possible to extrapolate these observations to a different hospital population. Nevertheless, these observations have provoked open and candid discussion and reappraisal in an attempt to define the appropriate application of CPR in hospitalized patients, as well as those in long-term care facilities.[260,261] Age alone should not preclude patients from receiving CPR.[246,261] At the same time, the presence of sepsis or cancer in an elderly patient who experiences an unwitnessed bradyarrhythmic cardiac arrest would be an example of a clinical circumstance in which resuscitative efforts would be unwarranted. As CPR and defibrillation become increasingly available, sophisticated clinical and ethical decision-making must assume a more dominant role in defining the appropriate application of resuscitation in hospitalized patients.

Resuscitation in the ICU is typically prompt and effective. Long delays in recognizing and treating cardiac arrest in general care areas of hospitals and outpatient medical facilities are common.[262] In an attempt to improve in-hospital resuscitation success rates in medical facilities (e.g., hospitals, outpatient clinics, and diagnostic centers), it is recommended that AEDs be made sufficiently available to ensure that defibrillation can occur within 3 minutes of collapse for most patients in medical facilities. Rather than identifying and training central resuscitation teams, general care nurses and other hospital employees should be trained in the use of AEDs and be authorized to initiate therapy when indicated. The Joint Commission on Accreditation of Heathcare Organizations, a U.S. regulatory agency working to improve patient care and safety, has included resuscitation response measures and procedures as an important area for review to ensure that victims of in-hospital cardiac arrest are provided prompt interventions by well-trained providers with appropriate systems for response, data collection, review, and tracking over several years.[262]

Circulation 102(Suppl I):I-1, 2000.)*

Do-Not-Resuscitate Orders

The increasing application of do-not-resuscitate (DNR) orders in hospitalized patients has necessitated the development of specific guidelines for the management of such patients. The CPR and emergency cardiac care guidelines addressed this issue in the section titled "Ethical Issues,"[9] and the American Medical Association Council on Ethical and Judicial Affairs developed guidelines for the use of DNR orders.[263] These documents provide helpful assistance in the use of DNR orders in hospitalized patients and should be consulted.

Pediatric Resuscitation (also see Chapters 82, 83, and 84)

It is now understood and accepted that pediatric resuscitation is an area of knowledge and skill with specific diagnostic and therapeutic considerations. Recognition of this perspective is evident in the current resuscitation guidelines.[9] However, health care providers must realize that the resuscitation recommendations intro-

duced in Guidelines 2005 for adult resuscitation apply to pediatric resuscitation as well. Like adults, pediatric chest compressions, when performed by a single rescuer, should be delivered at a rate of 100/min with two breaths interposed after every 30 compressions. Interruptions in chest compression during pediatric resuscitation should be kept to a minimum, even for airway management and defibrillation, just as in adult resuscitation. Like adults, prompt defibrillation rather than medications is most likely to be helpful to pediatric cardiac arrest victims. In light of this information, ACLS training provides sufficient consistencies in treatment recommendations extending from the young to the very old to be used effectively in the treatment of any cardiac arrest victim, young or old. AHA textbooks should be consulted for further specific details.

Basic Life Support

Primarily for convenience and uniformity in teaching, infants are considered to be 1 month to 1 year of age and children are 1 to 8 years old. Figure 97-16 depicts current recommendations for health care workers. In infants, detection of a brachial or femoral

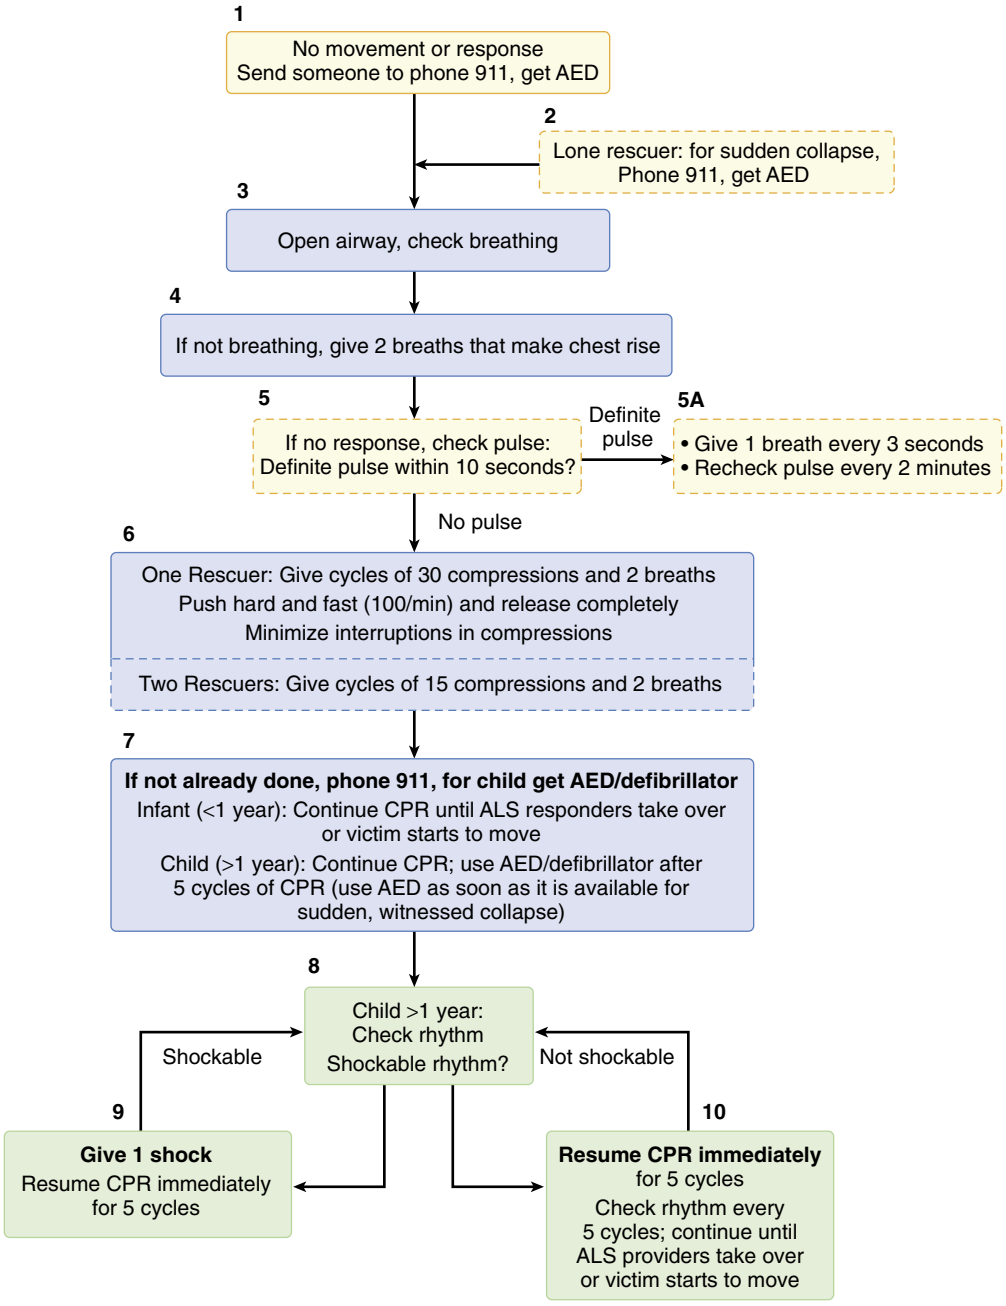

Figure 97-16 Pediatric health care provider BLS algorithm. Note that the *boxes* bordered by *dotted lines* are performed by health care providers and not by lay rescuers. Circulation 112:IV-158, 2005.)*

pulse is often difficult for both health care and lay rescuers.[264,265] If a pulse cannot be palpated in 10 seconds, chest compressions should commence. If a pulse is palpated in a child with a rate of less than 60 beats/min and the child demonstrates signs of poor perfusion (i.e., pallor, cyanosis), chest compressions should be started. In infants, chest compressions are performed over the lower half of the patient's sternum, with the depth of compression being a third to half the depth of the chest (approximately 0.5 to 1.0 inch) and a compression rate of 100/min. Chest radiographs and right heart angiograms in infants, children, and young adults 1 day to 19 years old have confirmed that the heart lies under the lower part of the sternum in all age groups,[266,267] and thus this location is considered optimal for chest compressions in this age group.

Lone rescuers should perform 30 chest compressions with two interposed breaths. If two rescuers are present, a 15:1 compression-to-ventilation pattern should be used, with the breath being delivered during a short delay in chest compressions. If an advanced airway is in place, rescue breaths can be performed at a rate of 8 to 10/min without interruption in chest compression. The majority of cardiac arrests in infants and children are the result of asphyxia.[268,269] If a rescuer is alone in the presence of a child in need of resuscitation, two minutes of CPR (five cycles of 30 chest compressions and two ventilations) should be performed before activating emergency medical services.

Use of Automated External Defibrillators in Infants and Children

Since publication of the last AHA resuscitation guidelines in 2000, AEDs have been proved safe for use in infants and children.[270,271] However, there is currently insufficient evidence for or against the use of AEDs in infants younger than 1 year. It is recommended that a pediatric attenuator be used when applying AED technology to the treatment of pediatric patients. The attenuator decreases the delivered AED energy to a dose more suitable for children. If a pediatric AED is not available, a standard AED can be used.

Advanced Life Support

Unlike adults, infants and children experience cardiorespiratory arrest secondarily, rarely as a result of a primary cardiac event.[9,268,272-276] This observation is critical because ACLS interventions directed primarily toward restoration of cardiac function may cause the physician to delay properly directed therapy. For example, a progressive decline in cardiac rate leading to bradycardic arrest is likely to be an ominous sign of hypoxia in infants and children. Treatment with atropine in a futile attempt to increase the heart rate would be misdirected therapy. Furthermore, VF and VT, so common in adults, are uncommon cardiac arrest arrhythmias in infants and small children,[274,275] although some evidence indicates that VF is not rare in children and adolescents experiencing prehospital cardiac arrest.[277] Thus, application of ACLS is indeed different in these patient populations. Because the cause of cardiac arrest in children is most commonly respiratory and not cardiogenic, the ensuing pathophysiologic events and mode of manifestation of the cardiac arrest state are different, and the subsequent initial efforts at resuscitation must be directed toward respiratory support maneuvers. In addition, of course, equipment, techniques, and drug dosages are of necessity different. All these facts mandate that physicians caring for infants and children have a clear understanding of the role of ACLS interventions in these patients.

Airway Control and Ventilation

The foregoing discussion underscores what is well known to anesthesiologists: definitive control of the airway, as well as oxygenation and ventilation, is the most decisive, pivotal, and critical ACLS intervention in pediatric cardiac arrest. As in adults, anesthesiologists ordinarily intubate the trachea for this purpose and then ventilate with such devices as anesthesia bags or bag-valve units with supplemental oxygen.[278] It should be noted that the evolution of experience with LMAs should be viewed as an adjunct in this setting, with the airway secured by an endotracheal tube being the gold standard during resuscitation.

Monitoring and Recognition of Arrhythmia

ECG monitoring permits immediate recognition of the arrest rhythm or, more likely in infants and children, the "pre-arrest" rhythm. Prompt intervention and correction in the latter event prevent cardiac arrest that may be irreversible if induced by unrecognized hypoxia and manifested by progressive bradycardia. With this in mind, potentially life-threatening arrhythmias are discussed first, followed by cardiac arrest.

Supraventricular Bradyarrhythmia

As already discussed, the appearance and progression of slowing of the heart rate in infants and children demand immediate assessment of the cause, first by ruling out the most likely culprit—hypoxia. The bradycardia at this point (before cardiac arrest) is most commonly sinus or junctional in origin. Second- or third-degree heart block may ensue if corrective treatment is not applied. If hypoxia has been ruled out and the bradycardia is accompanied by clinical evidence of impaired perfusion, usually with systemic hypotension, the patient should be treated with chest compressions and epinephrine.

Epinephrine is the drug of choice for treating bradycardia in infants and children. The recommended dose is 0.01 mg/kg of a 1:10,000 dilution injected intravenously or intraosseously and can be repeated if necessary every 3 to 5 minutes. If the drug is injected into the tracheobronchial tree through an endotracheal tube, 0.1 mg/kg of a 1:1000 dilution is recommended. Chest compressions should continue until termination of the bradyarrhythmia.

If the heart rate does not increase with epinephrine, atropine can be used in a dose of 0.02 mg/kg and repeated once. An algorithm depicting interventions recommended for pediatric bradyarrhythmias is shown in Figure 97-17.

Supraventricular Tachyarrhythmia

In infants and children, supraventricular tachycardia (SVT) may represent ectopic atrial rhythms, atrial flutter or fibrillation, or paroxysmal reentrant tachycardia.[257] Standard pediatric cardiology texts should be referred to for specific diagnostic and therapeutic details. Although SVT is usually well tolerated in most infants and older children, immediate cardioversion may be necessary when heart rates in the range of 240 to 300 beats/min are reached—rates that may result in severe and rapid hemodynamic

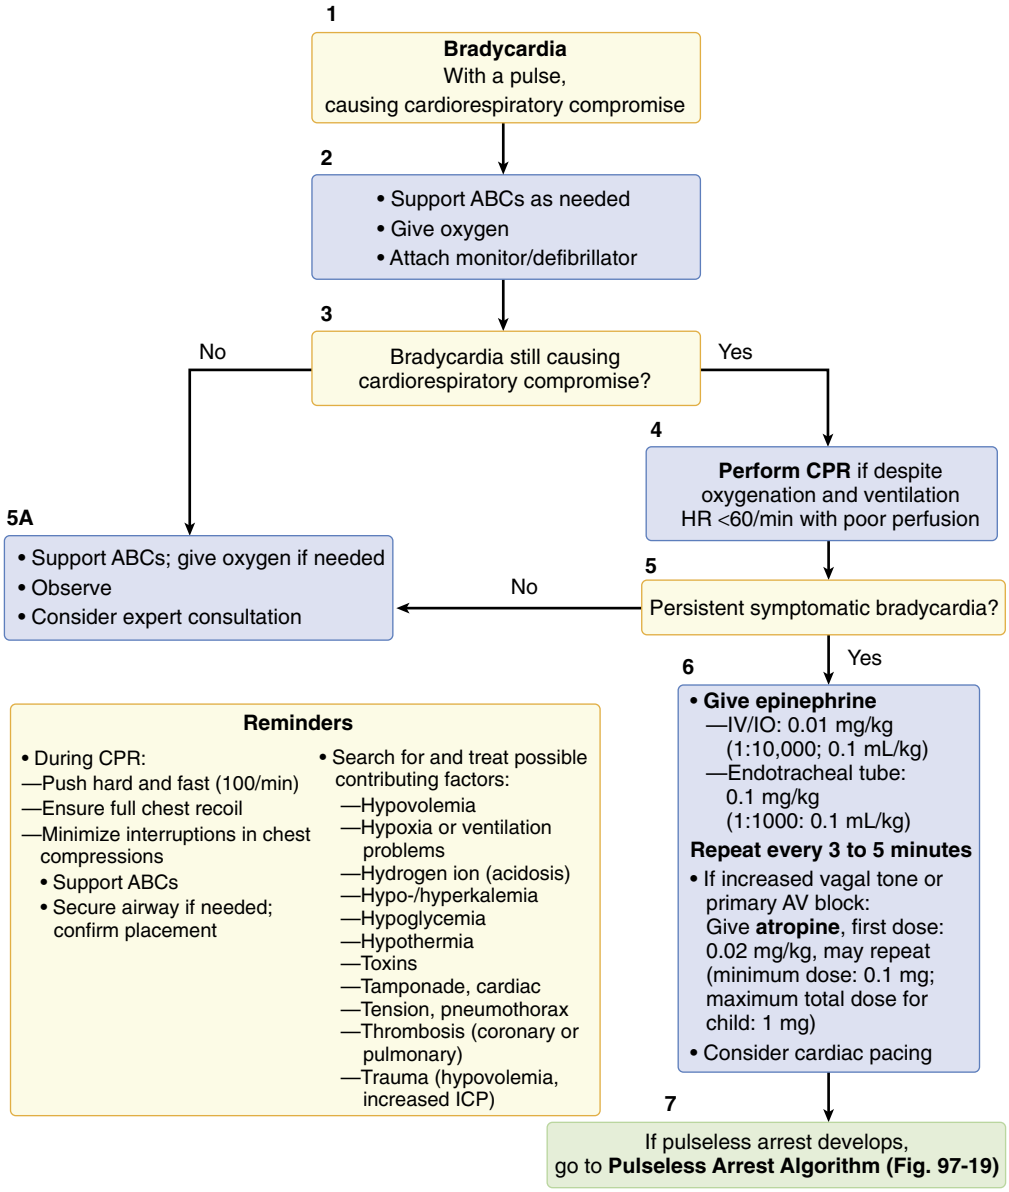

Figure 97-17 Bradycardia algorithm for pediatric advanced life support. ABC, airway, breathing, circulation; CPR, cardiopulmonary resuscitation; ICP, intracranial pressure; IO, intraosseous; IV, intravenous. *(From 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 112:IV-176, 2005.)*

compromise. In this emergency setting in which rapid SVT causes cardiovascular instability,[258] synchronized cardioversion is the treatment of choice. The initial energy dose is 0.5 J/kg body weight; if necessary, the energy dose is doubled.[279] If conversion to sinus rhythm still does not occur, the diagnosis of SVT should be reconsidered.

In hemodynamically stable children with SVT, vagal maneuvers are recommended before pharmacologic therapy. If vagal maneuvers are unsuccessful, adenosine is the drug of choice, as with adults. The drug can be given as a rapid bolus in a dose of 0.1 mg/kg intravenously or intraosseously, ideally injected into the closest port to the hub of the catheter and flushed with 2 to 3 mL of fluid. If the SVT persists or recurs, a second dose of 0.2 mg/kg intravenously or intraosseously can be given in 1 to 2 minutes.[9,259,279-281] The maximum single dose should not exceed 12 mg.

Verapamil is not recommended for pediatric SVT in an emergency setting because it may induce systemic hypotension and a state of depressed myocardial contractility.[282-284] Specifically, it is not recommended in this setting for infants younger than 1 year, children with congestive heart failure or myocardial depression, children receiving β-adrenergic–blocking drugs, or children who may have an accessory pathway between the atria and ventricles.[279]

In circumstances in which adenosine has been unsuccessful in converting hemodynamically stable SVT, procainamide and amiodarone can be considered ahead of cardioversion.[285,286] Procainamide, 15 mg/kg, can be delivered over a period of 30 to 60

minutes. Amiodarone, 5 mg/kg delivered over a 20- to 60-minute period, can also be considered. Procainamide and amiodarone should not be administered together.

The treatment algorithm for tachyarrhythmias in pediatric patients is presented in Figure 97-18.[9]

Ventricular Bradycardia

As with supraventricular bradyarrhythmias, a slow idioventricular rhythm that has not yet produced pulselessness must be considered indicative of severe hypoxia (see Fig. 97-17), and treatment must be directed accordingly. Only after this condition has been addressed should rate-accelerating therapy be invoked, as discussed for supraventricular bradycardia.

Ventricular Tachyarrhythmia

Despite a common misconception, VT is not always associated with severe hemodynamic compromise. Ventricular rates of 150 to 200 beats/min may be well tolerated, as defined as palpable pulses, but they should nonetheless be converted to a normal rhythm. Emphasis is placed on accurate diagnosis with 12-lead ECGs before treatment if the patient remains hemodynamically stable. In the setting of wide–QRS complex tachycardia, synchronized cardioversion is the indicated treatment, beginning at 0.5 J/kg and increasing to progressively higher doses up to 2 J/kg with either monophasic or biphasic waveform shocks. If pharmacologic therapy is undertaken, amiodarone is the drug of choice and is delivered as described for the treatment of SVT. Intravenous

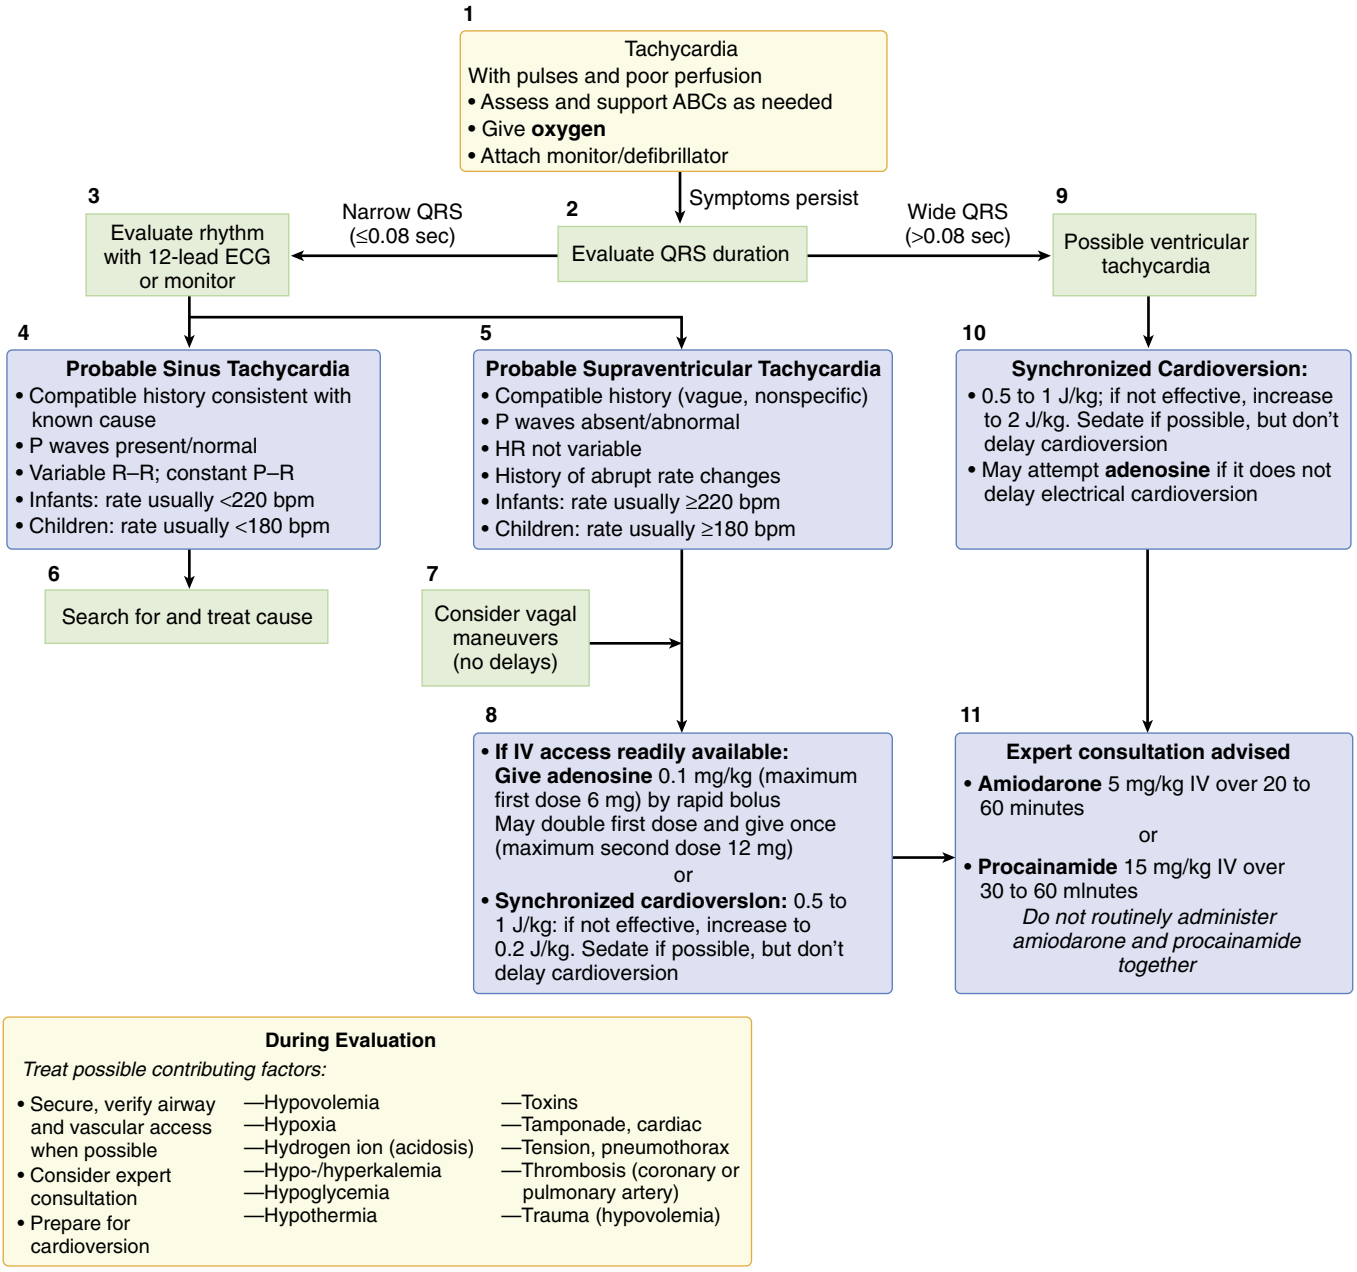

Figure 97-18 Tachycardia algorithm for pediatric advanced life support. ABCs, airway, breathing, circulation; ECG, electrocardiogram; HR, heart rate. *(From 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 112:IV-177, 2005.)*

procainamide (in doses identical for the treatment of SVT) can also be considered. The two drugs should not be administered together. If the tachycardia is very rapid (rates greater than 300/min) or cardiovascular collapse and loss of pulses occur, this situation should be treated like VF.

Management of Cardiac Arrest

Once pulselessness ensues, therapy must be directed not only at correcting the underlying rhythm disorder but also at maintaining organ viability during the period of cardiorespiratory arrest. Meticulous attention must be paid to ensuring proper chest compression rate and depth, avoidance of hyperventilation and interruption of chest compressions, and administration of medications that support perfusion pressure during resuscitation efforts. The pulseless arrest algorithm for pediatric advanced life support is shown in Figure 97-19.

In the great majority of pediatric cardiac arrests, bradyasystole is the terminal cardiac electrical activity (see Fig. 97-17).

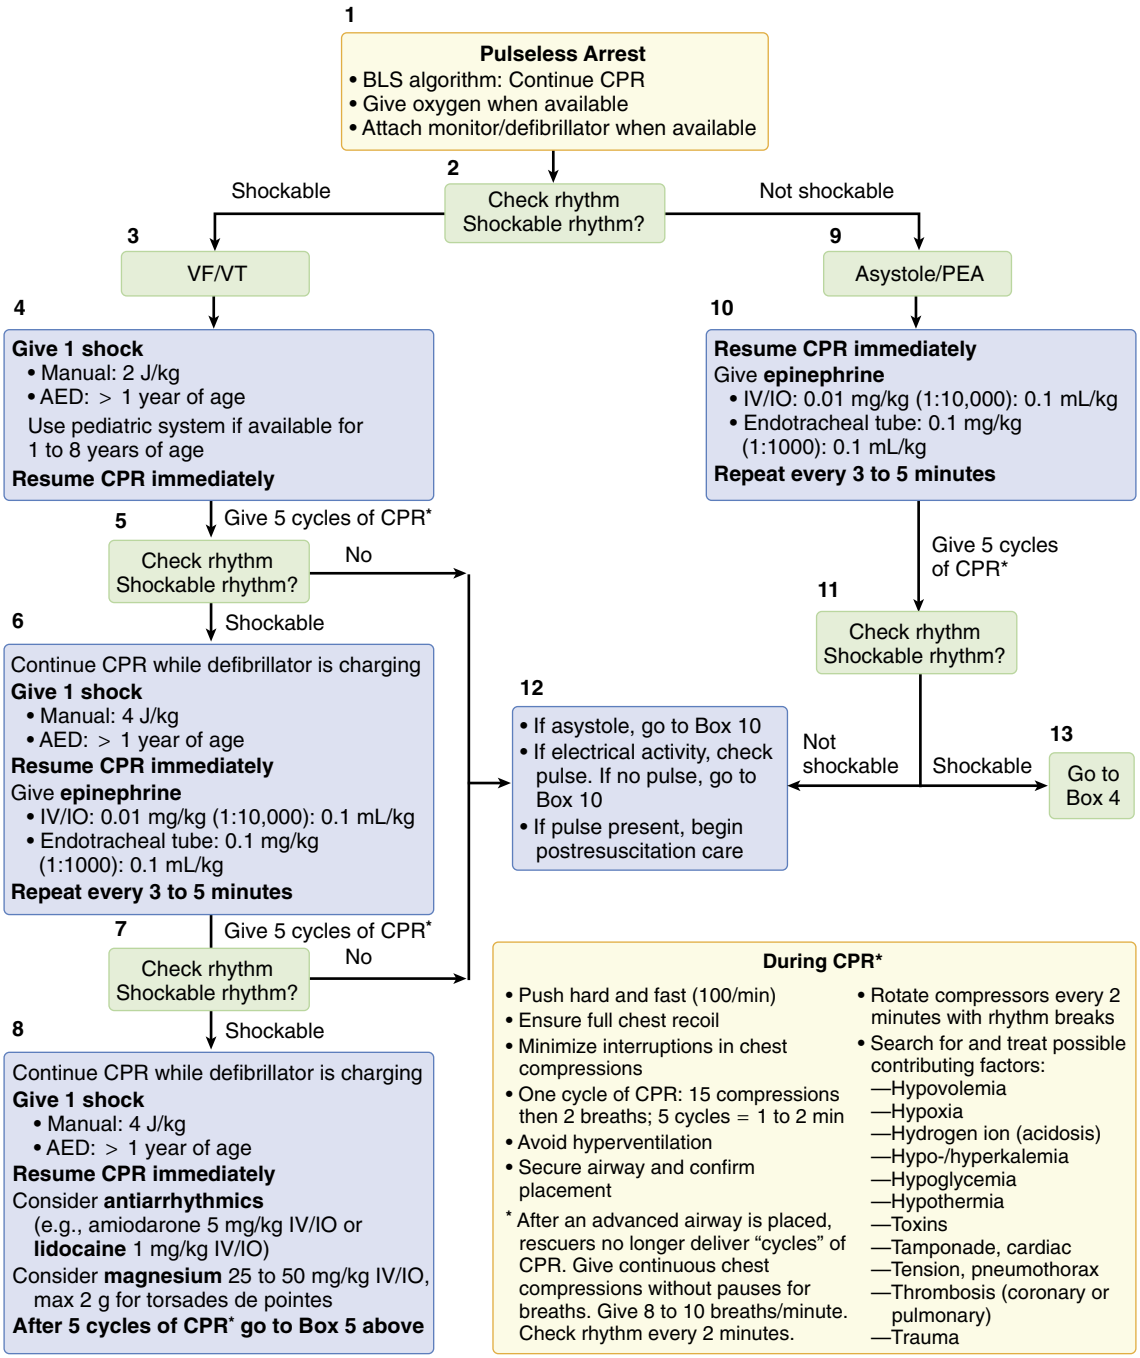

Figure 97-19 Pulseless arrest algorithm for pediatric advanced life support. AED, automated external defibrillator; BLS, basic life support; CPR, cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia. *(From 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 112:IV-173, 2005.)*

Early dominance of the parasympathetic nervous system and α-adrenergic activity may, in part, explain this dominance of brady-asystolic mechanisms as the terminal event in infants.[274] In addition, ventricular tachyarrhythmias (VT/VF) are most commonly seen in infants and children with congenital heart disease.[274] Such children may have cardiac hypertrophy and increased ventricular muscle mass sufficient to provide an anatomic substrate for reentrant wave fronts that initiate and sustain VT or VF.

Pulseless Electrical Activity and Asystole

PEA, as in adults, includes disorders in which some form of cardiac electrical activity is present, but without palpable pulses. In infants and children, this disorder is most commonly an idioventricular rhythm at a very slow and irregular rate (bradyasystole) and is the usual predecessor to ventricular asystole. When PEA is present, an immediate and aggressive effort should be made to identify treatable causes. As in adults, diagnoses to be considered immediately include hypovolemia, tension pneumothorax, cardiac tamponade, hypoxemia or acidosis (or both), or hypothermia. Immediate consideration of these possibilities and the corresponding direction of therapeutic effort may avoid administration of drugs for what will inevitably become a terminal situation if an underlying, potentially reversible catastrophe is present (see Fig. 97-18).

For both PEA and asystole, epinephrine is the drug of choice and is given initially at a dose of 0.01 mg/kg (0.1 mL/kg of a 1:10,000 solution) intravenously or intraosseously. Defibrillation is not associated with benefit in PEA or asystole. Emphasis is placed on correcting potentially reversible conditions.

If vascular access has not been achieved, initial treatment with epinephrine can be given through an intraosseous route or via an endotracheal tube. Intraosseous doses are equivalent to intravenous doses. Through the endotracheal route, 0.1 mg/kg of a 1:1000 solution is given. The dose can be repeated every 3 to 5 minutes, as long as the arrest persists. Epinephrine is presumed to have the same beneficial actions on elevating coronary and cerebral perfusion pressure discussed earlier in the adult resuscitation section. In an infant animal model (infant piglets), epinephrine increased cerebral and myocardial blood flow, a finding suggesting that it may have a similar beneficial action in infants and children.[287]

In pediatric cardiac arrest, if venous cannulation cannot be achieved in three attempts or 90 seconds, an intraosseous approach is now recommended and preferred for drug administration via the endotracheal tube route. Intraosseous access is a rapid, safe, and effective route for administering resuscitative fluids (including blood) and medications in both medical and traumatic emergencies. The needle is inserted perpendicular to the skin into the tibia approximately one fingerbreadth below the tubercle on the anteromedial surface. Loss of resistance will be felt as the needle passes through the bony cortex. Drug levels attained by intraosseous administration are nearly equivalent to those achieved with intravenous administration.[288] Fluid boluses are required to ensure that medications delivered intraosseously enter the circulation quickly.

In CPR of infants and children, it is recommended that a rapid glucose test be performed and glucose be injected if hypoglycemia is present.[9,279] For infants and children who do not respond to resuscitative therapy, glucose administration should also be considered. However, as expressed earlier in the discussion of adult cardiac arrest, routine use of glucose-containing solutions should be avoided because of a potentially adverse impact on neurologic outcome and because glucose administration may result in hyperglycemia and secondary osmotic diuresis. If glucose is necessary, the dose is 0.5 to 1.0 g/kg intravenously in a solution of 25% dextrose in water (2 to 4 mL/kg) for infants and children, preferably given as a continuous infusion rather than a bolus to avoid a sudden increase in serum osmolality.[9,279] The commercially available 50% dextrose in water solution can be diluted 1:1 with sterile water for this purpose. For neonates, in general, the concentration of glucose administered should not exceed 12.5%, thus necessitating further dilution of the 50% dextrose solution.

The same concerns discussed earlier regarding sodium bicarbonate therapy in adults also apply to pediatric patients. If it is used, 1 mEq/kg can be given initially and 0.5 mEq/kg at 10-minute intervals thereafter, unless arterial blood measurements of pH, $Paco_2$, and base deficit are available and indicate a different dosage scheme.[279] Likewise, no available evidence supports the continued use of calcium salts for cardiac arrest in infants and children. The use of calcium chloride should be reserved for the acute treatment of hyperkalemia, hypermagnesemia, hypocalcemia, or calcium channel–blocking drug toxicity. In these clinical situations, 0.2 to 0.25 mL/kg of 10% calcium chloride (5 to 7 mg/kg of elemental calcium) can be given and repeated once in 10 minutes.[277]

Pulseless Ventricular Tachycardia or Ventricular Fibrillation

VF occurs in 5% to 15% of all prehospital pediatric cardiac arrests[277,289] and in up to 20% of in-hospital pediatric cardiac arrests. VT and VF are relatively uncommon in infants and children, most likely to be seen with congenital heart disease. The increased cardiac muscle mass in congenital heart syndromes provide the anatomic electrophysiologic milieu for maintaining reentrant wave fronts. As in adults, the treatment of choice for VT/VF in children is defibrillation therapy, not medications.

Defibrillation can be accomplished with adult defibrillator pads for children weighing more than 10 kg, provided that more than 3 cm separates the pads. Infant paddles/pads should be used for patients younger than 1 year or those weighing less than 10 kg. Energy doses for safe and effective defibrillation in infants and children are not known. Guidelines 2005 recommends 2 J/kg for the first defibrillation attempt with either monophasic or biphasic defibrillators. Subsequent defibrillation attempts should use 4 J/kg.[9]

As long as the cardiac arrest persists, epinephrine should be given in the same concentrations, routes, and intervals as described for PEA-related cardiac arrest. There is insufficient evidence for using vasopressin in pediatric cardiac arrest. Amiodarone, 5 mg/kg intravenously or intraosseously, and lidocaine, 1 mg/kg intravenously or intraosseously, are also options for therapy in protracted VF unresponsive to defibrillation therapy. It must be remembered that fluid boluses must follow drug administration, as well as the need for uninterrupted chest compressions with avoidance of hyperventilation.

One of the most difficult aspects of pediatric resuscitation is determination of correct drug doses in the midst of a crisis, especially if one deals with cardiac arrest in infants and children infrequently. Various schemes have been proposed for simplifying this need. Table 97-3 incorporates a convenient scheme for selecting the proper dose of drug to be injected according to body

Table 97-3 Medications for Pediatric Resuscitation and Arrhythmias

Medication	Dose	Remarks
Adenosine	0.1 mg/kg (maximum: 6 mg) Repeat 0.2 mg/kg (maximum: 12 mg)	Monitor ECG Rapid IV/IO bolus
Amiodarone	5 mg/kg IV/IO; repeated up to 15 mg/kg Maximum: 300 mg	Monitor ECG and blood pressure Adjust administration rate to urgency (give more slowly when a perfusing rhythm is present) Use caution when administering with other drugs that prolong the QT interval (consider expert consultation)
Atropine	0.02 mg/kg IV/IO 0.03 mg/kg ET* Repeat once if needed Minimum dose: 0.1 mg Maximum single dose: Child: 0.5 mg Adolescent: 1 mg	Higher doses may be used with organophosphate poisoning
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg)	Slowly Adult dose: 5-10 mL
Epinephrine	0.01 mg/kg (0.1 mL/kg 1 : 10,000) IV/IO 0.1 mg/kg (0.1 mL/kg 1 : 1000) ET* Maximum dose: 1 mg IV/IO, 10 mg ET	May repeat q3-5 min
Glucose	0.5-1 g/kg IV/IO	$D_{10}W$: 5-10 mL/kg $D_{25}W$: 2-4 mL/kg $D_{50}W$:1-2 mL/kg
Lidocaine	Bolus: 1 mg/kg IV/IO Maximum dose: 100 mg Infusion: 20-50 µg/kg/min ET*: 2-3 mg	
Magnesium sulfate	25-50 mg/kg IV/IO over 10- to 20-min period; faster in torsades Maximum dose: 2 g	
Naloxone	<5 yr or ≤20 kg: 0.1 mg/kg IV/IO/ET* ≥5 yr or >20 kg: 2 mg IV/IO/ET*	Use lower doses to reverse respiratory depression associated with therapeutic opioid use (1-15 µg/kg)
Procainamide	15 mg/kg IV/IO over 30- to 60-min period Adult dose: 20-mg/min IV infusion up to total maximum dose of 17 mg/kg	Monitor ECG and blood pressure Use caution when administering with other drugs that prolong the QT interval (consider expert consultation)
Sodium bicarbonate	1 mEq/kg per dose IV/IO slowly	After adequate ventilation

$D_{10}W$, 10% dextrose in water; ECG, electrocardiogram; ET, via endotracheal tube; IO, intraosseous; IV, intravenous.
*Flush with 5 mL of normal saline and follow with five ventilations.

weight. It includes the major resuscitative drugs along with additional drugs that could be used in some cardiac arrests or other pediatric emergencies. The availability of a resuscitation team knowledgeable in pediatric resuscitation is critical for the proper management and resuscitation of a child victim of cardiac and near-cardiac arrest.

Termination of Pediatric Resuscitation Attempts

There are no clear clinical signs or reliable predictors indicating whether efforts made in resuscitating infants and children will be successful. Witnessed cardiac arrest, prompt effective chest compressions and ventilation, and rapid initiation of advanced resuscitative interventions improve the chance of a successful outcome but do not guarantee successful resuscitation. Prolonged resuscitation should be performed in infants and children with recurring or refractory VF or VT.[9] Emerging technologies (e.g., extracorporeal circulation and membrane oxygenation, ECMO) and their availability may influence decisions to terminate resuscitative events. The ethics of terminating resuscitative care have been addressed in Guidelines 2005, Part 2: "Ethical Issues."[9] Clinicians are encouraged to review these guidelines, as well as relevant guidelines developed in their local practice environment.

Educational Initiatives

As information has been thoroughly reviewed and considered in developing these most recent resuscitation guidelines, there is evidence that retention of resuscitation skills and knowledge

declines quickly, even in medical specialties where critical and timely interventions are the norm rather than exception,[123] thus suggesting a need for review at intervals within the period of advanced life support certification. Other avenues that must be addressed are the quality of resuscitation interventions (e.g., uninterrupted chest compressions, timely airway management, prompt defibrillation, accurate recognition of arrhythmias). Growing evidence suggests that health care providers are failing to provide effective BLS[16,65,66] and fail to deliver defibrillatory shocks in timely fashion.[290] It is likely that these issues will be scrutinized closely in the near future.

Acknowledgment

I would like to express my most sincere gratitude to my wife and children for their patience and support, to Sarah Meyer for her exceptional secretarial support and organizational skills, and to Roger D. White, M.D., for his priceless guidance and counsel throughout my career.

98 Brain Death

Key Points

1. The first description of cessation of brain functions using a concept similar to the modern definition of brain death appeared in 1959, although the subject became more controversial after the development of organ transplantation. Criteria for brain death were first published in 1968, a year after the first heart transplantation. Although cultural and religious diversity may lead to great differences in attitudes toward brain death and there is no global consensus in diagnostic criteria, the concept of brain death as defining the death of the individual is widely accepted, and many countries have published recommendations or legal requirements for the diagnosis of brain death, in particular, as a necessary prerequisite for organ donation.
2. The traditional concept of death has used the cessation of cardiac and respiratory functions as its basis because of the acceptance of simple and nonmedical concepts: that life begins with the first inspiration after birth, that death comes with the last expiration, and that cardiac activity ceases within a few minutes of the last expiration. In contrast, the modern concept of brain death adopts the conclusions of modern biologic science (central integrator theory of the brain): that the central nervous system (CNS), including the brainstem, is the control center for the living organism; that cessation of CNS functions represents cessation of the harmony of life; and that without CNS control, the living organism is nothing more than an aggregation of living cells. However, this notion has become controversial, because not all brain-dead patients inevitably deteriorate to cardiovascular collapse in a short time and they can assimilate nutrients, fight infections, heal wounds, and carry out a pregnancy.
3. Trauma to the brain or cerebrovascular injury produces brain edema. Because the brain is covered by a rigid bony skull, edema is accompanied by an increase in intracranial pressure, which, if sufficiently high, exceeds arterial blood pressure. When cerebral circulation ceases, aseptic necrosis of the brain ensues. Within 3 to 5 days, the brain becomes a liquefied mass. Such increased intracranial pressure compresses the entire brain, including the brainstem, and total brain infarction follows.
4. Clinical studies indicate that hypothalamic and anterior pituitary functions are preserved to some degree for a certain period after the onset of brain death. The response of the immune system to stimulation is modified considerably after total and irreversible loss of CNS functions. Hormonal changes and inflammatory responses after brain death are the theoretical and scientific basis of hormonal therapy for hemodynamic stabilization of brain-dead organ donors.
5. During the process of brain death after head injury or intracranial bleeding, intracranial pressure increases and compression of the brainstem leads to marked hypertension and bradycardia (i.e., Cushing phenomenon). At the onset of brain death by tonsillar herniation, sudden decrease of arterial blood pressure occurs, but the arterial pressure gradually returns to normal with the spinal cord gaining automaticity.
6. Determination of brain death confirms the irreversible cessation of all functions of the entire brain, including the brainstem. Irreversibility means that no treatment may be reasonably expected to change the condition. Although testing all functions of the brain is conceptually impossible, the cessation of all functions of the brain is practically determined by loss of consciousness, loss of brainstem responses, apnea, and confirmatory tests.
7. Cerebral death, the so-called persistent vegetative state, refers to cessation of the functions of the cerebral cortices. It is not the equivalent of death.
8. It is true that cultural and religious diversities may affect the notion of death, but there is a significant variability in policies and practices for determining brain death internationally and even among states and hospitals.
9. Tests to confirm brain death include an electroencephalogram, evoked responses, and measurement of blood flow.
10. Because of their intact spinal cord and the presence of somatic and visceral reflexes, brain-dead patients require special anesthetic management, including use of muscle relaxants, vasodilators, and perhaps sedation and analgesia. Anesthesiologists should understand the medical and legal definitions of death, as well as the ethical concepts behind them.

