Falls (24–43%) and assaults (30–50%) are the most common causes of mild head injury in the UK, followed by road accidents (25%), although these account for a far greater proportion of moderate to severe head injuries. Alcohol may be implicated in up to 65% of all adult head injuries (NICE 2003a).

Head injury is preventable. This is an area in which nurses should exercise their health education skills, e.g. by emphasising the dangers associated with head injury and its detrimental effects when communicating with patients who have experience of minor head injury with good recovery, and with their families. This may include consideration of driver behaviour or unsafe work practices. The use of seatbelts for the driver and all car passengers has led to a reduction in head injuries, as has the use of protective headgear for motorcyclists and horse riders (Headway 2004). Because a common contributing factor in head injury is overindulgence in alcohol, where appropriate, the patient can be encouraged to consider personal lifestyle and the consumption of alcohol.

PATHOPHYSIOLOGY

The adult skull can be considered as a rigid box divided into two major compartments, containing non-compressible components. A uniform pressure, called 'intracranial' pressure (ICP), is maintained. It is defined as the pressure exerted within the cerebral ventricular system. When an individual sustains a head injury or there is some abnormal pathology, e.g. a tumour, it can alter this delicate balance. When an increase in ICP occurs, the pressure in one compartment is higher than that in its counterpart, and abnormal movement of tissue from an area of high pressure to one of low pressure occurs, a process known as 'herniation' or 'coning'.

Three intracranial components are involved in the process of maintaining ICP:

- the brain
- the cerebrospinal fluid (CSF)
- blood.

The brain is the largest of these, occupying 80% of the content. The remaining 20% is taken up in equal proportion by the CSF and the blood. Under normal circumstances, ICP is maintained within normal limits, but when there is an alteration to the volume of one of these components within the confined space of the skull, the other two are compressed, resulting in a rise in ICP. The normal range of ICP is 0–15 mmHg and anything over 15 mmHg is considered abnormal. Transient rises in pressure occur with activities such as coughing or sneezing and this is a normal physiological response.