Because advancements in medicine have changed the definition and concept of death, legislation must also change accordingly. This issue results from progress in organ transplantation and the increasing number of patients who have a living body but nonfunctioning brain, which is a consequence of discoveries in resuscitative and life support techniques. Such refinements in critical care medicine mean that neurologists, neurosurgeons, and anesthesiologists must be able to make an appropriate diagnosis of death. Although cultural and religious diversity may lead to great differences in attitudes toward brain death and there is no global consensus in diagnostic criteria, the concept of brain death as defining the death of the individual is widely accepted,[1,2] and many countries have published recommendations or legal requirements for the diagnosis of brain death as a necessary prerequisite for organ donation.[3,4]

History

In 1902, Cushing[5] first reported cessation of cerebral circulation when intracranial pressure exceeded arterial blood pressure in monkeys. He also described the use of artificial ventilation to prolong cardiac function for 23 hours after cessation of spontaneous respiration in a patient with a brain tumor. In 1959, Bertrand and colleagues[6] reported the maintenance of respiration by mechanical means for 3 days after death of a patient with otitis media who underwent circulatory collapse. Repeated convulsions had preceded a deep coma. Autopsy revealed extensive brain necrosis of the cerebral and cerebellar cortices, basal ganglia, and brainstem nuclei, which was attributed to cessation of cerebral circulation during artificial ventilation. Also in 1959 appeared the first description of cessation of brain functions using a concept similar to the modern definition of brain death (i.e., le coma dépassé) by Mollaret and coworkers.[7]

These historical reports support the argument that the concept of brain death is independent of and was established before the start of organ transplantation from brain-dead patients. However, there is still dispute about whether brain death is or is not directly related to organ transplantation. The heated discussion on brain death started after the first heart implantation by Barnard in 1967. One year later, the ad hoc Committee of the Harvard Medical School to Examine the Definition of Brain Death published its criteria for brain death and defined "irreversible coma as a new criterion for death."[8] The committee deliberations focused on a whole-brain formulation to define brain death. In 1981 the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research[9] defined the brain as the "primary organ" and justified the application of a whole-brain definition for brain death in the United States. The whole-brain formulation of brain death was acknowledged by statute in the Uniform Determination of Death Act (UDDA)[10] by stating that "an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead." This formulation is the one most commonly applied worldwide and forms the foundation for legal codification in many Western nations. Numerous criteria on brain death have been offered by institutions, state agencies, expert groups, and governments (Tables 98-1 and 98-2).[1,3,4,11,12]

In contrast, brainstem definition for brain death was first pronounced in 1976 by the Conference of Medical Royal Colleges and their Faculties in the United Kingdom.[13] The document in 1995 entitled "Criteria for the Diagnosis of Brain Stem Death"[14] encouraged the use of the more correct term *brainstem death* rather than *brain death* and gave a definition of death, stating that "death is defined as the irreversible loss of the capacity for consciousness, combined with the irreversible loss of the capacity to breathe."

Traditional Concept of Death of an Organism

In Greek antiquity, two concepts existed regarding the body cavity, where "the principle of life," now known as "function of the brain," was housed. One is that of Plato, and another is Aristotle's. Plato first postulated the tripartite soul in the *Republic* and *Timaeus*. The first part is the reason, the second, emotion, and the third is appetite or desire. Reason, which we might today call "consciousness," is the reappearance of the God's soul (the divine), housed in the ideal shaped vessel, in which all distances from the center are the same (i.e., the head). The second soul, emotion, is located in the heart. It affects circulation, and its manifestations, such as pulse rate, are functions that correlate with what we think of as the autonomic nervous system. The neck is constructed as a kind of isthmus or boundary between the head and the chest to ensure that reason is not affected by emotion. The third part of the soul, that is, the appetite for food and drink or sexual desire, is the least noble part. It was housed in the stomach, separated from the heart by diaphragm, and thought to be punished by the bitterness of bile. However, we cannot interpret this too literally, because it was meant to be a sort of analogy for consumption by the ordinary citizen. Plato considered "death" to be the separation of reason from the mortal body, whereas Socrates, in his *Apology,* confessed that he did not know the fate of reason after death. The "vegetable state" in today's neurophysiology, is, according to Plato, the equivalent of death.

Unlike Plato, Aristotle, who is known as the founding father of genetics, stressed experience, or empirical knowledge, rather than abstract thinking. Aristotle postulated that all functions of the brain were housed in the heart, which he considered the most important organ of the body—the seat of the intelligence and the origin of motion and sensation. Other organs surrounding it, like the brain and the lungs, existed simply to cool the heart. Aristotle dissected dogs, horses, grasshoppers, crickets, and other living creatures to understand the reasons why, for instance, dogs cannot give birth to horses. He thought that animals "cook" foods in their digestive tracts and that blood transports nutrients to each organ from the heart. This transport corresponds to the electrical signals in the nerves in today's neurophysiology. According to Aristotle, the lungs cool the heart, and the cranium serves as a cooling apparatus for liquefying a transmitter, a kind of "pneuma."

In Aristotle's system, the vehicle that conveys commands from the control center to the peripheral organs and tissues, roughly equivalent to the electrical signals of the nervous system in today's neurophysiology, was assumed to be something like vapor or gas. This concept is the basis from which the idea of "pneuma" (breath or spirit) originates. God created man (Adam)

From Wijdicks EF: Brain death worldwide. Neurology 58:20, 2002.

out of the dust of the earth and inspired the breath of life into his nostrils, and a man became a living soul. Later, Eve was created from Adam's rib and, with God's breath, became a living soul as well. This story might call to mind the first cry of the neonate, which is the first activity of life caused by the God's "inspiration." This creative breathing, or inspiration, is the subject of Botticelli's painting *The Birth of Venus*, in which Zephyr, the west wind, puffs vigorously as his wife Chloris gently blows her warm breath on Venus, who stands on a shell. Aristotle's idea postulating the heart as the principal seat of the spirit had a profound influence on Western scientific thought for a long period. William Harvey's discovery, described in his *Circulation of Blood* (1628) is considered as the final scientific development of Aristotle's ideas and Aristotle is the thinker most cited in Harvey's book.

In the time before the known history of the world, the loss of the upper limbs meant the loss of the ability to fight and, hence, the death of the individual. The concept of "limb death" could have developed during this prehistorical period. The same is true of the concept of "renal death," since, in the age before the advent of hemodialysis/renal transplantation, severe renal dysfunction caused uremia, and death was inevitable, just as the irreversible elimination of the immune functions could bring about "immune death." These examples are meant to illustrate that human understanding of death need not be uniform nor universal and has not been throughout history. It has changed with different periods, areas, ethics, and stages of advance of technologic and scientific advance. Brain death should be discussed separately from organ transplantation, although the latter is an important issue in considering the concepts of life and death.

All living organisms take in oxygen by respiration, distribute the oxygen to peripheral tissues through circulation, and then excrete metabolites by means of the circulation and through respiration. Respiration and circulation are vital to the living organism. Respiration is the functional expression of the brainstem, and cessation of brainstem functions leads to the cessation of respiration. Because the brainstem maintains its function through its supply of oxygen and nutrients, cessation of circulation ultimately leads to cessation of respiration. The functions of the

Table 98-2 Diagnostic Criteria for the Clinical Diagnosis of Brain Death

A. Prerequisites. Brain death is the absence of clinical brain function when the proximate cause is known and demonstrably irreversible.
   1. Clinical or neuroimaging evidence of an acute central nervous system catastrophe that is compatible with the clinical diagnosis of brain death
   2. Exclusion of complicating medical conditions that may confound clinical assessment (no severe electrolyte, acid-base, or endocrine disturbance)
   3. No drug intoxication or poisoning
   4. Core temperature ≥ 32°C (90°F)

B. The three cardinal findings in brain death are coma or unresponsiveness, absence of brainstem reflexes, and apnea.
   1. Coma or unresponsiveness—no cerebral motor response to pain in all extremities (nail-bed pressure and supraorbital pressure)
   2. Absence of brainstem reflexes
      a. Pupils
         i. No response to bright light
         ii. Size: midposition (4 mm) to dilated (9 mm)
      b. Ocular movement
         i. No oculocephalic reflex (testing only when no fracture or instability of the cervical spine is apparent)
         ii. No deviation of eyes to irrigation in each ear with 50 mL of cold water (allow 1 minute after injection and at least 5 minutes between testing on each side)
      c. Facial sensation and facial motor response
         i. No corneal reflex to touch with a throat swab
         ii. No jaw reflex
         iii. No grimacing to deep pressure on nail bed, supraorbital ridge, or temporomandibular joint
      d. Pharyngeal and tracheal reflexes
         i. No response after stimulation of the posterior pharynx with tongue blade
         ii. No cough response to bronchial suctioning
   3. Apnea testing performed as follows:
      a. Prerequisites
         i. Core temperature ≥ 36.5°C or 97°F
         ii. Systolic blood pressure ≥ 90 mm Hg
         iii. Euvolemia. *Option:* positive fluid balance in the previous 6 hours
         iv. Normal $Paco_2$. *Option:* $Paco_2$ ≥ 40 mm Hg
         v. Normal Pao_2. *Option:* preoxygenation to obtain arterial Pao_2 ≥ 200 mm Hg
      b. Connect a pulse oximeter and disconnect the ventilator.
      c. Deliver 100% O_2, 6 L/min, into the trachea. *Option:* place a cannula at the level of the carina.
      d. Look closely for respiratory movements (abdominal or chest excursions that produce adequate tidal volumes).
      e. Measure arterial Pao_2, Pco_2, and pH after approximately 8 minutes and reconnect the ventilator.
      f. If respiratory movements are absent and arterial Pco_2 is ≥ 60 mm Hg (*option:* 20 mm Hg increase in Pco_2 over a baseline normal Pco_2), the apnea test result is positive (i.e., it supports the diagnosis of brain death).
      g. If respiratory movements are observed, the apnea test result is negative (i.e., it does not support the clinical diagnosis of brain death), the test should be repeated.
      h. Connect the ventilator if, during testing, the systolic blood pressure becomes ≤ 90 mm Hg or the pulse oximeter indicates significant oxygen desaturation and cardiac arrhythmias are present; immediately draw an arterial blood sample and analyze arterial blood gas. If Pco_2 is ≥ 60 mm Hg or Pco_2 increase is ≥ 20 mm Hg over baseline normal Pco_2, the apnea test result is positive (it supports the clinical diagnosis of brain death); if Pco_2 is < 60 mm Hg or Pco_2 increase is < 20 mm Hg over baseline normal Pco_2, the result is indeterminate, and an additional confirmatory test can be considered.

From Practice Parameters for Determining Brain Death in Adults: Report of the Quality Standards Subcommittee of the American Academy of Neurology. Neurology 45:1012, 1995.

brain, heart, and lungs are mutually dependent and share the basic role of maintaining life. An organism dies when one of these life-sustaining organ systems ceases to function. The traditional concept of death of an organism emphasized the cessation of respiration or circulation, without consideration of the role of the brain. This occurred because assessment of brain function was not easy to accomplish. When mechanical ventilation was not widely used, cessation of brain functions related directly to cessation of respiration and assessment of brainstem functions was unnecessary.

The Concept of Brain Death

Brain death represents death of the organism and not merely death or necrosis of the brain in a living body. The organism is an aggregation of living cells, although an aggregation of living cells does not necessarily constitute an organism. An organism exists only when the cell aggregation is under the control of modulating systems such as the central nervous system (CNS), the endocrine system, and the immune system. After any one of these systems ceases to function, death is inevitable unless artificial measures can be taken. The physiologic significance of brain death and cardiac death are essentially equal, and both represent an irreversible loss of communication between the control center and peripheral cells and tissues, as well as loss of modulation of an aggregation of cells. Without these systems, harmonious functioning of individual cells as constituents of the whole organism ceases. Because total and irreversible elimination of immune or endocrine function is not of practical significance, the concept of endocrine or immune death has not developed.

Previously, cessation of respiration was equivalent to immediate death of the organism, but artificial ventilation can

now prolong the life of a body for a certain period. Various functions are believed to reside in the hypothalamus and brainstem—the endocrine, autonomic, and immune functions, as well as others that are unknown. The brainstem also contains the main tracts for neural communication between the control center and peripheral tissues. All the motor outputs from the hemispheres have to travel through the brainstem, as do all the sensory inputs to the brain except sight and smell. Each of these functions of hypothalamus and brainstem can be monitored precisely and provided artificially. Autonomous respiratory function of the lower brainstem constitutes the border between life and death, and the need for mechanical devices to supply respiratory functions is defined as representing death of the individual. Possibly, most of the brain functions vital to life could be replaced with computers and drugs and the circulatory functions maintained for months or years. The only function advanced technology cannot provide is that constituting humanity or personality, both of which are possibly products of the telencephalon.

The traditional concept of death has used the cessation of cardiac and respiratory functions as its basis because of acceptance of simple and nonmedical concepts—that life begins with the first inspiration after birth, that death comes with the last expiration, and that cardiac activity ceases within a few minutes of the last expiration. In contrast, the current concept of brain death adopts the conclusions of modern biologic science—that the CNS, including the brainstem, is the control center for the living organism, that cessation of CNS functions represents cessation of the harmony of life, and that without CNS control, the living organism is nothing more than an aggregation of living cells.

Mechanism of Brain Death

Brain injury has a number of sources, such as traumatic or cerebrovascular injury and generalized hypoxia, all of which produce brain edema. Based on the pathologic mechanisms involved, brain edema is classified as vasogenic or cytotoxic.[15] Because it is rare that only one mechanism operates exclusively, the label of vasogenic or cytotoxic is only relative. Vasogenic edema is induced by an increase in cerebrovascular permeability after leaking of serum proteins into the brain parenchyma (i.e., after destruction of the blood-brain barrier). Chemical mediators such as histamine, serotonin, angiotensin, bradykinin, and prostaglandins can disrupt blood-brain barrier function.[16] Cytotoxic brain edema occurs in hypoxic and ischemic conditions and results from disturbance of cellular osmoregulation, a process that depends primarily on energy-dependent functioning of ionic pumps. The disturbance of osmoregulation increases entry of water into brain parenchyma. Although in a pure form of cytotoxic edema the blood-brain barrier would remain basically intact, cytotoxic edema would nevertheless disturb blood flow and induce hypoxia and vasogenic edema.

Brain edema may be focal at first, but it then spreads throughout the whole brain in a predictable sequence. Because the brain is covered by a rigid bony skull, its edema is accompanied by an increase in intracranial pressure, which, if sufficiently high, exceeds arterial blood pressure. When cerebral circulation ceases, aseptic necrosis of the brain ensues. Within 3 to 5 days, the brain becomes a liquefied mass, a condition known as respirator brain.[17] Such increased intracranial pressure compresses the entire brain, including the brainstem, and total brain infarction follows.[18]

Neurophysiologic Basis of Brain Death

Areas of the Brain Involved in Brain Death

By definition, brain death is a total irreversible cessation of functioning of the brain. However, "the whole brain" does not require the irreversible cessation of functioning of every brain neuron. Rather, it requires only the irreversible cessation of all clinical functions of the brain, namely, those measurable at the bedside by clinical examination.[2] The brain includes all the CNS structures except the spinal cord. It is generally agreed that brain death does not include lower portions of the spinal cord (caudal from C2), because their location outside the skull spares them from compression during brain edema. Histologic studies of human spinal cord in cases of brain death revealed divergent pathologic findings ranging from histologically intact tissues to complete destruction.[17]

The United Kingdom[13,14,19] and some other countries[3,4] supported a rather exceptional criterion for brain death, one that excludes involvement of the bilateral cerebral cortices. This state, known as "brainstem death," does not require recording of an electroencephalogram (EEG) for its diagnosis. In the United Kingdom, no confirmatory test (including an EEG) is required.[20] Grigg and colleagues reported that 11 of 56 clinically brainstem-dead patients (19.6%) had electroencephalographic activity and 2 patients (3.6%) even demonstrated sleeplike cortical electroencephalographic activity for as long as 168 hours, although none of the patients recovered.[21] The rationale for excluding the cerebral cortices is based on the facts that the brainstem, not the cerebral cortices, plays the major role in controlling whole-body vital activities such as respiration, circulation, and other homeostatic functions and that the reticular formation forms the basis of consciousness. However, some investigators strongly recommend confirmatory tests (EEG, transcranial Doppler, or brainstem auditory evoked potential) in supporting the diagnosis of brainstem death, especially when it is not possible to carry out all of the brainstem tests (e.g., in the presence of high spinal cord injury[22] or if the residual effect of sedative agents cannot be excluded[23]).

Consciousness and the Electroencephalogram

Moruzzi and Magoun[24] demonstrated the essential role of the brainstem reticular core in activating the cortical EEG. Segundo and associates[25] showed that destruction of the brainstem reticular core leads to a loss of consciousness in laboratory animals. These observations gave birth to the concept of the ascending reticular activating system (ARAS). Although the central insight of this concept, that structures in the brainstem regulate the state of consciousness, still holds true, the ARAS is no longer regarded

as a monolithic unit, nor is it restricted to the classically defined reticular nuclei of the brainstem. Maintenance of wakefulness or control of the sleep-wake cycle does not depend exclusively and unalterably on any single region of the brain.[26] In brain death, the patient is believed to have no consciousness, no intellectual activity, and therefore no true humanity. This state is defined as deep coma and is the basis for the concept of brainstem death.

Hockaday and colleagues[27] and Schwab and coworkers[28] studied the EEGs of 550 comatose patients, analyzed EEGs for 26 cases of sudden cardiac arrest and 13 cases of respiratory arrest, and classified abnormalities on EEGs into five grades according to final outcome. The prognosis for patients belonging to grade I was favorable. The determination of the prognosis for grade II and III patients required repeated recording of the EEG. When the EEG showed improvement on the day 2 or 3 recording session, the prognosis was favorable. When the EEG tended to deteriorate, the prognosis was poor. In this system, grade Vb, where there is no EEG at all, represented the EEG for brain death. Significant electroencephalographic changes occur when blood flow falls below 18 mL/100 g/min, and it becomes isoelectric when blood flow is in the range of 12 to 15 mL/100 g/min.[29] However, Paolin and associates[30] reported that 7 of 15 patients with clinical diagnosis of brain death showed persistent electrical activity, although cerebral blood flow measurements with xenon-133 and selective cerebral angiography showed intracranial circulatory arrest.

Respiration

The primary respiratory center, consisting of the inspiratory and expiratory neurons, is located in the reticular core of the medulla oblongata. Various abnormal patterns of respiration (e.g., gasping, apneusis, irregular shallow respirations) are observed in laboratory animals and humans with brainstem lesions. In brain death, spontaneous respiration does not occur in patients even when $Paco_2$ reaches 55 to 60 mm Hg. Mechanical stimulation of the carina to induce the cough reflex may be helpful in detecting residual functioning of the medullary respiratory neurons.

Cardiovascular Functions

The central neurons that control the circulatory system distribute diffusely in the pontine and medullary reticular core. Of these neurons, the vasomotor and cardioaccelerating neurons undergo negative-feedback control through the carotid and aortic sinus nerves, which relay at the nucleus tractus solitarius. Activation of these cells induces sympathetic nervous outflow, thereby increasing the heart rate and arterial blood pressure. Hypertension then suppresses these cells through the feedback mechanism, and circulation returns to preactivation levels.

During the process of brain death after head injury or intracranial bleeding, intracranial pressure increases, and compression of the brainstem leads to marked hypertension and bradycardia (i.e., the Cushing phenomenon). In an animal model of brain death, a precise mechanism of cardiovascular responses by the progression of CNS ischemia as a result of an expanding supratentorial mass was studied. When the entire cerebrum was ischemic, vagal activation with resultant decrease in heart rate, mean arterial pressure, and cardiac output was observed. As ischemia progresses rostrally to approach the pons, sympathetic stimulation was added to vagal stimulation, leading to bradycardia and hypertension (Cushing phenomenon). When the entire brainstem became ischemic, the vagal cardiomotor nucleus became ischemic, and there was unopposed sympathetic stimulation, leading to tachycardia, hypertension, and high blood levels of catecholamine (i.e., autonomic storm).[31,32] Some authorities think that myocardial damage may occur at this stage of autonomic storm, which may contribute to the early failure of some transplants and obscure or complicate the histologic manifestations of rejection in others.[31] However, in humans, this stage of tachycardia and hypertension may be brief, and attempts to reduce blood pressure may not be necessary or even not be recommended.[32]

When intracranial pressure is elevated, arterial blood pressure suddenly decreases (Fig. 98-1). This sudden decrease is the sign of tonsillar herniation (i.e., herniation of the cerebellar tonsils) through the foramen magnum on the cervical spinal cord, in which outflow of the cardioaccelerating and vasomotor neurons to the spinal cord suddenly ceases. This is one typical onset for brain death. Such dramatic changes in arterial blood pressure are not observed in other types of brain death such as that induced by hypoxia or those involving other intricate factors. Adequate volume replacement with balanced salt solution or colloid solution and, in some cases, blood transfusion is required. Inotropic agents, such as dopamine, epinephrine, and norepinephrine, are sometimes required to maintain an adequate blood pressure. The vasomotor and cardioaccelerating neurons of the spinal cord (located in the lateral horn) obtain automaticity within several days of disconnection from the supraspinal structures, and arterial blood pressure returns to normal without supplementation with vasopressors.[33] This situation is familiar to anesthesiologists because background arterial blood pressure is usually normal in tetraplegic patients.

After the establishment of brain death, different types of autonomic spinal cord reflexes develop, such as elevation of arterial blood pressure because of bladder distention. Surgical stimulation-induced hypertension and tachycardia are well known by anesthesiologists in tetraplegic patients. A similar phenomenon has been observed in brain-dead patients.[34] Vasodilators or general anesthesia, or both, should be used during the donation operation.[35] Although the cardioaccelerating and vasomotor neurons are located in the brainstem, changes in arterial blood pressure are not used as an index of brainstem function.

Regulation of Body Temperature

Rodbard[36] suggested that the neural mechanisms governing homeostatic temperature control developed in the hypothalamus from circulatory control neurons in the course of evolution from reptile to mammal. Body temperature is regulated when changes in blood temperature stimulate heat-sensitive receptors in the hypothalamus. Nerve impulses from cold receptors in the skin can also activate heat-producing neurons. The most important heat producers are the skeletal muscles, brain, liver, and heart. The greatest heat radiator is the skin, especially that on the hands. Local electrical stimulation of the heat-producing center induces shivering and constriction of blood vessels in the skin, activating vasomotor nerves and decreasing blood flow. Warming of the heat-loss center suppresses vasomotor nerve activity and in this way increases blood flow through the skin.

In brain death, the neural connection between the temperature-regulating center and peripheral body tissues is lost, and

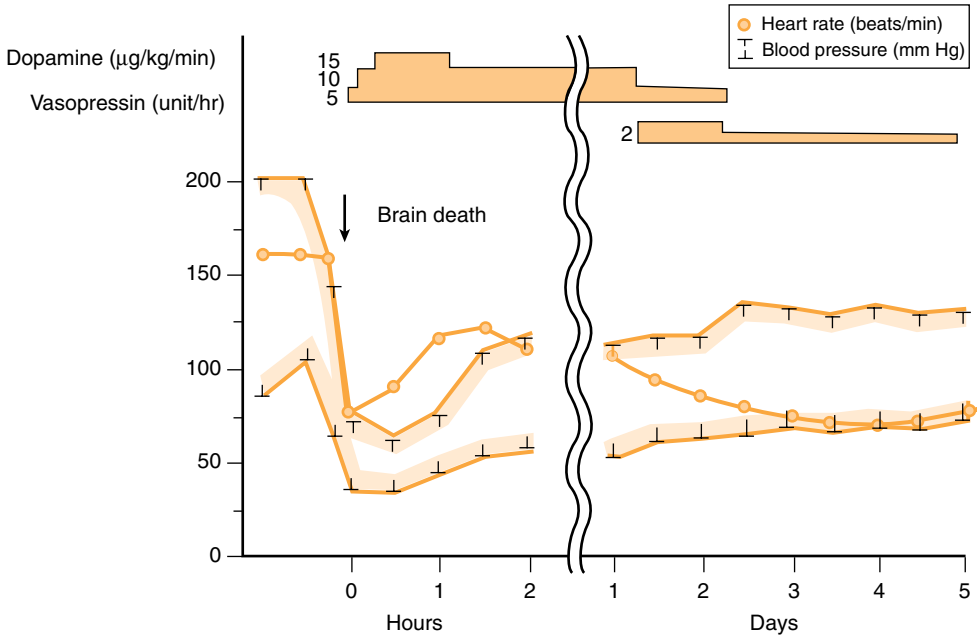

Figure 98-1 The representative time course of arterial blood pressure and heart rate before and after brain death. The 18-year-old male patient was involved in a traffic accident. Sustained hypertension was followed by a sudden and marked decrease in blood pressure. Dopamine was administered to increase blood pressure, which gradually became stable. Doses of dopamine were tapered and finally became unnecessary.

the patient becomes poikilothermic. When criteria from the National Institute of Neurological Diseases and Stroke (NINDS) were applied to establish brain death, such patients showed only a "tendency for the temperatures to be subnormal."[17] In contrast, when brain death was established using the criterion of cessation of all brainstem functions, "poikilothermia was found in all patients later than 24 hours after brain death."[37] Even if infection occurs, fever should not develop in cases of brain death, because the temperature-regulating centers no longer function. After brain death, body temperature tends to be hypothermic, even with vigorous application of external heat.

Hypothalamic-Pituitary Endocrine Functions

No criteria used to establish brain death attempt to determine whether functions of the hypothalamus are preserved. Clinical studies have indicated that hypothalamic and anterior pituitary functions are preserved to a certain degree for a certain period after the onset of brain death. Schrader and coworkers[38] reported normal levels of anterior pituitary hormones, the half-lives of which are less than 1 hour, such as thyroid-stimulating hormone, prolactin, growth hormone, and luteinizing hormone, as well as positive test results for the hypothalamic hormone luteinizing hormone–releasing hormone and thyrotropin-releasing hormone for 2 to 24 hours after determination of brain death. Sugimoto and associates[39] confirmed that concentrations of these hormones were normal for more than 1 week.

In contrast, the level of vasopressin, a hormone produced in the hypothalamus and stored in the posterior pituitary, decreased sharply after brain death.[39] However, the occurrence of diabetes insipidus is variable. In one study, many patients did not have diabetes insipidus after brain death.[40] Another study found that 24 (77%) of 31 patients with brain death had clinical diabetes insipidus.[41] When arginine vasopressin is added to the infusion in cases of brain death with diabetes insipidus, the heart beat can be maintained for several months.[42] It was reported that plasma levels of the thyroid hormones triiodothyronine (T_3) and thyroxin (T_4) were decreased markedly after brain death.[43]

The diaphragma sellae protects the pituitary gland from compression caused by swelling of the brain. Blood supply to the pituitary gland comes mostly from the superior, middle, and inferior hypophyseal arteries and the capsular arteries. The portal venous system is another source of blood supply to the anterior lobe. In brain death, blood supply through the superior hypophyseal artery and the portal vein can easily be blocked. However, blood supply through the cavernous portion of the internal carotid artery and its branches, such as the inferior hypophyseal artery and the capsular artery, may be spared.[44] Morphologic studies of brain death indicate that damage to the anterior lobe is incomplete but severe, whereas the posterior lobe is relatively preserved.[39] However, because vasopressin is synthesized in the hypothalamus and transferred to the posterior lobe of the pituitary through axoplasmic flow along the long axon, depletion of this hormone may be greater than would be expected from the slight morphologic damage seen in the posterior lobe.

In studies on brain death, the hypothalamic hormones, such as growth hormone–releasing hormone, corticotropin-releasing hormone, thyroxine-releasing hormone, and luteinizing hormone–releasing hormone were found in trace to subnormal levels.[39,45] Schrader and coworkers[38] reported a normal growth hormone response to hypoglycemic stimulation. Arita and associates[46] also demonstrated that insulin and arginine increased growth hormone levels in brain-dead patients. Hypoglycemia affects glucoreceptors in the ventromedial nucleus to stimulate growth hormone–releasing hormone and corticotropin-releasing hormone release and stimulates growth hormone or adrenocorticotropic hormone release, indicating that some hypothalamic function may be preserved. However, the origin of the hypothalamic hormones released in brain death cannot be identified. Results from morphologic studies on the hypothalamus are controversial. Walker and colleagues[17] reported that the neurons with lytic changes were intermingled with relatively normal cells, a result that may account for the sustained secretion of hypotha-

lamic hormones. In contrast, Sugimoto and coworkers[39] observed extensive necrosis of the hypothalamus after the sixth day of brain death and postulated a nonbrain supply of these hormones, such as the pancreas, intestine, or adrenal gland. As the hypothalamus receives its blood supply through the branches of the superior hypophyseal and posterior communicating arteries, blood flow to the hypothalamus, at least its basal part, may be preserved in relatively mild instances of intracranial hypertension.

Hormonal therapy for hemodynamic stabilization of brain-dead organ donors has been developed and recommended. The Cardiac Work Group of the Crystal City Conference led by United Network for Organ Sharing (UNOS) recommended a heart donor management algorithm that included four-drug hormonal resuscitation (T_3, vasopressin, methylprednisolone, and insulin) for donors with a left ventricular ejection fraction less than 45% or with unstable hemodynamics,[47] and Organ Procurement and Transplantation Network (OPTN)/UNOS multivariate studies on hormonal treatment of brain-dead donors (T_3/T_4, methylprednisolone, and arginine vasopressin) revealed significant increases in organs transplanted and in 1-year survival of kidneys and hearts.[48]

The Immune System

The CNS exerts significant influence over the immune system. Even if the immune system is intact, its response to stimulation is modified considerably after total and irreversible loss of CNS functions. Increased levels of inflammatory mediators, such as cytokines (IL-1β, IL-6, TNF-α)[49,50] and adhesion molecules (E-selectin, ICAM-1, VCAM-1)[51,52] in blood and in organs are observed in brain-dead patients, and it is thought that these cytokines are responsible for some of the endocrine and acute-phase reactant abnormalities found in these patients and for the low success rates after organ transplantation.

Brainstem Reflexes

Various brainstem reflexes are used to diagnose brain death, such as pupillary, oculocephalic, oculovestibular, and cough reflexes. Preservation of the cough reflex indicates preservation of the brainstem respiratory center. All the brainstem reflexes (except those of the respiratory centers) need not be present for the organism to be said to be alive, but they are tested to confirm preservation of brainstem functions.

Criteria and Tests for Determining Brain Death

Determination of brain death confirms the irreversible cessation of all functions of the entire brain, including the brainstem.[11] Irreversibility means that no treatment may be reasonably expected to change the condition. The responsible disorder may be thought of as structural, and it does not result from functional and potentially reversible causes such as drug intoxication, hypothermia, or metabolic or endocrine disturbance. The passage of time is also an essential component in determining that a lesion is irremediable. Although testing all functions of the brain is conceptually impossible, the cessation of all functions of the brain is practically determined by loss of consciousness, loss of brainstem responses, apnea, and confirmatory tests, including the lack of electroencephalographic activity.

Loss of Consciousness and Unresponsiveness

The patient should be in coma and scored as 3 on the Glasgow Coma Scale. Motor responses of the limbs or facial muscles to painful supraorbital pressure should be absent. Motor responses (i.e., the Lazarus sign) may occur spontaneously during apnea testing[53] and are considered to have a spinal origin. This sign is often observed during hypoxic or hypotensive episodes. Other spontaneous movements from spinal origin are observed.

Pupils

The shape of the pupils can be round, oval, or irregular. The size of the pupils may vary from 4 to 9 mm, but in most cases is 4 to 6 mm.[11,54] Sympathetic cervical pathways can be intact in the state of brain death, connect with the radially arranged fibers of the dilator muscle, and dilate the pupils.

Brainstem Responses

The tests for brainstem responses vary in different countries. The criteria of the American Academy of Neurology[11] include light reflex, oculocephalic reflex, caloric (vestibular) test, corneal reflex, jaw reflex, pharyngeal reflex, and cough reflex.

Apnea Test

Apnea testing is mandatory for the determination of brain death and considered as the most important testing, but there have been controversies about it. Its safety is a major issue. During the apnea test, marked hypotension or severe cardiac arrhythmias,[54] or both, and pneumothorax may occur[55] and the intracranial pressure can increase markedly. The apnea test should be performed as the last test after the other tests fulfill the criteria of brain death. Goudreau and coworkers[56] reported that, during the apnea test, complications such as a marked blood pressure decrease or the development of ventricular arrhythmia developed in 27 (39%) of 70 patients with pretest unfavorable factors but developed in only 11 (15%) of 74 patients without them. They pointed out that inadequate preoxygenation and acid-base or electrolyte abnormalities were the major unfavorable pretest factors. The American Academy of Neurology recommends preoxygenation with 100% oxygen for 10 minutes before apnea testing if Pa_{O_2} is 200 mm Hg or less and delivering 100% O_2, 6 L/min, into the trachea or administration of 100% O_2 through a catheter placed at the level of the carina during apnea testing (see Table 98-2).[11,54]

Another issue is the appropriate level of Pa_{CO_2} to be achieved. After equipment for analyzing blood gases became widespread, the importance of the value of Pa_{CO_2} rather than the

time for observation of apnea was confirmed. An increase in $Paco_2$ decreases pH in the cerebrospinal fluid, which stimulates the medullary respiratory chemical center. The normal ventilatory response to the increase in $Paco_2$ rises linearly to 80 mm Hg, and then the slope becomes less steep and peaks at about 150 mm Hg in dogs.[57] Damage in the medullary respiratory center may affect the level of $Paco_2$ for development of spontaneous respiration. The level of $Paco_2$ at which spontaneous respiration resumes is also modified by Pao_2. Wijdicks[4] reported that although most of all brain death guidelines in the world required apnea tests (71 of 80 nations), only 41 of 71 guidelines defined a definite $Paco_2$ target value (see Table 98-1), and he concluded that if the premise of documenting apnea using hypercarbia to maximally stimulate the respiratory centers was accepted, it could be concluded that in half of the countries the apnea test was not performed adequately. The exact level of $Paco_2$ to be achieved is still unknown, but the American Academy of Neurology criteria define various prerequisites and the procedure of apnea testing and adopt the level of $Paco_2$ greater than or equal to 60 mm Hg (see Table 98-2)[11,54] and the UK criteria requires a $Paco_2$ target of 6.65 kPa (50 mm Hg).[20]

Prerequisites for Diagnosing Brain Death

Several disorders mimic brain death and can lead to an erroneous diagnosis. The absence of these conditions must be confirmed and the following factors considered before the criteria for brain death are applied.

Deep Coma

The patient must be in a deep coma, and the cause of the coma must be identified. Organic brain damage must be confirmed as a prerequisite for diagnosing brain death. Drug intoxication, severe electrolyte, acid-base, or endocrine disturbance, hypothermia, and other common treatable disorders should be ruled out.

Body Temperature

After cessation of brainstem and hypothalamic functions and after complete disconnection of the spinal cord from supraspinal brain structures, the patient becomes poikilothermic, and body temperature tends to be hypothermic, even with vigorous warming. Because hypothermia suppresses CNS function and leads to misdiagnosis of brain death, body temperature must be within normal range (i.e., hypothermia must be corrected) before the criteria for brain death are applied.

Absence of Cardiovascular Collapse

When intracranial pressure increases, systemic hypertension occurs as a result of the Cushing phenomenon. This is followed by a sudden decrease in blood pressure because of sudden interruption of vasomotor output from the brainstem and hypothalamus to the spinal cord. Hypotension usually resolves spontaneously within several days because of restoration of spontaneous activity of the spinal cord's vasomotor neurons. Hypotension may result in compromised cerebral perfusion leading to loss of electroencephalographic activity, thus causing a spurious diagnosis. Therefore, administration of a vasopressor to achieve relative normotension should be considered; vasopressor therapy will occasionally restore electroencephalographic activity in the determination of brain death.

Clinical Diagnosis of Brain Death

The guidelines and clinical diagnosis for determining brain death differ in various countries[3,4] and among institutions in the United States and Canada. However, the principle seems similar,[1,3,4,11] and clinical diagnosis of brain death should be performed in three steps:

1. Establishing the cause of disease
2. Excluding certain potentially reversible syndromes that may produce signs similar to brain death
3. Demonstrating clinical signs of brain death: coma, brainstem areflexia, and apnea

Confirmatory tests in the determination of brain death are not always mandatory, but they are desirable, especially when the clinical picture is confusing. In general, two examinations separated by at least 6 hours are required to establish the diagnosis of brain death. Most codes mandate that the clinical diagnosis be confirmed by two or three physicians who are independent of the transplantation team, and at least one of the physicians is required to be a specialist in neurology, neurosurgery, or anesthesiology.

Special Considerations

Cerebral Death: Persistent Vegetative State

Cerebral death, the so-called persistent vegetative state, refers to cessation of the functions of the cerebral cortices. Brainstem functions governing the respiratory centers, autonomic nervous system, endocrine system, and immune system, which are vital for maintaining life, are preserved. Although the cortical EEG is flat, it is usually contaminated by electromyographic activity of the forehead, a sign of preservation of function of the facial nerve in the brainstem. The persistent vegetative state represents irreversible loss of consciousness but not irreversible loss of life or the mechanism of life; patients in this state can survive for months or years. The term *cerebral death* is occasionally used by mistake to indicate brain death, which includes the brainstem.

Cerebral death has not been accepted traditionally as equivalent to death.[58] However, some advocate that cerebral death should be accepted as the death of individuals because the critical elements of life are the organized cognition and "personhood" as the unique feature of human life, which originate from the cerebrum.[59] The problems with this notion are that the permanence of cerebral dysfunction cannot be easily predicted in most clinical

circumstances and threatens the severely senile and severely retarded, who may have severely damaged high-brain functions.[59,60] Of 40 patients referred to as being in the persistent vegetative state, 17 (43%) were considered to be misdiagnosed; they were aware of surroundings and able to communicate.[61]

The shortage of infant organs available for transplantation worldwide has promoted a growing recognition of the potential use of anencephalics, who are born without a forebrain and a cerebrum but with a rudimentary functional brainstem, as donors.[62,63] The natural course is that one half of the fetuses die in utero, and about 95% of live-born anencephalics usually die within 7 days.[63] In 1995, the American Medical Association Council on Ethical and Judicial Affairs supported the use of live anencephalic infants as organ donors,[62] although such a position opposes the legal and ethical application of the "dead-donor rule." It claimed that anencephalic neonates are definitely different from individuals who are in a persistent vegetative state, infants with profound neurologic injury, and elderly adults with severe dementia, because anencephalics have no history of consciousness and no possibility of ever being conscious. However, in 1996, it suspended its opinion because of concern about certain diagnoses of anencephaly and understanding of consciousness in these neonates.[64] In 1961, a kidney transplantation was first performed with an anencephalic newborn as a donor,[65] followed by some attempts of heart transplantation.[66] However, Western countries, with the exception of Germany, consider an anencephalic infant to be legally alive as long as the brainstem is functioning.[67]

Spinal Cord Reflexes and Surgery

The CNS structures essential to the definition of brain death do not include the spinal cord. Histologic studies have shown that the spinal cord is the best preserved part of the CNS in cases of brain death, and results have ranged from grossly normal histology to edema, neuronal loss, neurolysis, and, rarely, infarction.[17]

Spontaneous and reflex movements are found in brain-dead patients. Spontaneous body movements may be observed during the apnea test, while the body is being prepared for transport, at the time of a skin incision for the retrieval of organs, or in synchrony with the respirations produced by the mechanical ventilation.[1] In 5 of 60 cases of brain death after terminally turning off the ventilator or during apnea tests, Ropper[53] reported bizarre, seemingly purposeful movements of the upper extremities, called the Lazarus sign, in which the arms flexed quickly to the chest from the patient's side, the shoulders adducted, and in some patients, the hands crossed or opposed just below the chin. Saposnik and associates[68] reported that 15 (39%) of 38 patients who fulfilled criteria for brain death showed spontaneous or reflex movements; the most common movement was finger jerks, and the undulating toe flexion sign, triple flexion response, Lazarus sign, pronation-extension reflex, and facial myokymia also were seen. Health care staff should remember that a patient may move in response to noxious stimulation and that full curarization is required for surgical procedures involving brain death.

Considerations Regarding Children

The child's brain is a developing organ and it is believed that the anatomic neurodevelopment continues by 2 years of age or beyond the first decade of life. During this time, there are also changing patterns of vulnerability to injury and different responses to the injury itself.[69] Furthermore, the presence of open fontanelles and open sutures in young children makes the skull an expandable chamber. Intracranial pressure may not exceed mean arterial blood pressure, and cerebral blood flow continues. It is generally assumed that the child's brain is more resistant to insults leading to death, although this issue is controversial and lacks convincing clinical documentation.[70]

The need for facilitation of end-of-life decision and organ procurement in infants and children has increased. In 1987, the Task Force for the Determination of Brain Death in Children endorsed the Determination of Death Act and offered the Guidelines for the Determination of Brain Death in Children (Table 98-3).[70] The distinctions from the criteria for adults are three separate, longer observation periods, depending on the child's age, and the necessity for two corroborating EEGs or one EEG with corroborating radionuclide angiography. It is generally

Table 98-3 Brain Death Guidelines for Children

A. History: Determination of the proximate cause of coma to ensure absence of remediable or reversible conditions

B. Physical examination criteria:
   1. Coma and apnea
   2. Absence of brainstem function
      a. Midposition or fully dilated pupils
      b. Absence of spontaneous eye movements
      c. Absence of movement of bulbar musculature and corneal, gag, cough, sucking, and rooting reflexes
      d. Absence of respiratory movements with standardized testing for apnea
   3. Patient must not be hypothermic or hypotensive for age.
   4. Flaccid tone and absence of spontaneous or induced movements, excluding spinal cord events.
   5. The examination results should remain consistent with brain death throughout the observation and testing period.

C. Observation period according to age: the recommended observation period depends on the age of the patient and the laboratory test used.
   1. Seven days to 2 months: two examinations and electroencephalograms (EEGs) separated by at least 48 hours.
   2. Two months to 1 year: two examinations and EEGs separated by at least 24 hours.
   3. Older than 1 year: An observation period of at least 12 hours or, if it is difficult to assess the extent and reversibility of the brain damage, a more prolonged period of at least 24 hours. The observation period may be reduced in the presence of the electrocerebral silence of EEG or the lack of cerebral circulation.