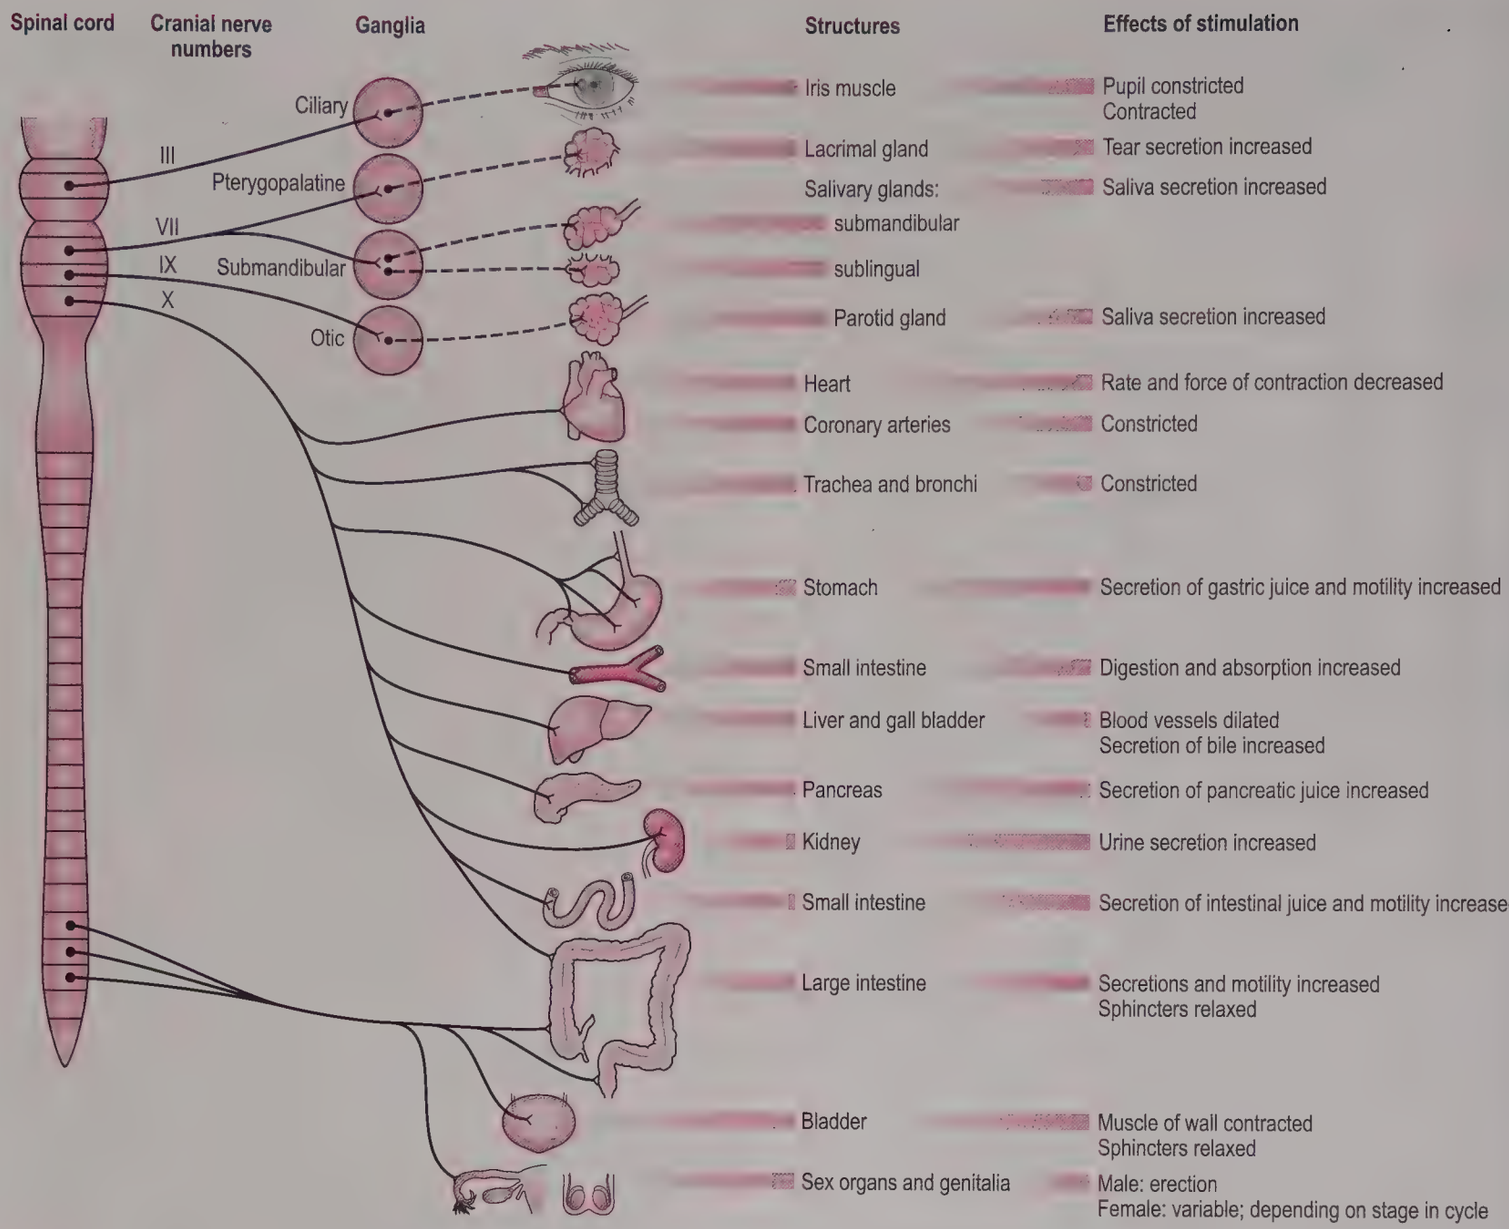

Fig. 9.17 The parasympathetic outflow, the main structures supplied and the effects of stimulation. Solid lines, preganglionic fibres; broken lines, postganglionic fibres. Where there are no broken lines, the second neurone is in the wall of the structure.

Changes to the brain and its associated structures following trauma may cause ICP to rise to a dangerous level, resulting in coma and leading to permanent brain damage.

The causes and presenting symptoms of raised ICP

Causes of raised ICP can be classified according to the intracranial components involved.

- *Brain* — brain tissue volume can be increased due to the presence of an expanding intracranial lesion, such as a brain tumour or a haematoma following head injury.
- *CSF* — increased production, decreased absorption or blockage of a CSF pathway will result in an abnormal accumulation of CSF within the cerebral ventricular system. This is a condition known as hydrocephalus.
- *Blood* — cerebral blood flow can be increased principally as a result of an abnormally high level of carbon dioxide in the blood (hypercapnia) and to a lesser extent due to a lack of oxygen in the tissues (hypoxia). These lead to congestion within the cerebral circulation, culminating in a raised ICP. Such a situation can be precipitated by neglect of the patient's airway during the postoperative period following neurosurgery or following head injury.

A rise in ICP can develop over a variable period of time. It can occur over a number of years in a slow-growing brain tumour, with the patient hardly noticing any symptoms, or it can occur in a matter of minutes following severe head injury, when the patient becomes profoundly unconscious. The underlying principle remains the same and is centred on the volume–pressure relationship curve (see Fig. 9.18).

A distinct correlation exists between ICP and conscious level. As ICP rises, conscious level deteriorates.

During the initial rise in ICP, compensatory mechanisms come into play, principally the ability of the cerebral ventricular system to reduce the volume of CSF by displacing it into a distensible spinal dural sac. A reduction in cerebral blood volume also occurs as a result of autoregulation, the ability of blood vessels to alter their diameter according

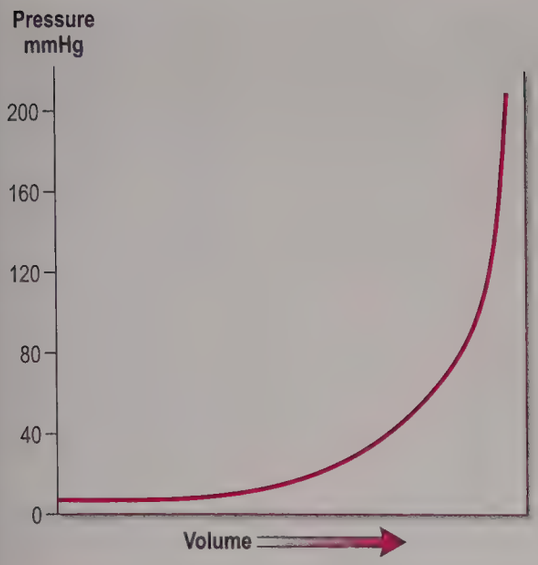

Fig. 9.18 Volume–pressure curve.

to local conditions. This is represented by the flattened part of the curve. However, this is only a temporary measure and, as the volume of the expanding lesion increases, compensation is overcome and the steep part of the curve is entered. The addition of the same volume to that which was added previously and produced very little change in ICP now results in dramatic increases. This process has four identifiable stages, as described in Box 9.3.

Other factors which have an influence on this complex process include cerebral blood flow and cerebral oedema.

For further information on influencing factors, see Hickey (2002).

Herniation

Herniation is the process by which tissue in a high-pressure compartment is compressed and forced through an available opening into an adjoining low-pressure compartment.

Box 9.3

Stages of the volume–pressure relationship in raised intracranial pressure

Stage 1	The compensation phase: there is no rise in ICP, and conscious level remains unaltered.
Stage 2	The early phase of reversible decompensation: a slight increase in brain mass will produce an elevated ICP. Early signs of deterioration in conscious level are noted.
Stage 3	The late phase of reversible decompensation: ICP is now very high and conscious level is deteriorating rapidly. Detrimental changes occur in the respiratory rate and pattern. ICP will soon equal mean arterial pressure with, ultimately, cessation of cerebral blood flow.
Stage 4	The irreversible decompensation phase: further deterioration leading to death will occur if intervention is not initiated.

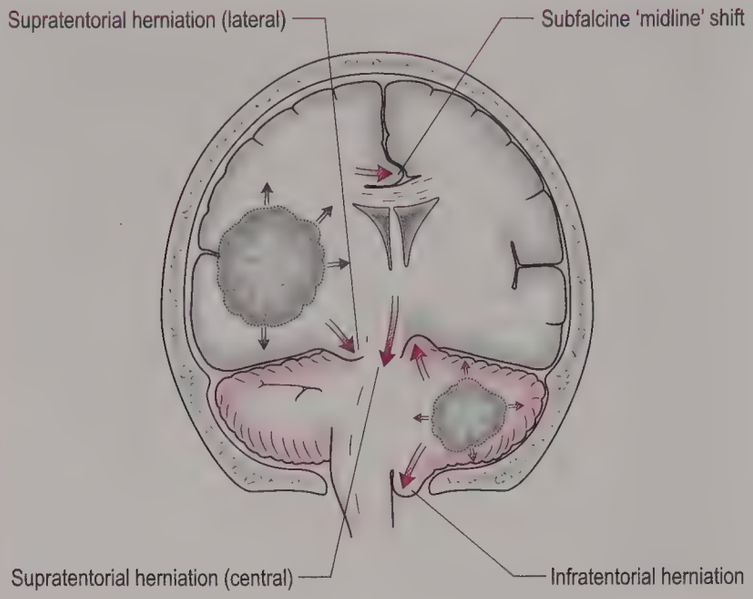

Fig. 9.19 Types of herniation.

Such a situation can exist in the patient with raised ICP. The skull has two compartments:

- the supratentorial, the region above the tentorium
- the infratentorial, the region below the tentorium.

The opening that permits supratentorial herniation is the tentorial notch, and that which permits infratentorial herniation is the foramen magnum.

Supratentorial herniation is either central tentorial herniation or lateral transtentorial herniation.

Central tentorial herniation is when symmetrical herniation is produced by a midline expanding lesion or generalised swelling of brain tissue. It involves the downward displacement of the cerebral hemispheres, diencephalon and midbrain. The nerves and posterior cerebral arteries are stretched and compression of the oculomotor nerve (IIIrd cranial nerve) occurs, resulting in a non-reactive pupil that may also be dilated. These and other structures are displaced into the posterior fossa.

Lateral transtentorial herniation occurs in the presence of an expanding lesion located close to the temporal lobe. The medial part of the temporal lobe (the uncus) is forced downwards. This type of herniation can inflict pressure on the reticular activating system, resulting in a decrease in conscious level (see Ch. 28). Lateral transtentorial herniation can subsequently develop into a central herniation (see Fig. 9.19).

Infratentorial herniation is the downward displacement of the lower part of the cerebellum (the cerebellar tonsils) through the foramen magnum, where compression of the medulla results. The offending lesion is located in the posterior fossa. This type of herniation is less common.

MEDICAL MANAGEMENT

Common presenting symptoms The head-injured patient with raised ICP may be fully alert and orientated or may range from experiencing drowsiness to being deeply unconscious. Neurological deficits can be found, e.g. alteration

of conscious level, onset of confusion or occurrence of a seizure. Answers to the questions listed below should be obtained as they have an influence on the management and outcome:

- *How long has the patient been unconscious?* The period of unconsciousness relates to the severity of brain damage, i.e. the longer the patient is unconscious, the more severe the damage.
- *Does post-traumatic amnesia (PTA) exist and for how long?* The patient's memory for events following injury is an indicator of the severity of brain damage, i.e. the longer the period of PTA, the worse the brain damage.
- *What were the cause and circumstances of the injury?* This may indicate if other extracranial injuries exist.
- *Does the patient have any headache or vomiting?* These would indicate the possibility of intracranial haemorrhage.

Table 9.2 lists the signs and symptoms of raised ICP.

Investigations In the head-injured patient, skull X-ray may reveal a fracture and computed tomography (CT) or magnetic resonance imaging (MRI) may demonstrate cerebral contusions or lacerations and/or an intracranial haematoma (Hickey 2002). Box 9.4 gives a description of the types of injury the brain may suffer.

ICP monitoring One of the most important diagnostic measures is the monitoring of ICP. This is an invasive technique involving direct measurement of ICP. A typical system comprises a fibreoptic transducer-tipped catheter, which can be placed in the lateral ventricle, subdural space or extradural space. The level of ICP is then transmitted to a digital data display or as a waveform. A pulsatile waveform will be demonstrated along with a pressure level indicating if the patient's ICP is within normal limits (≤15 mmHg) (see Fig. 9.20).

Treatment In the past, the treatment of head injury focused primarily on the interventions required to reduce ICP. However, greater emphasis is now placed on maintaining cerebral perfusion pressure (CPP) which is the blood pressure gradient across the brain, at more than 70 mmHg. This is because it has been shown that those patients with a high ICP, low blood pressure and low CPP make a poorer recovery. The means by which this is achieved are varied according to circumstances; however, the methods described here must not be used indiscriminately.

9.3 How is CPP calculated? (see Haslett et al 2002).

Hyperosmolar agents An intravenous infusion of 100 mL of 20% mannitol over 15 min will reduce ICP by establishing an osmotic gradient between the plasma and brain tissue, thus removing water from the oedematous brain tissue to the blood. This will 'buy' time to allow the patient to be prepared for transfer to a specialist unit or for surgery. However, if repeated boluses are administered, its effect is neutralised, leading to a rebound increase in ICP.

Controlled hyperventilation In the past it was recommended that the reduction of P_aCO_2 would reduce ICP. However, it also causes vasoconstriction, thus reducing cerebral blood volume. It is suggested by Lindsay and Bone (2004) that the resultant reduction in cerebral blood flow may itself cause ischaemic brain damage. Maintaining the blood pressure and CPP appear to be as important, if not more important, than lowering ICP.

Fluid management Views on the management of fluids have been contentious for some time. Some advocate restricting fluid in order to induce slight dehydration. By controlling intake, the extracellular fluid, including that of the brain, is decreased, thus reducing ICP. The intake may be set at 1–2.5 L/24 h. However, some now advocate achieving normovolaemia or increasing fluids. Doing this increases cerebral blood flow and thus improves oxygen delivery to the brain.

Sedatives After years of advocating that patients with a head injury should never be sedated, as this would impede assessment of conscious level, there are now special circumstances under which sedation may be used. If ICP fails to respond to standard measures then sedation, under carefully controlled conditions, may help by reducing cerebral

Box 9.4

Description of injury to the brain

Contusions
Described as a bruising of the cerebral tissue. Most commonly affects the frontal, occipital and undersurface of the temporal lobes. There are two types:

- coup — indicates haemorrhage and oedema immediately under the injury site
- contrecoup — damage occurs directly opposite the injury site. This is caused by the rapid acceleration or deceleration movement of the brain within the skull following severe trauma. Contused brain tissue affects the blood supply to that area, resulting in swelling of the brain which will raise ICP.