D. Laboratory testing:
   1. EEG
      EEG to document electrocerebral silence should, if performed, be done throughout a 30-minute period using standardized techniques for brain death determination.
   2. Angiography
      Cerebral death is confirmed by a cerebral radionuclide angiogram by demonstrating the lack of visualization of cerebral circulation.
   3. Techniques being investigated:
      Xenon CT, digital subtraction angiography, visualization of cerebral arterial pulsations by real-time cranial ultrasound, Doppler determination of cerebral blood flow velocity, and evoked potential

From Task Force for the Determination of Brain Death in Children: Guidelines for the determination of brain death in children. Neurology 37:1077, 1987; and Ashwal S: Brain death in early infancy. J Heart Lung Transplant 12(pt 2):S176, 1993.

agreed that, except in very immature, preterm newborns, the same criteria of brain death can apply to term newborns, infants older than 7 days, children, and adults[71] if an observation period is prolonged for smaller children. However, there have been several reports arguing against this notion. For example, some investigators recommended that $Paco_2$ greater than 12.0 kPa in infants and children should be achieved for an apnea test, because the carbon dioxide threshold necessary to determine apnea is occasionally higher in children than in adults.[69,72]

Ashwal and Serna-Fonseca[73] stressed that brain death could be diagnosed in newborns (even when younger than 7 days) if an observation period to confirm the diagnosis was prolonged to 48 hours; and if an EEG was isoelectric or a cerebral blood flow study showed no flow, the observation period could be shortened to 24 hours. They also suggested that the same time frame would be applicable to preterm infants. However, the Special Task Force excluded infants younger than 7 days from its guideline.[70] There are several concerns about the diagnosis of brain death in newborns.[74]

1. If the injury occurred in utero, the duration of the insult and severity may be difficult to establish.
2. Normal systemic arterial pressure in the newborn is not determined.
3. The EEG and transcranial Doppler (TCD) ultrasonography may not be 100% reliable.
4. The clinical examinations cannot be reliable because of immaturity.

It was reported that a premature infant sustained an intraventricular hemorrhage on day 2 of life and showed the absence of brainstem reflexes, apnea, and flaccidity but was never clinically brain dead[75] and that 15 of 20 neonates who had isoelectric EEGs preserved partial clinical brain function.[76] Since these guidelines were issued, a wide variation in practices or violation of these guidelines has been reported.[77,78] Mejia and colleagues[77] investigated variability in the practices of determining brain death and organ procurement in pediatric intensive care units. Although apnea testing has been considered the most important criterion for brain death even in children, it was not carried out for 23 (25%) of 93 brain-dead patients, and the methods of apnea testing were not consistent with the Guideline for Determination of Brain Death in Children for 20 patients (22%). Four of 30 patients younger than 1 year did not have a confirmatory test. They concluded that the variability in brain death determination practices might reflect differences in documentation, lack of knowledge of the guidelines, or disagreement with the guidelines.

Central Integrator Theory of the Brain

The notion that brain death is equivalent to the death of the individual is mainly based on the theory of "the brain as the central integrator of the body." In brain death, the body is no more an integrated organism but a mere and rapidly disintegrating collection of organs that have lost forever the capacity of working as a coordinated whole.[79] Patients with brain death were once thought to inevitably have a cardiac arrest within a short period time (usually within 1 or 2 weeks), regardless of the intensity of life support.

However, it has been recognized that not all brain-dead patients inevitably deteriorate to cardiovascular collapse in a short time and some of them show an adequate level of biologic integration for weeks or months (up to more than 14 years in one case) if they are provided with an appropriate life support. Furthermore, brain-dead patients can assimilate nutrients, eliminate wastes, fight infections, heal wounds, carry out a pregnancy, and so on, without the control of the brain. Zapperetti and coworkers argue that the "central integrator" theory rests more on what we think should happen to brain-dead patients, according to the definition, than on what can be observed clinically.[80]

Variability in Policies and Practices for Determining Brain Death

Although the concept of brain death as defining the death of the individual is widely accepted, there is a significant variability in policies and practices for determining brain death among nations and even within a nation, that is, among states and hospitals. Wijdicks[4] reported that of 80 countries examined, legal standards on organ transplantation were present in 55 countries (69%) and practice guidelines for brain death for adults were present in 70 countries (88%). All guidelines specifically specified exclusion of confounders, irreversible coma, absent motor response, and absent brainstem reflexes, but there were significant differences in the method of apnea testing, in time of observation, in the number and required expertise of examining physicians, and in requirement of confirmatory tests (see Table 98-1). Furthermore, because brain death practices are largely determined by individual hospitals in the United States and Canada, significant variabilities among hospital policies and guidelines for brain death were found. Wijdicks and other investigators stressed the need to standardize the practice of the neurologic determination of death.[4,81,82] The wide variation in practices was also reported in the pediatric population[77,78] and in the brainstem death criteria in the United Kingdom,[23] despite the existence of clear guidelines for performing the test.

Confirmatory Tests for Brain Death

Tests that confirm the loss of bioelectrical activity of the brain or the cerebral circulatory arrest are not always mandatory for adults but strongly recommended for children, especially those younger than 1 year (Table 98-4).[1,3,4,70] In several European, Central American, South American, and Asian countries, confirmatory testing is required by law (see Table 98-1).[1,3,4] In the United States, the choice of tests is left to the discretion of the physician. Young and associates[83] proposed criteria for ideal confirmatory ancillary tests:

Table 98-4 Confirmatory Testing for Determination of Brain Death

Cerebral Angiography
- The contrast medium should be injected under high pressure in the anterior and posterior circulation.
- No intracerebral filling should be detected at the level of entry of the carotid or vertebral artery to the skull.
- The external carotid circulation should be patent.
- The filling of the superior longitudinal sinus may be delayed.

Electroencephalography
- A minimum of eight scalp electrodes should be used.
- Interelectrode impedance should be between 100 and 10,000 ohms.
- The integrity of the entire recording system should be tested.
- The distance between electrodes should be at least 10 cm.
- The sensitivity should be increased to at least 2 μV for 30 minutes with inclusion of appropriate calibrations.
- The high-frequency filter setting should not be set below 30 Hz, and the low-frequency setting should not be above 1 Hz.
- Electroencephalography should demonstrate a lack of reactivity to intense somatosensory or audiovisual stimuli.

Transcranial Doppler Ultrasonography
- There should be bilateral insonation. The probe should be placed at the temporal bone above the zygomatic arch or the vertebrobasilar arteries through the suboccipital transcranial window.
- The abnormalities should include a lack of diastolic or reverberating flow and documentation of small systolic peaks in early systole. A finding of a complete absence of flow may not be reliable because of inadequate transtemporal windows for insonation.

Cerebral Scintigraphy (^{99m}Tc-hexametazime)
- The isotope should be injected within 30 minutes after its reconstitution.
- A static image of 500,000 counts should be obtained at several time points: immediately, between 30 and 60 minutes later, and at 2 hours.
- A correct intravenous injection may be confirmed with additional images of the liver demonstrating uptake (optional).

From Wijdicks EF: The diagnosis of brain death. N Engl J Med 344:1215, 2001.

1. There should be no instances of a "false positive"; that is, when the test confirms "brain death" there should be none who recovers or who has the potential to recover.
2. The test should be independently sufficient to establish that brain death is or is not present.
3. The test should not be susceptible to "confounders" such as drug effects or metabolic disturbances.
4. The test should be standardized in technology, technique, and classification of results.
5. The test should be available, safe, and readily applied. Testing should not be restricted to only a few research centers; ideally it could be applied within any intensive care unit (ICU) and the technique should be reliable and mastered without difficulty.

In all cases, confirmatory tests should be used in conjunction with appropriate clinical judgment.

Electroencephalographic Recording

The EEG is the most widely available neurophysiologic test and is used in many countries and institutions as a confirmatory test for brain death (whole brain death).[1-4] Loss of bioelectrical brain activity as shown on the EEG (i.e., isoelectric EEG) is a reliable confirmatory test for brain death. However, several problems must be considered. An isoelectric EEG can be found after drug intoxication (false positive), such as occurs with barbiturates,[84] and, conversely, residual electrical activity may persist after brainstem death or even in some patients who met clinical criteria for brain death (false negative).[21,85]

Electrocerebral inactivity (ECI) or electrocerebral silence (ECS) is defined as no electroencephalographic activity above 2 μV/mm when recording from scalp electrode pairs placed 10 or more cm apart and with interelectrode impedances less than 10,000 ohms but more than 100 ohms. Ten guidelines for electroencephalographic recordings[86] follow:

1. A minimum of eight scalp electrodes should be used.
2. Interelectrode impedances should be less than 10,000 ohms but more than 100 ohms.
3. The integrity of the entire recording system should be tested.
4. Interelectrode distances should be at least 10 cm.
5. Sensitivity must be increased from 7 μV/mm to at least 2 μV/mm for at least 30 minutes of the recording, with inclusion of appropriate calibrations.
6. Filter settings should be appropriate for the assessment of ECS.
7. Additional monitoring techniques should be employed when necessary.
8. There should be no electroencephalographic reactivity to intense somatosensory, auditory, or visual stimuli.
9. Recordings should be made only by a qualified technologist.
10. A repeat EEG should be performed if there is doubt about ECS.

Evoked Responses

Brainstem auditory evoked potentials (BAEPs) and median nerve somatosensory evoked potentials (SSEPs) are used for the diagnosis of brain death. Unlike EEG signals, the early components of BAEPs and SSEPs are minimally affected by sedative drugs and anesthetics. However, drugs and metabolic derangements affect middle and late BAEPs and SSEPs.[83] BAEPs are signals generated in the auditory nerves and brainstem after an acoustic stimulus. BAEPs consist of five identifiable waves generated from specific brainstem structures along the auditory pathways. Wave I represents the eighth nerve compound action potential; wave II, the eighth nerve and cochlear nerves; wave III, the lower pons including the superior olive; and waves IV and V, the upper pons and the midbrain, as high as the inferior colliculus.[87] Brainstem abnormalities can be detected with BAEPs. The loss of waves III to V or II to V or no reproducible BAEP on both sides is usually regarded as brain death,[85] although wave I sometimes remains. Preexisting deafness or severe peripheral auditory system damage may lead to a false-positive diagnosis.

After electrical stimulation of a peripheral nerve, waves of SSEPs are generated from the neural structures along the afferent somatosensory pathways: the brachial plexus, the upper cervical cord, the dorsal column nuclei, the ventroposterior thalamus, and the sensory cortex.[87] "Practice Parameters for Determining Brain Death in Adults," published in *Neurology,* recommended bilateral absence of N20-P22 responses with median nerve stimulation as a confirmatory laboratory test.[11] Facco and coworkers[88] reported

that the absence of components later than N13, which represents postsynaptic activity in the central gray matter of the cervical cord, or N13/P13 dissociation, was reliable to confirm brain death. These investigators also recommended the combined use of BAEPs and SSEPs for determining brain death. Sonoo considered a loss of N18 potential, which is supposedly generated at the cuneate nucleus in the medulla oblongata, as reliable for the diagnosis of brain death.[89]

Demonstration of Brain Perfusion and Measurement of Cerebral Blood Flow

Possible mechanisms for brain death include an obstruction of circulation by cerebral swelling. The demonstration of absent intracranial circulation indicates irreversible cerebral damage. Adopting this concept, Scandinavian nations have taken the stance that total-brain infarction constitutes brain death.[3] The following methods are used to demonstrate perfusion of the brain or measure of cerebral blood flow.

Angiography

Contrast Catheter Angiography

Four-vessel cerebral angiography is a traditional "gold standard" modality among ancillary tests for brain death. This method is primarily an anatomic and not a physiologic demonstration of perfusion, although nonquantitative inferences about perfusion rates may be made. The greatest advantage of catheter angiography for the determination of brain death is that it is influenced neither by CNS depressant drugs nor by hypothermia. This method has been widely recommended to confirm brain death.[30,85,90] "Practice Parameters for Determining Brain Death in Adults" recommended conventional angiography as a confirmatory test, and the following criteria were identified[11]: There should be no intracerebral filling at the level of the carotid bifurcation or circle of Willis; the external carotid circulation is patent; and filling of the superior longitudinal sinus may be delayed. Drawbacks of this method are that the patients need to be transported to the radiology suite and it is an invasive examination that needs an experienced neuroradiologist and may yield severe complications, such as vasospasm, subintimal injection, arterial dissection, and thromboembolism, leading to a false image of absent flow and cerebral ischemia. Intra-arterial (aortic arch) or intravenous (vena cava) digital subtraction angiography has been shown to be as effective as conventional four-vessel angiography, is less invasive, and is easier to perform.[91]

Radionuclide Angiography

Confirmation of brain death using conventional dynamic radionuclide angiography with blood pool agents has been used for a long time.[92] Such investigations are less invasive than others and may be carried out at the bedside using a mobile scintillation camera, but they cannot image the posterior fossa well. Radioligands such as technetium 99m (^{99m}Tc) hexamethylpropyleneamine-oxime (HMPAO), which cross the blood-brain barrier and are picked up and held by viable cells for several hours, are recommended to confirm brain death.[93] The lack of uptake of isotope in brain parenchyma (i.e., hollow skull phenomenon) is characteristic for brain death.[11] ^{99m}Tc-HMPAO single-photon emission computed tomography (SPECT) provides much more precise regional information and has been proven effective in the diagnosis of brain death both in children and adults.[94,95] The lack of signal from the intracranial compartment and the normal uptake in other parts of the head produce the "empty light bulb" and "hot nose" signs.[94,95] Munari and coworkers confirmed the reliability of SPECT in the diagnosis of brain death and recommended that it should be a good candidate for the standard diagnostic modality.[96]

Computed Tomography

Computed tomography (CT) angiography has been useful as a noninvasive test to confirm brain death.[97] After intravenous injection of contrast media, time-density analysis of a specific area can be obtained with a CT scanner equipped with a special software program that can evaluate blood flow. CT angiography has several advantages[97]: (1) it is easily accessible around the clock and present in almost all hospitals with an ICU, (2) it is fairly inexpensive, (3) imaging requires only minutes, (4) it delivers conventional CT images at the same imaging session and can also be combined with CT perfusion imaging, (5) it is noninvasive except for intravenous injection of the contrast agent, and (6) the images are easy to interpret. However, significant divergence with catheter angiography was observed; CT angiography demonstrated some opacified proximal anterior cerebral artery segments, although there was an absence of intracranial flow with catheter angiography,[98] which may relate to contrast stasis with CT angiography.

The xenon-CT cerebral blood flow method has been applied to the confirmation of brain death.[30] This technique is quantitative and allows co-registration of flow data with CT anatomy. Pistoria and associates[99] suggested that an average global flow of less than 5 mL/dL/min confirms brain death.

Magnetic Resonance

Magnetic resonance (MR) imaging (MRI) and MR angiography have been used for the confirmation of brain death with the advent of MRI-compatible ventilators.[100,101] MRI allows an assessment of intracranial contents and is particularly helpful in defining abnormalities in the posterior fossa, which may be obscured by bone artifact inherent in CT. Although currently experimental and limited in spatial resolution, phosphorus (^{31}P) and proton (^{1}H) MR spectroscopy (MRS) has been proposed for the determination of brain death.[102,103] MRS can demonstrate the total absence of high-energy phosphorus compound (including ATP), leaving only one single peak of inorganic phosphate in ^{31}P MRS and massive lactate concentration in ^{1}H MRS. Diffusion-weighted MRI, which detects the molecular diffusion of water, has been proposed as an adjunct in the diagnosis of brain death, because it can identify widespread cerebral ischemia.[104]

Transcranial Doppler Ultrasonography

TCD is a safe, noninvasive, and inexpensive method that can be performed at the bedside. However, the test requires skill and knowledge in its application to insonate the major intracranial arteries. The Neurosonology Research Group (NRSG) of the World Federation of Neurology (WFN) created a Task Force Group to evaluate the role of TCD as a confirmatory test for determining brain death and offered the criteria for the diagnosis of cerebral circulatory arrest.[105] According to the criteria, cerebral circulatory arrest can be confirmed if the following extracranial

and intracranial Doppler sonographic findings have been recorded and documented both intracranially and extracranially and bilaterally on two examinations at an interval of at least 30 minutes:

1. "Systolic spikes" or "oscillating flow" in any cerebral artery can be recorded by bilateral transcranial insonation of the internal carotid artery (ICA) and middle cerebral artery (MCA), respectively any branch or other artery which can be recorded (anterior and posterior circulation).
2. The diagnosis established by the intracranial examination must be confirmed by the extracranial bilateral recording of the common carotid artery, ICA, and vertebral arteries.
3. The lack of a signal during transcranial insonation of the basal cerebral arteries is not a reliable finding because this can be due to transmission problems.
4. Ventricular drains or large openings of the skull as in decompressive craniotomy possibly interfering with the development of the intracranial pressure are not present.

According to the report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology, the sensitivity of TCD for diagnosis of brain death ranges from 91% to 100%.[106] In a meta-analysis study of 10 studies concerning TCD examination, two high-quality studies showed a sensitivity of 95% and a specificity of 99% to detect brain death, and all 10 studies showed a sensitivity of 89% and a specificity of 99%.[107] Poularas and coworkers[108] reported that when they examined 40 clinically brain-dead patients by TCD and angiography the agreement between the TCD and angiography to confirm brain death was 100%. Young and coworkers,[83] however, strongly recommended that because of numerous caveats and lack of precise guidelines, TCD should not be, at this time, recommended as the sole test of brain perfusion in case of suspect brain death.

Positron Emission Tomography

Positron emission tomography (PET) imaging involves intravenous injection of radiotracers labeled with positron-emitting nuclides (e.g., oxygen 15 [^{15}O], carbon 11 [^{11}C], nitrogen 13 [^{13}N]). These radionuclides are incorporated into organic compounds that are chemically similar to those present in the body, and several physiologic parameters can be measured. A few of the reports about the use of PET in the setting of brain death indicated the utility of PET in the confirmation of brain death. No detectable glucose metabolism was reported using fluorine-18 fluorodeoxyglucose (^{18}F-FDG) in brain-dead patients.[109] On the other hand, Medlock and colleagues[110] reported a clinically brain-dead 2-month-old infant with no cerebral electrical activity who demonstrated the persistence of glucose metabolism by PET. These investigators speculated that the preservation of glucose metabolism was partly caused by glial cells, which are more resilient than neurons. The use of PET in the investigation of comatose or brain-dead patients is still in an early stage of development and limited by its high cost and need for special facilities. Laureys and associates[111] suggested that functional neuroimaging is providing new insights into cerebral activity in patients with severe brain damage and that measurements of cerebral metabolism and brain activations in response to sensory stimuli with PET, functional MRI, and electrophysiologic methods can provide information on the presence, degree, and location of any residual brain function.

Anesthesiologists in Organ Donation

The concept of brain death has been developed, at least in part, with the development of organ transplantation, and the main purpose of diagnosis of brain death is that it permits multiple vital organ procurement for transplantation. The "dead-donor rule,"[112] which requires that patients must be declared dead before the removal of any life-sustaining organs, is the ethical and legal axiom. Because of a critical shortage of organs for transplantation, various measures have been proposed to improve the rate of organ donation from brain-dead patients, such as "required request" and "presumed consent."[113,114] Furthermore, "non–heart beating organ donor" protocols, in which life-sustaining therapy is withheld on a imminently dying patient with the removal of the transplantable organs after the patient's cardiac arrest, have been introduced. Such protocols have gained popularity, especially after a qualified endorsement by the Institute of Medicine.[115,116]

Anesthesiologists should have ample knowledge about brain death and organ donation, because they would be involved not only in anesthetic management of a brain-dead patient for organ procurement but also in brain death diagnosis. In brain-dead patients, brainstem function with or without cortical functions is absent, and theoretically, the patients are unconscious. However, because their spinal cords are intact and somatic and visceral reflexes remain,[1,53] special care is required for anesthetic management. Muscle relaxants are necessary to suppress motor activity mediated by spinal reflexes. Vasodilators usually are employed to suppress hypertension and tachycardia by noxious stimuli. However, there is an opinion that sedation and analgesia should be given with muscle relaxation for organ donation, especially in cases of brainstem brain death,[35] although analgesic and anesthetic agents are theoretically unnecessary. Van Norman[113] stressed that anesthesiologists must have specific knowledge about the medical and legal definitions of death, as well as the ethical concepts behind them, and when anesthesiologists face anesthetic management for organ donation, they should consider the conditions of brain-dead patients and furthermore observe whether they are really brain dead.

James Kindscher and Melissa Rockford

99 Operating Room Management

Key Points

1. Reorganizing the governance structure of the OR to consolidate control and authority into one position, such as the OR medical director, has many advantages in making the OR function at an optimal level.
2. Improvement in the OR scheduling process may lead to the biggest gains in OR efficiency. Block time scheduling allows better predictability and satisfaction for OR personnel.
3. On-time OR starts, surgical case performance benchmarks, and room turnover are all critical elements in making an OR run efficiently.
4. Traditional OR utilization assessments may not reflect how well an OR is working. Newer methods that focus on OR productivity are increasingly being used to determine allocation of OR resources.
5. Managing the daily surgical schedule requires careful planning, as well as frequent re-evaluation, to deal with the variability in case times, add-ons, and cancellations.
6. The OR director must create a professional environment in the OR and not allow disruptive behavior patterns to exist.
7. A detailed OR information system is essential in tracking OR activity and creating reports for assessment and improvement projects. OR cost accounting is essential to the OR director in guiding decisions for resource application.

The operating room (OR) is a major source of both revenues and expenses for hospitals.[1] Hospital chief executive officers must focus on the profitability of the OR service, and this emphasis has led to the rapid growth and development of OR management. The goal of current OR management is to replace the previously ill-defined structures for OR decision-making and administration with more formal and efficient structures. Over a decade ago, little information existed concerning OR direction and management, but as the focus on OR management has expanded, most hospitals now realize that clear-cut, scientific OR management is crucial to success. The discussion of OR management has expanded, as evidenced by the increasing number of journals including articles devoted to this subject. *Anesthesia and Analgesia* now includes a section on economics, education, and health systems research, with focused articles on OR management. The *Journal of the Association of Operating Room Nurses* (AORN J) also includes many articles on OR management issues. Another journal, *OR Manager,* is devoted to advancing knowledge in this field. Professional organizations have developed nationally and internationally to educate hospital staff on the concept of OR management. Examples include Anesthetists in Management in the United Kingdom and the American Association of Clinical Directors (AACD), which is a society formed in 1988 to lead the development of OR management expertise among anesthesiologists. The purpose of this chapter is to describe the development of OR management structure as well as offer information on identifying the complexities of OR function to improve OR productivity.

History

The role of the OR within the hospital has evolved. The organized structure and daily management of the OR are markedly different than they were 20 to 30 years ago.[2] In the past, ORs generated large profits. The priorities of the OR were to maximize convenience for surgeons and attract a greater market share, with little emphasis on controlling costs. Hospital administrators assumed that any new investment in the OR would lead to increased revenue. This mentality thrived in a period when revenues were plentiful, which allowed hospitals to provide new equipment or OR expansions upon request. Surgeons could schedule procedures as they desired, usually on a first-come/first-served basis. The authority for OR management was dispersed between hospital administrators, with little direct OR experience, and the OR nurse managers, who managed all the complex activities in the OR. Because the hospital administrators had responsibilities for several areas of the hospital, they left daily control to the OR head nurse, who became the de facto leader of the unit. Many of the

supporting services (housekeeping, admitting, materials management, and laundry) had separate administrative reporting structures. The low procedure complexity of ORs allowed for these simplified support services. Physicians often had a limited role in directing OR function.

As surgical procedures became more complex and competition for OR time increased, surgeons became dissatisfied with the control structure of OR management. Physicians formed OR committees to voice their thoughts to hospital leadership. The hospital and OR committees created rules and policies governing OR function. Dedicated rooms for complex procedures and increased scheduling demands led to the development of guaranteed reserved OR times called "blocks." These blocks allowed better predictability for surgeons to perform their procedures and allowed the hospital to provide the necessary support for the cases. The authority for daily OR management still resided primarily with nursing.

As Diagnosis-Related Group (DRG) reimbursement and capitative payment for care became more common, OR revenues declined. Hospital administrators noted that ORs were very expensive to furnish and run. The overall hospital operating margin (profit) declined from 6.3% in 1997 to 2.7% in 1999.[3] By 1999, 43% of not-for-profit hospitals actually lost money. Such losses forced hospital leaders to rethink how to run ORs. If the ORs consumed 9% to 10% of the institution's annual budget, the hospital needed to analyze and control the costs.[4] With the advent of general medical restructuring and primary care "gatekeepers," hospitals predicted reduced demand for specialists and surgical services. They reduced inpatient beds and limited OR growth. The net effect of these changes was increased frustration with OR function and management.

Predictions of reduced surgical caseload volume proved untrue. Surgical demand began to increase faster than the supply of OR infrastructure, OR nursing, and anesthesia services. Shortages of hospital beds, intensive care units (ICUs), and personnel have increased pressure to manage ORs with maximum efficiency while controlling costs. The hospitals expected all these OR changes to occur simultaneously while maintaining high OR customer and patient satisfaction. Hospital administrators realized that they needed more direct physician leadership in complex OR matters. As a result, they appointed medical directors to give more voice and authority to physicians in OR leadership roles. This physician leadership structure began in academic departments but has now expanded to many public and private organizations throughout the world. The focus on leadership structure and management techniques to improve OR function has led to the organized approach to OR management described in this chapter.

Medical Management in the Operating Room

Operating rooms are complex and expensive facilities that require a well-defined governance structure. As medical needs and regulatory requirements evolve, an OR governance structure must rapidly adapt to accommodate these changes. Traditionally, ORs followed a "top-down" management style. Hospital administrators were distant and unfamiliar with the daily work flow of the OR. They would often appoint the OR nursing director to serve as the unit manager. Often this nursing director was unfamiliar with the specific needs of surgeons and anesthesiologists. This unfamiliarity created a roadblock to rapidly addressing the evolving needs of the OR. In response to this problem, the original concept of an OR medical director was created. This concept involved creating an "OR czar" or single-handed decision maker. This approach was also flawed because it implied an authoritarian ruling style. That sort of management style is rarely successful in actual practice.

The most recent model for an OR medical director arose in response to the competing priorities of the diverse groups working within the OR (surgeons, anesthesiologists, nurses, and hospital administrators). For the OR to function effectively, the medical director must balance the priorities of each group while working cooperatively among the groups. Surgeons want maximum convenience and service, easy OR access, and state-of-the-art equipment. Nurses want predictable hours and standardization of cases. Anesthesiologists want high utilization during peak business hours and adequate support for starting procedures and turnovers. Hospital administrators want high utilization and low cost for personnel and equipment. These competing priorities may create conflict and inhibit productivity. The purpose of a medical director is to align the forces working in the OR in an efficient and productive manner. The most important advantage to this structure is that providing control and authority to one knowledgeable individual allows the OR to adapt to changes and make critical improvements. Creating an organizational structure with a medical director improves OR performance; increases physician, nursing, and patient satisfaction; permits rapid adaptability to changing market forces; improves communications throughout the system; and strengthens accountability and enforcement of OR rules and regulations. Figure 99-1 shows an organization structure that describes how the medical director may fit into the hierarchy of OR governance.

Anesthesiologists are good candidates for this position for several reasons. They have a global view of the OR and understand each component of the OR process. They share with the hospital administrators a desire for a smooth-running and cost-effective global OR. Because anesthesiologists are familiar with preoperative, intraoperative, and postanesthesia care unit (PACU) processes, they appreciate how to make the OR function as a unit. They are also familiar with the different surgical specialties and can balance the needs of these groups. Anesthesiologists are present in the OR daily and can intervene in urgent situations. Table 99-1 identifies personal characteristics that are beneficial for a medical director.

Another position that may complement the role of OR medical director is that of Director of Perioperative services. Responsibilities of this individual include managing the workflow of the anesthesia preoperative clinic and the PACU. This person works closely with the OR director because preoperative and postoperative problems have direct input on the flow of the operating room. Bottlenecks in throughput that occur before or after the surgical procedure will neutralize efficiencies developed within the OR.

Medical directors face many challenges. The position requires time away from clinical practice to attend meetings, plan projects, and coordinate OR productivity. The physicians' group or department chair must accommodate these scheduling demands to accomplish the OR's mission. The hospital should

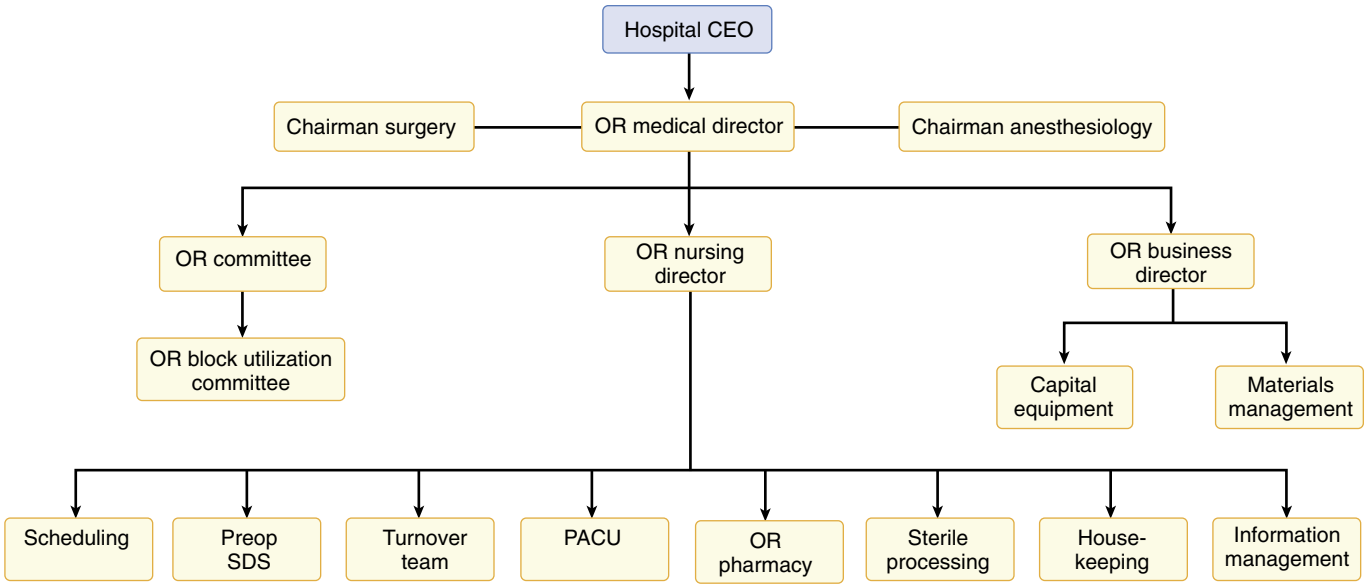

Figure 99-1 Organizational structure that describes how the medical director may fit into the operating room system. CEO, chief executive officer; OR, operating room; PACU, postanesthesia care unit; SDS, same-day surgery.

view the medical directorship as an investment and provide the appropriate financial support. Likewise, the chairs of surgery and anesthesia must cede some of their departmental control and authority involving OR matters. Time and energy demands may limit medical directors from advancing within their departments, organizations, or academic institutions. The medical director must make difficult decisions and be able to withstand criticism and challenges to his or her role. In addition, medical directors may require additional business training or data processing support.

Dealing with OR conflicts is another difficult aspect of management for OR directors, perhaps one of the least desirable roles of the position. With increased awareness of "culture" in the operating room, it is imperative to maintain a professional environment where staff members exhibit mutual respect for all parties.[5,6] The OR should develop performance policies including scheduling rules, surgeon presence in the OR, charting requirements, and behavioral expectations. The OR is one of the most common sites for disruptive physician behavior due to the high intensity and stress of the environment. The medical director should have a leading role in developing clear policies for addressing disruptive behavior. Table 99-2 lists steps for dealing with disruptive behavior.[7,8] Disruptive individuals or those who attempt to circumvent the established OR policies and rules create a dysfunctional system and dissatisfaction among the OR staff.[7] The medical director can set the tone for teamwork in the OR.

In 2002, AACD conducted a survey of its membership (Table 99-3).[9] The survey noted that the concept of a medical director, which began in academic organizations, has now spread to university-affiliated and private practice hospitals. Seventy-nine percent of OR medical directors served in hospitals with more than 200 beds. The survey disclosed that financial support varies, but most medical directors receive supplementation of less

Table 99-1 Characteristics of the Medical Director of an Operating Room

- Experienced individuals, usually in the middle of their careers
- Respected for clinical skills
- Strong interpersonal skills
- Integrity and trust by all groups
- Perceived neutrality and balanced views on issues
- Leadership style by consensus development
- Strong analytical and problem-solving skills
- Detailed data management traits
- Ability to commit significant time and focus to operating room
- Appreciation of hospital's goals
- Good long-range planning development
- Ability to address regulatory and oversight controls

Table 99-2 Dealing with Disruptive Behavior

- Educate the OR staff on hospital policies and definitions of disruptive behavior.
- Set a low threshold for identification and reporting.
- Respond immediately to an incident.
- Make the behavior the issue, not the individual.
- Focus on the acute behavior and not past frustrations.
- Do not accept excuses or explanations of justification.
- Set clear target goals for behavior modification and then follow up directly with the individual.
- Be sympathetic to the perspective of public humiliation of the individual. Deal with the individual in a quiet private setting with one or two witnesses.
- Seek out other issues in the physician's practice that may be the source of stress. Often, factors outside the OR lead to the disruptive behavior that is manifested in the OR.
- Be prepared to enforce your Disruptive Behavior Policy completely. If the physician does not reform or persists in the disruptive behavior, removal from the hospital staff may be the best solution.
- Enforce your policy evenly. Do not allow exceptions for behavior of high-profile individuals. Frequently, action against one physician will demonstrate the seriousness of your commitment to physician behavior standards and serve to deter others from acting out.

Table 99-3 American Association of Clinical Directors 2002 Survey of Operating Room Medical Directors

Hospital Type	
University teaching	44%
Community hospital	33%
University affiliated	33%
No. Hospital Beds	Size
<50	5%
50-100	4%
100-200	13%
200-500	54%
>500	25%
Hospital Compensation for Medical Director (per Year)	
None	40%
0-$10,000	25%
$10,000-$25,000	18%
$25,000-$50,000	13%
$>50,000	4%

than $10,000 per year. Appendix 99-1 provides the AACD guidelines for the role of medical director. Information is also available on the AACD website at www.AACDhq.org.

If an organization appoints an OR medical director, it should clearly define the director's responsibilities, expectations, and support. As stated earlier, the motivation for creating a medical director is often a result of frustration and low satisfaction among OR staff. Newly appointed medical directors can gain early success and acceptance by initially identifying issues that they can easily remedy. Coordination with the OR head nurse and OR business manager will unite the resources necessary for change. Regular communication with hospital superiors and OR staff will help define progress and identify future plans. Medical directors need to involve other physicians in setting goals and priorities. Success will require hospital administration and physicians to bring about change through compromise. The OR committee along with hospital administration should create reasonable rules and standards with equitable enforcement. While individual contributions should be rewarded, a team approach is essential. Alan Marco's "game theory" is a useful analogy for various situations a medical director may encounter in running the OR.[10,11] It should be emphasized that, albeit tedious at times, the position of medical director is often substantially rewarding.

Efficiency of Operation

Scheduling

Accurate scheduling in the OR is crucial to running an efficient surgical service. Poor scheduling causes delays and confusion on the day of surgery. It also results in dissatisfaction for patients, surgeons, and anesthesiologists. The process involves estimating, organizing, and assembling the necessary personnel, equipment, space, and time to perform a procedure.

Most ORs utilize a computerized scheduling system, and data integrity is paramount. Errors or omissions from documentation, including the patient's name, age, disposition (inpatient versus outpatient), procedure description, or surgical case duration, can have a major impact on how well the OR functions. Personnel who input these data should take precautions to reduce errors. Many computerized systems track posted cases to verify that available equipment matches resource needs. This prevents overbooking items with high demand including C-arm x-ray machines or microscopes.

Accurate prediction of surgical case times is also essential to scheduling. Errors in estimated times will affect the predicted start of every subsequent case. Gathering institution specific data is also important because operating times may significantly differ among hospitals.[12] Several authors have described how computer and statistical modeling can improve case duration estimates.[12-21]

Because there are wide differences among surgeons as well as multiple variations of a particular procedure, the potential times for a case may be difficult to predict. If the hospital has computerized historical data, it can base the surgical case time on a set number of similar performed cases. In our institution, the scheduling system will give the expected time for the procedure at the time it is posted. The surgeon may then increase or subtract time from this estimate based on his or her knowledge of the patient or predicted difficulty of the case. Based on this system, 50% of all cases in our ORs were completed within 30 minutes of the scheduled time. Fifteen percent of cases were 30 minutes longer than the scheduled time, whereas 35% of cases finished more than 30 minutes sooner than had been scheduled.

Historically, ORs were scheduled under an "open block" system. Surgeons scheduled cases in available rooms on a first-come-first-served basis. This system worked if there was little demand for OR time and each room was suited for all types of procedures. However, open block scheduling has many undesirable consequences. Surgeons with a short lead time in deciding to operate are unable to predict the availability of rooms. Personnel have to move complex equipment from room to room to accommodate demand from multiple types of surgeries. There is also marked variability between busy and light days resulting in poor overall OR efficiency and difficulty anticipating demand and allocating resources.

Because of the limitations of the "open block" system, ORs moved toward a system of "block" scheduling. Block scheduling guarantees a certain degree of OR availability. Under this system, the institution assigns a specific room on a specific day to a surgeon or surgical group. The surgeon or group may then schedule its cases for that room and day. This arrangement permitted the development of specialized ORs (i.e., rooms with heart-lung machines for cardiothoracic surgery, rooms with ophthalmologic fixed ceiling-mounted microscopes, and rooms with dedicated laparoscopic equipment).

The use of block scheduling has revealed several best practice standards. For example, block time works most effectively when it is granted to a surgical service (e.g., orthopedics or gynecology) rather than to an individual surgeon. In addition, full-day blocks (8 hours of OR availability) work better than half-day blocks because patient flow and case start times are more

Table 99-4 Guaranteed Room Starts

Service	Monday	Tuesday	Wednesday	Thursday	Friday
Cardiothoracic	3	3	3	3	3
General surgery	3	3	3	3	4
Orthopedics	4	3	4	3	3
Urology	2	2	2	2	2
Neurosurgery	1	2	2	2	2
Otolaryngology	2	2	3	3	2
Plastic surgery	1	1	1	2	1
Ophthalmology	0	1	0	0	1
Pediatric surgery	1	0	0	1	0
Gynecology	1	2	1	1	1
Nonoperating room cases	1	1	1	1	1
Open blocks	3	2	2	2	3

predictable. The reduced movement of personnel and equipment improves room setup and shortens turnover times. Tables 99-4 and 99-5 show examples of the block system at the University of Kansas Hospital.

In order for block scheduling to succeed, the institution should develop rules governing its use. For example, ORs may use measures of surgical demand, such as historical surgical hours per week, to grant the number of blocks to a surgical group. Key topics the rules should address include advance scheduling, turnover time,[21,22] and hold time or release time.[23,24] The release time, which varies among surgical specialties and institutions,[24] is the time when the block is no longer reserved for a particular service. Services performing procedures that have some urgency or a short lead time, such as heart or vascular surgery, have shorter times from release to the surgery date than services with a more elective practice, such as cosmetic plastic surgery or orthopedic joint replacement. Services with a high referral practice (cancer procedures or trauma) will also need shorter release periods for their blocks (Table 99-6). Once a release time is reached, remaining time (unused block time) is available to any surgeon on a first-come/first-served basis.

Table 99-6 Suggested Block Release Times

Service	Release Time
Cardiothoracic	1 day
Vascular surgery	2 days
Orthopedics	3 days
Neurosurgery	4 days
Pediatric surgery	1 wk
General surgery	1 wk
Gynecology	1 wk
Ophthalmology	1 wk
Otolaryngology	1 wk
Plastic surgery	2 wk

An institution should closely monitor block time utilization and adjust it as surgical practice changes within the hospital. For example, if a surgical service is filling more than 90% of its block time, it becomes difficult to perform additional cases or manage variability in the surgical referral base. On the other hand, if block utilization is low (60% to 70%), predictable OR time is not available to other surgeons who may need several days of advance planning to schedule cases. Each institution should set a threshold for block utilization to determine how services will gain or lose OR blocks.[25-28] A group with representatives from hospital administration, major surgeons, anesthesiology, and nursing should develop these thresholds. The institution should ensure it applies them equitably to avoid potential "games" to change OR availability.[10,11] The group should then monitor and enforce compliance with the rules.

Today, hospitals often schedule most of their ORs under a block system, reserving some ORs in open blocks to accommodate low volume surgeons and urgent add-ons.[26] The number and availability of open rooms will depend on the volume of urgent, emergency, and add-on cases. If the hospital has a significant number of elective cases, it may be appropriate to block schedule 80% of the ORs and leave the remaining 20% as "open" rooms. Several authors have described strategies to maximize surgical blocks and reduce variability to improve utilization.[29,30]

A final important aspect of scheduling is how to manage non-OR anesthesia cases such as endoscopy, radiology, computed

tomography, and magnetic resonance imaging. These patients often require perioperative resources although they do not enter the OR. They often require a dedicated anesthesia team, spend recovery time in the PACU, and are processed through the preoperative unit. Institutions should include these patients and procedures in the OR scheduling system in order to assist the perioperative units and anesthesia schedule runner, assign appropriate resources, and track progress of the daily schedule.

On-Time Starts

It is crucial to start the first procedure of the day on time. An on-time start provides tangible (scheduling) and intangible (mood and tone) benefits. If there is a delay in starting the first case, it can negatively affect the overall mood and support for performing the remaining cases efficiently. It is important for everyone to agree on a definition of start time. Surgeons often define start time as when incision is made. Anesthesiologists define start time based on when they complete induction. Nurses associate start time with the completion of room preparation. Disagreements in what constitutes start time will result in misunderstandings and dissatisfaction with room starts.

In 1997, a group in the AACD published a procedure times glossary that created standards for OR events and time periods.[30] This glossary is accepted by the American Society of Anesthesiologists, Association of Operating Room Nurses, and the American College of Surgeons and serves as the standard for descriptive terms in the OR. Appendix 99-2 contains an excerpt of the glossary. The glossary describes *start time* as the time the patient enters the OR. This time has not proved to be useful in identifying cause for delay on a case-by-case basis. Furthermore, surgeons indicate that the time the patient enters the room has little bearing on when the patient will be ready for the surgical incision. The newer concepts of "anesthesia ready" (AR) or "anesthesia release time" (ART)[31] may be more helpful in determining surgical preparation and incision times. The AACD glossary describes *anesthesia ready* as the time at which the patient has a sufficient level of anesthesia established to begin surgical preparation of the patient, and remaining anesthetic procedures do not preclude positioning and prepping the patient. At our institution we reviewed times from the patient entering the OR to completion of preparation. In uncomplicated cases (patient supine with no invasive monitoring lines), staff completed preparation in 15 minutes in 78% of cases. If the case was complicated (position other than supine, invasive monitors), the duration from start time to completion of preparation averaged 30 minutes. These data are useful for surgeons to anticipate the time from room start (patient in room) until completion of preparation.

On-time starts depend on the completion of many factors. Patients must arrive on time and complete preoperative preparations including compliance with all preoperative instructions (NPO, medications, laboratory tests). The admitting process should be streamlined and organized to meet the needs of the surgical patient.[32] Preoperative testing clinics and assessment protocols have helped reduce delays on the day of surgery, as well as reduce costs.[33-36] The preoperative/admitting process should have sufficient personnel, organization, and space to process patients and make them available to surgeons and anesthesiologists. Operating room nurses must prepare the operating room and equipment. Anesthesia personnel must check the equipment in the room, prepare drugs, complete paperwork, place intravenous lines, and address special patient or surgical needs. Surgeons must be available to complete the patient's consent, history, and physical examination and to address any patient questions or needs.

Table 99-7 Delays in Start of First Case of the Day

Surgeon controlled	45%
Patient controlled	23%
Anesthesia controlled	17%
Nurse controlled	15%

A common misconception is that anesthesia factors result in the majority of room start delays. Many anecdotal reports by OR clinical directors do not support this concept. We recently studied reasons for all delayed room starts and grouped delays into factors controlled by patients, surgeons, anesthesiologists, and nurses. The results (Table 99-7) demonstrate that surgeons controlled the largest number of delays in first starts. Table 99-8 lists some of the most common reasons for delays.