Lacerations
Brain tissue is lacerated as a result of, for example, a skull fracture, resulting in disruption to cellular activity which will produce focal neurological deficits such as hemiparesis. Contusions and cerebral oedema may also occur.

Haematoma
A localised collection of blood. These are named according to their location:

- extradural — situated or occurring outside the dura mater
- subdural — between the dura mater and the arachnoid
- intracerebral — within the brain substance.

Diffuse brain injury
Here, there is no specific focal pathology. Shearing of the white matter occurs, causing disruption and tearing of the axons.

Table 9.2 Signs and symptoms of raised intracranial pressure (ICP)

Clinical parameter	Signs/symptoms	Reasons
Conscious level	Deterioration in conscious level	Raised ICP will reduce the amount of oxygen received by the oxygen-sensitive cells of the cerebral cortex.
Respiration	Deterioration in respiratory pattern	A particular respiratory pattern will be seen in relation to the non-functioning area in the medulla and pons. *Breathing pattern* — *Non-functioning area* Cheyne–Stokes — Affects various areas Apneustic — Pons varolii Ataxic — Medulla Central neurogenic — Lower midbrain Hyperventilation — Upper pons Cluster breathing — Medulla
Pupils	(a) Alteration in pupil size (b) Reaction to light (c) Blurring of vision/diplopia (d) Ocular muscle paresis/paralysis	All the pupillary and eye movement responses to raised ICP are as a result of compression of the IIIrd cranial nerve (oculomotor). The ipsilateral pupil is usually affected first, followed by the other one.
Blood pressure	(a) An increase in systolic blood pressure followed by (b) a fall	The increase in blood pressure occurs as result of ischaemia (due to raised ICP) of the vasomotor centre. Implicated in this is a widening pulse pressure. If this is not corrected, the ICP continues to rise and the blood pressure then begins to fall dramatically until it is unrecordable.
Pulse	Initially bradycardia (<60 beats/min) develops with a full and bounding pulse. In the later stages the pulse becomes weak and thready	This is brought about as a result of increased workload on the heart which is attempting to overcome cerebral blood vessel resistance by pushing more blood into the cerebral circulation.
Motor function	Contralateral hemiparesis/ hemiplegia	The raised ICP affects pyramidal tract function, and continued deterioration will ensue until the limbs are unresponsive to deep painful stimuli.
	Headache usually in the early morning	Headache due to raised ICP is thought to be the result of displacement of the cerebrospinal fluid cushion producing dilatation of cerebral blood vessels, stretching of arteries at the base of the brain and traction of bridging veins. ICP will be adversely affected following REM sleep and by the retention of carbon dioxide during sleep, resulting in exacerbation of ICP in early morning.
'Cushing's triad'	Headache, becoming more severe or persistent Vomiting: may occur with early morning headache	This indicates that the ICP is rising and the intracranial contents are being compressed; 'herniation' may occur. The mechanism involved is not well understood.
	Projectile vomiting and problems with swallowing	These indicate that there is increasing pressure on the brain stem, where the control centres for these functions are located.
	Papilloedema	Occurs as a result of raised ICP being transmitted down the optic nerve to produce a swollen nerve head. This may be seen on direct fundoscopy. An unreliable sign, which is not constantly seen in all patients with raised ICP.
	Problems with speech or comprehension	These may indicate that ICP is rising and that there is pressure on the cerebral cortex.

No order is implied within the above set of signs and symptoms. Any combination in varying degrees can occur in each patient. Individually, each of the signs and symptoms can be caused by other pathology, including extracranially.

metabolism and thus offering a degree of protection for the brain (Lindsay & Bone 2004). Drugs that may be used include propofol and etomidate. However, each has associated side-effects that require to be countered. Propofol causes vasodilatation that may require to be counteracted to prevent blood pressure from falling and causing a reduction in cerebral perfusion. Etomidate inhibits steroid synthesis, and thus steroid cover will be required.

Surgical intervention Surgery may be performed to remove a focal lesion such as an expanding haematoma and this may be combined with decompression. Withdrawal of small amounts of CSF via a ventricular catheter results in a reduction of ICP, but this provides only temporary relief. To be effective, drainage would require to be continuous, but this is often impractical. Examples of neurosurgical approaches are given in Box 9.5.