Starting first cases on time is a complex and challenging process. When defining an on-time start as having the patient in the room by the start time, delays occur in 40% to 90% of first starts.[37,38] When defining an on-time start as having the patient in the room within 10 minutes of the scheduled start time, delays still occur in 5% to 50% of cases. Identifying causes of delays, removing barriers to smooth patient flow, improving communications between preoperative personnel, patients, surgeons, nurses, and anesthesiologists, and creating an atmosphere (culture) of shared ownership in starting on time will improve on-time starts. Table 99-9 lists other key factors for increasing the percentage of on-time starts.

Turnovers

The definition of *turnover* varies among OR personnel, leading to confusion. A surgeon may view surgical "down time" (the time between closing the incision on one patient and beginning the incision on the next patient) as turnover. Academic surgeons consider turnover to be the period between leaving the OR (before the incision is closed by a junior resident or medical student) and returning for the beginning of the next case. Thus, surgeons frequently complain that slow turnovers between cases cause significant delays in completing the surgery schedule. The OR nurse may treat turnover as the time from removing the used equipment from the first case until the equipment is in place for the next patient. Anesthesia personnel believe that turnover is the time between leaving the previous patient in PACU and bringing the next patient into the room. With varying definitions of turnover, it can be difficult to measure and create improvements in this area of OR function.[39] The AACD glossary (see Appendix

Table 99-8 Reasons for Surgeon-Controlled Delays

- No history and physical examination in chart
- No consent obtained
- Ordered new laboratory test; results not available
- Changed schedule order or procedure
- Surgeon not available

Table 99-9 Key Factors to Increasing On-Time Starts and Decreasing Turnover Times

Keys to Increasing On-Time Starts

- Do not require the surgeon to be present before the patient enters the operating room.
- Use guaranteed block time to allow for predictable operating room times and locations for surgeons.
- Have specialty teams dedicated to complex cases.
- Standardize preoperative orders and testing.
- Review the patient's chart the day before surgery to identify potential delays in getting the patient ready.
- Call patients the day before surgery to clarify instructions and answer questions.
- Triage personnel in the preoperative area to effectively manage patient needs before start of the procedure.

Keys to Decreasing Turnover Times

- Organize a turnover team to clean and prepare the room.
- Have the same surgeon follow in the same room with all their cases.
- Use specialty-specific nurses and anesthesiologists.
- Maintain an accurate surgery schedule and reduce changes in the surgical list (i.e., order changes, cancellations, add-ons).
- Streamline the preoperative process.
- Ensure that the communication process informs all personnel involved with case turnover in a timely manner.

99-2) defines *turnover* as the time from when one patient exits the OR until the succeeding patient enters. This turnover time applies only when the second case is scheduled to immediately follow the first case.

The period between patients occupying the OR is busy. The nurses must return used instruments to decontamination processing. A housekeeping service must clean the floors and sterilize all surfaces, including the OR table. Nurses must assemble and organize equipment for the next case. They must also check on the next patient and verify that the paperwork is complete and the procedure is correctly listed. Anesthesiologists must transport the previous patient to the PACU, assess vital signs, give report to the PACU nurse, and submit required paperwork. They must return unused drugs and prepare new drugs for the next case. They must also ensure that anesthesia equipment is replaced and prepared for the next patient. Finally, they must see the next patient, complete preoperative paperwork, obtain consent forms, discuss anesthesia plans with the patient, and answer questions.

Multiple system factors can affect turnover time, and several units must function efficiently together to be successful. Attention should be given to the preoperative process (see Chapter 34) to efficiently prepare patients for surgery and readily locate the required paperwork and preoperative test results. Hospital transportation services should allow patients to be reliably available when called for the OR. The drug management system must permit access to medications and manage controlled substances. A turnover team must organize, clean, and prepare the OR for the next case. The PACU must function well to allow efficient OR throughput.[40,41] Recently, problems with hospital floor and ICU bed availability have resulted in the PACU being filled to capacity, creating a back-up of patients in the OR. Chapter 85 further discusses ways to improve PACU function. Each of these individual factors contributes to the overall ability of the team to facilitate turnover.

There is no national standard for acceptable turnover time. In most facilities, turnover represents 10% to 20% of the total case time. When performing turnover between simple procedures, such as cataract extractions, it is reasonable to expect a turnover time of 10 minutes. However, when changing between heart bypass procedures or complex orthopedic cases, the turnover may require 45 minutes or longer. The complexity of room set-up and need for specialized patient preparation contribute to length of turnover. Table 99-10 illustrates average turnover times for various types of surgical procedures.[42] Some benchmarking data are available on turnover for specific procedures.[42-44] A review at four academic institutions indicated that turnover times ranged from 34 to 66 minutes.[44] Our academic institution averages turnover times of 33 to 38 minutes, whereas a private practice hospital may consider 20- to 30-minute turnovers more reasonable. An institution should consider this information when it looks at its specific turnover data to determine realistic goals for OR improvement.

Although reductions in turnover times may save 5 to 10 minutes per case, these time savings do not usually translate into large time reductions in a single OR's schedule. Reducing turnover time does improve efficiency and focus, which may translate to improvement in surgical preparation and case completion times. The intangible benefits of reducing turnover may be the most important. Reducing turnover can build teamwork and the institution's focus on achieving maximum OR efficiency. However, excessive focus on turnover time is counterproductive. Staff risk losing more time strategizing than can realistically be gained from the resulting changes.[43,44] Turnover time is also a favorite topic of consultants because it tends to strike an emotional chord with surgeons and hospital administrators. In reality, most efforts to reduce turnover times result in modest reductions in completion of the surgical schedule.[44] As an example, if an OR performs 4 cases in a day and can reduce turnovers by 10 minutes, the total time that can be saved is 30 minutes (3 turnovers × 10 minutes = 30 minutes). This small time savings may result in reduced overtime expenses and improved satisfaction measures, but it will not provide sufficient time to perform additional cases.[45]

OR of the Future

The increasing pressure on hospitals, surgeons, and anesthesiologists to improve throughput of patients has led to new concepts in streamlining cases. One area of discussion involves the use of dedicated anesthesia induction rooms and early recovery areas to minimize nonoperative time spent in the operating room. Induction rooms have been used in some European countries but are largely unknown in the United States. In attempting to apply new

Table 99-10 Average Turnover Times

Total-hip replacement	44 min
Total-knee replacement	46 min
Knee arthroscopy	38 min
Coronary artery bypass	52 min
Laparoscopic cholecystectomy	30 min
Cataract extraction	21 min

designs to optimize OR throughput, Sandberg described a concept known as the "Operating Room of the Future."[46] In addition, other investigators have described how this concept could be applied to their specific OR characteristics.[47,48]

By setting up processes to run in parallel instead of in series, nonsurgical time is reduced up to 40%. In Sandberg's 2005 study, parallel processes resulted in 30 fewer minutes of nonsurgical time. When anesthesia induction, line placement, and emergence from anesthesia take place in rooms adjacent to the OR, the time spent in the OR can be concentrated on performance of the procedure followed by simple OR housekeeping turnover. The advantage of this new process is more cases performed in the OR per day.

The disadvantage for this parallel process is the significant resource requirements. An additional 200 to 300 square feet of space in close proximity to the OR must be available for the induction and early recovery rooms. Capital equipment, including anesthesia machines and monitors, must be duplicated for these locations at a cost of $40,000 to $60,000 per room. The staffing requirements must be increased to allow nursing and physician coverage of the expanded patient care areas. Typically, because the net costs to the anesthesia team are increased, it is necessary for the facility to provide funding to offset these costs. This funding may be obtained by the additional revenue generated from the additional cases performed; however, additional cases do not completely offset the cost.

The applicability of this type of OR process has generated much debate and analysis.[46-52] Because complex variables such as OR procedure length, staffing plans, OR space availability, staff availability, patient demand, and hospital investment all have an impact on this type of process redesign, it is difficult to predict whether this concept will be applied to more OR locations in the future.

The Daily Schedule

The "running" of the daily schedule is a complex job.[53,54] An accurate and realistic schedule is one of the most important factors in a successful surgical day. Frequently, an anesthesiologist partners with an OR nursing leader to run the daily surgery schedule. The scheduler must be able to make fair decisions regarding moving cases, dealing with add-on cases, and using the nursing and anesthesia workforce to complete the surgical list efficiently.

Making the cases flow smoothly takes several steps (Table 99-11). The initial step is to review the schedule of cases the evening before and again the morning of surgery. These reviews should focus on identifying potential obstacles to patient flow and opportunities to deal with add-ons or changes. During the course of the day, the scheduler should frequently walk the "floor" in the OR to check on the status of room starts, case progression, and turnovers. Because surgical procedures have a high degree of variability, plans on how cases should proceed change frequently, and adaptation is paramount. The OR should create a tracking system to monitor the day's progress. This system does not need to be elaborate but should be available for people working in the OR to see schedule adjustments including starts, finishes, and add-ons.

Every OR has add-ons and case cancellations. As the number of add-ons and cancellations increases, so does the complexity of scheduling.[55-60] There are no national benchmarks for schedule changes, but planning measures to keep add-on rates less than 12% and cancellation rates less than 4% will help to effectively and efficiently manage the schedule. The cancellation rate varies based on patient population and surgical procedures but is generally in the range of 6% to 9%.[33,34] If an OR has higher rates, staff should assess why these changes are taking place. One strategy to reduce cancellations is to evaluate patients in an organized and efficient preoperative clinic with standardized algorithms for further testing and evaluation. These clinics reduce delays and cancellations on the day of surgery.[19,33-36] Table 99-12 shows some of the common issues in case cancellations.[61]

Table 99-11 Ten Steps to Completing the Daily Schedule

1. Recheck the schedule the afternoon before surgery to look for potential difficulties and to identify opportunities.
2. Review the schedule early in the morning on the day of surgery and note cancellations and add-ons.
3. Ensure that rooms are starting on time by walking through the operating room suites.
4. Set expectations for surgical case progress by using benchmark case times if available.
5. Organize the turnover process to manage peak room changes from midmorning until early afternoon.
6. Develop a well-understood policy for working add-on cases into the schedule.
7. Look for open room time to move cases from late-running rooms or to move add-on cases into.
8. Identify cancellations early and redeploy the room and personnel resources to complete other cases.
9. Set realistic staffing patterns to meet the surgical caseload demand. Use nonstandard shifts so that rooms do not have to be closed in the early afternoon.
10. Use a case-tracking system so that others can see where resources are needed to complete the caseload.

Table 99-12 Common Case Cancellation Issues

Patient
Self-cancellation or no-show
Desired second opinion
Patient not NPO
Preferred transfer to another institution
Surgeon
Not available; busy with an emergency or another case
Decided surgery was not indicated
Patient needed further workup
Anesthesiologist
Patient needed further workup
Hospital
Nursing staff not available
Lack required equipment or implants for case
Scheduling error; wrong date for surgery
Lack beds; ICU at capacity

Table 99-13 Add-on Case Management

Emergency	Urgent	Elective
Come to the OR within 30 min	Come to the OR within 2 hr	No time constraints
Example: gunshot to the abdomen	***Example:*** appendectomy or ectopic pregnancy	***Example:*** revision dialysis shunt
Place in any open room	Place in available staffed open block room or in room with cancellations. If no room is open, bump the posting surgeon's elective cases. If posting surgeon has no room, bump same surgical division. If no cases within same surgical division, bump room with the shortest surgical list.	Follow elective cases in first available room.

There should be a well-defined system for triage to improve the efficiency of performing add-on cases. Generally, the scheduled elective cases take precedence over add-on cases, but there are exceptions. Situations will arise in which an urgent or emergency case will delay or "bump" a planned elective case from the schedule. As a result, managing and scheduling urgent or emergency cases must also follow a well-understood system.[53] Table 99-13 shows one algorithm used to handle emergency cases.

Surgeons often help to control add-on placement by scheduling OR availability during specific days. If a group or division of surgeons is busy, they may have set OR days when they are available for surgical procedures and other days when they are committed to clinic visits and are unavailable. Often, the surgeons' add-on cases are self-channeled into days that they are already in the OR. In this situation, the add-ons should be scheduled into that surgeon's preexisting room. If a hospital system has a large number of add-ons that surgeons must perform at the end of the elective schedule late in the day, the OR should be scheduled to properly staff and support these times. Nursing shifts using the traditional 8-hour (7 AM to 3 PM) shift may need to be modified to cover late rooms by creating either 12-hour shifts (7 AM to 7 PM) or staggered shifts (10 AM to 6 PM). Anesthesiology departments must also address coverage of this off-peak OR time.

Despite the best planning, the daily schedule is challenging because cases are often unpredictable and surgeons are motivated to meet their own targets. A good rapport among schedulers and surgeons is helpful in diffusing potential scheduling conflicts. Alan Marco's articles on game theory create an interesting analogy of these interactions as they apply to the OR.[10,11] This perspective can be helpful in scheduling efficiently and seeking support for organizational success. Routine reviews of utilization reports and the daily schedule are important to identify opportunities for improvement, including decreasing unused OR time (Figs. 99-2 and 99-3). Regardless of goals to schedule efficiently, the quality of a patient's care should remain the top priority.

Operating Room Utilization

OR utilization is an important concept that guides the direction of OR management.[62] It is also a significant part of the OR medical director's job. To understand the concept of OR utilization, it is important to understand several definitions from the AACD glossary (see also Appendix 99-2):

- *Case time* is the time from the start of room setup to the end of room cleanup. It accounts for the entire time that the OR is dedicated to the performance of a procedure and cannot be used for any other purpose.
- *Resource hours* are the total number of hours that a room is staffed and available for the performance of procedures. Many ORs are staffed for 8 hours of regular resource hours (e.g., 7 AM to 3 PM). Resource hours do not include overtime or periods when on-call personnel are staffing the OR. Resource hours serve as the denominator in calculating utilization of the available blocked or open scheduled elective OR time.
- *Raw utilization* is the ratio of the time that patients are in the OR to the available resource hours. It does not include time spent preparing the OR or turnover time; therefore, it understates the actual time that the OR is committed to a case.
- *Adjusted percent utilization* is similar to raw utilization, but it includes case setup time and turnover time. This figure more accurately reflects the time that the OR is used for case performance and is unavailable for any other activity.

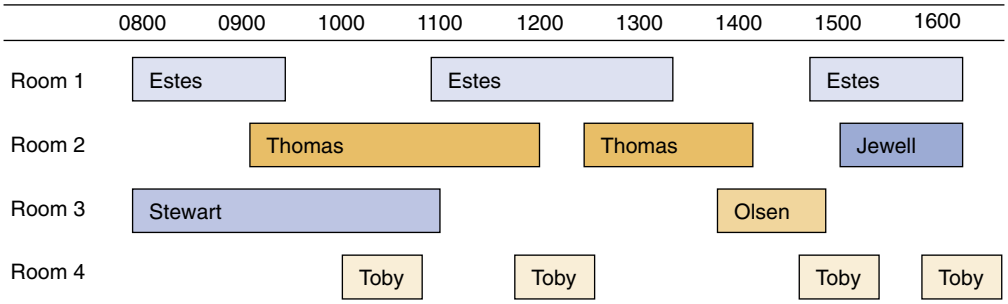

Figure 99-2 An example of schedule utilization.

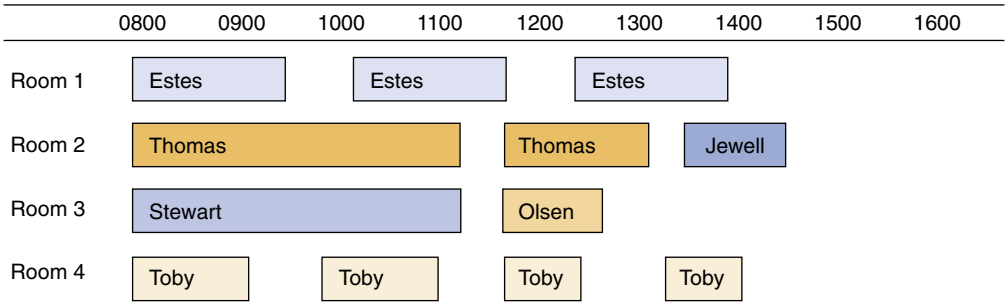

Figure 99-3 Improved schedule utilization.

Utilization is most commonly determined for a service or group of surgeons based on their set amount of block time. For example, if a group of orthopedic surgeons has block time in two rooms on Monday through Friday, their resource hours per week are 80 (2 rooms × 5 days per week × 8 hours per day). If their total case time (in-room time plus turnover) is 72 hours per week, the adjusted percent utilization is 90% (72 hours per week ÷ 80 hours per week).

Regularly tracking utilization is important. To achieve an efficient balance of available times for surgical divisions, hospitals should reassess block times based on utilization on a 3- to 6-month basis. For hospitals using utilization to track surgery performance and allocate block time, it is better to assign block time to a group of surgeons or a surgical division. Granting block time to individual surgeons produces more variability in use and may result in lower utilization. Table 99-14 contains an example of a raw utilization report from our institution.

There is no defined target for optimal utilization. Opinions of optimal utilization vary among entities involved in the OR (Table 99-15). As utilization increases above 80%, surgeons may have difficulty scheduling patients and the increased wait time may create patient dissatisfaction. Studies have shown that for elective procedures in the United States, most patients are willing to wait 1 week.[29] Waiting longer than this because of unavailable block time will lead to patient and surgeon dissatisfaction and possibly loss of the case to another institution. Utilization percentages that are very low represent lost opportunities to generate revenue. Anesthesiologists prefer to be busy during regular resource hours yet have some flexibility for covering urgent and emergent cases.

The exact break-even point for utilization is dependent on the OR's fixed versus variable costs and reimbursement mix. Consultants often quote 80% to 85% utilization as a target. This figure was used as a benchmark in the 1970s as hospitals were required to demonstrate a certificate of need prior to expansion of OR facilities. Most ORs seek a utilization of 70% to 85% to maximize benefits and reduce stress on the system. Trends have shown that with increasing surgical volume and reduction in OR availability, the overall raw utilization has been steadily increasing in hospitals (Fig. 99-4). Data from 1999 revealed that hospital-based ORs have higher utilization than ambulatory ORs (73% versus 55%).[63] Tracking overall OR utilization may be beneficial in demonstrating the need to expand OR capacity.

There are costs associated with both underutilization and overutilization. There are fixed costs for ORs regardless of utilization. Underutilization results in lower revenue generation to offset the fixed costs. Overutilization (cases running late) may require overtime pay for nurses or hiring temporary nurse services, which results in higher costs per minute of OR use. In addition, personnel who frequently must stay late may become dissatisfied and quit, increasing the costs associated with recruitment. Many recent studies have identified ways to maximize utilization or to assist with scheduling to improve percent utilization.[63-66] Because many ORs have frequent last-minute changes, cancellations, add-ons, and emergency cases, the ability to apply these simulations to actual OR practice may be limited.

Table 99-14 Operating Room Utilization: January-June

	% Utilization		
	Avg hr/wk	**Starts/wk**	**Block**
Orthopedics	125	17	92
General surgery	128	16	100
Urology	71	10	88

>100%	++	—	——	———
85%-100%	+++++	++	–	—
70%-85%	+++	++++	+	±
55%-70%	+	+++	+++	++
<55%	—	–	++	++++

From Mazzei W: AACD Workshop on Operating Room Management, 2003.

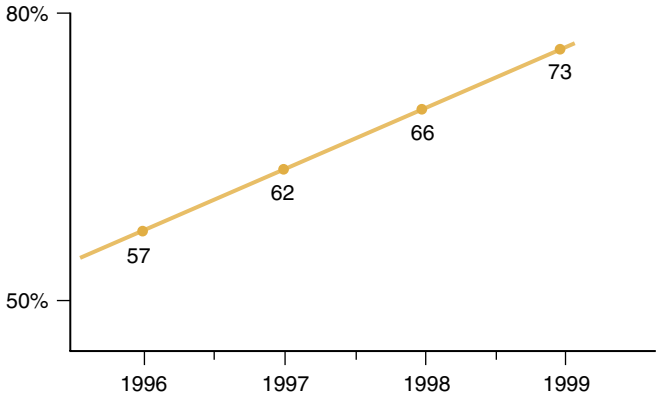

Figure 99-4 Raw utilization for operating rooms.

Table 99-16 Raw Utilization Calculations

	Case Time (hr)	No. Cases Performed	Total In-Room Time (hr)
Surgeon A	2.5	3	7.5
Surgeon B	1.0	6	6.0
Surgeon A	7.5 hr in room time ÷ 8.0-hr block available = 94% raw utilization		
Surgeon B	6.0 hr in room time ÷ 8.0-hr block available = 75% raw utilization		

Table 99-17 Operating Room Assessment Report

Surgeon	Cases	Collection	Avg Collection/Case	OR Minutes	Avg Minutes/Case	Collection per OR Minute
Green	53	$43,116	$813	1150	22	$37.49
Jones	17	$16,802	$988	989	58	$16.99
Smith	10	$17,179	$1718	588	59	$29.22
Rogers	19	$11,947	$629	800	42	$14.93
Wilson	12	$13,341	$1112	1052	88	$12.69
Lynch	13	$7,398	$569	883	68	$8.38

Utilization should not be used to assess how efficiently an OR is working. Utilization is only a measure of resource consumption. For example, if surgeon A takes 2.5 hours to perform a laparoscopic cholecystectomy and conducts three procedures in an 8-hour block, this results in a raw utilization of 94% (2.5 hours per case × 3 cases = 7.5 hours; 7.5 hours per 8-hour block = 94%). However, surgeon B, who completes laparoscopic cholecystectomies in 1 hour and is able to do six procedures during an 8-hour block, has a raw utilization of 75% (1.0 hour per case × 6 = 6 hours; 6 hours per 8-hour block = 75%). Even though surgeon A has higher utilization, surgeon B's financial margin is better. Table 99-16 illustrates these calculations.

Hospitals are becoming more refined at analyzing OR production. By looking at revenue generation and associated costs for each surgeon, they can determine the profit margin for each individual. Although studies have shown that nearly all surgeons contribute a positive profit margin for their OR cases, the range of profit margin is wide.[67] Table 99-17 shows an example of a report generated with this approach. OR managers and hospitals are increasingly using this type of information to make decisions concerning OR resources. Table 99-18 contains a list of key issues to improve OR utilization, throughput, and efficiency.

Anesthesia Service Management

It is important for OR directors to include anesthesia service management in the scope of OR management. If an OR director succeeds in streamlining and maximizing the efficiency of the OR, productivity within the anesthesia service will increase. Better OR scheduling, on-time starts, efficient turnovers, and proper management of add-ons and cancellations will result in concomitant improvement in anesthesia service utilization.

The two main components of anesthesia service management involve personnel issues and pharmaceutical costs. Anesthesia-related costs represent 3% to 5% of the total health care expenditures in the United States.[68] Although most of these costs involve personnel,[69] anesthesia-related drugs comprise the majority of the 20 most costly drugs used in the hospital.

Many authors have reviewed optimal staffing patterns for providing anesthesia coverage for the surgical schedule.[70-72] Staffing coverage depends on provider availability as well as local conditions. The benefits of physician-only versus concurrent supervision of multiple providers are not clear cut.[73] ORs must also consider the requirements for specialty teams to cover areas such as cardiac, organ transplant, obstetric, trauma, and pediatric

Table 99-18 Keys to Increasing Operating Room Throughput

- Schedule full-day blocks rather than half-day blocks.
- Surgeons should follow themselves in the same operating room.
- Verify schedule accuracy to decrease delays in case completion.
- Streamline preoperative processes and standardize testing.
- Use specialty teams of nurses and anesthesiologists.
- Organize supply and equipment needs for easy room setup.
- Focus attention on room starts and turnover to create a culture of timeliness and efficiency.
- If you have a significant number of add-on cases, plan for an open room or be able to move cases to available time slots.
- Ensure that the communication pattern throughout the perioperative area informs all necessary individuals of case progression.

cases, which may limit the ability to maximize staff utilization. Today, more anesthesia groups are negotiating financial support from hospitals for added call coverage for these specialty teams.

As a result of growing pressure to quantify anesthesia output, ORs have refined the measurement of anesthesia productivity.[74,75] Methods to track anesthesia output have evolved from simple availability to more sophisticated measurements of production and call coverage.[76] Clear differences exist between academic and private settings. Abouleish and colleagues showed that an anesthesiologist in an academic setting needed to work 30% longer than one in private practice to generate the same level of billable services (7.8 hours versus 6.0 hours).[75] Development of incentive plans can be useful to improve productivity and retain physicians.[77-82]

Anesthesia drugs are expensive and are a frequent focus for reducing hospital expenses.[83] Overall, pharmaceutical costs approximate 5.6% of a hospital's total operating costs.[84] Anesthesia drugs represent 22% of the total pharmacy costs.[85] Newly developed anesthesia drugs often have significantly higher costs (muscle relaxants, narcotics, antiemetics). Although these drugs may appear to be cost effective by improving patient throughput (decrease OR or PACU times) or increasing patient satisfaction (faster discharge, less postoperative nausea and vomiting), studies have been inconsistent in demonstrating those benefits.[86,87] Because there are many variables that contribute to change in resource utilization and drug cost, true assessment of the resulting changes from drug choices is difficult. It is also difficult to assess the fixed versus variable costs of those changes. If anesthesia-controlled costs represent 6% of the total cost for a surgical patient, it is likely that half of these costs are fixed. ORs can modify the remaining 3% of costs (drugs and supplies); however, experience has shown that intensive restructuring of anesthesia drug use only results in small reductions in overall pharmacy costs. In many cases, the savings are difficult to sustain and ORs return to previous drug choices.[85]

Operating Room Information Systems

ORs are the largest and most complex areas of the hospital and generate the greatest revenue (as well as expenses), yet OR use of information technology remains underdeveloped. Hospitals are 10 to 15 years behind industry in adopting and implementing information management systems. However, information systems are critical for today's OR director to manage effectively. A well-designed system can improve many processes, including OR scheduling, automated records, materials management, preoperative data, laboratory tracking, medication tracking, cost data, patient tracking, and quality improvement/quality assessment (QI/QA).[88-90] Most hospitals continue to use basic systems to manage scheduling, generate statistical reports, and create equipment lists.

Information systems are complex and expensive. It is a challenge for companies to create information systems that are able to integrate large volumes of information from many different sources. A single OR case can create over 1 million data bits in 3 hours.[90,91] Manual transcription of this information is problematic by creating difficulty for ORs to demonstrate regulatory compliance, to avoid legibility and medical errors, and to reduce the risk of legal concerns. Manual data entry also requires significant time; 30% to 40% of an anesthesia provider's time in the OR is spent as an information scribe.[92]

Hospitals have been slow to adopt information systems in the OR for many reasons. These systems are expensive, with an average cost of $1 million to $2 million for a medium-sized hospital. Hospitals frequently require a return-on-investment analysis to justify the expense. Integration of the new system into the OR also requires resources and the continual support of a systems manager. Hospitals are also concerned with vendor credibility in delivering the advertised benefits of the system.

The applicability of information systems must be carefully reviewed. Recently, Vigoda published an account of medicolegal concerns pertaining to time stamps for documentation of certain events.[93] Information systems are useful in tracking drug utilization and identifying discrepancies of controlled substances.[93-96] Information systems are a necessity for the OR director to maintain an efficient and competitive OR and to monitor and adjust the OR process. These systems can improve charge data and simplify managing equipment and personnel. Data on OR resources can also improve QI/QA assessment. Clear, accurate information allows the OR manager to focus on areas of improvement and create behavior changes in the system to remain efficient and competitive.

Cost Accounting in the Operating Room

Financially managing the OR is a difficult task for the OR director. Most physicians have not had a formal business education and are not familiar with OR financial management concepts. Health care is a complicated financial industry. In the United States, there was more than $2 trillion in health care spending in 2005, or 16% of the U.S. gross domestic product.[97] The health care industry provided 13.5 million jobs according to the 2004 Bureau of Labor Statistics.[98] It is essential to understand financial management theories of the OR because strong financial management within the hospital is essential for success.

The concept of management control in nonprofit organizations is becoming more sophisticated.[99] Financial management of the OR is analogous to running a business.[100,101] A hospital can classify an OR as an expense center or a profit center. If it is an expense center, attempts to improve the financial position of the hospital would focus on minimizing costs. If, however, the OR is a profit center, the OR director must pay attention to the margin between costs and revenues and attempt to maximize profit. It is reasonable for hospitals to focus on the financial performance of the OR. The OR averages 40% of the total costs of a hospital, but it is responsible for as much as 70% of the revenue.[1] As ambulatory health care activity has moved out of the hospital, many hospitals have become primarily tertiary care surgical facilities. Managing costs and increasing revenue in the OR will result in a hospital with strong profitability and the ability to expand its health care delivery.

The OR director needs a basic understanding of cost accounting to ensure effective OR decision-making. Cost accounting focuses on understanding the costs of running the OR to

Table 99-19 Operating Room Accounting Terminology

Charges	The fee listed for an item or procedure based on assumptions of resource consumption
Costs	The actual expenses incurred in delivery of a service
Fixed costs	Overhead. Costs that do not change up or down over a finite period, regardless of the volume of activity
Variable costs	Costs that change directly up or down with changes in volume of activity
Profit	Revenue–costs (both fixed and variable)
Contribution margin	Revenue–variable costs
Capacity	Maximum amount of activity that a facility can deliver without increasing fixed costs

determine an optimal price for services. Hospital management should use the information that cost accounting provides to plan and control activities, to make strategic decisions, and to improve the quality and efficiency of services in the OR. Table 99-19 contains a listing of certain accounting terms.

It is important to recognize the difference between costs and charges. Costs include all of the fixed and variable expenses associated with a specific procedure. Charges are the sum of all the costs plus the amount of profit over the costs that the hospital bills to insurers. In the 1970s and 1980s, most hospitals used the theory of cost-plus billing. In cost-plus billing, the hospital added an amount of money (profit) to the costs for a procedure. It submitted the resulting charge to insurers. However, as reimbursements declined, insurers began to contract services for a specific price, regardless of the hospital's costs for that service. The ratio of costs to charges varied widely for different services throughout the hospital.[1] For example, the cost-to-charge ratios at Stanford Hospital were 0.29 for anesthesia, 0.50 for laboratory, and 0.92 for the surgery admission unit.[1]

Because of the arbitrary nature of assigning charges to a service, as well as the variable reimbursement, decisions concerning OR management should use costs and not charges. Costs are either fixed or variable. Fixed costs (overhead) are costs that do not change in the short term regardless of the number of completed procedures. In the OR, these costs include rent or depreciation of the surgical suite, capital equipment in the OR, salaried employees, and administrative overhead (OR directors, medical records, admitting personnel). Fixed costs may change over longer periods if the hospital changes the number of OR suites or the budgeted number of OR staff. Variable costs will increase or decrease directly with the level of surgical activity. In the OR, variable costs include disposable supplies, sutures, linens, implants, and contracted labor. Fifty-six percent to 84% of operating room costs are fixed.[102,103] Short- and intermediate-term cost reductions will apply only to the variable portion of OR costs, representing a smaller part of the total OR costs as fixed costs remain unchanged.

The two methods to account for costs in the OR are either top-down or bottom-up. Top-down accounting uses cost-to-charge ratios to average and estimate the costs for a particular procedure. This is an easy and simplified calculation but has critical disadvantages. Top-down accounting is imprecise, and the ratio will vary because of changes in either costs or charges. This makes period to period comparisons difficult because it is difficult to isolate whether the cost-to-charge ratio trend is due to changes in costs, charges, or a combination of both. Bottom-up accounting (microcosting) is more precise, requiring a detailed measurement of all the expenses for a procedure. Bottom-up accounting also requires classifying costs as fixed or variable, which makes decision-making easier in OR planning.

Profit for the OR is equal to the total revenues minus the total costs. The OR must produce profit to pay for other areas within the hospital (e.g., emergency department) that operate at a loss. However, in assessing changes in surgical activity, the "contribution margin" is more important. Contribution margin is equal to the total revenues minus the variable costs. A larger contribution margin indicates that more money is available to pay the overall fixed costs of the institution.

A specific example of OR cost analysis is provided by the 1999 review of costs by Marcario. In the review, he found that the majority of costs for care of a patient undergoing laparoscopic cholecystectomy occurred in the OR.[103] The OR (37%), anesthesia (7%), PACU (6%), and OR-related laboratory and pharmacy costs accounted for more than 50% of the total hospital costs. For any OR procedure, most of the costs occur in the first hour of the case. These costs include room preparation, opening basic supplies, linens, and use of instruments or implants for the procedure. Subsequent time in the OR is less expensive and consists primarily of labor costs. Using a detailed analysis, Marcario established that the basic costs of an OR, exclusive of procedure-specific needs (e.g., trocars or implants) was $13.54 per minute.[103] Of this amount, 62% of the costs were fixed and 38% were variable. Cost-savings measures (i.e., changing physician practice) will affect only the variable costs of this expense. OR costs vary by institution, depending on labor and overhead costs.[104,105] Ambulatory surgical facilities, with reduced overhead, may have overall OR costs 20% less than hospital facilities have.

The potential benefit of cost analysis is illustrated by considering the amount of costs that can be reasonably reduced. For example, anesthesia costs, such as machine depreciation, supplies, and drugs, average 6% of the total hospital costs for a procedure.[1] Of these costs, approximately 50% are fixed and 50% are variable. To reduce overall anesthesia costs in the OR, a hospital can only modify the variable part of the anesthesia costs. Therefore, it is only possible to manage 3% of the total hospital costs when reviewing the anesthesia practice for cost savings.[106] The PACU is also an area with high fixed costs—up to 67% of the total PACU costs.[1] For this reason, opportunities for large cost reductions in the PACU by changing practice are difficult.

The largest variable costs associated with health care and the OR are personnel costs.[107] The unpredictable nature of the surgical volume, as well as late-running cases, may lead to increased labor costs. The Fair Labor Standards Act requires overtime wages of 150% of regular wages for hours worked over 40 per week. As a result, personnel costs increase significantly with poorly planned labor use in the OR. Strategies to minimize overtime including using 12-hour shifts, staggering nurse work times, and creating greater scheduling control will help reduce these labor costs. Careful analysis of nursing requirements and the creation of optimal staffing patterns can have a significant impact on OR costs.[108-110]

Studies on the contribution margin of individual surgeons to the hospital have shown that nearly all surgeons have a positive contribution margin.[67,111] However, the difference in the

contribution margin between surgeons varies greatly, in some cases by as much as 1,000%.[112] To improve profitability for the OR, efforts to increase the volume of highly profitable surgeons will have the greatest impact. However, before assigning more OR time to these surgeons, several questions must be addressed. Will the surgeon's utilization decrease if volume or OR time is increased? Do the surgeon's cases require hospital resources (ICU beds, specialty nursing) that have limited capacity? Does the system have enough overall capacity (OR rooms, nurses, anesthesia coverage) to increase volumes of services and hold fixed costs neutral? If additional volume of cases requires building more infrastructure (new rooms or more OR nurses), the fixed costs will increase and negate profit. Clear, accurate information is necessary for the OR director to track costs and make rational decisions to improve OR performance.

Regulatory Issues

OR activities are complex and critical to the delivery of health care. A large number of agencies and regulations oversee how an OR functions. The OR director must be familiar with these various agencies and regulations to ensure compliance within the OR. Table 99-20 lists these entities.

The OR director must focus on meeting the regulatory requirements for hospital accreditation. Patient and employee safety (infective agents, fire safety, laser safety, electrical safety), and proper use and tracking of drugs and medical devices are also important areas of focus. State and local regulations, as well as hospital policies, have specific requirements for the OR. Privileging and monitoring the quality of outcomes for physicians in the OR are paramount. Internal data collection and quality measures should be designed to demonstrate the performance of individual physicians and the OR. Initiatives brought forth by nongovernmental groups such as Leapfrog and the Institute for Healthcare Improvement (IHI) have challenged hospitals to apply best practice standards to the care delivered. Programs such as IHI's "100,000 Lives Campaign" have enlisted hospitals to adopt these standards to reduce morbidity, mortality, and health care costs. Recently, Medicare has begun to implement performance standards for best practice care relating to the OR. The Surgical Care Improvement Project (SCIP) was initially designed to reduce surgical infections by applying best practice standards to antibiotic use, hair removal, and temperature maintenance. Medicare has indicated tying hospital reimbursement to targeted performance standards. Pay-for-Performance (P4P) is a Medicare plan that ties reimbursement to specific physician activities.[113] Developing plans for insuring best practice, utilizing OR information systems, and partnering with the hospital leadership in meeting these requirements are a crucial part of the OR director's duties.[88,113-117]

- Health Insurance Portability and Accountability Act (HIPAA)

Summary

Operating rooms are complex environments that are vital to the success of hospitals. Hospitals have re-evaluated OR management structure to improve efficiency while emphasizing quality and cost. Redesigning OR governance has been essential in addressing the changes required to make ORs run more effectively. Such redesign has resulted in an increasing trend to place overall responsibility in the hands of a single person, the OR director.

The OR director must understand OR economics and use sound strategies for cost control and revenue enhancement. A comprehensive OR information system that can capture and organize OR data is essential for the OR director. Hospitals set targets for performance, and regulatory organizations set quality measures for the OR. Information systems help to monitor whether the OR is meeting these targets and standards. Detailed data are required for instituting a successful business plan for the OR and implementing changes in how the OR functions.

The OR director's position has evolved into a broad and encompassing role as a manager of the perioperative process. The director must focus efforts on ensuring smooth, efficient throughput of patients in the perioperative area. Accurate scheduling, on-time OR starts, efficient turnover, and proper surgical case management are critical to the success of running the surgical schedule. OR directors must develop strategies to manage surgical schedule variability as a result of add-ons, emergency cases, and cancellations. They must also construct systems to control surgical and anesthesia costs. Although the challenges in making an OR function optimally are great, the benefits of an efficient and successful OR are critical to the hospital, to anesthesiologists, and to surgeons who work in this environment.

APPENDIX 99-1

Guidelines for the Role of the Clinical Director of Anesthesiology and Director of the Operating Rooms

I. Responsibilities to the Department of Anesthesiology
  A. Personnel management
    1. Long-term faculty scheduling
    2. Daily faculty/resident/certified registered nurse anesthetist assignments; assurance of comprehensive resident case exposure/coordination with program director
    3. Staffing calculations and planning; recommendations to chairman
    4. Creation of management team representing all clinical aspects of the department
  B. Subspecialty coverage
    1. Develop appropriate faculty daily and on-call coverage
    2. Participate in resident subspecialty rotation development
  C. Daily operations
    1. Early morning review of schedule
    2. Morning clinical/staffing conference
    3. Assignment changes during the day
    4. Chief arbiter of clinical and interstaff disputes
  D. Participative roles (with significant institutional variations)
    1. Preoperative evaluation clinic/preadmission testing procedure
    2. Anesthesia equipment/monitoring
    3. Quality assurance/quality management process
    4. Disaster planning
  E. Evaluation and promotion of the clinical director
    1. Clinical management-oriented job may require special criteria
    2. Clinical tract appointment most appropriate
    3. Teaching time may be limited
    4. Research areas may exist in management and statistical and clinical studies

II. Responsibilities to the OR/Hospital/Medical Staff
  A. Scheduling and data collection
    1. Daily review/final arbiter of OR scheduling
    2. Supervisor of scheduling/data processing personnel
    3. Enforce scheduling policy
    4. Management of OR utilization data and submission of reports to appropriate governing body
  B. Communications center (OR desk)
    1. Establish practices that provide expeditious service
    2. Supervise OR desk personnel
  C. Clinical director's role with OR nurses, PACU nurses, and support staff (with significant institutional variation)
    1. Leadership and supervisory role for OR personnel
    2. Strong working relationship with nursing hierarchy and hospital administration
    3. May function as OR manager with budgetary, materials management, and quality assurance functions
  D. Chief liaison to:
    1. Hospital administration (formal position)
    2. Nursing administration
    3. OR committee (may serve as chairman of the committee). Authority must be delegated from surgical and anesthesiology departments and hospital administration
  E. Basic support from hospital administration
    1. Office, secretary, scheduler, and other personnel as necessary
    2. Financial subsidy may be appropriate
    3. Administrative authority

III. General Qualifications
  A. Seniority, appropriate academic rank—associate or professor level may facilitate the role
  B. Clinical proficiency/commitment—being respected for clinical abilities is a significant attribute
  C. Educational qualifications—formal training or experience in negotiation and interpersonal relationships and business administration may be desirable

APPENDIX 99-2

Selected Items from the Procedural Times Glossary of the American Association of Clinical Directors

Room ready: Time when the room is cleaned and supplies and equipment necessary for beginning of next case are present

Start time: Patient in room time

Preparation completed: Time at which prepping and draping have been completed and patient is ready for the procedure or surgery to start

Case time: Time from room setup start to room cleanup finished. This definition includes all the time for which a given procedure requires an OR. It allows for the different duration of room setup and room cleanup times that occur because of the varying supply and equipment needs for a particular procedure.

Turnover time: Time from prior patient out of room to succeeding patient in room for sequentially scheduled cases

Resource hours: Total number of hours scheduled to be available for performance of procedures (i.e., the sum of all available block time and open time)

Block time: Hours of OR time reserved for a given service or surgeon. Within a defined cutoff period (e.g., 72 hours prior to day of surgery), this is time into which only the given service may schedule.

Open time: Hours of OR time not reserved for any particular service, into which any service or surgeon may schedule according to the rules established by the given institution

Raw utilization: For the system as a whole, this is the percent of time that patients are in the room during resource hours. For an individual service, this is the percent of its block time during which it has a patient in the OR.

Adjusted percentage: (in-own block hours plus outside-own block hours × 100/block time)

Service utilization: This measures the percentage of time a service utilizes its block time during resource hours. It is adjusted compared to raw utilization, in that it gives a service "credit" for the time necessary to set up and clean up a room, during which time a patient cannot be in the room. It may exceed 100% because of the inclusion of cases performed during resource hours that are outside-own block hours.

Lawrence Litt

100 Electrical Safety in the Operating Room

Key Points

Fire Safety Issues

1. When setting up the anesthesia machine and drug cart before a case, be sure to know about the operation and the location of emergency equipment. Questions to ask oneself include the following
   - Where is the nearest fire extinguisher—there should be one in every operating room?
   - Where are the oxygen shut-off valves and how do I operate them to stop oxygen flow to the operating room?
   - Where is the nearest fire alarm should it be impractical to call the hospital's equivalent of "911" (fire alarms are often recessed in the wall near fire hoses)?
   - Where is the nearest escape passage?
   - Where is the nearest defibrillator and code cart?
2. Recall that electrical fires, particularly those that involve the electric panel, require a special approach. If possible, quickly cut all electric power that feeds an electrical fire (which then converts it into an ordinary fire). In fighting a fire, the proper type of fire extinguisher must be used. The most common type of fire extinguisher sprays water. However, water must never be thrown or sprayed onto an electrical fire or onto burning flammable liquids. Electrical fires require a dry chemical extinguisher, but CO_2 extinguishers, which are optimal for control of burning oils and liquids, may also be used.
3. Avoid use of high "blow-by" oxygen flow from an open facemask if after "blowing by" the patient, the flow ends up providing oxygen enrichment at a site of electrosurgery.

Macroshock Electrical Issues

1. All electrical equipment used in the operating room should be grounded (although internally such equipment can contain ungrounded circuits). If the power cord for a piece of equipment has a plug with only two prongs (i.e., no grounding prong to go in the third hole in the outlet), the equipment should not be in the operating room. When connecting or disconnecting plugs from outlets, do not yank the plug by the cord. Similarly, do not use equipment whose power plugs have been damaged, and do not let heavy equipment crush power cords by rolling over them.
2. Patients should not be directly connected to the operating room's electrical ground.
3. When electrosurgery is in use, a grounding pad should be used that connects the patient to the ground connection provided on the electrosurgery machine. The grounding pad should be well gelled and placed in contact with the patient across a large area. The grounding pad should be inspected during lengthy operations and gelled again or replaced if necessary. The electrosurgical grounding pad should be placed as near the operative site as reasonably possible and as far as possible from any pacemaker wires and ECG wires. When grounding pads are removed, the underlying skin should be inspected for burns.
4. The anesthesiologist should be concerned if increasing current levels are required for electrosurgery and take it as a cue to check for faulty connection of the electrosurgical grounding pad. In the event of very "wet" operations, with or without increasing current levels for electrical surgery, the physician should beware of errant current paths that include the grounding pad and other electrical contacts (e.g., ECG electrodes). For example, saline and body fluids in an abdominal procedure can extend under the drapes beyond the operative site and potentially form an electrical connection to a grounding pad or ECG electrodes.
5. If the line isolation monitor (LIM) sounds an alarm after someone activates equipment, the offending piece of equipment should be unplugged immediately. Plugging in that equipment has allowed the secondary side of the main isolation transformer to be coupled to the ground. It is also possible that so many items were plugged in simultaneously that the secondary side of the main transformer was coupled to ground by their combined capacitance. The anesthesiologist can try various combinations of unplugging one piece of equipment and plugging in another. However, if it is found that one piece of equipment causes the LIM to sound an alarm under several combinations, that piece of equipment should be removed from the operating room and examined for an unwanted connection to the ground contact.

6. All electrical equipment should be tested periodically by experienced personnel, usually a clinical bioengineering group associated with the operating rooms. Anesthesiologists should verify that equipment has been maintained properly, that standards of performance have been met, and that the entire electrical environment also meets National Fire Protection Association standards.[21,51-56]

Microshock Electrical Issues with Pacemakers

1. Patients with an automated implanted cardioverter-defibrillator (AICD) need to have the AICD turned off before surgery starts after first having established Zoll pad connections. Turning off the AICD feature is commonly done by magnet placement but can also be done by reprogramming. It should be appreciated that magnets do not change the pacing program that is in an AICD. Thus, preoperative cardiac electrophysiology consultation is essential for establishing appropriate pacing.
2. If possible, bipolar electrocautery units should be used instead of unipolar electrocautery.
3. All programmable pacemakers should be interrogated preoperatively to ensure proper function.
4. Pacemaker-dependent patients need to have asynchronous pacing programmed along with all rate-sensing features disabled. A conventional defibrillator should be available.
5. Other pacemaker patients should have a pacing strategy established by preoperative cardiac electrophysiology consultation.
6. A plan for pharmacologic treatment of complete heart block should be in place, particularly for pacemaker-dependent patients, and isoproterenol should be readily available on the anesthesia drug cart.
7. If electrophysiologic monitoring is being done, the anesthesiologist should review the locations of grounding pads that will be placed by the electrophysiologist.

MRI Issues

1. When using a pulse oximeter to monitor the oxygen saturation of patients in an MRI scanner, the connection between the oximeter console and the patient must take place through a long fiberoptic cable having no wires or conducting segments.
2. Items with internal wires should not be present during an MRI examination, including pulmonary artery catheters that have a wire for determination of temperature and certain epidural catheters with wires.
3. Because of missile danger, ferromagnetic anesthesia equipment may not be brought into the magnet room.
4. Essential anesthesia equipment that can be sucked into a magnet must be bolted to a wall and tested before entry of the patient into the scanner.
5. Anesthesiologists who stay in the magnet room during examinations must wear ear plugs to avoid permanent hearing loss from high-decibel acoustic noise.

Common to All Issues

If the cause of an electrical burn or incident is uncertain, the relevant equipment or areas should be secured until experienced biomedical personnel mount a thorough investigation that may include simulation of patient conditions.

Despite technologic advances that have increased the sophistication of operating room electrical equipment, three types of danger persist from the days of flammable anesthetics: fire, electrical burns, and electrical shocks (macroshocks and microshocks). Improved alarm systems and safeguards have accompanied the technologic progress, but there has also been an increase in the size and number of electrical devices used per case. The result is the introduction of new ways to create unsafe electrical configurations that can lead to severe injury during surgery and anesthesia. Inattention to electrical safety can have serious consequences. Tragic events continue to be reported in the medical literature, in some cases in which a moment of injury leads to a lifetime of patient suffering. Frequently, the culprit is unsafe surgical equipment or its unsafe use. However, disasters can also originate in damaged or misused anesthesia equipment, including physiologic monitoring devices.

Recently, there has been a surge in the number of important articles about intraoperative fires,[1-6] with cause analyses being based on the "fire triangle," or the three requirements for a fire: oxygen, fuel, and an ignition source.[6] Operating room fires fall into one of three basic categories: the patient or something in the patient is on fire, there is equipment with an electrical fire (i.e., one initiated and sustained by electric currents), or the surgical drapes or other operating room items are on fire. Inadvertent ignition is often involved and easily identified, for example, when burning of surgical drapes is initiated by electronically generated sparks or by high temperature. However, ignition sources can also be complex and not immediately understood, as in the case of an exploding expiratory valve in an anesthetic breathing circuit.[7] In the operating room, anesthesiologists need to be aware of fire safety concerns, do all they can to keep ignition sources away from fuel sources, and be safe about the use of supplemental oxygen. Apart from fires, severe burns have also been caused by electrical equipment with inadequate grounding or other faults and by induced currents from radiofrequency fields. One report described a neonate with third-degree burns after the application of an external cardiac pacing device for a prolonged period.[8] Another report described serious burns occurring from the direct electric current (DC) generated by a 9-V battery in a small neuromuscular stimulator.[9] Fortunately, patient electrocution is now uncommon, although it was once a well-recognized hazard of surgery and the operating room and even of hospitalization in general.[10-13]

Even though many types of modern equipment appear different from their ancestral counterparts, the injuries caused by electricity are similar or identical to those occurring generations

ago. Electrical malfunctions in the operating room continue to cause fires and explosions, central and peripheral nerve stimulation and damage, muscle stimulation and contracture, tissue burns, pacemaker interference, and sudden loss of power to important equipment. Safety standards for medical equipment have been improving, and most complications can be avoided by preventive maintenance of equipment, careful attention to the electrical contacts used on patients, and appropriate responses to alarm signals. Understanding electrical safety is an especially important responsibility for anesthesiologists because perioperative electrical dangers can often be identified before they lead to disruption of patient care or to injury.[14-18]

Having described the general situation, we now turn to the essential details of electrical safety. The "Key Points" provides guidelines for safe clinical practice.

Electrical Ground

What is "electrical ground"? This question is important because discussions of electrical safety often center on whether circuits are "grounded." To the clinician, an electrical ground is the wire connected to the third prong on plugs that are inserted into electrical wall outlets. With regard to circuits, an electrical ground is any object connected to a circuit that is capable of instantaneously supplying or receiving arbitrarily large amounts of electrical charge. The National Electrical Code of the National Fire Protection Association (NFPA*) defines electrical ground as a conducting connection, intentional or accidental, between an electrical circuit or equipment and earth or as a connection to some conducting body that serves in place of the earth. Because the earth can be taken as an infinite reservoir of electrical charge with a limitless ability to give up or receive electrons, any charged object connected to earth loses its charge and assumes the same potential as the earth.[14] Relative to earth and to each other, the voltage between two grounded objects is zero.

When a circuit is intentionally grounded, the physical objects chosen to serve as the electrical ground can vary. In a remotely located mobile army surgical hospital unit or recreational camping van, equipment may be grounded by connections to a spike that goes into the earth. In a large urban medical center, the ground may consist of a subterranean network of pipes. For a very small, hand-held radio, a human being may serve as the connection to ground.

In hospital settings, the clinician does not need to understand the details regarding the choice of ground. However, clinicians must often know whether they, their patients, or their pieces of equipment are grounded. Living organisms tolerate only limited amounts of electric current. Unintended new contacts with electrical ground can sometimes be injurious when they enable very small electric currents to reach the heart or neural tissue. However, they are always dangerous when they permit large electric currents to travel through the body. Fortunately, it is possible to design alarms for operating rooms and surgical equipment that provide danger signals before errant currents are established by a sudden, new, unwanted ground connection. If the operating room has a *line isolation monitor* (LIM), which is explained later, hearing its loud warning sound means that a faulty ground connection is one step away from establishing a large current in the patient. Human protection from large currents can be ensured if connections to ground always occur through a sizable resistance. The danger of being grounded through an electrical resistance that is too small can be illustrated by an unrealistic but vivid hypothetical example. Imagine a person standing on top of a giant copper cylinder that extended down to the molten core of the earth. This low-resistance connection to the largest imaginable electrical ground would be quite unsafe because the person would essentially be a fuse, poised to suffer whatever large electric current is applied. The safety that would be achieved by inserting very large electrical resistance between the person and the copper cylinder—but not so large a resistance that it causes perfect insulation—explains a requirement that was established long ago when explosive anesthetic gases such as cyclopropane were used. Operating rooms were then required to have conductive floors made of specific resistive materials. Such substances had high carbon content, making them neither as conductive as metal nor as insulating as rubber. The high carbon content imparted a dark black color, one that can commonly be found today in many operating room tables and cushions made of resistive material.

In the United States, electrical plugs have three prongs, with only two providing voltage or, equivalently, power. A special third prong serves only as a connection to ground (i.e., to an object that makes an electrical connection with the earth or with a metal network such as iron pipes.) Travelers to Europe and elsewhere may recall seeing electrical outlets for plugs that have only two prongs and no separate ground wire. A two-wire system becomes especially unsafe if three-pronged equipment is plugged into it with the third prong left unattached.

A ground fault current interrupter (GFCI) electrical outlet allows a person to test that the third connection in the outlet is connected to a functional ground. More significantly, GFCI outlets enhance electrical safety by serving as emergency circuit breakers that shut off power when one of the two power lines in the outlet is accidentally connected to ground. Thus, the GFCI is a "first fault" detector. GFCI outlets, found in hospitals and homes, have two buttons: "TEST" and "RESET." Pushing TEST causes a special resistor to be connected across the power and ground terminals in the receptacle. If the ground connection (i.e., the third wire) is in place and connected to the system ground, as it should be, current flows through the resistor and causes a circuit breaker in the outlet to open. No electricity can then be delivered by the outlet. Pushing RESET resets the circuit breaker and restores electrical power. Pushing TEST would not cause the circuit breaker to open if, for example, a contractor accidentally forgot to install the ground wire or if an earthquake or other mishap caused a break in an installed ground wire. Protection against accidental grounding of one power line in an outlet is required by the NFPA for wet environments such as operating rooms. Installation of GFCI electrical outlets is one way to satisfy NFPA protection requirements. As discussed later, a second way (the traditional but more expensive way) is to have power come from an isolation transformer equipped with an LIM.[19,20] In the operating room, if a power outlet is not part of an isolated system with a LIM, it should be a GFCI outlet.

Electrical engineers commonly choose the ground as a reference location where the voltage is defined to be zero. Therefore,

*National Fire Protection Association, 1 Batterymarch Park, P.O. Box 9146, Quincy, MA 02269-9959. http://www.nfpa.org. Standards are available for download at http://webstore.ansi.org.

the voltage at any point in a circuit is the difference between the voltage at that point and the voltage at the electrical ground. Because of this, ground connections in commercial circuits help professional personnel check for proper functioning. A technician connects one voltmeter probe to ground while touching different circuit elements with the other voltmeter probe. The manufacturer's table can be used to compare readings and, in this way, identify problems in the circuit. Specifying the location of the electrical ground helps people communicate standards for circuit performance.

Isolation of Electric Power from Ground

Electrical contacts with "ground" can cause injury if they occur in two different locations such that a circuit is completed and permits a large flow of current through "ground." One strategy for ensuring safety is to isolate all electric power sources from "ground," thus making it impossible for "ground" to be used as a path for injurious or damaging currents.

Traditionally, implementation of this strategy in the operating room has been accomplished by means of isolation transformers, which usually take the form of large wall panels that have outlets and meters. The term *isolation transformer* comes from the fact that power output is isolated from the electrical ground. Figure 100-1A shows a schematic diagram of an isolation transformer. A device built into the transformer constantly checks that all is well with this setup. It monitors the extent to which the output power lines are isolated from the ground and is called the LIM. Next we review how the LIM came into existence, why it can be important, and precisely what it is.

Electric power for an operating room comes from a primary hospital source that usually originates from a connection to an alternating electric current (AC) station of the local power company. (Sometimes an emergency, gasoline-powered electrical generator is the primary source.) In the traditional setup, after arriving at an operating room, electric power is modulated, isolated, and dispensed to electrical outlets in the room by the secondary coils of one or more large isolation transformers. Such transformers are very expensive, and the traditional setup is found less often in new hospitals. However, when there is a transformer, connections in three-hole power outlets in the operating rooms are somewhat different from connections in standard outlets found elsewhere in the hospital.[18] In such operating rooms, a circuit cannot be completed by connecting one of the two power contacts to the ground contact.

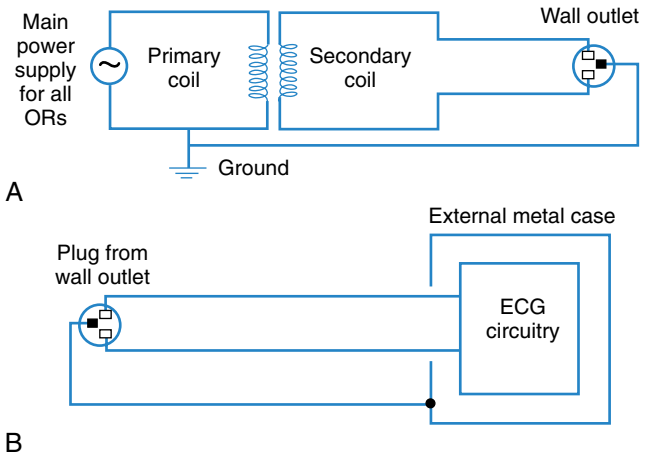

Figure 100-1 Schematic diagrams of an isolation transformer (**A**) and electric grounding (**B**) for an electrocardiographic (ECG) unit in the operating room (OR) (i.e., outlet to equipment).

The panel of each isolation transformer is required to have an LIM, which is an electric current meter that demonstrates isolation of the transformer's output power from ground. Large isolation transformers were originally required by the NFPA in all operating rooms because of the use of inflammable anesthetic.[19] It is permissible for operating rooms to be built without them as long as basic safety is maintained by otherwise isolating electrical circuits from ground. Such is now accomplished by a power transformer inside most electrical devices that isolates voltage applied to the device's circuits. Instead of there being one large isolation transformer for all equipment, each piece of electrical equipment has a small isolation transformer inside it. Such was not the case when large isolation transformers were initially required. It is therefore possible to argue for the total abolition of operating room isolation transformers and their LIMs. In support of such an argument is the observation that isolation transformers and LIMs have always been absent in intensive care units and postanesthesia care units, places where medical personnel use the same electrical instruments that are used in operating rooms. Should anesthesiologists advocate the elimination of future installations of isolation transformers and LIMs in operating rooms? The answer can be either yes nor no,[19,20] depending on the type of electrical equipment that is used and the surgical situation. Surgery can involve having very wet patients covered or soaked with fluids that conduct electricity and find pathways to "ground." In these situations, currents can be established through the errant pathways from electrosurgical tools, such as through saline solutions to electrocardiographic (ECG) electrodes or the operating room table. New operating rooms in ambulatory surgery centers would seem to not need isolation transformers, although they are well suited for operating rooms for liver transplants and other procedures involving a large amount of fluid.

The schematic diagram of an isolation transformer in Figure 100-1A shows what is presented by the power outlet to any power cord that gets plugged in. Each power outlet has two hot-wire contacts coming from the secondary coil of the transformer. The third contact in the power outlet is connected to the standard hospital ground and not to the isolation transformer. Note that the primary circuit of the transformer is attached to "ground" but the secondary circuit of the transformer is not.

When an ECG monitor is plugged into a power outlet in the operating room (see Fig. 100-1B), neither of the two hot wires from the secondary coil of the transformer is connected to the ground by the ECG circuitry. This demonstrates the general principle that electrical circuits within an apparatus need not be grounded, although the metal case that houses the circuits is always grounded. For many circuits, proper functioning depends on good isolation. The statement "all operating room equipment must be grounded" means that the "ground" connection on a power cord that comes from equipment must always end up in contact with the "ground" provided by the transformer. In the example given in Figure 100-1B, the electrocardiograph case is

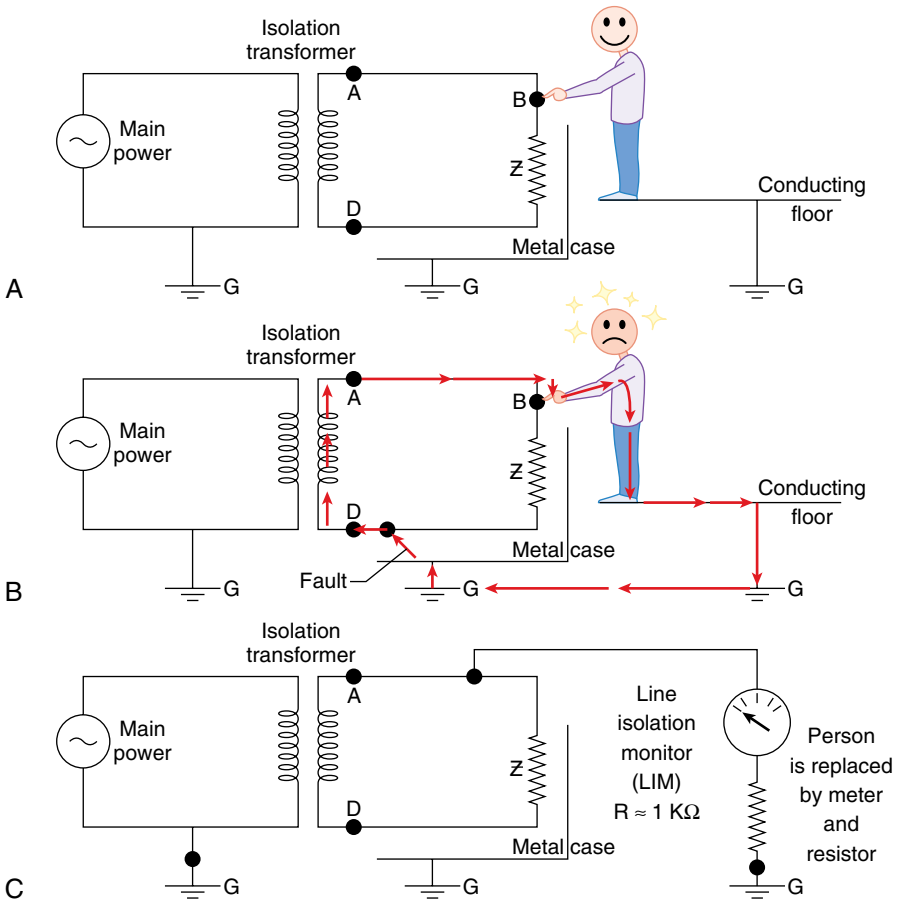

Figure 100-2 **A,** When the transformer output is ungrounded, no electric shock occurs to the person at the right if an isolated power line is touched. **B,** An electric shock does take place if the person touches the circuit after occurrence of the ground fault shown at the *bottom*. In the potentially injurious electricity path, shown in *red*, current comes up from ground through the fault, circles around, and returns to ground by traveling through the person's body. **C,** The person suffering the electric shock has been replaced by a current meter and a large resistance to ground. This is the basis for detection of the "first fault" by the line isolation monitor.

connected to the hospital's electrical ground, and the internal circuitry is connected to the output of the isolation transformer. This safe system is worthy of further discussion.

Let us suppose that mechanical or electrical damage causes concern about the electrical safety of an ECG monitor. Could a failure occur inside the ECG monitor that would place the patient or anesthesiologist in contact with the internal circuitry? If so, would electric current travel through the person from the ECG circuitry to the ground and cause injury or distress? If the ECG circuitry remains isolated from ground, the answer is no.

Figure 100-2A and B show how isolation provides safety. A grounded person is touching the internal circuitry at point B. The isolation transformer supplies current to pathways that connect the two hot leads in the outlet, indicated by points A and D. However, the only way for electric current to get from point A to D is through impedance Z. Because each of the hot points in the wall outlet are not grounded, the person in Figure 100-2B is safe from shock.

Figure 100-2C, however, shows that two inadvertent ground contacts could produce a dangerous situation, especially if one of those contacts is a human being. Suppose that a fault occurs near point D and causes the internal circuitry to come in contact with the external metal case. A dangerous shock would result from touching the circuit at point B. Because of the fault, current could complete a pathway through the person and ground (i.e., from point A to D). It is useful to isolate power lines from ground and know when isolation is compromised by a fault.

Every isolation transformer has an LIM that monitors isolation of the transformer's two power output lines from ground. Figure 100-2C shows how the LIM (an ammeter) replaces the smiling and frowning people in Figure 100-2A and B. When very low amperage is indicated, the LIM verifies that the power output lines of the transformer are isolated from the electrical ground, as in Figure 100-2A. The reality of the LIM connections is different because either of the hot wires could become grounded accidentally. The LIM is actually connected to both sides of the isolated power output (Fig. 100-3) and is set to sound an alarm when either side has an impedance to ground that is less than 25,000 Ω or when the maximum current that a short circuit could

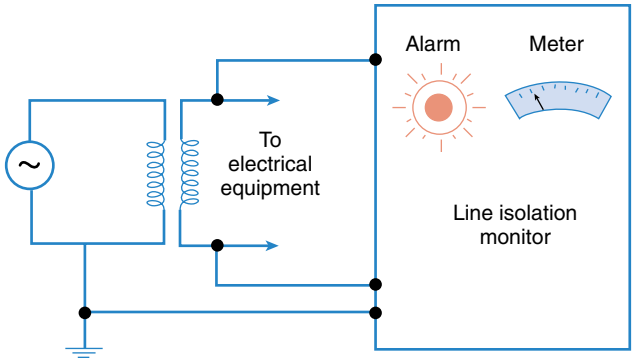

Figure 100-3 Schematic diagram shows the complete connections of the line isolation monitor (LIM). The alarm sounds a "first fault" if either isolated power line has less than 25,000 Ω of impedance, which corresponds to 2 mA or more being drawn through the LIM.

cause exceeds 2 mA. The LIM is insensitive to currents below 2 mA. As discussed later, the LIM provides no protection against microamp currents and microshock.

Many events that occur commonly in operating rooms can produce a short circuit between the power and ground and result in the LIM going off. For example, a short circuit can be produced by dripping or spilling saline, blood, or other conducting liquid into the receptacles of an electrical extension cord that is on the floor near the operating table. For this reason, NFPA and The Joint Commission (TJC) (formerly the Joint Commission on Accreditation of Hospital Organizations) rules have evolved to generally forbid the use of electrical extension cords in operating rooms and other clinical areas. Ideally, every piece of electrical equipment in the operating room is supposed to have a power cord that is safely routed to a wall outlet. In the rare circumstance when an exemption permits the use of an electrical extension cord, the cord must tolerate very high current and have watertight covers that flip into place over unused outlets. If wet receptacles on an extension cord appear to set off an LIM, the extension cord should be changed. If the LIM rings suddenly and unexpectedly or immediately after a new piece of equipment is plugged in, that equipment should be unplugged immediately. If plugging in a piece of equipment repeatedly causes the LIM to sound an alarm, the equipment should not be used until it is checked. Similarly, if use of a particular power outlet repeatedly causes an alarm, it should not be used until it has been checked. When an LIM alarm indicates a first fault (i.e., one power line is grounded), large, potentially damaging currents may subsequently occur through ground connections if there is a second ground fault. The path of damage may include the anesthesiologist, the patient, or an essential piece of equipment. An alarming LIM warns that someone in the operating room may receive an electrical shock or burn when touching connections to electrical equipment.

As noted earlier in the chapter, detection of a first fault in grounding is possible without the use of isolation transformers and LIMs. GFCI outlets provide protection against a first fault. However, they provide protection by suddenly shutting off all power from the outlet. An advantage of the LIM is that operating room personnel learn about a first fault without losing electric power. A disadvantage of the LIM is its susceptibility to newly developed artifactual causes of alarm. Certain devices used in operating rooms emit electrical radiation, intentionally or incidentally, that falsely causes LIMs to sound an alarm. Such devices include instruments that generate ultrasonic sound waves for disintegration of tumor and surgical navigation systems for stereotaxic surgery or anatomic localization, such as STEALTH and BRAINLAB. These systems use electromagnetic waves to track fiducial markers attached to patients so that locations on the patient can be linked to locations on three-dimensional magnetic resonance imaging (MRI) and computed tomography scans.

Capacitive Coupling

The direct connection of two circuit elements by a wire or resistor is known as resistive coupling. It is the easiest type of coupling for an anesthesiologist to recognize and understand. The connection is visible and the effects of the connection are apparent for circuits carrying DC or AC at all frequencies. More subtle and abstract is the concept of capacitive coupling, which applies only

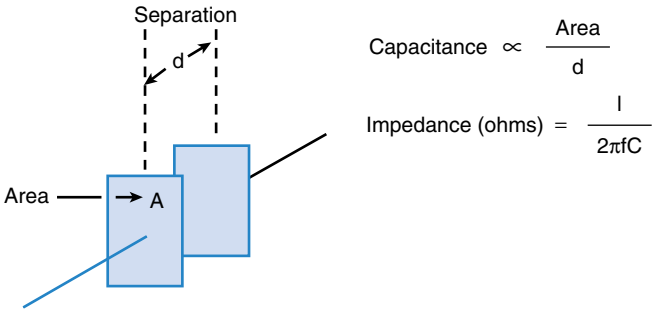

Figure 100-4 Schematic diagram of a parallel-plate capacitor. C, Capacitance in farads; f, frequency of alternating current.

to AC currents. This concept is relevant to anesthesiologists because it can account for electrical connections being present at high current frequencies. If the alarm of an LIM goes off only when the electrosurgical electrode delivers high-frequency current to the patient, the dangerous pathway to the ground may be caused by capacitive coupling, and there may be some power outlets that are safe for low-frequency currents but not for high-frequency currents. Grounding pads, connections to electrical plugs, and equipment may need to be separated even farther from each other before the problem is remedied. The rationale follows directly from the basic principles governing capacitive coupling.

The parallel-plate capacitor (Fig. 100-4) is a circuit element that permits temporary storage of electrical charge and the passage of AC. Parallel-plate capacitors, however, do not permit the passage of DC. The electrical impedance of an object is quantified by the total number of ohms that it has for obstructing AC or DC. This concept, which is a generalization of electrical resistance, permits frequency-dependent assignment of ohms to all circuit elements: capacitors, inductors, and resistors. For capacitors, the ohmic calculation is done with a simple formula. The impedance (Z, in ohms) of a pure parallel-plate capacitor is a function of the AC frequency (f):

$$Z = \frac{1}{2\pi fC}$$

In this instance, capacitance (C, in farads) is directly proportional to the area of the capacitor plates and inversely proportional to the space between the plates. As frequency (f) increases, impedance to the flow of current decreases. For DC, f equals 0, and impedance becomes infinitely large.

At very high frequencies, capacitive coupling to the ground occurs through fewer ohms of impedance than at low frequencies. Because any two conducting objects in a room have surface area and an average distance of separation, they form a kind of capacitor. Any two objects have a capacitive coupling, which means that each of the two output lines of an isolation transformer is always coupled to the ground at AC frequencies.

Although such capacitive coupling is usually insignificant, it can sometimes be significant at frequencies of 60 cycles/sec (i.e., 60 Hz). More commonly, capacitive coupling becomes a problem during electrosurgery performed at higher frequencies, typically hundreds to thousands of kilocycles per second. Capacitive coupling, which lets high-frequency currents pass easily, is commonly used by manufacturers in two connections: between the electrosurgical unit and the electrosurgical pencil (i.e., cutting or coagu-

lation tip) and between the electrosurgical unit and the large-area "grounding pad" that attaches to the patient. The formal term for this large-area conducting pad is *dispersive electrode*. Capacitive coupling gives high-frequency electrosurgery currents a low-impedance path to and from the patient. At the same time, by presenting high-impedance paths at low frequencies, capacitive coupling prevents the electrosurgical pencil and the large-area conducting pad from participating in dangerous low-frequency grounding of the patient.

Capacitive coupling in an electrosurgical unit might have prevented a serious burn caused by the DC of a 9.5-V battery within an anesthesiologist's damaged nerve stimulator.[9] An older electrosurgical unit was used in that case, and it was not capacitively coupled to the large-area grounding pad on the patient. The damaged nerve stimulator had a connection to the ground contact that permitted completion of a DC circuit (i.e., the patient through the faulty connection to ground and then ground through the large-area pad back to the patient). The DC persisted throughout the case, even when the stimulator was not pulsing. In laparoscopic and endoscopic surgery, it is important for surgeons to avoid unwanted capacitive coupling between the unipolar cautery tool and neighboring metal conductors such as trocar cannulas. Stray currents from unwanted capacitive coupling can involve and injure organs such as the bile duct and bowel.[21,22] Anesthesiologists need to be aware of such potential surgical complications, particularly if they may be erroneously attributed to anesthesia.

Capacitive coupling can be responsible for severe patient burns from conventional pulse oximetry (with nonfiberoptic cable) in patients anesthetized for MRI.[23-25] However, the possibility of being burned by a faulty pulse oximeter probe exists independently of capacitive coupling or radiofrequency currents induced by the MRI environment.[26,27] In the setting for such a burn, the patient is external to a malfunctioning electrical circuit that causes the probe (i.e., the unit that contains the photodiode and attaches to the patient) to overheat and burn tissue. Such a catastrophe can be caused by connecting the wrong kind of probe (e.g., one from another type of unit) to an oximeter console.

It has long been known that a perfectly safe conventional pulse oximeter (with nonfiberoptic cable) can be transformed into a dangerous, burn-causing device if it is attached to a patient being scanned in an MRI magnet. The problem arises from magnetic and electric fields that oscillate at megahertz frequencies (in radiofrequency coils) and at kilohertz frequencies (in gradient coils) during acquisition of MRI data. Capacitive coupling can connect a patient to wires in a pulse oximeter cable and to metal in a pulse oximeter probe. In such a situation, the patient becomes part of a high-frequency loop circuit, with currents entering and exiting at the points of capacitive coupling, particularly at the site of probe attachment.[28-31] Fortunately, anesthesiologists now know to use only pulse oximeter cables that have long, nonconducting fiberoptic connections between the photogenerating and photodetecting parts. Connections of the console to the cable are outside the magnet, distanced from pulsing MRI coils, and only nonconducting components are connected to the patient in the magnet. The absence of metal or conducting components of the cable or probe attachment eliminates the possibility of patient burns from induced currents during MRI.

Anesthesiologists monitoring patients with pulse oximetry in MRI magnets must use only units that are MRI safe and MRI compatible—those with a long fiberoptic cable as described previously. Severe burns can occur if for some reason the anesthesiologist decided to take a conventional pulse oximeter from an operating room to the MRI suite and attach it to a patient in an MRI magnet.

Electrical Shock

Macroshock

Macroshock refers to disturbances in neural or muscular function, or both, caused by the application of high voltage or current. Problems can arise if macroshocks occur near the heart, as in a fatal case when a patient's ECG leads were accidentally attached to a power cord.[10] However, macroshock can also cause injury if contact is made at locations remote from the heart.

If someone's hand or arm accidentally touches a voltage terminal, the response to electric current flowing through the arm will depend on the amplitude and frequency of the current. Sensation of a 60-cycle current occurs at approximately 300 μA, and pain occurs at approximately 1 mA. If the current exceeds a certain value, called the let-go current, the person is unable to release objects.[32] The value of the let-go current varies with frequency and among individuals. Figure 100-5 shows the range of average values as a function of AC frequency. The 50- and 60-cycle/sec currents have the lowest values and are therefore the most dangerous. The response of cardiac muscle to electroshock also depends on frequency. Electric current is more important than voltage when issues of safety arise. Table 100-1 indicates the physiologic responses to increasing total-body current.

Continuous, total-body currents that reach 0.1 to 2.5 A (approximately 10 times the let-go value) can cause ventricular fibrillation. The electric current generated by one pulse of an implanted cardiac pacemaker ranges from 0.1 to 50 μA. Only a small part of the total-body current needs to pass through the heart to affect cardiac function. An electrosurgical unit generates

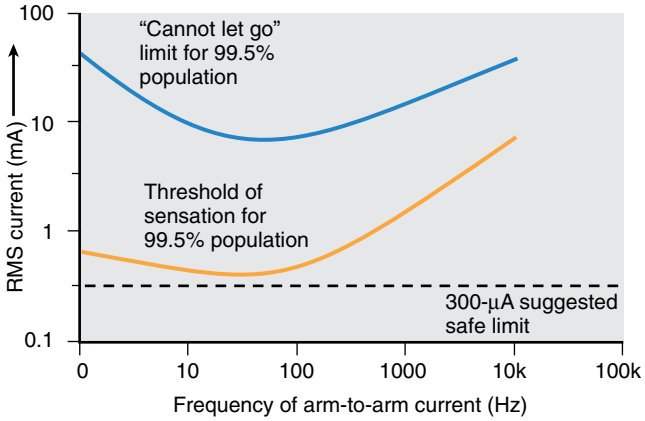

Figure 100-5 The response to electric current flowing through an arm when the hand accidentally touches a voltage terminal depends on the amplitude and the frequency of the current. Sensation of a 60-cycle current occurs at approximately 300 μA, and pain occurs at approximately 1 mA. If the current exceeds a certain value, called the "let go" current, the person is unable to release objects. The value of the let-go current varies with frequency and among individuals. RMS, root-mean-square average.

Table 100-1 Average Effects on Humans of 60-Hz Currents Applied at Body Surface and Passing through the Trunk

Current (mA) for 1-Second Contact	Effect
1	Threshold of perception
5	Accepted as maximum harmless current intensity
10-20	"Let-go" value is exceeded; sustained muscle contraction is next
50-100	Pain; possible fainting, exhaustion, mechanical injury; heart and respiratory function continue
100-2500	Ventricular fibrillation; respiratory center intact
≥6000	Sustained myocardial contraction followed by normal rhythm; temporary respiratory paralysis; burns if the current density is high (usually if current >100 mA/cm^2)

Adapted from Bruner JMR: Hazards of electrical apparatus. Anesthesiology 28:396, 1967.

so much power that it can induce microshock currents when it is used near implanted pacemaker wires. However, thanks to compliance with the safe grounding practices described earlier, the last convincing report of ventricular fibrillation induced by electrosurgery occurred in 1968.[33]

Defibrillation is often based on the same principle—that the skin is a good electrical insulator that requires large electric fields at its surface for the production of small electric fields internally. A jolt of 360 watt-seconds (or joules) during closed-chest cardiopulmonary resuscitation delivers energy to the body comparable to that produced by a large-caliber handgun. (A 0.45-caliber bullet weighs 250 grains and has a muzzle velocity of 860 ft/sec when fired. This corresponds to an energy of approximately 540 watt-seconds.) Only a very small portion of a defibrillator's energy dose is needed to depolarize the heart.

Microshock

The passage of even small amounts of electric current through the body can interfere with normal functioning of muscles and nerves. *Microshock* refers to the direct application of very low voltage or current to the heart, often intentionally, by means of external or internal cardiac pacemaker electrodes. Inadvertent microshock, however, is dangerous because it can produce ventricular fibrillation. Deaths from accidental microshock were caused by a faulty endoscope and by faulty dialysis equipment.[9,34] Before 1980, arterial and central venous pressure transducers were a potential source of microshock because they brought electrodes very close to heparinized saline in contact with the intravascular compartment.[35,36] However, in 1982, miniature disposable pressure transducers appeared that could be powered and operated with low-voltage telephone cables. They are now used exclusively, and their safety with respect to microshock has been demonstrated by years of frequent use without reported complications. Such systems, however, are vulnerable to more subtle dangers, as was reported when a faulty cable connection permitted precision pressure tracings but caused a substantially lower pressure reading.[37]

Electric current is the most appropriate variable to address when setting safety limits. Because investigators have reported that electric current passing through the human heart needs to be at least 50 μA before ventricular fibrillation occurs,[32,38,39] the American National Standards Institute (ANSI), on December 2, 1993, set 10 μA as the maximum leakage of current allowable through electrodes or catheters contacting the heart. This amount of current is considerably smaller than the peak electric current generated by an implanted pacemaker during a single pulse (0.1 to 10 μA). Because 2 mA is the LIM warning level, the LIM does not provide protection against microshock hazards.

ECG monitoring electrodes are electrically isolated from power circuits in the monitor by an isolation transformer in the main unit, a second level of isolation. However, an anesthesiologist who wishes to perform intravenous or intracardiac ECG monitoring, as occurs during p-wave guided brachial placement of a central venous pressure catheter, should have qualified personnel check the ECG monitor for current leaks. In some ECG and electroencephalographic (EEG) systems, electrode signals from the patient are translated into optical signals by a battery-powered amplifier with a photodiode output that is optically coupled to the main ECG or EEG unit, an even more thorough second level of isolation.

Endovascular procedures performed by interventional neuroradiologists include the placement of procoagulant coils inside certain types of intracranial aneurysms. The coils are placed directly in aneurysms with a considerable depth and a narrow neck. However, when the aneurysm has a wide entrance and a short depth, concern is high that a loose coil could get carried away and act as a thrombus wherever it lodged. Therefore, in such cases a detachable coil is generally used to completely occlude the unfilled region. After being convinced of the coil's location and stability, the angiographer sends a short electrical pulse through the coil, as though it were a unipolar surgical knife, which causes detachment at a known location. Although anesthesiologists should be aware of potential electrical hazards that come with new techniques,[40] they should feel comfortable about electrical issues in detachable coils inasmuch as they do not cause macroshock or microshock.

Electrosurgery

Most concerns with electrical safety in the operating room arise from the use of electrosurgical units because they are capable of causing electrical shock, burns, explosions, arrhythmias, and disturbances in pacemaker functioning.[41] Electrosurgical units operate at frequencies of approximately 300,000 to 2,000,000 cycles/sec (300 kHz to 2 MHz) to minimize the likelihood of ventricular fibrillation. During electrosurgery, high currents enter the patient through a small-area surface electrode at the tip of the cutting tool. The combination of high resistance (R), which is attributable to the small area, and high current (I) causes local tissue heating proportional to I^2R, which produces cutting or coagulation. The tip of the electrode is also designed to produce lower current densities (low I^2R) at points farther than a few millimeters from the electrode tip. Figure 100-6 shows fanning out of the electric current. Electrosurgery is therefore a form of highly controlled localized burning of tissue.

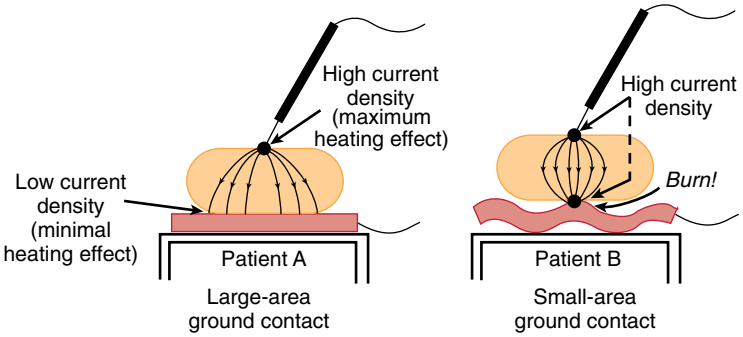

Figure 100-6 Flow of electric current through the body when small-area or large-area grounding pads are used.

Concern about suffering an unwanted electrosurgical burn is a legitimate issue for patients with metal jewelry that pierces the body, such as umbilical rings, nipple rings, earrings, tongue studs, etc. Obviously the best solution is to remove all metal jewelry prior to surgery, and this is highly recommended. However, there are times when removal of metal jewelry is cumbersome, burdensome, inconvenient, or simply unwanted by the patient. In such instances, it is reasonable to leave the jewelry in place if the site of electrosurgery is far from the jewelry, and if the jewelry is not directly within the path of the electrical current that travels from the cutting electrode to the grounding pad. For example, a nipple ring should be removed if there is surgery on the breast with the nipple, and if a nipple ring is allowed to remain on the opposite breast, the grounding pad should not also be on the patient's opposite side. We have just mentioned that in the case of no metal jewelry, electrical current fans out rapidly as it leaves the cutting electrode. The concern with metal jewelry is that it might re-concentrate electrical current that passes near it, and thereby cause a burn. Thus metal jewelry that is left in contact with the skin should be held with tape in as large a contact area as possible. For example, a metal umbilical ring would be taped flat against the abdomen. If instead of a grounding pad there is use of a capacitive coupled return electrode, all metal jewelry should be removed. Because all metal objects have a surface area that can form capacitive coupling with a capacitive coupled electrode, its use in certain circumstances can dangerously increase the risk of burns.

Because there is often smoke where there is fire, concern has been expressed regarding the safety of inhaling smoke from electrocautery. One group, assisted by the National Institute of Occupational Safety and Health, used the Ames test to examine the potential mutagenicity of electrocautery smoke collected during breast surgery.[42] Although the compounds collected were mutagenic, it is not known whether electrocautery smoke represents a serious health risk to operating room personnel. Nevertheless, the study recommended that surgeons minimize the production of electrocautery smoke and exposure of human beings to the smoke.

Because there is often fire where there is smoke, it is also important that nonflammable materials be used during electrosurgery. Fires have occurred in operating rooms because highly combustible surgical boundary drapes were placed close to electrosurgical units.[43] The smoke from such fires can contain toxic substances.

From the preceding discussion it is not surprising to find that electrosurgical units are powerful enough to provide excess electric currents capable of causing extensive tissue burns. Surgical patients who become wet with blood, saline, urine, or other conducting fluids can form electrical contacts with the operating table, the ground, or other conductors, including monitoring electrodes and surgical retractors. Such contacts can create potentially dangerous current pathways. For example, current from an electrosurgical unit may enter a patient through the grounding pad and return to the unit through one or more ECG electrodes. In this situation, the electrosurgical unit can provide current that burns the patient but never passes through the tip of the electrosurgical pencil used in the operative procedure.

The dangers of electrosurgery in a wet environment, especially the possibility of establishing ground faults through wet connections, account for the presence of an isolation transformer (and LIM) in modern operating rooms. As noted earlier, GFCI outlets protect against ground faults by causing sudden deprivation of power, whereas isolation transformer setups turn on an LIM alarm instead and thereby permit less disruption. Loss of electric power during cardiac surgery can be a very serious concern, which is one reason why anesthesiologists must know how to hand-crank cardiopulmonary bypass pumps.[44] Desflurane vaporizers require electricity for operation. The NFPA requires first ground fault detectors in operating rooms. However, anesthesiologists, surgical colleagues, and hospital administrators are free to choose GFCIs or isolation transformers with LIMs, whichever best suits local conditions and practices.[19,20]

Unipolar Electrosurgery

It is important to understand the difference between unipolar and bipolar electrosurgery. In both cases the surgeon applies electrodes directly to tissue to produce electric currents that burn and cut or burn and coagulate. In unipolar electrosurgery, the more common of the two, the electric current that enters the patient through one electrode travels throughout the body and is collected outside the surgical field by a large, wide-area, well-jelled grounding pad (i.e., the dispersive electrode). Skin burns can occur if the grounding pad is dry (i.e., most of the conducting gel is gone) or is otherwise in poor contact with the patient. In such situations, the electric current collected by the grounding pad is required to traverse small surface areas, and these inherently have high electrical resistance. Because I^2R can increase substantially at such small areas of grounding pad contact, increases in resistance can lead to electrical burns of the skin.[45] Electrical burns have also occurred at the site of ECG leads when the grounding pad was defective and the leads became an alternative path for returning high-frequency electrosurgery currents.[46,47]

A much more powerful unipolar electrosurgical tool, the argon beam coagulator (ABC), has become popular among surgeons who must cut or coagulate very vascular tissue.[48] Operating room personnel unfamiliar with the design and use of the ABC

can easily mistake it for an argon laser because a well-collimated, brightly colored beam of argon light glows at the tip of the electrosurgical pencil. The glow, which has the same color as light emitted from an argon laser, represents a continuous electrical discharge in a small, flowing column of argon gas having a density that supports electric current. The ABC was developed to solve a problem occurring with metal coagulation or cutting tips. In regions where there is a lot of blood, electrosurgical currents result in adherence of sticky, burned tissue to the tip of the cutting electrode, thus electrically insulating it and making further use impossible until the tissue is scraped off. Surgery must stop while the tip is scraped clean. When large areas of vascular tissue must be traversed (e.g., in hepatic resection or repair of traumatic lacerations of the liver), conventional metal tips become difficult surgical tools. With the ABC, no metal surface is present to attract sticky, burned tissue. The tip of the cutting electrode is a cushion of argon gas that can transmit current so long as it touches tissue.