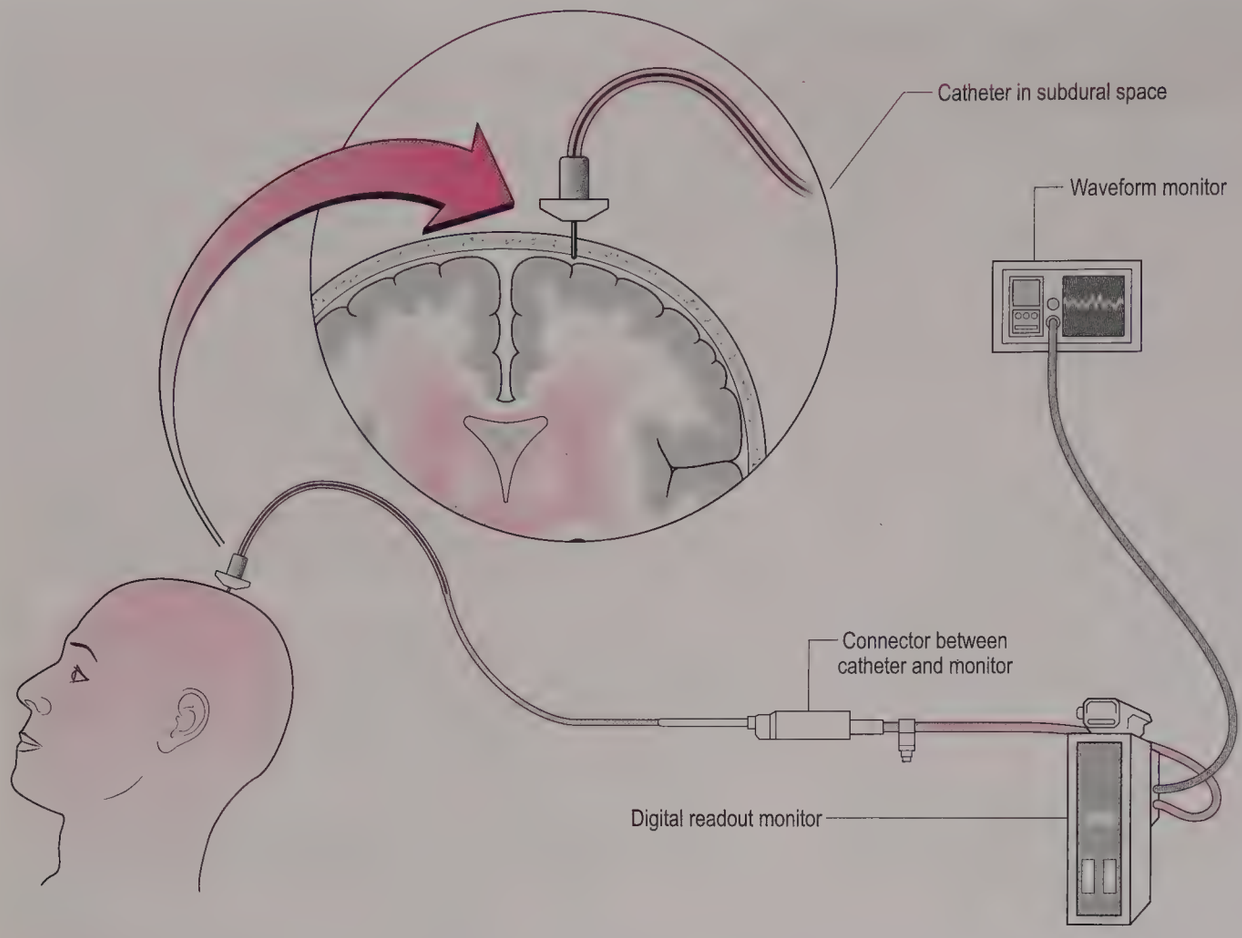

Fig. 9.20 The fibreoptic transducer-tipped catheter system for monitoring intracranial pressure (Camino system). (Adapted from Hickey 2002.)

Box 9.5

Neurosurgical approaches

Burr hole
A burr hole is a hole drilled through the cranium to allow access to the brain, usually to obtain a biopsy of tumour tissue.

Craniotomy
Access is gained to the brain via the formation of a bone flap, which is fashioned by several burr holes in a circular formation. The bone between the burr holes is cut with a wire saw and usually replaced at the close of surgery.

Craniectomy
This is a hole made in the skull by chipping away the bone, which means that it cannot be replaced. Usually used in the posterior fossa approach where the bone is particularly thick.

Trans-sphenoidal approach
This approach gains access to the pituitary gland and the incision is upper submucosa. This allows easier access to the pituitary gland (Hickey 2002).

An additional surgical technique is the transoral route. To gain access to the base of the brain and upper cervical spinal cord, an approach via the patient's mouth has been successfully used. This particular approach is not usually indicated for tumour removal.

NURSING PRIORITIES AND MANAGEMENT: Head injury

Head-injured patients with raised ICP can present in different ways on admission to hospital. The person may initially appear not to have sustained an injury, but can progress to become drowsy or confused, or develop speech problems or limb deficits. Seizure activity may occur.

Immediate priorities

The immediate nursing aim is to prevent further damaging rises in ICP and the first priority is to identify any alteration in respiratory function due to an obstructed airway or an absent cough or gag reflex. The appropriate interventions are described in Box 9.6.

The nurse should be aware of the presence of other injuries, e.g. multiple injuries, if the patient has been in a road traffic accident. Elaboration of the assessment and appropriate interventions for this can be found in Chapters 18 and 27.

Assessment of neurological status

This is performed in order to:

- make an initial assessment of the patient, which may influence any immediate action that needs to be taken
- have a baseline with which to compare the patient's condition and detect any changes in their condition.

Box 9.6

Respiratory care priorities in a patient with raised intracranial pressure

1. Assess the rate, depth and pattern of respirations to indicate the patency of the airway. Report if the rate is less than 14 and more than 24, and any irregularities in rate or rhythm, as these would indicate a rise in ICP.
2. Assess the skin for cyanosis, which would indicate inadequate respiration.
3. Apply oropharyngeal and tracheal suctioning only as required to remove secretions. Suction for no more than 15 s and consider pre-oxygenation prior to suctioning with 100% oxygen to prevent a build-up of carbon dioxide in the blood, resulting in further elevation of ICP.
4. Institute measures to achieve optimal respiratory status including insertion of a Guedel airway, positioning the patient on their side with a 30° head-up tilt, and administer oxygen as prescribed.
5. Assist with monitoring arterial blood gases and mechanical ventilation as required.

Any deterioration in neurological status may be an early indication that ICP is rising further, thus increasing the likelihood of herniation. Neurological assessment is important, as this may be the only indication that the patient's condition is deteriorating and a standardised method of monitoring neurological status will enhance this process. One commonly used method is the Glasgow Coma Scale (Fischer & Mathieson 2001). This is described in detail in Chapter 28.

The frequency of observations is determined by the patient's condition, ranging from intervals of 15 min to 4 h. Medical staff should be promptly informed of any pertinent changes in the patient's neurological status.

The nurse, as the health care professional who normally spends most time with the patient, should learn to observe changes in the patient's behaviour which may herald an impending change in neurological status. These may include the patient who does not answer questions so readily or who is becoming agitated and restless.

The expert neurosurgical nurse will be alert to the early warning signs which must be reported so that either surgical or conservative treatment can be carried out as soon as possible (see p. 409). Quite subtle changes in the patient's condition may be the only initial indication that ICP is rising.

9.4 Consider the experience of caring for a patient with raised ICP. What range of signs and symptoms might occur?

Cardiovascular assessment

The final life-threatening concern in a patient with a rising ICP is the effect of alterations to systemic and cerebral circulation, due to shock and cardiovascular instability. Unless requested by medical staff to do otherwise, the nurse should always report if:

- systolic pressure is less than 90 or more than 170 mmHg
- diastolic pressure is less than 50 or more than 100 mmHg
- the pulse rate is less than 50 or more than 100 beats/min.

Readings which are outwith these parameters will render the patient more susceptible to brain damage as a result of raised ICP and lowered cerebral perfusion pressure. The recognition of the vulnerable patient has been greatly facilitated by the use of the early warning system chart.

Surgery

Preoperative care Urgent surgery may be indicated on admission or in response to subsequent deterioration. The nurse may need to prepare the patient in a very short time and also provide adequate explanation and reassurance (see Ch. 26).

The approaches used in surgery are outlined in Box 9.5.

Postoperative care The overall priorities for patients following neurosurgery are:

- continuous assessment of neurological status (see Ch. 28, p. 970)
- instituting measures to avoid secondary brain damage
- administration of appropriate therapies.

The main complications of neurosurgery are outlined in Table 9.3.

As the patient progresses, their needs will require to be reassessed and the nursing interventions adjusted accordingly. Each patient will progress at a different rate, so continuing assessment and meeting the identified needs on an individual basis are important. The aim of care is to ensure optimum function and the early detection of complications.

Subsequent considerations

All of the nursing interventions identified in Chapter 26 will apply. Only those interventions specific to the patient who is unconscious due to raised ICP are included here. The main aim of care remains that of preventing further rises in ICP.

9.5 Using the information on care of the head-injured patient, select an approach to care that you are not familiar with and reflect on the care required for the first postoperative day following craniotomy (see also Ch. 28).

The patient care outlined in the following sections uses the Roper et al (2000) framework of the activities of living model.

Communicating

Unpleasant stimuli are known to cause a rise in ICP, so the nurse should take a calm, reassuring approach. Relatives should be encouraged to talk to the patient and, although they may feel rather foolish at first, they will be encouraged if they see the nurse doing this. They should, however, be warned to avoid discussing potentially upsetting topics. Everyone should be made aware that the unconscious patient may still be able to hear (Hickey 2002) and that they should therefore be sensitive to what they discuss in the patient's presence.

Non-verbal communication, particularly touch, has been shown to decrease ICP, so relatives should be encouraged to touch the patient, e.g. by holding hands or gently stroking

Table 9.3 Complications of neurosurgery

Complications	Cause	Interventions
Altered conscious level	Increased ICP due to cerebral haemorrhage/oedema	Frequent assessment of neurological status
Onset of seizures	Cerebral irritation	Observation of seizures. Appropriate interventions if they occur (see p. 427)
Limb weakness	Increased ICP due to cerebral haemorrhage/oedema	Frequent assessment of limb movements
Speech problems	Increased ICP due to cerebral haemorrhage/oedema	Frequent assessment of verbal responses
Respiratory problems	Increased ICP due to cerebral haemorrhage/oedema	Frequent assessment of respiratory status
Loss of swallowing reflex	Increased ICP due to cerebral haemorrhage/oedema	Frequent assessment of swallowing reflex
Loss of corneal reflex	Increased ICP due to cerebral haemorrhage/oedema	Frequent assessment of corneal reflex
Periorbital oedema	Direct result of surgery	Observe for swollen/bruised periorbital tissues

the patient's arm, despite the extensive equipment which may surround them.

Any investigations that are to be performed should be explained to the patient and their family, who will be anxious and distressed at this time, particularly as outcomes may be uncertain.

Breathing

Respiratory assessment and appropriate intervention, as outlined in the previous section, will continue as long as the ICP remains elevated. The patient's position should be changed every 2 h or as the need arises, and chest physiotherapy should be instituted as this helps prevent pooling of secretions in the lungs and atelectasis. The patient, if able, should be encouraged to undertake deep-breathing exercises. There is evidence to demonstrate the benefits of adopting the prone position to improve respiratory status; however, this is not recommended in this instance as it may lead to a further rise in ICP (Sullivan 2000) (see Ch. 29, p. 995).

Maintaining a safe environment

The patient's bed should be positioned where they can be easily observed. If the patient is restless or agitated, the nurse should attempt to find out why. Adequate non-narcotic analgesics, such as codeine phosphate and dihydrocodeine, can relieve a headache and are the analgesics of choice, as they do not mask conscious level and will minimise the risk of raising ICP. If the patient is confused, they may attempt to climb out of bed, despite explanations as to why they should not do so. They may not appreciate their limb deficit and may attempt to walk, thus endangering themselves. If appropriate, relatives can help persuade the patient to stay in bed and, as a last resort, sedation may be necessary. The use of side rails should be considered, but the correct precautions must be taken. If the patient proves very difficult to manage, it may be necessary to replace the bed with a mattress on the floor or to care for the patient sitting in a chair, possibly with a table secured in front. Such situations should be fully explained to relatives beforehand.

The nurse should always be aware of the possibility of a seizure and appropriate interventions carried out should this occur (see p. 427).

Controlling body temperature

Each 1°C rise in body temperature increases the metabolic demand of the brain by 10% (Hickey 2002). This increases blood pressure and encourages vasodilatation, which will increase ICP. Body temperature should be recorded at least 4-hourly, as pyrexia may indicate hypothalamic damage or the presence of infection. Any source of potential infection, such as leakage of CSF from the patient's ears (otorrhoea) or nose (rhinorrhoea) from a base-of-skull or anterior-fossa fracture must be identified and reported. Confirmation of this is obtained by testing the fluid for the presence of glucose, using a reagent strip. A positive result, although not absolutely conclusive, is indicative of the presence of CSF. The identification of a fracture on the skull X-ray will confirm the evidence. CSF leakage left undetected increases the risk of developing meningitis.

Necessary measures to reduce the patient's temperature include tepid sponging, cool fanning or medication, such as paracetamol suppositories.

Mobility

The patient will require frequent positional changes to avoid developing pressure ulcers. Semi-prone and lateral positions are both suitable. Moving the patient also encourages expansion of the lungs and prevents pooling of secretions. A slight head-up tilt of 30° will not only reduce ICP but also aid lung expansion and prevent chest infection. The patient's body should be maintained in neutral alignment, avoiding neck flexion and rotation. The hips should be carefully positioned, avoiding flexion over 90°. These positions aid venous drainage as they minimise intra-abdominal and intrathoracic pressure, which will help to decrease ICP.