The anesthesiologist must understand that use of the ABC means that much electrosurgery is taking place and that safety measures are more important than ever. As in conventional electrosurgery, surgical cutting and coagulation with the ABC come from local I^2R heating losses at the point where the electrosurgical pencil is applied—in this case, where the argon gas meets the tissue. ABC operation therefore resembles conventional arc welding. Because the ABC is perhaps the ultimate spark generator, its use illustrates the extent to which we have abandoned one safety concern that was prominent in the days of inflammable anesthetic gases.

Some body locations are never safe for unipolar electrosurgery. This situation is encountered frequently during neurosurgery and in patients with implanted cardiac pacemakers. The solution is bipolar electrosurgery.

Bipolar Electrosurgery

In bipolar electrosurgery, as in unipolar electrosurgery, current enters the patient through one electrode. However, instead of traversing the body to be collected by a dispersive electrode at a site remote from the surgery, injected current is collected millimeters away from the first electrode by a second electrode that appears identical to the first. Bipolar surgery is performed by two pencil-point electrodes arranged at the tips of a forceps. Electric current flows through patient tissue only at the site of surgery, where it is confined to the few millimeters between the electrodes. Bipolar devices are required when electrosurgery is performed on an ovary or a fallopian tube. Several cases of fatal bowel injury have occurred after female sterilization with unipolar devices.[49,50]

Patients with an implanted pacemaker or an automatic implanted cardioverter-defibrillator (AICD) frequently come to the operating room for procedures requiring electrosurgery (see Chapter 43). For such patients, bipolar devices should be used whenever possible. Nevertheless, on rare occasions in such cases, interference with the pacemaker can occur. Regardless of the type of electrosurgery being performed, an AICD should be turned off during surgery because unexpected intraoperative delivery of its 3- to 20-J defibrillation shock could result in injury not only to the patient but also to the surgeon and others near or in contact with the patient. People in contact with the patient at the moment of an AICD's defibrillation shock can also receive a dangerous, painful electrical shock. Placement of a magnet over an AICD turns off its defibrillation feature and converts it to pacemaker mode alone. However, magnet placement does not affect the pacing program of a programmable pacemaker. (All AICDs have pacemaker circuitry.) Zoll pads connecting the patient to an external defibrillator/pacer should be fully operational when the AICD's defibrillator is turned off, with the obvious exception being situations involving "code" resuscitation, such as when an advanced cardiac life support (ACLS) team has defibrillator pads ready for use. If anesthesiologists on ACLS teams arrive at a cardiac arrest situation and find that the patient has an implanted pacing device, they should immediately learn whether the device is an AICD so that precautions such as magnet placement can be taken to avoid shocking the "code blue" team during resuscitation.

Because so many different types of pacemakers are now in use, the plan for avoiding intraoperative pacemaker interference must be based on the details of each particular case.[51,52] In general, the likelihood of interference depends not only on patient factors, such as the type of pacing electrodes (i.e., unipolar or bipolar) and how well the pacemaker circuitry is shielded, but also on surgical factors, such as the proximity of the cutting electrode's discharge and the path of the electric current within the patient. In all such cases, grounding pads should be placed as far away as possible from the pacemaker and its wires. In addition, if possible, the path from the grounding pad to the surgeon's electrosurgical cutting electrode should not traverse the path from the pacemaker circuit to the heart. Because of capacitive coupling, it is potentially possible for electrosurgical noise to either affect the heart directly or disrupt processing by the pacer's program in a programmable pacemaker. Such interference can result in complete heart block and no pacing or in severe tachycardia. Descriptions of incidents can be found in numerous recent reports.[53-57]

Although anesthesiologists should always be prepared to reset a pacemaker to the asynchronous mode (i.e., regular, uninhibited pacing), it is no longer correct to assume that magnet placement always converts a pacemaker to asynchronous mode, which is the mode needed by pacemaker-dependent patients. Because of pacemaker diversity, preoperative consultation with an electrophysiology cardiologist is always appropriate and often essential, as is preoperative assurance that programmable pacemakers have recently been interrogated and found to have no faults and then properly reprogrammed. Although some precautions to take with programmable pacemakers can easily be understood, such as turning off rate-sensing features, consultation can often be the only way for many essential pacemaker details[51,52] to be reviewed by someone with the proper expertise. Most hospitals have a cardiologist on call who can be reached for an immediate electrophysiology consultation.

Finally, the anesthesiologist should be familiar with the use of isoproterenol, a pharmacologic pacer, which should be available on the anesthesiologist's drug cart. Concentrations of 1 μg/mL are appropriate for small bolus injections.

Safe Practice

One approach to safe practice involves having complete, efficient checklists to consult for each concern, such as fire safety or safety

for patients with pacemakers. The anesthesiologist should go through the checklists relevant to every case, just as the pilot and the copilot of a commercial airplane do for air travel. Years ago the word "vigilance" was used more commonly to describe how anesthesiologists' eyes and mind are repeatedly and systematically scanning everything in the operating room. "Vigilance" is now used more appropriately to describe the virtues of sophisticated electronic monitors and alarms in the operating room. However, there are no electronic monitors to direct the anesthesiologist's attention to issues "outside the alarms," to issues related to organization and planning, such as having enough electric power outlets in the operating room to accommodate all the equipment while also avoiding circuit overloads. Limitations of checklists include the danger of "finding only what one looks for and recognizing only what one knows."[58] Even though safe practice is boosted by checklists, anesthesiologists should also always be vigilant for new problems. Thus, the guidelines that the Key Points present should be seen as a minimal summary that directs safe electrical practice, with a natural assumption that many anesthesiologists will add refinements and elaborations.

101 Environmental Safety Including Chemical Dependency

Key Points

1. Escape of anesthetic vapors into the operating room atmosphere is unavoidable. In the United States, the limits of exposure to atmospheric waste gases are set by NIOSH, which recommends a time-weighted average of 25 ppm for nitrous oxide and a ceiling of 2 ppm for volatile anesthetics.
2. No definitive evidence has shown that trace concentrations of anesthetics in the ambient air of the operating room present a health hazard.
3. Occupational exposure to radiation comes primarily from x-rays scattered by the patient and surrounding equipment. A distance of 6 feet from the patient provides the same protection as 2.5 mm of lead. A distance of 3 feet from the patient is recommended to minimize occupational exposure.
4. Occupational exposure to HIV is most often the result of a percutaneous injury. The risk of transmission is greatest from hollow-bore needles, needles contaminated with visible blood, and a source patient with high viral titer.
5. Post-exposure prophylaxis is recommended after occupational exposure to HIV or hepatitis B virus. The U.S. Public Health Service–recommended guidelines for post-exposure prophylaxis are available on the Centers for Disease Control and Prevention (CDC) website. The National Post-Exposure Prophylaxis Hotline is open 24 hours a day for expert advice (1-888-448-4911).
6. To minimize occupational exposure to blood-borne pathogens, standard precautions should be practiced at all times. The appropriate barrier precautions for anticipated contact with blood or body fluids are published by the CDC. Whenever possible, needleless systems should be used.
7. Sleep deprivation has an adverse effect on physician mood, cognitive function, reaction time, and vigilance. Although it is clear that sleep deprivation and fatigue adversely affect clinical performance, their full impact on patient outcome has not yet been determined.
8. Anesthesiologists are overrepresented in drug treatment centers. The preference for and access to potent opioids contribute to the prevalence of drug addiction among anesthesiologists.
9. The rate of drug-related deaths is more than twice as high in anesthesiologists as internists.
10. Although many recovered anesthesiologists return to the practice of anesthesia, there is a significant relapse rate. The chance of relapse is highest in physicians who become addicted to potent narcotics early in their career. Successful recovery requires a lifelong commitment to treatment. In some cases, a change in specialty is the only solution.

It is impossible to practice anesthesia without exposure to a number of potentially harmful environmental factors. Exposure to inhalation agents, transmissible diseases, and radiation are unavoidable in the operating room environment. Fortunately, the past several decades have produced a number of technical advancements and guidelines that serve to minimize the adverse effects of these occupational exposures. Efficient gas scavenger systems, needle-less systems, protect IVs, and post-exposure prophylaxis (PEP) protocols are now commonplace in contemporary anesthesia practice. But while these measures all serve to minimize occupational exposure and risk, they do not completely eliminate them.

In addition to environmental exposures, the access to potent opioids, the tradition of extended work hours, and the unique role the anesthesiologist plays in critical clinical situations contribute to the anesthesiologist's risk of chemical dependence, fatigue, and emotional distress. This chapter examines the relative risk of each of these environmental and situational hazards and reviews the measures one can take to avoid them. Awareness is essential to safe anesthesia practice.

Waste Gases

Trace amounts of waste gases enter the operating room atmosphere each time an inhaled anesthetic is delivered. Thus it is important to accurately detect, measure, and limit ambient anesthetic levels in order to minimize passive exposure of operating room personnel to waste gases.

Concentrations of waste gases are reported on a volume-per-volume basis in parts per million (ppm). For example, 100% halothane, such as in the saturated vapor above the liquid in a bottle or vaporizer, has a concentration of 1 million ppm. Similarly, 1% halothane represents 10,000 ppm. The National Institute for Occupational Safety and Health (NIOSH) recommends an exposure limit of 25 ppm for nitrous oxide (measured as a time weighted average over the duration of exposure) and a ceiling of 2 ppm for halogenated agents in the ambient air of the operating room.[1] When used in combination with nitrous oxide the ceiling for halogenated agents is reduced to 0.5 ppm.[2] To put these figures into perspective, assuming that 1 mL of a volatile liquid anesthetic produces 200 mL of vapor, that volume of liquid spilled in a closed room measuring 20 by 20 by 9 feet results in a concentration of vapor of nearly 2 ppm. The maximal concentration of halothane recommended by NIOSH is several-fold lower than the lowest concentration that humans can recognize. Only fifty percent of volunteers are able to detect halothane at concentrations as low as 33 ppm. The threshold of perception ranges from less than 3 to more than 100 ppm.[3] If the anesthetic can be smelled, its concentration is well above the maximum recommended level.

Waste nitrous oxide and halogenated anesthetics in the absence of scavenging may approach concentrations as high as 3000 and 50 ppm, respectively.[3] Although the concentration of waste gases can be well controlled with proper scavenging, in practice, the levels recommended by the NIOSH are not consistently met in the routine delivery of anesthesia. Mask inductions, circuit disconnects, the use of laryngeal mask airways and cuffless endotracheal tubes all contribute to operating room contamination. While the exposure to anesthetic gases is more common in pediatric anesthesia where mask inductions and uncuffed endotracheal tubes are the standard of care, the introduction of the laryngeal mask to anesthesia practice has increased operating room exposure to waste gases in adult cases as well. One study of inhaled induction of anesthesia and maintenance with sevoflurane and nitrous oxide in adults resulted in violations of NIOSH standards 50% of the time.[4]

The universal use of scavenging systems can lead to a false sense of security among operating room personnel. Kanmura and colleagues found abnormally high ambient concentrations of N_2O in 402 delivered anesthetics, of which 42% were the result of mask ventilation, 19.2% a disconnected scavenging system, 12.5% a leak around pediatric endotracheal tubes and 11.5% the result of equipment leakage. Although dysfunction of the scavenging system was not the most common cause of ambient contamination, scavenging system disconnects resulted in higher contamination levels than levels resulting from inhaled inductions. Furthermore, all of the scavenging system disconnects in this study were due to human error rather than equipment failure.[5] Because anesthesia machines are not equipped to recognize unconnected scavenging systems, a failure of the system may not be readily apparent. A thorough understanding and diligent maintenance of anesthesia scavenging systems is essential to comply with NIOSH standards and more importantly to minimize operating room exposure.

Simply transferring the patient from the operating room to the PACU does not eliminate the risk of exposure to waste gases, as patients continue to exhale trace amounts of N_2O for 5 to 8 hours after arrival in the PACU.[6] Sessler and Badgwell measured the concentrations of gases at the shoulder (and lapel) of recovery room nurses caring for patients who received inhalation anesthesia during their first hour in the PACU. In this study breathing zone anesthetic concentrations were in excess of NIOSH recommendations in 37% of patients who received isoflurane, 87% of patients who received desflurane and 53% of patients who received N_2O.[7] A more recent but similar study reported a much lower average concentration (3.1 ppm) of N_2O in the breathing zone of recovering patients in a Canadian PACU.[6] These studies demonstrate the importance of proper ventilation in postanesthesia care units. Both groups reported PACU room air exchanges of 8 vols/hr; however, much of the air in the Sessler study was recirculated. Nitrous oxide levels can be reduced to undetectable levels with air exchanges of 20 per hour with 25% of each exchange taken from fresh air.[8]

Although the Occupational Safety and Health Administration (OSHA) does not currently regulate exposure to N_2O and halogenated agents, the agency does provide guidelines designed to minimize workplace exposure. These include the appropriate assembly and monitoring of scavenging systems, detection and correction of machine leaks, and the installation of effective ventilation systems (American Institute of Architects, 2001).[1] In the operating room, the recommended air exchange rate is a minimum of 15 air exchanges per hour with at least 3 air exchanges of outdoor air per hour. In the recovery room at least 6 air changes are required with a minimum of two exchanges of outdoor air per hour. The agency recommends air sampling for anesthetic gases be done on a biannual basis in order to document the extent of worker exposure and the effectiveness of scavenging and ventilation systems.

Health Risks

The possibility that chronic exposure to anesthetic waste gases could result in adverse health effects was first appreciated in the late 1960s when a report of potential harm appeared in the Russian literature. In 1967, Vaisman reported an increased incidence of abortions among female anesthetists. Specifically, this study noted 18 spontaneous abortions in 31 pregnancies.[9] After this initial report a multitude of retrospective studies followed. Of these, three large studies conducted during the mid-1970s in the United States and the United Kingdom all concluded that the prevalence of abortion was substantially higher in female anesthesiologists than in female physicians working outside the operating room. Studies in this era also concluded that the incidence of congenital anomalies in children of male and female anesthesiologists was higher than in the control groups of physicians. In addition to these reproductive effects, meta-analysis of six of these early studies linked the exposure to anesthetic gases to hepatic disease in males[10] and cervical cancer, liver disease, and kidney disease in females.[11]

Subsequently, numerous reports appeared in the literature that criticized these original studies, citing faulty methodology as

a basis for erroneous conclusions; conclusions that were disproved when the data were reanalyzed. Biases may have arisen for many reasons, including inadequate response rates; lack of control for confounding variables, such as age, nutrition, obstetric history, drinking, smoking, exposure to methylmethacrylate, and radiation; lack of quantification of the exposure to anesthetic vapors; losses to follow-up; inappropriate comparison groups; and lack of independent verification of the reported data.[10,12,13] Even the titles of some questionnaires, such as "Effects of Waste Anesthetics on Health" and "Anesthetic Practice and Pregnancy," may have introduced selection and recall bias by stimulating respondents who work with anesthetics to over-report their past experiences.[14,15] Nevertheless, as late as 1997 a meta-analysis of over 19 studies completed between 1984 and 1992 reported an RR of abortion in females exposed to anesthetic gases to be 1.48 (CI 95%) 1.4-1.58.[16]

Given the persistence of this controversy, a Task Force on Trace Anesthetic Gases was convened by the American Society of Anesthesiologists (ASA) Committee on Occupational Health of Operating Room Personnel. The task force analyzed data from all of the available epidemiologic studies at the time and concluded that there was no proof of an association between occupational exposure to waste anesthetic gases and adverse health effects. In addition to the analysis of retrospective studies, their report, published in 1999, cited interim data from the only prospective survey in progress. This study monitored 11,500 female physicians in the United Kingdom and documented occupation, work practices, lifestyle, and medical and obstetric history, as well as hours of exposure and the use of scavenging equipment. This preliminary report showed the incidence of infertility, spontaneous abortion and children with congenital abnormalities in female anesthesiologists to be the same as that in other physicians.[17]

While there is no conclusive evidence to support the claim that current recommended levels of anesthetic waste gases present a health hazard, more recent studies suggest there remains a lingering concern among anesthesiologists. In 2003, Swedish investigators reported an increased incidence of multiple sclerosis among nurse anesthetists and proposed a link between waste gas exposure and the disease.[18] The nurse anesthetists were identified by "an appeal in monthly magazine(s)" and the incidence was based on questionnaires returned by respondents. The authors noted that volatile anesthetics are chemically similar to industrial solvents that have been linked to MS in the past. Once again, this study was soundly criticized for the method of data collection, the fact that dosage of exposure to waste anesthetic was not measured, and lack of control for possible confounding factors.[19] Concern may also have influenced anesthetic practice. In 2007, 59% of members of the Association of Paediatric Anesthetists in the UK reported a decreased use of N_2O over the last 5 years. Fifty-four percent considered occupational exposure to N_2O to be problematic, and 24% indicated that this concern for the possible harmful effect on operating room staff influenced their decision.[20]

Effect on Performance

The NIOSH recommendations arose from a study by Bruce and Bach in which healthy volunteers in the laboratory suffered a decrease in psychomotor performance when exposed to concentrations of nitrous oxide as low as 50 ppm, alone or in combination with 1 ppm of halothane. The same study showed that 25 ppm of nitrous oxide combined with 0.5 ppm of halothane had no effect.[1,21] Subsequently, three other groups of researchers studying volunteers in laboratories have been unable to confirm the findings of Bruce and Bach. The lack of agreement between investigators has led some to conclude "that there is no convincing evidence that anesthetic agents in concentrations equal to those found in unscavenged operating theatres have any effect on the psychomotor performance of healthy subjects in the laboratory."[22] A study conducted on volunteers in an operating room during normal clinical activities in which trace concentrations of nitrous oxide and halothane ranged from 0 to 2300 and 0 to 37 ppm, respectively, also failed to detect impairment in psychomotor performance.[23] These studies suggest there is no definitive cut-off above which psychomotor performance is depressed. Hence occupational limits vary among countries. The standards set by the regulating bodies in Canada, UK and Western Europe are often less stringent than the U.S. (Table 101-1).[3]

Radiation (also see Chapter 79)

The anesthesiologist is routinely exposed to both ionizing and nonionizing electromagnetic radiation. The former is primarily from x-rays and occasionally from radioactive isotopes that release gamma rays, and the latter is from lasers. Less common is contact with ionizing radiation from radioactive isotopes that release either alpha or beta particles. Ionizing radiation has enough energy to create both free radicals and ionized molecules in tissues by driving electrons completely out of their stable orbitals. If the radiation exposure is severe enough, tissues may be destroyed or chromosomal changes may cause malignant growth. Nonionizing radiation may excite electrons to move from the ground state to higher orbitals in molecules, but the electrons

Table 101-1 Occupational Exposure Standards (Time Weighted Average) in ppm in Different Countries with the Dates of Their Introduction

Country	Nitrous Oxide	Halothane	Enflurane	Isoflurane
UK (COSHH, 1996)	100	10	50	50
US (NIOSH, 1977)	25	2	2	2
Denmark (1988)	100	5	2	–

remain in the molecule. In this case, damage to tissues may result from the heat produced by the absorbed radiation.

Ionizing Radiation: X-rays

In the past, exposure to radiation occurred mostly in the operating room with the use of portable fluoroscopy and x-ray machines. Over the past several decades, however, anesthesiologists are increasingly exposed to radiation in remote locations. The advancement of endovascular surgery has led to an explosion of procedures performed in the radiology suite, significantly increasing exposure of anesthesia personnel to ionizing radiation. Because this type of radiation is undetectable with our normal senses, a basic understanding of its features will permit one to keep personal exposure to a minimum. Film badges, although not protective, provide a means of monitoring exposure.

Exposure is commonly reported in units of rem (roentgen equivalents man). A rem is essentially a measure of the biologic damage from radiation adjusted to apply to all tissues.[24] Estimates of radiation exposure from natural sources vary, depending on geographic location. The average in the United States ranges from 80 to 200 millirems (mrem) per year. Natural radiation comes primarily from cosmic rays (about 40 mrem at sea level, with an increase of 10 mrem/1000 ft), as well as from radioactive compounds found in soil, brick, and concrete. For most physicians, the additional radiation from occupational exposure is no greater than that from natural sources. Although the maximum yearly occupational exposure is mandated to be no more than 5 rem, radiology personnel rarely absorb more than 10% of this dose. Their greatest source of exposure is fluoroscopy. During pregnancy, radiograph personnel are advised to limit their exposure to a maximum of 500 mrem.[25]

Occupational exposure to radiation comes primarily from x-rays scattered by the patient and the surrounding equipment. One chest radiograph results in about 25 mrem of exposure to the patient; procedures requiring multiple films occasionally involve more than 1 rem. The amount of radiation generated during fluoroscopy depends on how long the x-ray beam is on. Just as light is reflected from surfaces, x-rays are reflected from the surfaces on which they impinge. This scattering accounts for most occupational exposure. Because the intensity of scattered radiation is inversely proportional to the square of the distance from the source, the best protection is physical separation. A distance of at least 3 feet from the patient is recommended. Six feet of air provides protection the equivalent of 9 inches of concrete or 2.5 mm of lead.[26] Although they are uncomfortable, aprons containing the equivalent of 0.25 to 0.5 mm of lead sheet are effective in blocking most scattered radiation and such devices are recommended to be worn whenever there is an exposure risk.[27] Uncovered areas, such as the lens of the eye, still bear the risk of injury. Intraoperative radiation measurements have shown that exposure is inversely related to the experience of the surgeon and the amount of radiation received by the anesthesiologist during orthopedic procedures is unmeasurable.[28]

Radiation physicists recommend adhering to the ALARA program: radiation exposure should be kept as low as reasonably achievable. The staff of departments of radiology have been extensively schooled in the safety of occupational exposure. Attention to recommended methods of protection will limit exposure to minimal levels.

Nonionizing Radiation: Lasers

Laser is an acronym for light amplification by stimulated emission of radiation. Lasers produce infrared, visible, or ultraviolet light. Although the radiation from lasers is nonionizing, it is potentially unsafe both because of its intensity and because of the matter released from tissues during treatment.

Lasers are used in many surgical specialties, including ophthalmology, plastic surgery, gynecology, neurosurgery, urology, head and neck surgery, and gastrointestinal surgery. A surgical laser produces intense focused electromagnetic radiation to cut or destroy tissues. The radiation is usually infrared or visible light and is created in a "laser medium" that is stimulated by high-intensity energy to release photons of identical wavelength (coherent or monochromatic light) from a laser chamber. The material in the medium (e.g., carbon dioxide, argon) is responsible for the wavelength produced by the laser. Of those in common clinical use, carbon dioxide and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers emit light in the far-infrared and near-infrared wavelengths, respectively; argon and tunable dye lasers produce visible light.[29]

Eye injuries are the greatest risk to personnel working near lasers (see also Chapter 77). Strict standards for protection have been developed on the basis of current understanding but are subject to periodic revision as more experience is gained with these instruments. Either direct exposure or reflected radiation may cause eye damage. Injuries include burns to the cornea and retina, destruction of the macula or optic nerve, and cataract formation. Protective eyewear is designed to filter out the radiation produced by a specific type of laser while still permitting vision. For example, clear plastic lenses block the far-infrared (10.6 μm) radiation from carbon dioxide lasers but provide no protection against the near-infrared (1060 nm) radiation emitted by Nd:YAG lasers. The type of protection provided by a given filter is marked on the frame of the goggles and should be checked before use. Filters that are scratched should not be used. Because certain filters block portions of the visible spectrum, it is prudent to confirm preoperatively that patient monitors can be seen and interpreted correctly with goggles in place. Protective eyewear is recommended for all personnel because reflected radiation can be as hazardous as direct radiation and the intensity is not diminished significantly in the distances traveled in the average operating room.[29]

Until recently, the plume—the vapor and cellular debris produced during laser surgery—was not considered to be harmful. Now, there is concern that the plume may present a significant risk. The median size of particles in plume samples obtained intraoperatively is 0.31 μm in diameter (range, 0.1 to 0.8 μm). Most surgical masks do not trap such small particles.[30] Even after filtration of particles greater than 0.5 μm in diameter, exhaust smoke from tissues treated with a carbon dioxide laser causes pulmonary lesions in laboratory animals. If all particles larger than 0.1 μm are scavenged, no lung damage occurs, thus pointing out the importance of scrupulous removal of the plume.[31] Under experimental conditions, viable bacteria have been recovered from the plume emanating from laser irradiation.[32] Intact DNA from human papillomavirus (HPV) has been detected in the vapor from both laser-treated plantar warts and genital condylomata.[33,34] Human immunodeficiency virus (HIV) proviral DNA has been found in laser smoke produced by vaporizing cultures

of HIV-positive cells. Although these experiments, which used tissue cultures, do not replicate the clinical situation, they stress the importance of strict attention to smoke removal.[35] With adequate evacuation and filtration using equipment specifically designed to scavenge such vapors, it is unlikely that operating room personnel will be contaminated by laser-dispersed HPV DNA.[34] However, a case report has documented the appearance of laryngeal papillomas in a laser surgeon who had previously treated several patients infected with anal condylomata without the benefit of a laser smoke evacuator. Tissue from the surgeon's laryngeal tumors contained HPV DNA types 6 and 11, the same viral types that are commonly harbored by anogenital condylomata. Though not conclusive, these findings suggest that the laryngeal papillomas may have been caused by inhaled virus particles.[36] Hence, it is prudent to scavenge all vaporized debris.

Infection

Transmission of Blood-Borne Pathogens

In March 1992, OSHA issued comprehensive, enforceable standards designed to minimize occupational exposure to blood-borne pathogens. These standards hold the employer responsible for the maintenance of an exposure control plan that protects all health care workers who have potential for contact with blood or blood products. Protective equipment, including gloves, gowns, and eye shields, must be supplied by the employer at no cost to the employee. The standard also provides for hand-washing facilities, proper receptacles for contaminated materials, methods for handling contaminated laundry, and management of waste, among many other things.[37] In the event of an exposure to infected blood or body fluid, health care workers should immediately contact their on-site Occupational Health Department and the National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) at 1-888-448-4911 for expert advice. This hotline can be accessed 24 hours a day. Updated guidelines for the management of occupational exposures to blood-borne pathogens are available on the Centers for Disease Control and Prevention (CDC) website at http://www.cdc.gov/mmwr.

Contaminated Percutaneous Injuries

Despite the adoption of standard precautions, contaminated needlestick injuries in health care workers persisted at an unacceptable rate. In 2000, the CDC estimated that more than 380,000 contaminated percutaneous injuries occur in hospital workers in the United States on an annual basis.[38] As a result, Congress revised the blood-borne pathogen standard to include the "Needlestick Safety and Prevention Act" (H.R. S178).[39,40] This act emphasizes the use of safety devices and needle-less systems, in addition to requiring that employers establish an exposure control plan with records documenting each incident. Since the act was signed into law in November 2000, as part of a comprehensive program to prevent the transmission of blood-borne pathogens in health care workers, the National Institute for Occupational Safety and Health has called for the elimination of needle devices when "safe and effective alternatives are available." This recommendation was based on accumulating evidence in the 1990s showing that devices with safety features could reduce needlestick injuries.[41]

The risk of contaminated percutaneous injury correlates with medical specialty and clinical experience.The Duke Health and Safety Surveillance System tracked blood and body fluid (BBF) exposures among 24,425 health care workers over a 4-year period ending in 2002. They reported an average rate of 3.9 percutaneous injuries (PCI) per 100 full-time employees (FTE), with higher rates among persons employed less than 4 years. Anesthesia house staff reported among the highest rates at 19.1 PCI per 100 FTE.[42]

Extended work hours were implicated as a major causative factor in a recent study of PCIs in interns. In this study 498 percutaneous injuries were reported from a total of 17,003 monthly surveys. Whereas lapse in concentration (64%) and fatigue (34%) were the two most commonly reported contributing factors, PCIs were significantly more frequent during extended work hours (OR 1.61) and night time (OR 2.04).[43]

Hepatitis

Viral hepatitis may result from infection with any of several different pathogens. Of greatest interest to the anesthesiologist are hepatitis B (HBV) and C (HCV), the major cause of non-A, non-B (NANB) hepatitis. In contrast to these pathogens, hepatitis A is normally transmitted by the fecal-oral route and almost never by contact with blood. It is usually self-limited and rarely produces significant long-term sequelae. The appearance of antibodies to the virus several weeks after exposure confirms the diagnosis. Treatment is limited to one dose of gamma globulin.[44]

Hepatitis B

In the 1970s the prevalence of HBV infection in health care workers was 10 times higher than that in the general population. In the 1980s, it was estimated that 200 to 300 health care workers would die annually from the effects of hepatitis B. Fortunately, the introduction of an effective vaccine for hepatitis B has dramatically decreased the incidence, morbidity, and mortality of the disease.[45] Infection may be documented serologically by the appearance of HBV surface antigen (HBsAg), HBV surface antibody (anti-HBs), or HBV core antibody (anti-HBe) in serum. Before routine vaccination, the development of covert seropositivity for hepatitis B during residency was common. In a multicenter study involving hospitals in both rural and metropolitan areas, the overall prevalence of serologic indicators for hepatitis B in anesthesiology residents who had received neither hepatitis vaccine nor hepatitis B immune globulin (HBIG) was 17.8% in 267 tested. Most seropositive residents were unaware of having been exposed to hepatitis. No correlation was found between the incidence and geographic location, but the incidence of seropositivity increased in parallel with clinical experience. Thirty percent of residents with more than 11 total years of experience, including their current residency and previous work in other specialties, were seropositive for HBV. Routine use of gloves and attention to obtaining detailed histories from patients did not appear to decrease the incidence of infection.[46]

An estimated 200,000 new cases of HBV infection occur each year. Of these cases, jaundice will develop in 50,000 and 10,000 will require hospitalization. As many as 12,000 to 20,000 annually become asymptomatic carriers of HBsAg, with the total

Table 101-2 Risk of Contracting Hepatitis from Percutaneous Injury Related to Degree of Contact and HBeAg Status of Source

HBeAg Status of Source	Degree of Contact	Risk (%)
HBsAg+/HBeAg+	Clinical hepatitis	22-31
	Seroconversion	37-62
HBsAg+/HBeAg–	Clinical hepatitis	1-6
	Seroconversion	23-37

From CDC: 2001 MMWR US Public Health Service Guidelines for the Management of Occupational Transmission of HBV, HCV, and HIV and Recommendations for Postexposure Prophylaxis. MMWR 50 (RR11):1-42, 2001.

number of carriers in the United States estimated to be nearly 800,000.[47] It is this group that most threatens nonimmunized anesthesiologists. While the incidence of seroconversion after parenteral inoculation with HBV can be as high as 40%, the rate conversion is proportional to the infectivity of the host and the magnitude of contact with the blood.[48] In addition to the degree of contact, the most recent CDC guidelines report that the risk of contraction of HBV from a percutaneous injury directly correlates the HbeAg status of the source (Table 101-2).[49]

Neither treatment at 60°C for 4 hours nor the use of disinfectants containing phenol or chlorine is sufficient to inactivate the hepatitis B particle with certainty. It remains viable on needles, environmental surfaces, and gloves for longer than 14 days.[50] Because gloves do not guarantee protection from accidental needlestick and because HBV is relatively resistant, accidental contact with live virus may occur in the course of patient management and also during cleaning of equipment.

Active immunization of seronegative health care workers with hepatitis B vaccine is imperative for prophylaxis against infection. The first vaccine was composed of inactivated particles of surface antigen prepared from the sera of HBsAg carriers. Ninety percent of recipients of the vaccine became seropositive and thus were protected against infection.[47] Despite the efficacy and the safety of the early vaccine, in the mid-1980s, substantial numbers of anesthesia personnel refused to be immunized.[46] Some were concerned that the vaccine for hepatitis B was prepared from sera obtained from patients at high risk for HIV. In the late 1980s, the vaccine was synthesized in yeast by the use of recombinant DNA.[51] The current OSHA standard on blood-borne pathogens mandates that employers make vaccination against HBV available at no cost to all employees who have a reasonable chance of exposure to the virus.[37]

Unvaccinated anesthesiologists who suspect HBV exposure with an HBsAg-positive source should be passively immunized with HBIG and begin a series of three injections of hepatitis B vaccine (Table 101-3).[45] The combination of HBIG and HBV vaccine prophylaxis is believed to be 85% to 90% effective, while either treatment alone is 70% to 75% effective.

The PEP protocol for previously vaccinated personnel is dependent upon the person's seroconversion or "responder"status. Nonresponders have mounted an inadequate response to vaccination with a measured serum HBsAg < 10 mIU/mL; while responders have adequate levels, HBsAg > 10 mIU/mL. Evidence of seroconversion in the health care worker eliminates the need for prophylaxis, while nonresponders are treated according to the protocol for unvaccinated workers. If responder status is unknown, the exposed person should be tested for HBs antibody, and if the level is unadequate, treated with HBIG and HBV vaccine (see Table 101-3).

Hepatitis C

HCV is the predominant source of hepatitis from transfusion. Chronic hepatitis develops in more than 85% of hepatitis C infections, with 20% of cases progressing to cirrhosis and 3% to hepatocellular carcinoma. It may also result in the development of a chronic carrier state.[52]

Important discoveries in the diagnosis of HCV were reported in 1989 when a segment of the genome of an NANB

Table 101-3 Recommended Post-exposure Prophylaxis for Exposure to Hepatitis B Virus

Vaccination and Antibody Response Status of Exposed Workers*	Treatment		
	Source HBsAg-Positive	Source HBsAg-Negative	Source Unknown or Not Available for Testing
Unvaccinated	HBIG† × 1 and initiate vaccine series	Initiate HBV vaccine series	Initiate HBV vaccine series
Previously vaccinated			
Known responder‡	No treatment	No treatment	No treatment
Known nonresponder§	HBIG × 1 and initiate revaccination or HBIG × 2‖	No treatment	If known high-risk source, treat as though source were HBsAg positive
Antibody response unknown	Test exposed person for anti-HBs 1. If adequate,‡ no treatment is necessary 2. If inadequate,§ administer HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBs 1. If adequate,‡ no treatment is necessary 2. If inadequate,§ administer vaccine booster and recheck titer in 1-2 mo

*Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.
†HBIG, 0.06 mL/kg intramuscularly.
‡A responder is a person with adequate levels of serum antibody to HBsAg (e.g., anti-HBs ≥10 mIU/mL).
§A nonresponder is a person with an inadequate response to vaccination (i.e., serum anti-HBs <10 mIU/mL).
‖The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second three-dose vaccine series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.
Anti-HBs, HBV surface antibody; HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.
From U.S. Public Health Service: Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. MMWR Recomm Rep 50(RR-11):1-42, 2001.

virus was isolated, cloned, and designated hepatitis C virus and when an assay for circulating anti-HCV antibodies was developed (see also Chapter 55).[53,54] Like HBV, HCV appears to be transmitted principally by infected blood. Studies using the anti-HCV assay have shown that HCV is responsible for up to 90% of transfusion-related NANB hepatitis.[55] With this assay, some have reported only a 1% to 2% incidence of antibody to HCV in health care workers (similar to that seen in volunteer donors), thus suggesting that HCV is not easily transmitted.[55,56] Reports based on the same assay indicate that transmission of HCV by contaminated needles occurs in less than 4% of these injuries.[57] More sensitive assays for HCV are currently under investigation. One of these assays, detection of HCV RNA by polymerase chain reaction, documented a 10% incidence of HCV infection in health care workers.[58] This method is limited to laboratory investigation, it is not licensed for clinical use, and its accuracy is widely variable.[49] At present, no effective postexposure treatment is available for HCV exposure. Instead, the recommendations for postexposure management are geared toward early recognition and intervention in chronic disease. Health care workers who are exposed to HCV should undergo baseline testing for anti-HCV and alanine aminotransferase activity as soon as possible after the injury, with follow-up testing 3 and 6 months after exposure.[49] Serum immune globulin prophylaxis is of little value because anti-HCV antibodies are not consistently found in production lots of immune globulin.[48]

Acquired Immunodeficiency Syndrome (see also Chapter 55)

Fortunately, HIV is a relatively fragile virus. To put it in perspective, the risk of becoming infected with a needle contaminated with HIV is approximately 0.3% as compared with 3% and 30% respectively for hepatitis C and hepatitis B. With proper attention to cleanliness and care in performing invasive procedures, the likelihood that the disease will develop in an anesthesiologist during the course of patient management is very low.

The human immunodeficiency viruses, HIV-1 and HIV-2, are retroviruses that attach to cells with $CD4^+$ surface antigen (predominantly helper T lymphocytes) and ultimately replicate by integrating virally produced DNA into the nucleus of the host cell.[59]

Initial infection with HIV follows within 2 to 10 weeks of inoculation. It is usually a self-limited, nonspecific, febrile viral syndrome lasting 1 or 2 weeks. An individual is considered to be both infected with HIV and infective if the results of both a serologic screening test, the enzyme-linked immunosorbent assay (ELISA), and a supplemental, more sensitive test, either Western blot or indirect fluorescent antibody, are positive. ELISA tests are relatively easy to perform in a clinical laboratory but may be subject to false-positive results. Supplemental tests are time consuming but necessary for confirmation. Results of the tests become positive within weeks of inoculation, but the median latency for the first opportunistic disease may be as long as 11 years.[59]

Epidemiology of AIDS

The apparent incidence, death rates, and other epidemiologic features of AIDS have been influenced over the years by the methods used to obtain these values. In 1993, the criteria for defining AIDS were expanded from those determined in 1987. Newer criteria included objective laboratory data and illnesses that were not previously used in confirming the diagnosis. With these changes, all HIV-infected patients with $CD4^+$ T-lymphocyte counts of less than 200/μL, as well as those with opportunistic infections, including pulmonary tuberculosis, recurrent pneumonia, and cervical cancer, were defined as having AIDS. The result was an apparent 200% increase in cases of the disease reported in early 1993.[60] At that time, nearly 900,000 persons in the United States were estimated to be infected with HIV. In spite of these methodologic changes, the proportional rate of the annual increase in cases of HIV continued to decline in the late 1990s.[61,62] Despite these overall declines, the incidence of AIDS increased in certain subpopulations, including black men and women and persons born after 1960.[61,62] The surveillance of AIDS in the United States continues to evolve. In January 2000, the surveillance case definition for HIV infection was revised again to include a single definition for adults, adolescents, and children older than 18 months. The revised criteria include positive results or reports of a detectable quantity of HIV nucleic acid or plasma HIV RNA.[63]

Regardless of these epidemiological statistics, health care workers will invariably care for unidentified carriers of the disease at some point during their career. The observation that more than 4% of 2300 patients treated in an urban emergency department had unrecognized HIV infection[64] underlines the need to treat all patients with universal precautions.

AIDS and Health Care Workers

Health care workers account for 5% of cases of AIDS in the United States. Although occupationally related infections have been reported, the vast majority of cases have been attributed to nonvocational contact.[65] By mid-2001, the CDC had documented 57 cases of occupationally acquired HIV infection in the United States.[66] Of these, 48 were due to percutaneous exposure. Of 1746 reported cases of AIDS in physicians, only 6 were directly linked to occupational exposure.

Because there is a latency period between infection with the virus and laboratory confirmation of the virus, health care workers may be unknowingly exposed if contact with the patient occurs during this time. It is reassuring that as late as 2002 there were no documented cases of HIV transmission to a U.S. health care worker from a patient who was in the window period for seroconversion.[67]

Injury from a needle is the most likely route of occupational related HIV infection for anesthesiologists. Of 493 anesthesia personnel surveyed in a multicenter study, 32% reported having been stuck with a contaminated needle at least once in the preceding 12 months. Of those, only half sought treatment.[68] The risk of infection is greater with hollow-bore than with solid needles and is further increased with large-bore needles and deep intramuscular injection.[59] In a study evaluating percutaneous injuries in anesthesia personnel, nearly 90% were from hollow-bore needles, were self-inflicted, most commonly involved the nondominant hand, and were deemed preventable. A significant number of the injuries occurred during disposal of contaminated needles.[69] Although the minimal dose of contaminated blood needed to infect humans is unknown,[70] the likelihood of development of antibodies to HIV is related to the volume of the inoculum and the concentration of viral particles.[45] Consequently, most

seroconversions have been associated with deep intramuscular injection of contaminated blood through large-bore needles.

The theoretical risk for occupational infection in anesthesiologists over a 30-year exposure period has been calculated to be 0.049% for HIV and 0.45% for HCV depending on the infectivity of the patient population.[71]

The CDC reports an overall risk of seroconversion in health care workers after a documented percutaneous exposure to HIV-infected body fluids of about 0.3%. Although seroconversion has been documented after nonintact skin has been in contact with infected blood, the incidence from this route is far lower than from needle injuries.[45]

The risk of transmission of HIV from health care workers to patients, with the exception of errors in technique, is extremely small. No infections were identified in more than 19,000 patients who had been treated by 57 infected health care workers, including 29 dentists, 12 surgeons, and 16 physicians in nonsurgical specialties. The only documented infections have been in 6 of 1100 patients treated by a dentist in Florida.[72]

With proper attention to routine methods of disinfection, sterilization, and housekeeping, the AIDS virus on instruments, surfaces, and laundry can be destroyed. At concentrations of 5 orders of magnitude greater than normally found clinically, HIV may survive for several days after being dried. This situation represents an extreme, however. Several hours of drying generally inactivates 90% to 99% of viable virus. The amount of HIV usually found on contaminated surgical instruments and equipment used in anesthetic management can be killed with "high-level disinfection." Such disinfection involves careful cleaning, followed by exposure either to one of the commercially available germicides or to a 1 : 10 to 1 : 100 dilution of sodium hypochlorite (household bleach). These methods annihilate bacteria and viruses but may not be effective against bacterial spores. If the instruments are to be sterilized, they should be thoroughly cleaned first. Contaminated hospital linen should not be washed or rinsed in the operating room or another patient care area; instead, it should be placed directly in sealed, water-impenetrable bags. It can safely be laundered by normal methods. Infective waste, including secretions, blood, and other body fluids, should be incinerated or autoclaved. Alternatively, large volumes of fluids may be discarded in a sanitary sewer.[73] Personal protection and protection of patients are afforded by standard precautions.

The best defense is a good offense, and there is no substitute for strict adherence to universal precautions. If in spite of these efforts you or a coworker are exposed to HIV, postexposure prophylaxis is available. Because most occupational exposures do not result in HIV transmission, the guidelines for postexposure prophylaxis weigh the relative risk of infection against the potential toxicity of treatment. The relative risk of infection depends on both the type and amount of blood exposure. The risk of transmission is increased by: (1) percutaneous exposure; (2) devices contaminated with visible blood; (3) hollow-bore needles; and (4) high viral titer (i.e., a patient late in the course of the disease). The three classes of antiretroviral agents recommended for prophylactic treatment include nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, and protease inhibitors. All are associated with a number of toxicities. A basic two-drug regimen is most often recommended, with an expanded three-drug regimen reserved for high-risk exposure (Table 101-4). The U.S. Public Health Service guidelines recommend that clinicians consider known drug resistance in their area or documented drug resistance in the source patient, or both, when selecting a prophylactic protocol.[49,74] The duration of treatment is 4 weeks.

Evaluation for postexposure prophylaxis and baseline HIV testing should be completed within hours of exposure. Prophylaxis should begin as soon as possible, because animal studies show that prophylaxis is less effective if begun more than 24 to

Table 101-4 Recommended HIV Post-exposure Prophylaxis (PEP) for Percutaneous Injuries

	Infection Status of Source				
Exposure Type	**HIV-Positive Class 1***	**HIV-Positive Class 2***	**Source of Unknown HIV Status†**	**Unknown Source‡**	**HIV Negative**
Less severe§	Recommend basic 2-drug PEP	Recommend expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP‖ for source with HIV risk factors¶	Generally, no PEP warranted; however, consider basic 2-drug PEP‖ in settings where exposure to HIV-infected persons is likely	No PEP warranted
More severe**	Recommend expanded 3-drug PEP	Recommend expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP‖ for source with HIV risk factors¶	Generally, no PEP warranted; however, consider basic 2-drug PEP‖ in settings where exposure to HIV-infected persons is likely	No PEP warranted

*HIV-positive, class 1—asymptomatic HIV infection or known low viral load (e.g., <1500 RNA copies/mL). HIV-positive, class 2— symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

†Source of unknown HIV status (e.g., deceased source person with no samples available for HIV testing).

‡Unknown source (e.g., a needle from a sharps disposal container).

§Less severe (e.g., solid needle and superficial injury).

‖The designation "consider PEP" indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.

¶If PEP is offered and taken and the source is later determined to be HIV negative, PEP should be discontinued.

**More severe (e.g., large-bore hollow needle, deep puncture, blood visible on device, or needle used in a patient's artery or vein).

From U.S. Public Health Service: Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. MMWR Recomm Rep 50(RR-11):1-42, 2001.

36 hours after exposure. Because the time to no benefit in humans is unclear, the U.S. Public Health Service advises beginning prophylaxis up to 1 week after exposure. Four weeks of treatment is recommended if tolerated. Regardless of whether postexposure prophylaxis is initiated, follow-up should include counseling and HIV antibody testing at 6 and 12 weeks and again at 6 months after exposure.[74]

There are insufficient data on the efficacy of PEP in health care workers, primarily because seroconversion from occupational exposure in health care workers is rare. A single retrospective study of HIV PEP with ZDV in health care professionals after percutaneous injury showed a risk reduction of 81% (95% CI, 45% to 94%).[75]

Tuberculosis

Tuberculosis, the leading cause of death in the early 20th century, appeared to be steadily decreasing in incidence with the advent of streptomycin in 1946, isoniazid in 1952, and rifampin in 1970. However, in 1985, the incidence in the United States began to climb significantly. Between then and 1990, reported cases increased by 16%, with a 10% increase in 1990 alone. This increase was the largest since national reporting began in 1953.[76] Most cases were from reactivation of old infection in immigrants or in patients whose immune system had been compromised, and many cases involved multidrug-resistant strains of *Mycobacterium tuberculosis*. Epidemic transmission between hospitalized patients and from patients to health care workers also occurred.[77,78] Common to most of these cases was a low index of suspicion for tuberculosis, which was occasionally not confirmed before postmortem examination.[79]

In response to the resurgence of TB in the United States in the mid 1980s, the CDC published new guidelines for the prevention of transmission of TB in 1990. These guidelines were revised throughout the decade; first in 1992, and again in 1994. The 1992 guidelines targeted the prevention of transmission of tuberculosis in the hospital setting, and the 1994 guidelines added recommendations for the management of multidrug-resistant tuberculosis.[80,81] The updated guidelines in the 1990s included a comprehensive program for the prevention of multidrug-resistant tuberculosis in health care facilities.[82] The program places the responsibility for managing prevention of tuberculosis on individual health care facilities rather than requiring identical standards for all hospitals. Paramount are identification and treatment of patients with tuberculosis; development of engineering controls, including isolation rooms, filters, and ventilation; use of personal protective equipment; and implementation of educational programs for health care workers.

Since the implementation of CDC guidelines in the 1990s, the number of new cases of tuberculosis has steadily declined such that the number of cases now being reported is the lowest since 1953, the first year of reporting in the United States.

In 2004, the overall incidence of tuberculosis in the United States was 4.9 cases per 100,000 population. This was down from 8/100,000 reported in 1996. Despite this general decline, there remains a marked geographical variation in incidence. The highest incidence is found in the District of Columbia (14.6/100,000), followed by California (8.3/100,000) and New York (7.1/100,000). Previous studies found the rate to be highest among immigrants (31/100,000), most of whom were from Asia and the Caribbean. The lowest rate of infection is documented in Wyoming (1/100,000), while the highest rates are found in coastal areas of the country.[82] The risk to health care workers correlates with the region in which they practice.

The goal of the CDC is to decrease the rate of TB infection in the United States to less than 1 per million by 2010.[82] Accordingly, the CDC continually updates the guidelines to address the changing face of the disease, in regard to both emerging drug resistance and epidemiology. Acknowledging the success of the earlier guidelines in decreasing the incidence of TB throughout the 1990s, the most recent revision, drafted in 2005, emphasizes the measures needed to prevent another resurgence of the disease. To this end, the scope of the current recommendations are significantly broadened to include health care "settings." The term *health care settings* in this document encompasses all facilities in which health care is delivered, including clinics, correctional facilities, and so on.[82]

Tuberculosis spreads by small (1- to 5-μm) airborne droplets released when a person with pulmonary or laryngeal TB speaks, coughs, sneezes, or sings. The probability of transmission is directly related to the concentration of infectious droplets (up to 600,000 droplets may be expelled with each cough) and the duration of exposure. Droplets can travel up to 3 feet from the source and remain viable and airborne for several days.[76] Not surprisingly, intubation is second only to bronchoscopy as a risk for skin test conversion in health care workers. In healthy persons who have inhaled contaminated droplets, the resulting systemic infection is usually limited by the immune system within 2-10 weeks. In these individuals, the lifetime risk of developing active tuberculosis after infection is approximately 10%. The likelihood is higher in patients with HIV who have a 7% to 10% risk of converting per year.[82]

All health care workers at high risk for exposure to *M. tuberculosis* should be skin-tested at the time of employment. Those whose test results are negative should be retested annually. A positive test in a person who has not tested positive in the past suggests a new infection. A two-step test is recommended in anyone who tests negative more than a year after TB exposure or previous tuberculin testing. This is because latent infection can produce false negative results from waning over time of the delayed-type hypersensitivity response. The first test will "boost" the response, leading to a positive result. The second test, performed 1 to 3 weeks after the first, increases the predictive value of the test.

The commonly used tuberculin skin test (purified protein derivative) provides a qualitative measure of TB infection. A newer quantitative test for TB is now available, but requires a blood sample. This test can identify infection with atypical organisms.[82]

A newly positive skin test requires exclusion of active disease by chest x-ray and clinical evaluation. If TB is diagnosed, treatment according to recommended guidelines should begin immediately. Disease reporting laws generally require notification of local or state health departments within 24 hours. If active disease is excluded, a 6- to 9-month course of drug therapy for latent TB infection should be considered (Table 101-5). Treatment should be managed by a specialist in the area, given the documented liver toxicity of these drug regimens. Risks and benefits must be weighed carefully to identify persons who may not be candidates for prophylactic treatment (i.e., those with a history of excessive alcohol consumption, hepatitis, ESLD). Baseline and

Table 101-5 Standard Drug Regimens for Treatment of Latent TB Infection (LTBI)

Drug	Duration (months)	Interval	Minimum No. of Standard Doses
Isoniazid	9*	Daily	270
		Twice weekly	76
Isoniazid	6	Daily	180
		Twice weekly	52
Rifampin	4	Daily	120
Rifampin/ Pyrazinamide	†	†	†

*Nine months of isoniazid is preferred, but 6 months of isoniazid and 4 months of rifampin are acceptable alternatives.
†Generally should not be offered for treatment of LTBI.
From American Thoracic Society/CDC: Targeted tuberculin testing and treatment of latent tuberculosis infection. MMWR Recomm Rep 49(RR-06):1, 2000; and Centers for Disease Control and Prevention: Guidelines for Preventing the Transmission of Mycobacterium tuberculosis in Health-Care Settings. Available at http://www.cdc.gov/mmwR/preview/mmwrhtml/rr5417a1.htm, 2005.

follow up monitoring of aminotransferases are required. Asymptomatic conversion does not preclude the anesthesiologist from working.

OSHA standards to prevent airborne contamination include both environmental controls and respiratory protection. Environmental controls include engineering measures to manage exhaust ventilation and general ventilation. These include air exchange rates, HEPA filtration (high-frequency particulate air filters), and UVGI (irradiation of the air in the upper portion of a room, or within ducts and recirculating units). Respiratory protection requires masks with the ability to filter particles < 1 μm in size with a filter efficiency of 95%, at inspiratory flow rates up to 50 L/min. If worn properly, even with strenuous activity in the work setting, less than 5% of infectious particles will escape filtration. These masks are typically referred to as N95 masks. Essential to proper mask function are tight mask fit so as not to allow entrained air with inspiration, and a clean filter. To this end the NOISH requires the oversight of mask fit and maintenance by the employer.

SARS

SARS is caused by infection with a single-stranded RNA coronavirus, whose origins lie in an animal strain found in rural China. The first known case of SARS was identified in that country in November of 2002, and spread rapidly to Hong Kong, Vietnam, and Singapore, before finally appearing in North America. In all, more than 8000 cases were reported by July 2003. The overall mortality rate is 9.6%, with peak rates of 26.3% to 28% in patients older than 70.[83]

SARS is a clinical diagnosis based on exposure and clinical criteria prior to confirmatory laboratory tests, which are nonspecific and not widely or rapidly available. Initial flulike symptoms include fever, chills, headache, and myalgia that are followed by nonproductive cough (with or without fever). Individuals are not contagious for 4 to 6 days after infection (range 2 to 10 days) when they become symptomatic, and are no longer infective by 10 days after resolution of fever. The virus is transmitted through contact with respiratory secretions or bodily secretions. As with TB, strict environmental regulations are required. Negative pressure rooms, or HEPA filtration with a minimal of 12 air exchanges per hour are needed to decontaminate the atmosphere. Respiratory precautions are the same as with TB. An N95 mask is required. A surgical mask placed over the N95 can trap larger droplets.[83]

Creutzfeldt-Jakob Disease

In February 2004, British investigators published a study in *The Lancet* titled "Possible transmission of variant Creutzfeldt-Jakob disease by blood transfusion."[84] This report came on the heels of the first documented case of bovine spongiform encephalopathy, or "mad cow" disease, in the United States. It is only one of a number of studies on transmissible spongiform encephalopathies (TSEs) that have populated the British literature since the mid-1990s when the mad cow epidemic erupted in the United Kingdom.[85-87]

Although transmission of Creutzfeldt-Jakob disease (CJD) is extremely rare, a number of factors combine to make the disease particularly threatening to health care personnel. TSEs result in rapidly progressive and devastating neurologic deterioration and are uniformly fatal. The time from infection to clinical symptoms is a matter of years, during which time the disease may be unknowingly transmitted to others. To date, there is no reliable method to screen blood from an infected patient. Moreover, prions are resistant to the conventional means used to decontaminate medical devices.

TSEs have been transmitted from animal to animal, animal to human, and human to human. Until the mid-1990s, transmission among humans was thought to be dependent on the transmission of neurologic tissue, either by transplantation or by contaminated surgical instruments. In 1995, mad cow disease was linked to a new variant of CJD in England.[88] The new variant (vCJD) is thought to be the result of transmission of bovine spongiform encephalopathy from cattle to humans by the ingestion of infected beef products. Unlike CJD, vCJD is found in lymphoreticular tissue and can theoretically be transmitted by the transfusion of blood or blood products. This section focuses on the possibility of blood-borne transmission of this devastating disease.

Transmission

Pruisner coined the term prion in 1982 to describe the proteinaceous infectious agent responsible for the transmission of scrapie in sheep.[89] The equivalent disease in humans, CJD, was first described in the 1920s as a rapidly progressive dementia followed by ataxia and myoclonus.[90] Subsequent epidemiologic studies have shown that CJD can be sporadic, inherited, or acquired. Kuru is the most exotic example of the acquired form because of its transmission by ritualistic cannibalism among the natives of New Guinea.[90] The first iatrogenic transmission of CJD was documented in 1974. It was the first of three cases of CJD to result from corneal transplantation. Since then, over 300 cases of iatrogenic transmission have been documented in the literature. Most are the result of cadaveric pituitary–derived growth hormone used to treat children of short stature (162 cases). However, transmission by dura mater grafts (136 cases), human gonadotropin

(5 cases), stereotactic electrodes (2 cases), and neurosurgical instruments (4 cases) has been reported.[91]

A number of studies have demonstrated hematologic transmission of TSEs from animal to animal, and several studies have demonstrated transmission of CJD from humans to animals in the laboratory.[86] Whereas CJD is confined to neurologic tissue, the new variant is found in lymphatic tissue, including the tonsils, spleen, thymus, lymph nodes, and appendix.[85,92-94] vCJD resides in lymphatic tissue early in the incubation phase of the disease when the patient is asymptomatic.[85,95,96]

Despite reports of possible transmission of vCJD by blood products, to date there has been no definitive proof of transfusion-related transmission in humans. Even the most recent epidemiologic data are not conclusive.[84] In fact, reassuring evidence suggests that the disease is not transmitted by blood. Such evidence includes four epidemiologic case-control studies in the United States, Japan, and the United Kingdom in which it was found that the percentage of patients with CJD who had received blood transfusions was no higher than the percentage in matched controls.[86] Another study conducted by the CDC and the Red Cross monitored 178 recipients of transfusions from patients in whom CJD later developed; in no recipient did clinical disease develop up to 24 years after transfusion (although many died of other causes early on).[97] Additionally, no increase in the incidence of CJD has been reported in patients whose disease requires numerous transfusions of whole blood or blood products.[86,97]

In 2003, tonsillar biopsy was identified as a way to reliably diagnose vCJD antemortem.[92] The presence of vCJD in tonsillar tissue potentially puts anesthesia caregivers and ear, nose, and throat surgeons at increased risk of occupational exposure when performing routine tonsillectomies. Because of the prolonged incubation period during which infected patients remain asymptomatic, all adenotonsillectomies in the United Kingdom are performed with single-use disposable surgical and anesthesia equipment.[98]

Routine decontamination protocols do not inactivate prions. The proteins are resistant to proteases, and autoclaving alone is not effective. Attempts to clean instruments before autoclaving can result in further fixation of the protein to the instruments. Once the protein is allowed to dry, it becomes even more resistant to decontamination methods. As a result, the World Health Organization has developed guidelines for infection control when caring for patients with suspected CJD:

1. Disposable instruments should be used whenever possible.
2. Reusable surgical instruments should be kept moist until autoclaving.
3. Disinfection with 1N sodium hydroxide is to be used in combination with autoclaving at 134°C.[99]

By spring 2003, 135 cases of vCJD had been verified in the United Kingdom and 1 in the United States.[91] Because of the lack of an effective screen to identify vCJD in asymptomatic persons, the blood donor policy in the United States currently excludes donations from anyone who lived in or visited the United Kingdom for a cumulative period of more than 6 months between 1980 and 1996.[100] The United Kingdom currently imports all plasma for transfusion. All whole blood from U.K. donors is filtered to eliminate white blood cells.[101]

OSHA Standards

Universal Precautions

In the late 1980s, the CDC prepared a series of guidelines for health care workers who have contact with patients or body fluids.[73,102] They were subsequently incorporated into the OSHA standard on occupational exposure to blood-borne pathogens.[37] The recommendations can best be summarized by stating that because no symptoms or signs conclusively reflect the presence of blood-borne pathogens, all patients, blood, and body fluids should be considered potentially infective. The same safeguards should be used for all; hence, the guidelines were given the title "universal precautions."

In 1996, updated guidelines addressed isolation precautions in hospitals including transport and placement of infected patients, design and use of protective gear for medical personnel, equipment used in patient care, linen, laundry, and cleaning of spaces inhabited by infected patients.[103]

Standard Precautions

The guideline is composed of two tiers, standard precautions and transmission-based precautions. Standard precautions merge the principles of universal precautions and body substance isolation to reduce the risk of transmission of pathogens from moist body substances through the use of gloves. Standard precautions should be used during all encounters with patients. Transmission-based precautions are necessary in the management of patients known to be or suspected of being infected or colonized with epidemiologically important pathogens. The isolation methods used depend on the pathogen involved.[103] The following are taken almost verbatim from CDC publications.[37,102,103] Barrier precautions appropriate for the procedure being performed, including gloves, gowns, masks, and eye shields, should be worn when the potential for contact with blood or body fluids is present. Precautions apply to blood, all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; nonintact skin; and mucous membranes. Strict attention should be given to hand washing after gloves are removed, even if there has been no direct contact with blood or fluid. Needles should not be recapped, bent, or broken by hand but instead should be discarded in a puncture-resistant container. Resuscitation equipment that prevents the need for mouth-to-mouth contact should be available. All specimens sent to laboratories should be handled as though they are infected.

Transmission-Based Precautions

Transmission-based precautions should be followed when patients are known to be or are suspected of being infected with highly transmissible or epidemiologically important pathogens. These precautions are based on the properties of specific pathogens and are to be used in addition to standard precautions.

1. Airborne precautions are to be used when transmission of small particles or droplets (< 5 μm) is likely. Because these particles can be carried for long distances, special filtration and air handling are necessary. Diseases in this category include measles, varicella, and tuberculosis.

2. Droplet precautions apply to diseases transmitted by large particles (> 5 μm). Because of their size and because the droplets do not remain suspended in air, transmission is limited to short distances; a meter or less is the norm. Examples are invasive *Haemophilus influenzae* type b meningitis and epiglottitis, *Mycoplasma pneumoniae* pneumonia, streptococcal pharyngitis, and rubella.
3. Contact precautions apply to direct skin-to-skin contact, including hands. Indirect contact may also occur if surfaces in an infected patient's environment are contaminated. Included are colonies of antibiotic-resistant organisms, hepatitis A virus, herpes simplex virus, viral conjunctivitis, and major abscesses.[103]

Latex Allergy

Since 1992, health care workers who come in contact with infectious materials have been required to use barrier precautions, including protective gloves.[37] Coincidental with this mandate has been a progressively increasing number of allergic reactions to latex-containing products, especially in health care workers. Responses may be limited to irritant contact dermatitis, a delayed type IV reaction mediated by T cells, or they may be manifested by more serious IgE-mediated type I reactions. The latter include contact urticaria, rhinitis, conjunctivitis, asthma, and occasionally, full-blown anaphylactic shock.[104]

The prevalence appears to be more frequent in persons who have regular contact with latex-containing products. One report indicated that nearly 16% of the staff of a single anesthesia department had positive skin test results to latex, although of those tested, respiratory changes during work hours developed in far fewer.[105] Allergic responses to latex are also associated with a history of atopy and with allergies to certain foods such as avocado, potato, banana, tomato, chestnuts, kiwi fruit, and papaya. In some individuals, such a severe sensitivity developed that they are no longer able to work in areas containing airborne latex particles or to eat food that has come in contact with latex.

NIOSH has developed recommendations for the prevention of latex allergies as they currently exist. These recommendations include protection of workers from undue exposure to latex, hand washing after removing gloves, and educational programs for hospital workers.[106] Modifications of manufacturing processes for latex products, more accurate methods to assess allergies to latex, and perhaps the development of substitutes are additional goals of the recommendations. Up-to-date information concerning this dynamic area of interest is available on several Internet web sites.

Fatigue

Long and grueling work hours are a time-honored tradition in medical practice, especially for physicians in training. Although medical culture has historically considered overwork a virtue, this section will address the cultural evolution set into motion more than 20 years ago in response to the case of Libby Zion, an 18-year-old college freshman.[107,108] In March 1984, Libby Zion was taken to New York Hospital by her parents with a high fever, dehydration, and chills. She was admitted to the general medicine ward for observation. She was never examined by an attending physician; instead, she was cared for by an intern and a junior resident, both of whom had been up for 18 hours at the time of her admission. Throughout the night she became increasingly delirious and was placed in physical restraints without an interim examination by a physician. By morning, she was dead.

Over time Libby's death has been attributed to the inexperience and fatigue of resident physicians who lacked the direct supervision of an attending physician. The Bell Commission appointed to investigate the case cited inadequate supervision as the root cause of the outcome; a grand jury investigating the incident blamed too great a work assignment. At the time, neither body cited lack of sleep or long work hours as the primary cause of the incident. However, since Libby's death, addressing extended work hours and sleep deprivation have become central to the effort of the medical community to reduce medical errors.[109]

Fatigue and Clinical Performance

Well-defined periods of vulnerability to sleep have been identified in humans. The major peak occurs between 2 and 7 AM, and a smaller peak occurs in the midafternoon.[110] These peaks appear to be enhanced by irregular work schedules and sleep disruption, and they may also contribute to diurnal variation in the frequency of mishaps. For example, single-occupant motor vehicle accidents occur with alarming regularity in the early morning. Their timing is attributed in part to this cycle. Similar relationships have been observed in the timing of catastrophic industrial accidents. The nuclear reactor accidents at Three Mile Island, Chernobyl, and two other sites in the United States all began between 1 and 5 AM. Human error was a significant factor in each mishap. Critical errors in judgment involving the Challenger space shuttle accident were made in the early morning hours by personnel working irregular shifts. Again, human error was a contributing element. Although none of these accidents can be conclusively attributed to sleep-related processes, all involved a lack of proper response by well-trained personnel working to the best of their abilities at the time of the accident.[111] On the basis of these observations, the Committee on Catastrophes, Sleep, and Public Policy of the Association of Professional Sleep Societies has made the following recommendations:

1. Management should be made aware that performance errors are more common between 1 and 8 am.
2. Programs should be developed to identify signs of sleep-related error.
3. Because inadequate sleep or irregular sleep patterns enhance the tendency for error, work hours should be limited to permit adequate sleep.[111]

Despite mounting evidence regarding the detrimental effects of sleep deprivation on work performance, altered patterns of sleep continue to be a way of life for anesthesiologists.[112] Numerous studies have attempted to quantify the consequences of sleep deprivation on the practice of medicine. Many of these early studies measure clinical surrogates such as cognitive function, dexterity, and vigilance, whereas others focus on the effect of sleep deprivation and fatigue on physician well-being. Few have attempted to measure a direct effect on patient care.[113-115]

The chronic fatigue of being on call every third or fourth night has been shown to have a negative impact on the cognitive

function of university house staff on standardized tests.[116] In the practice of anesthesia, sleep deprivation may have subtle effects on vigilance in the operating room and may contribute to critical incidents.[117] However, when patient simulation was used to study the effects of sleep deprivation on the psychomotor and clinical performance of anesthesia residents, psychomotor performance and mood were found to suffer, whereas clinical performance did not.[118] This lack of correlation between psychomotor and cognitive testing and clinical performance has been noted in the surgical literature also.[119,120]

Although historically it has been difficult to link clinical performance with a documented decrease in cognitive and psychomotor function, there is accumulating evidence that fatigue does affect clinical outcome. For instance, resident physicians were found to make fewer medication errors after their work hours were adjusted to minimize sleep deprivation and fatigue. This study in a university-affiliated Veterans Affairs Medical Center also demonstrated a decrease in the length of patient stay and the number of laboratory tests ordered.[121] In another survey of 225 physicians, 48.8% blamed tiredness and 19.5% blamed the pressure of overwork to be a significant cause of clinical mistakes and suboptimal patient care.[122]

Regulation of Resident Work Hours

The sensationalism of the Libby Zion case has significantly influenced how medicine will be practiced in the future. The facts of the case suggest that insufficient attending physician supervision and excessive patient workload were major contributors to the adverse outcome. Subsequent reviews cited resident fatigue and sleep deprivation as contributing factors. As a result, in 1989 the state of New York limited resident work hours.[123] In July 2003, the Accreditation Council for Graduate Medical Education (ACGME) adopted similar resident work hour limitations for all accredited residency programs. The restrictions on resident duty hours for each of the ACGME-accredited specialties can be found at ftp://www.acgme.org/new/dutyhrequirem.pdf.

Although limitation of physician work hours is here to stay, some in the profession worry that patient care will suffer as a result. They fear that "shift work mentality," combined with increased transfer of patient care, will result in decreased professionalism and continuity of care. Although early studies suggest that patient care suffers from a discontinuity of care, recent studies suggest that limiting work hours may in fact decrease medical errors. In 2004 companion papers in the New England Journal of Medicine documented both fewer attentional failures and medical errors when intern work hours were reduced from 80 to 60 hours per week.[124,125] In an effort to determine the effect of work hour regulations on clinical outcome, two large-scale nationwide multicenter studies measured patient mortality within 30 days of hospital admission both two years before and after the rules went into effect in July of 2003.[126,127] They compared death rates between hospitals with a large number of residents (thought to be most affected by the rule change) to those with few residents. While they found no difference in mortality after the regulations went into effect among millions of Medicare recipients in both more and less teaching-intensive hospitals, a smaller scale VA study did suggest an improvement in patient outcome in a subset of medical patients. So while it is clear that sleep deprivation, overwork, and fatigue contribute to medical errors, patient outcome will depend on a delicate balance between discontinuity of care and the effects of fatigue on medical judgment.[128-131]

Physician Well-Being

Sleep deprivation has been shown to have an impact on physician well-being. The most obvious consequence of sleep deprivation on physician well-being is the well documented increased frequency of automobile accidents in post-call house staff.[132-134] More recent data indicate that percutaneous injury correlates with nighttime shifts and duration of time at work. Less obvious is the effect of sleep deprivation on physician mood. Interns in the United States report an increased incidence of fatigue and depression after a night on call,[135] and their incidence of major depression has been shown to be higher than that expected in an equivalent age group in the general population.[136] A study of house officers showed that sleep deprivation resulted in an adverse effect on mood, as well as cognitive testing of vigilance and reaction time.[137] Overwork played a significant role in the depressive illness suffered by 28% of preregistration house officers in Great Britain.[122,138]

Although significant attention has been placed on eliminating fatigue in resident physicians, inadequate supervision has yet to be vigorously addressed, and it continues to be a source of stress among physicians in training. When asked to describe a particularly stressful incident in their preregistration year, the number one stressor identified by house officers in the United Kingdom was the lack of supervision by superiors in situations where they were forced to take responsibility beyond their experience. Not surprisingly, these events occurred mostly at night. Only a small minority of house officers attributed stressful situations to fatigue alone, but fatigue together with work intensity combined to make "overwork" a significant factor.[139]

Additional Stressors

Stress in the workplace continues beyond the residency years. In a study conducted in Great Britain, the most significant source of stress for those beyond their training years was lack of control of circumstances at work.[140] Specific causes included professional relationships (especially with surgeons), work overload, threats of litigation, peer review, and increasing administrative responsibilities. It is not surprising, then, that a subsequent survey of retired members of the ASA identified similar stressors. Difficult anesthetic cases, the threat of professional liability, and the stress of night call were all considered to be significant causes of stress.[140]

Perhaps more than any other medical specialty, the practice of anesthesia requires uninterrupted vigilance with immediate reaction to life-threatening situations. An inappropriate response can prove to be acutely fatal to an otherwise healthy patient. It is reasonable, then, to ask whether the day-to-day practice of anesthesia produces episodes of significant physiologic stress in the practitioner. Studies to date do not support this hypothesis. In an investigation of 38 anesthesiologists over the course of 203 anesthetics, clinically significant changes in physiologic stress as measured by changes in heart rate, blood pressure, and cortisol levels could not be documented.[141]

Management of stress is rarely addressed in medical school or in continuing medical education seminars for anesthesiologists, but it should be. Stress is a universal phenomenon to which no one is immune. Vital to our interactions with others is the ability to recognize stressed behavior, not only in them but also in ourselves. Healthy means of coping with stress include an ability to communicate, appropriate assertiveness, interactive management of conflicts, adequate time with family, and time for recreational pastimes totally unrelated to professional activities.[142]

Chemical Dependence

Drug addiction has long been an occupational hazard in the practice of medicine (see also Chapters 27 and 30). In the late 19th century, Merck and Company began producing cocaine for commercial use. It was initially touted by Freud and others as a cure for alcoholism and morphine addiction, as well as an agent to increase endurance.[143] In 1884, Sir William Halstead successfully injected cocaine into a sensory nerve trunk to create the first regional anesthetic, a discovery that not only revolutionized the practice of surgery but also marked the beginning of his lifelong struggle with drug addiction.[144]

William Halstead attended Yale University and was captain of the football team before enrolling in the Columbia University College of Physicians and Surgeons. After graduation in 1877, he studied medicine abroad before returning to the United States, where he eventually became one of the founding members of the Johns Hopkins University School of Medicine. His contributions to modern-day surgery are legendary and include the introduction of antiseptic technique, surgical gloves, and vascular clamps into surgical practice. He performed the first total mastectomy for cancer and described the first hernia repair. Throughout his career, Halstead was addicted to morphine. At the peak of his career he is said to have used in excess of 180 mg/day, and despite numerous attempts to quit, he was believed to be addicted until the time of his death in 1922. By all accounts, Halstead became addicted to morphine in his effort to cure his addiction to cocaine.[144]

William Halstead's addiction to cocaine and morphine are mentioned here in order to illustrate the following characteristics that are often associated with drug addiction in anesthesiologists today. He was academically accomplished, his addiction began early in his career with an element of curiosity, he was a polydrug abuser, and he had easy access to potent drugs. His colleagues at work were the last to know.

The abuse potential of the psychotropic drugs used in the practice of anesthesia is well documented. Potent psychoactive drugs are readily available and familiar to anesthesiologists in the course of their daily practice. Even the inhaled drugs nitrous oxide and vapor anesthetics pose an abuse potential to health care workers with easy access to them. Zacny and Galinkin reported a case of an Air Force pharmacist court-marshaled during the 1991 Gulf War for abusing isoflurane.[145] More recently a fatality from sevoflurane abuse has been reported.[146] No doubt, familiarity and availability contribute to the increase in propofol abuse by anesthesia residents over the last 10 years.[147,148] Although abuse of ketamine by anesthesiologists is not new, its recent increased recreational use at rave parties may contribute to increased occupational abuse in the future.[145]

Addiction

A growing body of scientific evidence indicates that addiction is a chronic, relapsing disease resulting from the long-term effects of drugs on the brain.[149] Acceptance of this fact is crucial for those dealing with chemically dependent physicians. This section provides information about chemical dependence in anesthesiologists and the steps required to help a colleague or yourself.

Prevalence

Numerous studies have attempted to estimate the prevalence of substance abuse among physicians,[150,151] interns and residents,[152-154] and medical students.[155] A national survey published in 1992 reported a 2.1% annual and a 7.9% lifetime prevalence of substance abuse among physicians. This rate was substantially lower than the corresponding rate of 16% reported for the general population and thus disproved the myth that physicians are more likely to become substance-addicted than the population in general.[153] Although physicians are less likely to use cigarettes and illicit substances such as marijuana, cocaine, and heroin, they are five times as likely to take sedatives and minor tranquilizers without medical supervision.[156] This tendency to self-prescribe begins in medical school with tranquilizers and continues in residency with benzodiazepines and prescription opioids. Alcohol abuse is of particular concern in physicians. In 1991, over 87% of medical students reported alcohol use within "the last month" versus 83% of matched controls.[155] Although heavy alcohol use is less in young physicians than in matched controls, the incidence increases with age in the physician population and decreases with age in the general population. By the mid-50s, heavy use of alcohol in physicians surpasses that of the general population.[157]

Three retrospective surveys suggest that the prevalence of drug abuse in anesthesiologists ranges from 1% to 2%.[158-160] These published percentages rely on the recall of directors of U.S. anesthesiology programs and the honesty of individual anesthesiologists responding to questionnaires. Nevertheless, the estimates from these surveys are remarkably similar, and the prevalence is in line with published studies of anesthesia trainees in Australia and New Zealand.[161] In 1993 it was estimated that approximately 2% of U.S. anesthesia residents would become addicted to a substance during their residency.[162]

When comparing the published incidence of substance abuse in physicians as a whole with that of anesthesiologists, it is apparent that the overall incidence of abuse is not consistently higher in the practice of anesthesia than in other specialties.[163] However, it is notable that anesthesiologists are consistently overrepresented in drug treatment centers.[164] Although anesthesiologists account for 12% to 14% of physicians treated in three well-known treatment programs, they constitute only 4% of physicians in the United States.[165-167] This 3:1 overrepresentation of anesthesiologists in drug treatment centers is relatively consistent across state lines and over time. For example, data from the California Physicians Diversion Program have anesthesiologists accounting for 17% of physicians in treatment and 5% of physicians in practice.[168] Although these statistics imply that the incidence of chemical dependence is significantly greater among anesthesiologists, these data may instead be a reflection of the potency of the drugs abused, the ability of anesthesiologists to

recognize the disease in their colleagues, and the diligence within the specialty to refer colleagues for treatment. Additionally, the referral pattern mandated by the individual state medical boards and their associated legal ramifications may influence the percentages of impaired physicians enrolled in treatment.

The time until detection of abuse is inversely proportional to the potency of the drug abused. Much of the overrepresentation of anesthesiologists in treatment centers may reflect their preference for and access to potent narcotics. For instance, abuse of sufentanil is typically detected within the first 1 to 6 months while the abuse of fentanyl is not detected until 6 to 12 months. In contrast, alcohol abuse may not be detected for more than 20 years.[169] In the intitial published reports from state-run impaired physician treatment programs that began in the 1980s,[167-169,171] all of the anesthesiologists were chemically dependent, whereas 10% of the remaining physicians had other forms of impairment, such as depression.[165,166,168] Nearly 50% of anesthesiologists were younger than 35 years, and a third were residents. Half used both drugs and alcohol, 40% used drugs alone, and a minority used only alcohol. Fentanyl was the most commonly abused narcotic, followed by sufentanil, meperidine, morphine, and oral drugs.

The ASA Task Force on Chemical Dependence[170] has identified the following characteristics of addicted anesthesiologists:

- 50% are younger than 35 years
- Residents are overrepresented
- Many are members of AOA
- 76-90% abuse opioids as their drug of choice
- 33-50% are polydrug abusers
- 33% have a family history of addictive disease
- 65% are associated with academic departments

Causes

Stress

Occupational stressors first surface in residency where long hours preclude much time for relaxation and certain patients may evoke negative emotions. The death of a patient under one's care may cause a sense of professional inadequacy to surface for the first time.[171] Without doubt, the practice of medicine can be stressful, and it is tempting to assume that stress is a major cause of drug addiction among physicians. Contrary to common belief, however, stress is not necessarily the precipitating factor in a physician's addiction to drugs. Preexisting personality traits, a family history of substance abuse, and previous recreational drug use have been associated with substance abuse among physicians.[157,163]

Availability

Anesthesiologists are unique among physicians in that they administer drugs directly rather than order their administration by others. Drugs are immediately available, which is perhaps the most important cause of addiction in the specialty. One report indicated that 85% of anesthesiology residents treated in one large program stated that having drugs within reach influenced their career choice.[165] Over the last 15 years anesthesia departments have introduced measures to closely monitor the use of controlled substances by staff and resident physicians.

It is discouraging that an increased level of accountability of controlled substances in U.S. residency programs has thus far not correlated with a decreased incidence of drug dependence.[172] In a 2002 survey of 123 academic anesthesia departments, measures were introduced to regulate the use of controlled substances including changes in drug dispensing, disposing, and accountability. The study covered a span of 7 years, during which time drug dispensing was shifted from nurses to satellite pharmacies (42%) or dispensing machines (31%). Opened, but unused drugs were either returned to the pharmacy (52%) or wasted in front of a witness (41%), and the amount of drug administered was compared with the amount dispensed (80%). Despite these changes in drug dispensing and accountability, the incidence of drug abuse did not decrease.[173]

In the future the direct monitoring of atypical drug transactions from automated dispensing systems may more accurately identify drug diversion.[174,175]Additionally, the use of linkage of anesthesia information management systems with medication dispensing systems has been proposed as a means to accurately detect medication discrepancies.[176]

Drug Potency

Abuse of drugs by physicians is much more common than addiction. Patterns of abuse differ by specialty and are influenced by familiarity and availability. Psychiatrists most frequently abuse oral benzodiazepines, whereas anesthesiologists preferentially abuse potent narcotics. Casual abuse of alcohol obviously does not always lead to addiction, and although exceedingly risky, neither does abuse of morphine, meperidine, or codeine.[150] In contrast, the addictive potential of fentanyl and other potent opioids is so great that anyone who experiments with these drugs is at enormous risk of becoming chemically dependent.[165] Rapidly developing tolerance stimulates the ever-increasing doses needed to attain the desired sensation. The use of 50 to 100 mL of fentanyl or 10 to 20 mL of sufentanil per day is common in an addicted physician. These doses are easily reached within a few months for fentanyl and a few weeks for sufentanil. The potency of these drugs is reflected in associated fatality statistics. Between 1990 and 1997, 18% of identified substance abusers in academic departments either died or required resuscitation before substance abuse was suspected.[161] Fentanyl was most often the drug of choice.

Other Factors

Chemical dependence is a complex disease influenced by multiple factors. To identify availability and potency as the only significant factors in chemical dependence in anesthesiologists risks overlooking other significant factors such as previous use of drugs and a family history of drug abuse. A history of experimental use of drugs is known to increase the risk of future addiction.[150] Genetic predisposition may contribute to the progression from abuse to addiction.

Intervention

Drug addiction in anesthesia can result in the loss of one's job, profession, and family. Sadly, loss of life may be the first indication that there is a problem. Numerous studies have examined the mortality risk of physicians in general[177,178] and anesthesiologists specifically[179-181] versus that of the general population. This research has shown that the death rate from all causes is lower among physicians than the public in general. This difference is attributed to lifestyle awareness among physicians that results in

decreased rates of destructive behavior such as smoking. The higher socioeconomic status of physicians and greater access to health care may also contribute to this advantage. Although the mortality risk for anesthesiologists is no higher than that for other medical specialties, their risk of drug-related death and suicide is alarmingly high. Studies have shown a twofold increase in suicide among U.S. white male anesthesiologists[179] and British (mostly female) anaesthetists when compared with appropriate population controls.[178] A recent study in the United States reported the relative risk of suicide in anesthesiologists to be 1.45 when compared to internists. The relative risk of a drug-related death was even higher at 2.79.[181] All these studies identify drug-related death as a significant occupational hazard in the practice of anesthesia.

Management

Management of physicians who are chemically dependent includes identification, intervention, referral for treatment, and help with reentry. Each department should have an established mechanism in place to deal with impaired physicians.

Identification

Identification of a chemically dependent physician does not usually occur until the disease is in its late phases, when performance at work becomes significantly impaired. Although none of its signs and symptoms are diagnostic, an awareness of the usual sequence of events may help identify an ill colleague in the earlier stages of the disease (Table 101-6).

Normally, withdrawal from outside interests is the first sign. Examples include giving up athletics, community activities, church, and getting together with friends. Next comes increased turmoil at home. Domestic arguments, sexual problems, and lack of interest in family matters are common. Third is the appearance of frequent unexplained illnesses, personality changes, multiple jobs, and frequent moves between cities. This progression, which may take years to become apparent, is common with addictions that develop slowly.

The last activity to be affected is usually job performance. Page operators and nurses may be the first to recognize behavioral changes. Record keeping may become sloppy. Excessive use of certain drugs becomes apparent, perhaps accompanied by an unusual compulsion to explain the need for these drugs in patient management. Colleagues may note similar changes. Direct observation of self-administration confirms the diagnosis, but it is not common.[182]

Impaired physicians disclaim their illness by using superficially logical reasons to explain their bizarre patterns of behavior. Colleagues, too, use denial. Typically, they would rather accept these explanations than consider that a friend is a drug addict. For these reasons, the diagnosis is not usually made until its manifestations are clear.

Table 101-6 Signs and Symptoms of Chemical Dependence

At Work	At Home
Unusual changes in behavior (e.g., wide mood swings, depression, anger, euphoria)	Withdrawal from family, friends, and leisure activities
Gossip by others	Changes in behavior (e.g., wide mood swings)
Progressive increase in apparent narcotic use for anesthetic management	Fights and arguments at home
Careless charting	Frequent unexplained illness (common in alcoholism)
Preference for working alone	Gambling
Frequent requests for bathroom breaks	Extramarital affairs
Unusual willingness to provide relief for others	Legal problems (e.g., arrests for driving while intoxicated)
Inappropriate willingness to take calls	Decrease in sexual drive
Often appears in the hospital when not on call	Drugs and syringes found in the home
Frequent unexplained absences	Seclusive behavior at home
Difficult to find when on call	Odor of alcohol on breath
Excessive postoperative pain in patients cared for by an individual	Weight loss
Commonly wears long-sleeved gowns (to prevent chills often seen in early withdrawal and to hide needle tracks)	Pinpoint pupils (in persons addicted to opioids)
Pinpoint pupils	Symptoms of withdrawal (e.g., diaphoresis, tremulousness)
Weight loss	Denial of drug or alcohol use if confronted
Found comatose	
Found dead	
Witnessed self-administration (the only pathognomonic sign)	

Intervention

The appropriate initial response to the discovery of chemical dependence in a colleague is to seek help. A call to a person experienced in managing chemically dependent physicians initiates the next steps.[168,183] Most state medical societies in the United States have committees on impaired physicians to act as advocates for sick physicians. Advocacy continues as long as the physician cooperates with the committee's recommendations. These committees serve as a buffer between the physician and the medical board or licensing agency. They also provide advisers to aid in confirmation of the diagnosis and to intervene and refer impaired physicians to appropriate treatment centers. Although laws vary, the committees are usually required to notify the board of a physician's recalcitrance at any stage of treatment. In many states, the board does not censure impaired physicians who comply with the committee's recommendations.

Intervention is the process of demonstrating to chemically dependent persons that they are ill and need treatment.[184] Interventions should never be attempted with less than two concerned persons and ideally should be directed by a person with previous experience. Prior to meeting, the group must collect documentation of drug usage including pharmacy records, anesthetic records, and other pertinent testimony. It is important to rehearse with members of the group (colleagues, psychiatrists, family members, etc.) prior to meeting with the patient. Many suggest

that each participant prepare written notes to be used for reference during the intervention. The objectives are to present irrefutable proof of the addict's symptoms in a compassionate manner and to begin an appropriate treatment regimen. A recovering physician at the intervention can be a valuable role model for the patient. Arrangements for in-patient treatment and travel, if anticipated, should be made prior to the intervention.

When all is in order, the patient is invited into a room in which the other participants are already seated. Each in turn should express concern for the colleague's well-being and, without passing judgment, should describe the aberrant behavior that has been seen personally. If necessary, the documents at hand can be shown. The basics of the disease and its treatment should be explained, and the patient should be urged to accept the proposed plan. If the patient refuses, as many do initially for fear of losing control, the patient should be told that the ultimate decision regarding therapy will not be made until after a thorough evaluation by a group of specialists at the facility.[183] If the evaluation does not confirm the diagnosis, the patient will be discharged. Otherwise, formal treatment, perhaps lasting several months, will start. If still reluctant, the individual should be advised that the interveners must, by law, report that person to both the medical board and the controlled substance authorities. Although acceptance of treatment does not provide legal immunity, it is looked on favorably by many courts.

After the intervention, someone should stay with the patient continuously, not only to prevent the possibility of self-inflicted injury but also to provide friendship. With adequate preparation, most interventions are successful.

Principles of Treatment

Treatment consists of an in-depth evaluation, which is usually followed by both inpatient and outpatient therapy. Formal therapy may last as long as several months,[166] but on the basis of the initial workup, some programs permit a recovering physician to continue practicing medicine during what may be several years of outpatient care.[168] Although this is debated by some, physicians often fare better if treated at a facility experienced in managing physicians. Philosophies of treatment vary between programs, but the common goal is to provide a recovering physician with the ability to remain sober. The physician is assisted in developing a strong relationship with peer support groups such as Alcoholics Anonymous and Narcotics Anonymous.

Reentry into the Workplace

Return from treatment is a difficult process for a recovering physician. The comprehensive treatment program has provided a structured environment that is much different from the workplace. For this reason, reentry is greatly facilitated by understanding, compassionate peers who are willing to provide emotional support to the recovering physician. Gradual return to work, perhaps with others initially managing narcotic administration, is important. Without this support, the likelihood of relapse may be much greater.