Passive movement exercises, which are joint movements undertaken without effort on the part of the patient, should be performed to prevent muscle wasting and limb contractures as these will hinder rehabilitation. However, isometric exercising (see Ch. 10) should be avoided as this raises ICP. Thromboembolism deterrent (TED) stockings should be used to minimise the risk of deep venous thrombosis.

As the patient's condition improves, further movement should be encouraged. The physiotherapist will provide specialised exercises if there is a limb deficit (Hickey 2002). Sitting out of bed in a chair will help to reduce respiratory

complications and encourage limb movements. It may also act as an important psychological boost for the patient and their family as they will view this as progress.

Eating and drinking

As soon as the patient is able, oral food and fluid intake should be encouraged. Intravenous fluids may be required, however, and fluid restrictions should be carefully monitored and recorded to avoid inadvertent increases in ICP due to worsening cerebral oedema. Some patients may require enteral feeding, and the nurse should observe all the usual precautions, as detailed in Chapters 4 and 21. The patient with a basal skull fracture must not have the tube passed nasally as there is a danger of further damage and infection and therefore passing the tube orally is suggested.

Eliminating

Observation of urinary output should be monitored, in line with any restricted intake, and some patients require urinary catheterisation. The precautions and associated nursing care for this can be found in Chapter 8. As consciousness is regained, the patient may attempt to remove the catheter, an indication that normal functioning is returning. Constipation should be avoided to minimise rises in ICP caused by straining at stool (see Ch. 4).

9.6 Discuss with your mentor the approaches to care you have seen in practice with the care of the unconscious patient. Consider the appropriateness of these approaches and whether there might be better alternatives.

Rehabilitation

This forms a crucial part of the recovery process and the principles outlined in Chapter 34 apply. The aim is to maintain and promote function, and prevent further deterioration and occurrence of complications. The neurological deficits which can impede progress during the rehabilitation process are described in Box 9.7.

The patient with a head injury may experience neurological deficits including limb weaknesses and speech and visual problems. They may also experience changes in personality, memory and intellect, and a combination of all these factors makes full rehabilitation very difficult to achieve.

The ward team, in partnership with the patient's family and friends, should aim to assess the patient's needs and provide optimal care and support. Realistic goals should be set as the rehabilitative process may take months or years to achieve. Some patients may remain in a persistent vegetative state requiring constant nursing in a care facility (see Ch. 28, p. 970).

In some circumstances, the patient's role within the family changes. They may previously have been the provider within a family and may now have to revert to being dependent on others. Employment prospects may alter and, for some, a return to work is impossible. This can affect both the family's short- and long-term plans and may also have financial implications. An alteration to the patient's personality may affect relationships within a family, resulting in stress and discord. Indeed, some families will report that the person has completely changed and is now different from the person they knew before (see also Ch. 34). Often, due to the distress caused by such changes, repeated explanations are required and the reactions of the family can range from apparent calm acceptance to rudeness and even verbal aggression towards nursing staff. This should be accepted and seen as part of the family's way of coming to terms with the reality of the situation.

The multidisciplinary approach

Early and close liaison between the many health care professionals involved in hospital and community work is essential. The resources of the voluntary sector and self-help groups should be brought in, as well as the patient's family and friends. Sinnakaruppan and Williams (2001) reviewed the perceived needs of family carers and identified that information giving and emotional support were the two most important.

Preparation for discharge

Many patients and their families will be particularly anxious as the time for discharge approaches. Much of this anxiety can be allayed by appropriate preparation and reassurance and an effective plan for discharge. The residual problems that may persist vary widely, ranging from headache to major behavioural changes, with or without neurological deficits. The degree of residual deficits will determine what intervention is required in the discharge plan. Other factors may include whether the patient requires further surgery or other therapies, necessitating attendance at a hospital or rehabilitation centre. A home assessment may be performed jointly by the occupational therapist and community nurse. Pre-discharge visits home may be considered and will help to identify potential problems. If appropriate, referral to a community liaison nurse and/or to the primary health care team should be made to enable optimal assessment and support within the community setting.

Despite these preparations, it is not usually until the patient is at home that the family members fully appreciate the difficulties that may be before them. Home routines may require to be adjusted, and whilst this may be easy in the early stages, it becomes more difficult to accept in the long term. Other members of the family will often view the

Box 9.7

Neurological deficits that can impede rehabilitation

- Motor impairment, e.g. spasticity or ataxia
- Sensory impairment, e.g. loss of sense of pain or touch
- Communication disability, e.g. dysphasia
- Psychological disability
  - cognitive intelligence, e.g. memory loss
  - perceptual, e.g. eye–hand coordination
  - emotional, e.g. irritability
  - behaviour or personality, e.g. poor self-image
- Social disability, e.g. social withdrawal
- Educational or vocational disability

All the above have an effect on the patient's ability to resume educational or vocational activities.

disruption to their personal lives negatively and eventually much of the early support gradually disappears. If the patient is still at a stage in which they require support, this withdrawal can be catastrophic. Often the patient's partner may be left to shoulder the burden alone, and in this situation, a support group such as Headway (see 'Useful websites') may help. This organisation seeks to provide help and assistance to patients and their families. Regular meetings and other special outings are arranged, along with helpful literature. Relatives are provided with a forum for discussion of the problems they face and many appreciate sharing their problems with others who are similarly placed. Some families acknowledge a sense of failure should the patient require to be admitted for long-term care. They may feel that they have let their loved one down and do not like to admit that they are unable to cope.

CEREBROVASCULAR DISEASE

'Cerebrovascular disease' can be defined as brain disease occurring as a result of a pathological disorder of the blood vessels or of the blood supply. This section considers:

- stroke, the most common cerebrovascular disorder
- subarachnoid haemorrhage, an uncommon but major life-threatening situation that demands acute neurosurgical intervention.

Stroke

A stroke, uncommon in children, can occur at any time during adult life. Thrombotic stroke tends to be seen in the 60–90 year age group, and embolic and haemorrhagic stroke in the 25–60 year age group.

Stroke is the third most common cause of death in developed countries: 200 per 100 000 will have a stroke each year. Age increases the risk. Most strokes occur in the 65–75 year age group and are more common in men. In the UK, 100 000–120 000 strokes occur per annum, of which 70 000 result in death. The mortality rate rises in proportion to the length of time the patient is unconscious. Of patients unconscious for 48 h or more, 98% will die, compared with 12% where there is no loss of consciousness (Lindsay & Bone 2004).