In many states, the committee on impaired physicians plays a vital role in recovery. At discharge from formal treatment, the committee prepares an "aftercare contract" with the physician, who agrees to be bound by the committee's recommendations. The contract usually stipulates the number and the type of meetings that the physician must attend, the name of a "monitoring physician," the requirement for random urine samples on demand, and the procedures to be used in the event of a relapse.[166,185,186] Many recovery programs insist on the use of naltrexone or disulfiram, or both, for 6 months or more after returning. Novel treatments for alcohol dependence include investigational drugs such as acamprosate, bromocriptine, selective serotonin reuptake inhibitors, and buspirone.[187] As long as physicians adhere to the contract, the committee continues to serve as their advocate.

Federal law in the United States (the Americans with Disabilities Act [ADA]) provides limited protection against employment discrimination for recovering individuals.[188] Although persons who are currently using drugs are not protected by this law, those who have been successfully treated and are otherwise capable of working are considered to be "qualified individuals with a disability." The ADA defines a history of chemical dependence as a disability. Although it does not require an employer to provide for treatment, the ADA may require that "reasonable accommodation" be made for a qualified individual who wants to return to practice. For a recovering physician, such accommodation might include a modified work schedule, such as no call for several months and assistance with administration of narcotics. An employer is not required to make accommodation if "undue hardship" for the employer would result. For example, it could be argued in court that the accommodations needed to permit a recovering physician to return might have a negative impact on other employees or could result in prohibitive costs for the employer. Whether the ADA can be used also depends on the type of employer-employee relationship between an individual and a hospital or group practice. Clearly, any person who seeks the support of the ADA needs competent legal guidance.

Prognosis

As indicated by reports from treatment programs, most recovering physicians are able to return to a productive professional life.[189] Successful outcomes are dependent on lifelong participation in aftercare programs, total abstinence from drugs and alcohol, and continual acknowledgment of one's disease. Some now believe that the prognosis for long-term sobriety in anesthesiologists depends on the age and the status of the physician at the time of identification. Residents who have been dependent on fentanyl appear to have a significant rate of relapse.[160] Although each case must be handled separately, strong consideration should be given to a change in specialty for junior residents who become addicted to potent opioids.

The American Board of Anesthesiology (ABA) permits a physician recovering from alcoholism or other drug dependence, who is otherwise qualified, to take both the written and oral examinations. After a candidate with this history has satisfied the requirements for certification, "the [board] will determine whether it should defer awarding its certification to the candidate for a period of time in order to avoid certification of a candidate who poses a direct threat to the health and safety of others."[190] If the ABA deems that such deferral is appropriate, "the [board] will determine the length of time the candidate's certification is deferred following an individual assessment of the specific circumstances of the candidate's history of alcoholism or illegal use of drugs." This practice is in keeping with the intent of the ADA.[190]

Summary

Despite the many occupational hazards in the operating room, the relative risk of each of the hazards discussed in this chapter has evolved with the times. The introduction of efficient scavenging systems has made anesthetic gas exposure less of a concern in recent years, whereas the AIDS epidemic of the 1980s and 1990s has placed an emphasis on infection control. In 2009 it is clear that substance abuse and drug-related death have emerged as prominent occupational hazards to be addressed in the future. Ongoing education and awareness within the specialty will continue to reduce these risks and improve the safety of our specialty.

102 Statistical Methods in Anesthesia

Key Points

1. Always plot your data. Significant trends should be visible to the eye.
2. Know your statistics program well enough to be sure that it is calculating what you want.
3. Interval data should not be treated like categorical data—the mathematics is different.
4. Many statistical methods assume that the data are distributed "normally," that is, in a symmetric bell-shaped curve; these methods can be misleading if the data are not normally distributed.
5. Standard deviation (SD) is used to describe the spread of data, and standard error of the mean (SEM) is used to compare data sets.
6. Multivariate regression, which relates the outcome variable to more than one other factor, requires more data but will probably pick up correlations that may be missed if only univariate regression is used.
7. When using multivariate regression, if two variables correlate closely with each other, the statistical package may miss reporting one as correlating with the outcome.
8. In hypothesis testing, a negative result may indicate no real difference or may just mean that the study was underpowered to pick up a true, but small difference.
9. A *P* value is the probability that the observed result will occur, assuming no true difference between the tested hypotheses, which is not the same as the probability of the difference being true.
10. A bayesian approach to diagnostic testing recognizes the fact that the value of a test depends on the patient population: if the test is almost always truly positive in the population, false-negative results will outnumber true-negative ones and make the test less useful. This is also the situation if the test is almost always truly negative, in which case false-positive results cause the confusion.
11. Selection biases make many real-life clinical studies difficult to interpret. Randomized clinical trials are the best way to minimize this problem.
12. Beware of the error of "data dredging." Applying too many tests to insufficient data will probably find something that, misleadingly, seems significant.

The advance of scientific knowledge in the past half millennium has been closely related to the linkage between experimental results and mathematical assessment of empirical observations. It is the role of the branch of mathematics termed *statistics* to describe the results of experiments and analyze, as best as can be done mathematically, the causes and effects behind the experiments.

A serious problem for a clinician or clinical scientist who wishes to use statistical methodology is that it is a modern branch of mathematics, much of it developed in the past century. Its mathematical sophistication is often considerably beyond that of the university-level calculus that is the upper limit of conventional medical training. Furthermore, many statistical methods involve extremely long and tedious calculations that require computerized techniques to be practical. This drawback leads us to the quandary that although statistical methods are useful and often essential to the understanding of medical science, they may be subtle to comprehend and difficult to use.

It cannot be the role of a chapter in a book such as this to derive or even genuinely explain the mathematics behind statistical methods. Many accessible introductory texts give some of the reasoning and rough, cookbook approaches to practical usage (see Bibliography). In real life, almost no one ever does any sort of statistical calculations beyond the most simple with paper and pencil. Application programs for statistical calculations are widely available for personal computers. Many of them are reasonably well documented and simple enough to use without much preparation.

The problem we have with these statistical programs for personal computers is that the assumptions behind the statistics remain obscure. It is very easy to use the wrong method or approach and still have the program generate an output that,

although appearing to be correct, is simply wrong. The old computer adage of "garbage in (statistically misleading), garbage out" is very easy to achieve with a computer package and a data file.

It is the goal of this chapter to provide some of the correct language for describing statistics and to suggest the proper methodology for the use of statistics in some standard situations. Some of the classic errors common in medical statistics will be indicated. Of course, readers must be familiar with whatever program they actually use.

Statistical Approaches

Within the broad rubric of statistics, several distinct and valuable areas can be viewed separately. "Descriptive statistics" is the use of mathematical methods to describe or categorize a collection of data that result from a set of empirical observations. "Statistical testing" is the broad approach to the determination of conclusions from a set of observations. Within each of these categories are many separate techniques.

Types of Data

It must be remembered that behind every statistical methodology there are formal mathematical definitions and proofs. Although it may sometimes seem that a simple intuitive approach is sufficient to understand what is happening, mathematical statistics can be misleading and unforgiving. The mathematical proofs and calculations that are behind our statistical tables and computation programs make strict distinctions among the several types of data (Table 102-1).

One type of data, termed *interval* data, are simple *continuous* numerical measurements (e.g., 1.2, 33.4). Often, we describe *discrete* numerical measurements, such as counts or integral quantities in the same categorization. This approach is occasionally misleading: the claim that a "typical family has 2.3 children" is meaningful in a crude way, even though the quantification of children is obviously not a continuous numerical fraction. In practical use, both continuous and discrete data can be handled by techniques similar to those used for interval data.

The other major grouping of data is *categorical* data. One type of categorical data is *ordinal* data, which refers to the ordering or ranking of subjects (e.g., 1st, 3rd, 10th). It is important to be careful to resist the temptation to regard the number of the ranking as an interval number, that is, to confuse "first" with the number "1," and so on. Such grouping does not usually have much numerical meaning and is false to the mathematics if an attempt is then made to manipulate the number as though it were an interval value. The arithmetic manipulation of arbitrary numerical assignments may easily produce misleading results.

Another similar category is *binary* data (e.g., up versus down, greater versus lesser). The most general grouping is the simple *category* (e.g., red, green, blue; cancer, diabetes, ulcer). When using simple or binary categories it is incorrect to attach numbers to the groups and try to get numerical results—the mathematics are not appropriate and the results are not likely to mean much. Specific statistical techniques for categorical data are necessary.

Table 102-1 Types of Data

Data Type	Examples
Interval	1.1, 22
Ordinal	1st, 3rd
Categorical—binary	Male/female, alive/dead
Categorical—multiple	Red, green, blue

Descriptive Statistics

Our most general statistical goal is to describe our data set. The simplest method is to just present all the crude data. For small data sets, the actual measurements can be presented. For larger amounts of data, a graph or statistical plot of the data can be helpful. One can frequently see trends and groupings in a picture that are very difficult to describe numerically. It is often suggested that before any mathematical method is applied to data analysis, a graphic plot should be produced. If the data do not look "right" to the naked eye, the statistical analyst should be very careful to avoid erroneous results. The choice of the correct format for the statistical plot can be an art form, and special data manipulation computer programs can be useful to search for visual clues in a data set.

Normal Distribution

Perhaps the most powerful numerical concept of mathematical statistics is the *normal distribution,* often called the "bell-shaped curve." The idea of a most likely central value with other values scattered evenly to both sides is a classic statistical concept with deep mathematical roots. It fits in nicely with our intuitive idea of a "true" value with measurements distributed randomly around that true value such that more values are close to the center than are distant.

Many typical data sets follow a normal distribution around a center point. This distribution, sometimes also called a gaussian distribution, is derived from the assumption that there is a center, "true" value and that deviations from the center are random and diminish in likelihood the farther the values get from the center (Fig. 102-1).

The strict use of normal distribution implies very large amounts of continuous interval data. When, as is usual, our data set does not meet this criterion, approximations are needed. Fortunately, most computerized statistical programs can deal with this problem with good effect.

In general, the mathematical description of the placement of the values is termed the *distribution.* There are many, mostly uncommon distributions other than normal distribution. They yield different curves and have specific mathematical properties. Not all data sets, even if they look like a bell-shaped curve, are normal distributions. If the curve is too wide (i.e., many distant outlying points) or too narrow or uneven, the mathematics derived for normal distributions will not work well.

When data follow a normal distribution or, more generally, any specific mathematical distribution, the methods of *parametric statistics* can be used. The term *parametric* refers to the ability to

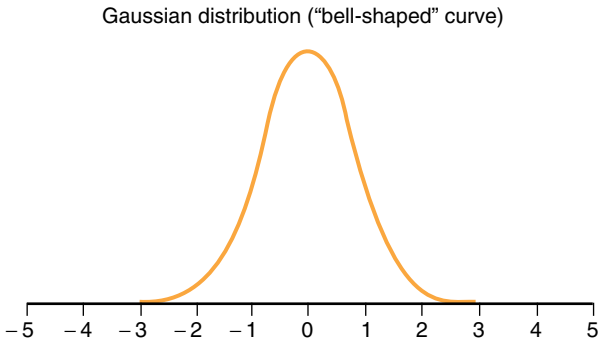

Figure 102-1 Gaussian distribution in a bell-shaped curve. The x-axis is in units of standard deviation.

describe the distribution with a specific set of values. Frequently, such is not possible, and *nonparametric* statistical methods are necessary. These methods make fewer mathematical assumptions about the distribution of the data, but they are more difficult and can be less robust in finding statistical distinctions. Conversely, if parametric statistical methods are applied to data that are not normally distributed, false or misleading results can be calculated. This type of error is common and can be prevented by using appropriate tests or checking the data for normality before applying tests that assume it.

In practical use, we often treat our data as though they follow a normal distribution. However, wise investigators will use the tests in their computer statistics packages to test for normality and recognize that if the data do not follow a normal distribution, other methods will be needed.

Measures of Central Tendency

In describing data, the first task is to give some indication of the approximate value, range, or size of what is being described. How this is done depends on the type of data involved (Table 102-2). For categorical or binary data, all that may be possible is to give the counts in each group. For categorical data with many groups, the most populous groups may be named and listed in order. For ordinal data, summary description may be difficult; often, first place or last place will be the most interesting.

The *median* is the center or middle data point if the data can be ordered from smallest to largest. This value would apply both to interval data and to ordinal types of categorical data. For interval data, many mathematical techniques can be applied. The simplest is the *mean,* or the simple average value of the numerical data, with each data point being counted equally. In a *weighted mean,* the individual points may be added in unequally, with some getting more credit (i.e., "weight") than others.

For interval data that can be analyzed mathematically, the data may be fitted to a curve, which means that a mathematical formula is computed that closely fits the measured data points, often by using a computer and sophisticated calculations. The relationship can be as simple as a straight line, or a complicated mathematical formula with exponentials, polynomials, or other functions included as may be needed. The various computed values in these formula would be the *parameters* of the curves. The data would thus be described by the parameters of the formula approximated to the observed data. For the simple case of a straight-line approximation to data, the parameters would be the slope and intercept of the line. For complex equations fitted to data, the parameters would be the various computed numbers that make up the equations.

Table 102-2 Measures of Central Tendency

Mean ± standard deviation
Mode
Median
Percentiles

The *mode* is the most common value in a set of data points. This concept can be misleading if the data are truly continuous because every data point would then probably be different (if only infinitesimally so) from every other point. Hence, to describe the mode of continuous data it makes the most sense to group the values into brief intervals. In this sense, the interval with the most points within it is the modal interval. The mode may also be a very misleading description of the central tendency of a data set because there may be no reason for the most common value to be anywhere near the middle.

Numerical data can be described by categorizing the values into *percentiles* or similar groups. The meaning here is that for the, say, 10th percentile, 10% of the data points are at or below that value. The 50th percentile corresponds to the median of the data set, and the 99th percentile is the value at or above 99% of the data points. Similarly, quartiles, quintiles, or other groups can be computed. With any method used to describe data, the choice of the description may subtly bias us in how we think about the result. In the simple data set [2, 2, 3, 7, 14], the mode = 2, the median = 3, and the mean = 5.6. Which, if any, of these representations is more accurate? The answer depends on how we want to use the data because no one representation is perfect.

Measures of Dispersion

Often we want to describe not only the values of our data but also how the data are spread out. For data that follow a normal distribution, the classic approach is to compute the *standard deviation* (SD) of the data. With this value, roughly 68% of the data fall within 1 SD of the mean and roughly 95% fall within 2 SD of the mean value. The larger the SD, the wider the "bell-shaped" curve, and the smaller the SD, the narrower the curve.

Another way of looking at this concept is to consider that if we were making measurements of an unknown value and our values were scattered in a random normal distribution around that value, it is likely that about 68% of the data points would be within 1 SD of the true value. Of course, this result is only the most probable outcome and in any real set of randomly distributed data we could be unlucky and have very atypical points.

For data that do not follow a normal distribution, it can be difficult to describe the dispersion of the data set in a standard fashion. Often, just the *range* of the data, from lowest to highest, is given. Occasionally, the data may be so scattered, with very distant extremes, that the range is not as useful as reporting the 25th to 75th percentiles of the data.

Caution

Because it is so easy to use a computer package to calculate the SD, we must be particularly cautious about using it. Frequently, data do not fit nicely into the normal distribution with a symmetric bell shape and unbounded tails out in both directions. As

an example, consider a data set of subjects with widely dispersed ages including many children. It would be easy to get a value of 10 for the mean age, with an SD of 15. Clearly, no values lie at the lower end of the distribution with ages of −5. In such situations, the SD has some merit in describing the spread of the data but is, by strict mathematics, being misapplied.

Standard Error of the Mean

Just as random numerical data can often be described by the SD, the means computed from multiple grouped determinations of the data set can be described by making a computation very similar to the SD but applied not to the measured data but to the computed means. This computed quantity is termed the *standard error of the mean* (SEM). As more data sets are gathered, with each data point being a measurement of what is a "true," but unknown, value, the means of the data sets will very probably get closer and closer to that true value. Hence, as more and more data are gathered, the SEM will get smaller and smaller. This concept is intuitively very reasonable—as we make more and more measurements of a value, we should be getting a mean value closer and closer to the "true" value, even if the data points themselves remain scattered.

The difference between SD and SEM is important. SD is used to describe the data, and SEM is used for computations about the certainty of the mean of the data. Because our computer packages can as easily provide either of these values and SEM is a smaller value, one is tempted to describe the data by the SEM. Although this is not dishonest if clearly labeled, it can certainly be misleading. If you have a very large number of data points, the SEM will be very small, but widely dispersed data will have a large SD no matter how many points are measured.

Graphing the Data

All experienced statisticians will stress that before statistical calculations are applied to a new data set, the data must be plotted in some graphic format. If the data are widely scattered, look asymmetric, or have a specific pattern, that information is useful in determining the statistical tools to be applied. Furthermore, noting the presence of extreme outlying points may be a clue to mathematical or experimental errors.

Regression Analysis

Data may often fit a mathematical formula, which may be a straight line (e.g., a linear relationship) or just about any sort of continuous mathematical formula. In *regression analysis,* we use the power of the computer program to determine the mathematical formula that best fits the data. To do this, we have to provide the program with the type of curve to use, for example, a straight line, quadratic equation, or exponential curve. The program will then provide us with the parameters within the selected equation that best fit the data points.

The art of regression is complex. The first problem is to pick the appropriate mathematical relationship to fit the data. Graphing the data is obviously very useful for this. There are also some mathematical subtleties in how to best fit the data to the curve, but by far, the most common method is a *least-squares* approach that minimizes the square of the distance of each data point from the proposed curve. Although this methodology is about 2 centuries old, it clearly benefits from the use of modern computerized calculations, without which it would be practically unusable.

The computer program for regression analysis will provide the parameters of the fitted equation, such as the slope and y intercept for a straight line, and also some information about how well these parameters fit the data. The user has to be cautious in using the fitted equation if the agreement is poor because almost any jumble of data can be fitted to some equation, albeit with terrible agreement. It is fair to stress that the human eye has real power to judge trends, so if a graph of the data does not look like it fits the curve, the wise user will be very skeptical of the result.

Univariate Versus Multivariate Regression

In fitting data in a regression analysis, the first step is to choose the variables that will be used as independent variables. In *univariate* analysis, only one variable is used for the data fit and the data are plotted and the computations are performed by using that one variable to describe the data. As an example, the weights of a group of subjects may be compared with their heights. However, in the real world, many possible variables can almost always be used to determine an outcome. In *multivariate* analysis, more than one variable is used to describe the observed results. In the weight example, the subjects' weights might be analyzed by using heights, ages, and gender. Note that in this multivariate example, the outcome is a continuous interval variable but is determined by a collection of interval variables (age, height) and a categorical variable (gender). The precise mathematical techniques that are used for multivariate analysis will depend on the nature of the variable used; in general, a mixed group of variables makes the most sense with real-world data.

On first approaching analysis of a data set, a simple univariate analysis may help in understanding the relationships involved. However, the data analyst must be cautioned that subtle relationships can be missed with only univariate analysis if the relevant variable is not used. As an example, heart rate may correlate with the dosage of pain medicine in an injured patient, but the causal relationship for both is likely to depend on the degree of pain.

With multivariate regression analysis, many potential pitfalls can readily be encountered with computerized calculations. One critical category of problems derives from the relationships that the various variables may have with one another, which is often described by indicating how *independent* these variables are in relation to one another. For an independent variable, the values of one variable do not tell what the values of the other would be. In the example of weight versus age and height, we would expect age and height to be independent in adults. Mathematically, it would be determined that age and height are *uncorrelated.* However, in children, age and height are correlated, so weight could be expressed as a function of weight versus age or weight versus height. In this last case, a multivariate analysis that focused on independent variables might just produce the result that weight is a function of height and throw out the relationship between weight and age. Hence, when many variables are involved, caution must be applied so that experimentally important relationships are not missed because they do not add mathematically to the results. Sophisticated statistical computer packages will look for these sorts of problems. Identification of significant correlation among the different variables would suggest that some information may be lost if only independent variables are reported. If a simpler statistical program is used, it would be wise to perform multivariate analyses with some of the variables left out to see whether other possible relevant relationships appear.

Another type of problem that can be misleading with multivariable relationships occurs in the situation in which the computer program produces a variable that correlates only weakly with the data but does so with high reliability. This situation would be expressed in linear analysis as a result with a small correlation coefficient but a very good "*P* value" (more about "*P*" later). The fact that the correlation likely is real (i.e., it is not a statistical fluke) does not offer much to the experimental analysis if the correlation is small—the data are not well explained by the relationship. Here, the confusion comes from the fact that although the correlation is weak and does not explain much, the calculation shows very high confidence in the presence of this weak correlation.

Hypothesis Testing

A very common use of statistical techniques is to test a question, called the *hypothesis*. Also often termed *significance testing,* this approach yields the valuable concept of the "*P* value." It is this *P* value that is often used to summarize the statistical strength of the data analysis in supporting or rejecting the hypothesis. If we were comparing groups, we often describe the test as a comparison of the *null hypothesis,* which states that there is no difference between two groups of data, and the *alternative hypothesis,* which states that there is a difference. If we were analyzing a single grouping of data and performing a comparison of two descriptions of the data, such as determining whether the mean value of the group as calculated from the data is different from 0, the two hypotheses would be "mean = 0" versus "mean = measured value ≠ 0."

The *P* value is computed from the observed data as the probability of obtaining this data set if in reality the null hypothesis were true. It is important to note that this calculation assumes the null hypothesis and is not the same as saying that *P* is the probability that the alternative hypothesis is true. If in reality the null hypothesis is true, it would be unlikely that we observe something else in our data. In actual experimental situations, all data have some randomness, so we can never be certain that our observation is not just chance and bad luck.

In hypothesis testing we choose a *level of significance,* termed the *alpha* value, and declare that if *P* is less than alpha, the result is statistically significant and accepted as true. If *P* is not less than alpha, we reject the hypothesis (equivalent to accepting the null hypothesis). Remember the logical sequence: we choose alpha in advance, then compute *P* from the data. If *P* is less than alpha, we agree to accept the hypothesis and we reject the null hypothesis. The *P* value is the chance that the null hypothesis was true but, through our bad luck, the data came out as observed anyhow. Typically, we set alpha equal to .05 and want *P* less than that. For that *P* value, it would mean that the chance of the data coming out this way was less than a probability of 5% ($P = .05$) if the null hypothesis were in fact true.

Choosing the level of significance is an arbitrary decision. We might want to be very sure that we did not erroneously reject the null hypothesis and set alpha at .01. It is common in biomedical studies to pick an alpha value of .05. Also be aware that a very small *P* value may lead us to reject the null hypothesis but may not give us much information about the exact nature of the alternative. As an example, tossing a coin and getting six heads in a row might lead us to reject the null hypothesis that the coin is a fair coin, but it is not enough information to convince us that the coin always comes up heads. We calculate the *P* value from the data assuming the null hypothesis and use a small value of *P* to allow us to reject the null hypothesis, yet that does not fully characterize the alternative hypothesis.

Power

It should seem intuitively obvious that the ability of a statistical test to make a valid determination depends on the amount of data available. With only a few observations or data points, we cannot be as certain about a conclusion as if we had large amounts of data. If our goal were determining the fairness of a coin, tossing it twice would not convince us of much; tossing it a thousand times, however, would give us a good idea about its nature. In statistical hypothesis testing, the *power* of a study is a description of the ability of the study to detect a true difference. A statistical hypothesis test may fail to achieve significance (fail to get $P <$ alpha) if either the data truly do not reflect a difference or if there are so few data points that the mathematics yields a poor *P* value. We define a *beta error* as the probability of falsely accepting the null hypothesis (calculated by assuming that the alternative hypothesis is true), and the *power* = 1 − beta. For the power to be good, that is, the beta value to be small, we want our study to have enough data points so that if a difference is observed between the null and alternative hypotheses, we can accept it with reliability.

A sample size calculation is often performed before an experiment is undertaken to determine how much data would be necessary to have a reasonable chance of observing what is guessed to be the observed result. Standard computer programs are available that will compute the number of data points necessary when the alpha and power values are provided and some estimate is made of the likely observed effect. It is important to be cautious about any study that is interpreted as "negative," that is, reports no significant difference between the study groups. It may be that no difference truly exists, but it may also be that the sample size was too small to determine a difference with statistical significance.

Confidence Intervals

It is becoming more common in reporting statistical measurements to use *confidence intervals* as a description of the statistical determination. A range of values may be given such that it is determined with some likelihood (often picked at 95%) that the true values lie within that range. For expressing simple results, the confidence interval is equivalent to providing a mean ± SD. This method becomes particularly useful for describing results when we want to describe "no difference" in correct statistical fashion. Here, the proper description would be that the true difference lies in an interval less than "x" with the given statistical confidence.

In sum, for hypothesis testing we want the following:

- Null hypothesis—e.g., mean = measure value "m"
- Alternative hypothesis—e.g., mean = 0
- Alpha value (chosen in advance)—e.g., alpha = .05
- Power (chosen in advance in conjunction with a sample size calculation so that we have enough data points)—e.g., power = 0.8
- P value—computed for data

We can say that we have a significant difference between the null and alternative hypotheses if P is less than alpha. If we are describing a value, we can give it as a confidence interval; and

if we are saying that there is "no difference," we can describe it as a difference (if any) in the interval less than some computed value.

Study Design

The essence of scientific study is generally some numerical determination of a result. It is this numerical analysis that we approach with our statistical calculations. However, without a careful design of the study in the way that the numerical data are generated, formal statistical analysis of the numbers will yield scant benefits and may even be very misleading. In the typical study we are usually attempting to either characterize some variable (e.g., mean or trend) or make a choice to accept or reject among various hypotheses. No matter what the question is in our minds, we must always be careful that the results genuinely answer the question and that we are not misleading ourselves with inappropriate conclusions.

Scientific studies may be *observational studies* in which we gather data without performing any specific intervention affecting the assignment of groups or effects on group members. Because in an observational study we have to take what we find as data, we are always very subject to other unrecognized factors that may distort our interpretation or limit our ability to ask questions about our data.

In an *interventional* study, we pick the group members, determine what is being done to them, and attempt to look out for and eliminate potential confusion before the data are collected. A *clinical trial* is a typical interventional study in which different therapies are compared.

In the design of a scientific study, one major fear is a statistical *bias,* which is a systematic effect in the study that produces an error in our interpretation of the results. When considering the various possible study designs, we need to beware of the potential biases that may creep in. A *selection bias* occurs when we are comparing groups with respect to some variable but do not realize that the groups are different in other (but important) ways. Because groups of subjects may differ in multiple ways, our assignment of subjects into groups may result, either from misdirected choice or just random "bad luck," in groups that are not fairly comparable. So although we think that our results are determined by the variable under study, it may really be that some other factor misleads us in our conclusion. As an example, consider a study that is comparing surgical and medical treatment of some illness and ends up with a grouping in which a higher proportion of men than women are undergoing surgical therapy. Any conclusion from this study about surgery versus medical therapy is biased and might be truly just reflecting a difference in the results of therapy on men versus women.

A *confounding bias* occurs when multiple variables are intimately intertwined so that although we may assume that the variable under study is important, the truth is that the confounding variable is more important. As an example, consider a study attempting to determine the effects of obesity on longevity. Because diabetes mellitus is very closely correlated to obesity, a result that purported to be about obesity might easily be more accurate about diabetes. When variables do not correlate with each other so that changes in one do not go along with changes in the other, we call them (in a rough nonmathematical sense) *independent variables.* Variables that are correlated with each other are not independent.

A *measurement* bias occurs if the methods used for making measurements when comparing different groups have different scales or sensitivities. As an example, consider attempting to get a history of chest pain in groups of patients with and without known coronary artery disease. Patients who know that they have heart disease might be imagined to remember brief pain more thoroughly than healthy patients do, or perhaps they might deny pain more in their wish to believe that they are healthy. Here the art of the experimenter is to predict and avoid such biases.

In a *blinded* study (more properly called a *masked* study), measurement bias may be avoided if the person performing the measurement does not know which group is being measured so that subtle bias in approaching or determining the data can be avoided. As an example, consider an active drug being compared with an inactive placebo. A researcher who knew which patient was taking the active drug might be more diligent in pursuing benefits or side effects. In a *double-blind* clinical study, neither the patients nor the experimenters obtaining the data should know which subjects are in which group to avoid subtle measurement bias.

Observational studies may be categorized as case, case-control, or cohort studies. In a simple *case study,* an individual case or group of cases is reported. Such reports may demonstrate the existence of some observation or effect, provide the presumably typical character of the observation, and suggest a therapy or natural history. These types of studies do not have the nature of a proof because it is always a possibility that some other hidden effect is producing the observation or that the observed characteristics are atypical in some fashion. Nevertheless, often "seeing is believing," so much of what is reported in medicine is in the form of case observations.

The distinction between cohort and case-control studies is important but often misinterpreted. In both categories, groups of subjects are compared, usually in regard to the effects of some intervention. In a *case-control* study, the factor separating the groups is determined *after* the intervention. Typically, a comparison is made of some outcome in one group, the case group, versus a similar group that does not have the outcome and functions as the control group. Because the groups are separated after the intervention, selection biases or unappreciated confounding variables can mislead the investigators. As an example, consider a study investigating the effects of hypertension on surgical mortality. If the groups are divided into patients with and without perioperative cardiac events, it may well be that one group will be different from the other. However, such a result may be misleading; perhaps it is really the renal disease that is associated with the hypertension that is significant (a confounding bias). Alternatively, perhaps patients with hypertension are sent to surgery by their physicians only when they have worse surgical problems, so the groups are not fairly compared (a selection bias).

In a cohort study, the study group is monitored before the intervention occurs. The group is assembled to be as similar as possible and then monitored forward in time. Such studies are useful for describing the natural history of disease and may be helpful in suggesting causes. However, as with the other observational studies, selection and confounding bias may occur and lead to misleading results.

A case-control study is sometimes termed a *retrospective* study because the analysis can only be done after the subjects

complete the study (so that it can be determined to which group they belong). In this sense, a cohort study is a *prospective* study inasmuch as the data must be gathered before the intervention. Unfortunately, these terms may be misused because, obviously, a case-control study can be planned in advance ("prospectively"). In addition, no matter how truly prospective a study is, once the data are gathered, the analyses are performed after the fact ("retrospectively"). These terms are best avoided.

After considering the nature of observational trials we can see the strength of the interventional clinical trial, where the investigators determine the membership of the groups to be compared in advance and attempt to make the groups as alike as possible. In a *randomized clinical trial,* the subjects are assigned by chance to the groups so that if there are some fluctuations in the subjects or some subtle selection bias, the effect will be the same in each group (and presumably cancel out in the result). Such a study is necessarily prospective in nature.

Randomized clinical trials are the idealized standard in medical research because they give the best chance to minimize biases. However, the effort and expense in setting up a clinical trial may be very considerable. Recognize that such a trial requires patients to be enrolled before the medical intervention is performed. Patients give up choice of the therapy that they receive and allow their therapy to be randomly selected among various options. Such trials (even if they involve standard therapies) require full ethical board clearance and explicit patient consent.

Even with the best clinical trial methodology, potential difficulties include dealing with subtle selection biases regarding who is entered into the trial. Studies that are actively watched by investigators and their highly motivated associates may result in atypical practices that cannot be generalized into standard clinical practice. The patients in clinical trials are themselves mostly motivated by the search for personal benefit and cannot be depended on to follow protocols strictly or to stay with a program that does not appear to be successful to them.

Data Dredging and the Problem of Multiple Comparisons

In all our statistical interpretations regarding the acceptance of data-determined conclusions, we always recognize that there is the random chance of a highly unlikely statistical result being misinterpreted as the typical true conclusion. A coin tossed six times and coming up all heads might lead us to conclude the coin was not fairly balanced, yet that will happen every $2^6 = 64$ times that it is attempted even with an entirely fair coin. When we pick an alpha value of .05, we are roughly saying that about 5% of the time we will accept misleading random errors as though they were true. This is roughly equivalent to recognizing that for every 20 experiments we do, perhaps 1 will be wrongly accepted as true based solely on bad luck and random chance. If we analyze a large set of data in many ways, some random results may appear statistically significant just based on this sort of chance. This is the error of *data dredging* and typically occurs when too many variables are examined for correlations within a single data set—by random chance something will be found that appears significant.

In a similar manner, if a very large number of independent comparisons are made between two groups of subjects and we accept an error rate of 5%, we might get a false, but statistically "significant" result about once for every 20 comparisons made. This is the error of *multiple comparisons.* Mathematical methods are available to correct for these errors—what is most relevant for the consumer of the statistical analysis is to recognize the presence of the error and look for the correction.

Choice of Tests

Nonparametric Statistics

When calculating the random distribution of some variable it is easy to visualize the values as clustered around some center value in the well-known bell-shaped (termed *normal*) distribution. However, as noted earlier, not all data have such a nice distribution. Data that are not in interval format, such as nominal data (e.g., red, black; male, female) or ordinal data (first, third), cannot be described by mathematical distributions with parameters such as the mean or SD. Such a situation calls for nonparametric statistics. Nonparametric statistical methods are typically used for the analysis of nominal or ordinal data. Data that are distributed in a very atypical skewed fashion (a *non-normal* distribution) will not be properly handled by analyses that have the mathematical assumptions of normality; such data will need nonparametric analysis.

The first step in considering the choice of a statistical test is to decide whether statistical methods that assume a normal distribution are appropriate or whether nonparametric methods are needed (Table 102-3). A test for normality is included in typical statistical computer packages. Often simple inspection of frequencies in tabular or graphic form will convey much information.

Contingency Tables

A very common nonparametric statistical problem is the analysis of a table of data in which each cell in the table is a count in a particular category. The question is to determine whether the groups are statistically different from one another. As an example, consider the question of men versus women and their political affiliation, Republican versus Democrat, in which a 2×2 table is generated. If additional political groups are added, say Green and Undeclared, we then have a 2×4 table. If we wished to analyze these data to determine whether men and women differ in political affiliation or whether Democrats versus Greens differ in gender distribution, we would apply nonparametric statistical methods appropriate to a contingency table.

Paired Versus Unpaired Data

If statistical methods are applied to analyze data from multiple groups and each individual data point comes from a separate and distinct source, the mathematics behind the statistics assumes an independence and randomness that would not be the same if the sources are highly related. As an example, consider a study of blood pressure in two groups of subjects, one treated with medication and the other untreated. Because blood pressure measurements can be widely scattered in distribution, depending on the subjects' previous medical condition, a small drug effect might be difficult to notice. However, if the same individuals were studied before and after therapy, the wide initial variations might cancel out and small effects would be noticed. In this latter study, the data points can be paired, one in each group, to detect these small

Table 102-3 Choice of Tests

Comparison Goal	Normally Distributed (Parametric) Interval Data	Nonparametric Interval Data	Categorical Data
Describe group	Mean ± SD	Median, mode, percentile	Counts and proportions
Compare group with value	t-Test	Wilcoxon	Chi-square
Compare two groups	Unpaired t-test	Mann-Whitney	Chi-square, Fisher
Two paired groups	Paired t-test	Wilcoxon	McNemar
Three or more groups	ANOVA	Kruskal-Wallis	Chi-square
Multiple matched groups	Repeated-measures ANOVA	Friedman	—
Regression	Linear regression	Nonparametric regression	Logistic regression

ANOVA, analysis of variance; SD, standard deviation.

effects. A study in which the data can be paired can be very sensitive in picking out small changes. Conversely, the erroneous use of paired statistics might suggest a statistically significant result when one does not exist.

Two-Group versus Multiple-Group Analysis

In a simple statistical analysis we may be characterizing one group of data or comparing that group with a standard value. It is slightly more intricate to compare two groups when we want to characterize each group and determine whether the groups are statistically different. Much more concern must be applied to the situation when we have three or more groups. In this case of multiple groups, two distinct types of questions can be asked. First, we might wish to know whether the groups are significantly different or whether they are all the same (with any numerical differences attributed solely to random fluctuations). Second, if we do conclude that the groups are statistically not all the same, we might want to know which groups are different from one another—that is, are they all distinct or are just one or a few different whereas the rest are similar to each other.

In summary, three questions should be asked when choosing between tests (see Table 102-3):

1. One group, two groups, or many groups?
2. Paired or unpaired groups?
3. Parametric (interval data following a normal distribution) or nonparametric methods?

Bayesian Approach to Probability

The commonsense meaning of the term *probability* can readily become confusing within the mathematical morass of formal statistics. In practice, we commonly use and interchange two definitions for probability. In the *frequentist* approach, we view the probability of an occurrence as the fraction of occasions that the selected event would occur if the trial were repeated many times. So we say that the probability of a fair coin coming up heads is .5 because if we toss it many times, we would get about 50% heads.

However, in many real-life situations we cannot repeat the trials many times to get a frequency of occurrence for an event. In the *subjectivist* approach, we assign a probability to an event based on our best guess or opinion. Such subjective assessments are very similar to what we do in medicine when we make an interpretation based on opinion and experience. This approach is often termed *bayesian* statistics because of a mathematical formula, Bayes' equation, that is used to manipulate subjective probabilities.

The powerful practical insight that comes from bayesian statistics lies in the requirement that we start statistical calculations with an initial probability of an event. This very much matches the real-life situation in which any test or prediction depends on the patient under study. It is generally medically unwise to consider a diagnosis for a patient unless we take the patient's own characteristics into account. It is obvious to any clinician that an abnormal cardiogram suggesting myocardial ischemia would not mean the same thing in a healthy 30-year-old as it would in his obese hypertensive grandfather. In a similar argument, a negative exercise stress test does not give us great confidence that a very high-risk patient is free of cardiac disease (because the chance of disease is so high and stress tests are notorious for missing disease in some patients).

In medical situations, bayesian statistics are mostly used for the interpretation of diagnostic or predictive data. The term *bayesian* is often an indication that the patients' or population's a priori chances of disease should be considered when applying a predictive test.

When using diagnostic or predictive tests, the concepts of sensitivity and specificity are very useful because they are not dependent on the population. *Sensitivity* is, roughly, the ability of the test to detect the disease when truly present, and *specificity* indicates the ability of the test to avoid a false indication of the disease when truly absent. To use these terms we define four possible situations:

True positive (TP): The patient has disease and the test is positive.
False positive (FP): The patient does not have disease and the test is positive.
True negative (TN): The patient does not have disease and the test is negative.
False negative (FN): The patient has disease and the test is negative.

By definition,

$$\text{Sensitivity} = \text{TP}/(\text{TP}+\text{FN})$$

$$\text{Specificity} = \text{TN}/(\text{TN}+\text{FP})$$

The ideal test has a sensitivity of 1, which indicates that the test picks up all the patients with the disease, and a specificity of 1, which indicates that the test never falsely claims that a healthy patient is diseased.

It is also sometimes useful to define the following:

$$\text{Positive predictive value (PPV)} = \text{TP}/(\text{TP}+\text{FP})$$

$$\text{Negaive predictive value (NPV)} = \text{TN}/(\text{TN}+\text{FN})$$

Remember that although the sensitivity and specificity of a test do not depend on the characteristics of the population, they certainly do depend on the quality of the test. However, PPV and NPV are dependent on the tested population—this situation is where our comment about "bayesian" is relevant. (Although it is not the goal of this chapter to prove these claims, the reader may be convinced by considering what happens to sensitivity, specificity, PPV, and NPV in situations in which the test is applied to a population in whom the disease is absent so that only TN and FP are nonzero: PPV is vanishingly small and NPV approaches 1. Similarly, for a population with almost all patients having disease, PPV goes to 1 and NPV vanishes.)

The bayesian insight can now be stated that we apply diagnostic or predictive tests only to populations of subjects who are somewhat likely to test positive, but not "excessively" so. If we test subjects who are very likely to test positive, a positive test is confirmatory and a negative may be more likely to be a false-negative than a true-negative result. Similarly, if the tested population is very unlikely to have the specified disease, a negative test is only confirmatory and a positive test is more likely to be a false-positive than a true result.

Evidence-Based Medicine

Making judgments in science is an intricate process. Our decisions are formed by theoretical reasoning, extrapolation from empirical data, traditional conventions, and, often, local authorities. Most modern philosophers of science recognize that the old view of the scientific method as a totally unbiased approach to the interpretation of raw data is naive. All the data we collect in any experiment is created, selected, and interpreted within the context of our theory-based view of the world. Science is the derivation of a set of generalized laws, consistent with each other, based on empirical data and able to predict or explain further data. Often, more than one theoretical explanation can generally be given for any one set of data. The choice of a scientific explanation, similar to the choice of a statistical test, is always based on our prior understanding of the data and experimental situation.

All this being the case, it must still be stressed that modern medicine has passed from the era when "practice" and "art" were sufficient justification for medical decision making. *Evidence-based medicine* is the fashionable term for the approach to medical decision making in which careful use is made of the applicable experimental scientific data. Controlled clinical trials and large-scale observational studies are important methods for this approach. A *meta-analysis* is a report of data that combines results from multiple similar studies to create a statistically more powerful study with many more data points and a better opportunity to come to a statistically significant conclusion.

The practicing clinician has many sources that analyze empirical evidence and provide guidance for medical decisions. Governmental groups and private medical organizations have produced many guidelines and clinical practice documents that assess the quality of available evidence and make suggestions. To give further guidance, these suggestions may also be ranked by confidence. The most reliable data backed by well-established theories would give recommendations with the greatest weight. Reports that are backed by weaker data such as uncontrolled studies give recommendations with less confidence in the evidence.

Summary

Clinicians use statistical methodology both to analyze their own data and to assess the value of others' scientific reports. Because data analysis is generally the application of one of a number of commercial computer packages, each with its own menus, formatting, and subtle caveats, the most valuable suggestion to the budding statistician is to know the program, read the manual, and plot the data. The human visual system is well adapted to see groups and trends—if the conclusions do not look like they fit the data, caution and skepticism are prudent.

When assessing the value of a scientific report, a careful clinician reads the "methods" section and asks the questions suggested earlier: Are the subjects selected to minimize bias? Are the statistical methods appropriate? Is the study large enough to be statistically powerful? Are the conclusions warranted by the evidence? Can the conclusions from this study be extended to cover more general cases or do they apply only to the limited situation under study?

Finally, despite the best statistical approaches and the most careful experimental procedures, a wise clinician recognizes that even some apparently well done experiments can yield erroneous conclusions. A study that produces an important clinical conclusion, especially one that seems to change tradition or violate previous theoretical understanding, bears confirmation by another group using different patients in a different setting. Healthy skepticism is the basis of good statistics and good science.

Bibliography

Standard Statistical Computer Packages

Instat, GraphPad Software, San Diego, California.
A simple, very user-friendly program with good built-in help.

JMP, SAS Institute, Cary, North Carolina.
The SAS group's simple stand-alone program. Although relatively simple when compared with the full SAS program, its completeness leads to some complexity for the beginner.

SPSS, SPSS Inc., Chicago, Illinois.
A full featured, expensive, and very powerful program that is accessible to the nonprofessional statistics user. The help files are usable and exhaustive.

SAS, SAS Institute, Cary, North Carolina.
Expensive, very complex, very powerful. This standard package of programs is the one most commonly used by professional biomedical statisticians. Not for the amateur.

(*Note:* there are many simple and midlevel statistical programs available, all of which require careful reading of the manual to be reliable!!)

Selected Introductory Statistics Texts

Altman D: Practical Statistics for Medical Research. Boca Raton, FL, CRC Press, 1990.
Well organized and complete. A good course textbook.

Dawson B, Trapp RG: Basic & Clinical Biostatistics. New York, McGraw-Hill, 2004.
Suitable for self-study, fairly complete.

Feinstein A: Clinical Epidemiology. Philadelphia, WB Saunders, 1985.
Enormously insightful about the structure and problems of clinical research.

Glantz S: Primer of Biostatistics. New York, McGraw-Hill, 2001.
Very clear, very popular; also has a very simple-to-use statistics program that may be purchased with the book.