Subarachnoid haemorrhage

Subarachnoid haemorrhage is often wrongly referred to as 'cerebral' or 'brain haemorrhage'. A subarachnoid haemorrhage is experienced by 10 000–15 000 people per year, with 15% dying before they reach hospital. It has a male bias in the under-40s, but this reverts to a female bias in the over-40s (Lindsay & Bone 2004).

PATHOPHYSIOLOGY

Causes of stroke

There are three main causes of stroke:

- cerebral thrombosis
- cerebral embolus
- cerebral haemorrhage.

As a result of the rise in substance abuse, an increasing cause of stroke in the under-45s is the pharmacological action of drugs such as crack and crack cocaine (see Ch. 36).

Cerebral thrombosis This is the most common cause of stroke, in which atherosclerosis causes narrowing of the lumen of the affected blood vessels (Lindsay & Bone 2004) (see Ch. 2). It occurs either during sleep or shortly after waking and is thought to be due to the older person's poorer reflex response to changes in position (postural hypotension). As the atheroma builds up, it initially only partially occludes the blood vessel until the blood supply is suddenly disrupted. During the 24–48 h following this, neurological deficits frequently worsen.

Cerebral embolus An embolus may lodge in the narrowed lumen of a bifurcation in the cerebral circulation. The usual origin of the embolus is a cardiac thrombus, in the presence of cardiac disease such as myocardial infarction. Air or fat, the latter for example from a fractured femur, can also act as an embolus. Embolic stroke can occur at any time.

Cerebral haemorrhage Haemorrhage can occur into:

- the cerebral tissues — intracerebral haemorrhage
- the subarachnoid space — subarachnoid haemorrhage.

The most common cause of subarachnoid haemorrhage is a weakness in the wall of a cerebral blood vessel, which causes a dilatation (an 'aneurysm'). Other causes include arteriovenous malformations (AVMs), but in some patients no cause is identified. Hypertension, although seen in some patients, is not always present, but damage caused by arteriosclerotic changes is common. Cerebral aneurysms may be described eponymously as 'Berry' or as 'saccular'. Most aneurysms form on the anterior part of the circle of Willis (see Ch. 2) and some patients have multiple aneurysms.

The exact cause of aneurysm formation remains unknown and some remain silent, causing no symptoms. Some bleeding can occur through the very thin aneurysmal wall and produce mild signs and symptoms of subarachnoid haemorrhage without rupture occurring.

Risk factors

Certain predisposing contributory factors increase the likelihood of cerebrovascular disease (see p. 14).

The effects of a stroke

The occurrence of a stroke, for whatever reason, will result in an interruption of the cerebral blood supply, diminishing the essential oxygen and glucose levels of the brain. Within hours, oedema occurs at the site of the main lesion as a result of the changes to the cell membranes, allowing fluid to leak into the extracellular space. This gradually worsens, peaking between the fifth and seventh day and then gradually resolving.

A classification system for stroke is given in Box 9.8.

The damage caused by a stroke is due largely to the extent of ischaemia that occurs. It has been established that there is a reduction in global cerebral blood flow following stroke. In and around the immediate area of the infarction, more subtle changes are detected in regional cerebral blood

Box 9.8

Classification of stroke

Transient ischaemic attacks
- Onset and disappearance of a neurological deficit within 24 h due to temporary disturbance of blood supply to the brain
- No residual neurological deficit
- Symptoms commonly last from several minutes to 2–3 h, but may last up to 24 h

Reversible ischaemic neurological deficit
- Neurological deficit persists longer than 12–24 h
- Symptoms may last days or weeks
- Minimal, partial or no residual neurological deficit

Stroke in evolution
- Symptoms persist beyond 24 h with an associated progressive deterioration of neurological status
- Residual neurological deficits
- Probably due to a failure of collateral circulation

Completed stroke
- Condition stabilises and neurological deficit remains

Box 9.9

Common types of disability caused by stroke

Motor deficits
- Movement deficits
  - — loss of movement in the limbs on one side of the body (hemiplegia)
  - — weakness in the arms and legs (hemiparesis)
- Speech difficulties, such as:
  - — dysarthria, where the patient has distorted and indistinct speech but is able to understand what is said and can still read and write
  - — dysphasia, i.e. loss of the ability to talk, read and write
- Facial paralysis on the affected side, causing drooling, indistinct speech and difficulty in chewing and swallowing

Sensory deficits
- Visual deficits
  - — partial loss of the visual field
  - — double vision
  - — poorer vision than previously
- Poor response to superficial sensation, e.g. heat and cold
- Perceptual deficits, such as incorrect perception of the environment or loss of sense of smell
- Lack of awareness of the disabled part of the body

Loss of consciousness
- From mild impairment to coma
- Loss of memory or shortened attention span

Emotional deficits
- Emotional disturbances, e.g. change of personality, from quiet and pleasant to surly and aggressive, or vice versa
- Loss of self-control or inhibitions
- Confusion
- Depression

Bladder/bowel dysfunction
- Loss of bladder and/or bowel control (incontinence)
- Frequency
- Urgency

flow. These comprise areas of reduced blood flow bordered by areas of increased flow due to vasodilatation of the arteriolar bed. Progression from reversible ischaemia to infarction depends on the degree and duration of the reduced blood flow (Lindsay & Bone 2004). The affected area of the brain loses its ability to carry out its function, e.g.:

- controlling movement in a specific part of the body
- controlling cognitive or emotional processes, speech or language
- experiencing sight, sound, taste or touch.

Another influence on the course of events is the occurrence of cerebral oedema. As the oedema starts to subside, cells begin to function again, explaining the rapid progress potentially made in the first 2–3 weeks.

After this initial period, recovery is slower, partly due to other cells taking over the functions of the permanently damaged cells. At this stage, the patient begins to learn ways of handling their disability and regains their self-confidence and interest in general affairs.

Generally speaking, if a patient shows a marked improvement within the first week, then minimal deficit will result. Conversely, if little or no improvement is made during this time, the outcome is likely to be poorer. The most common types of residual disability are listed in Box 9.9.

Common presenting symptoms The onset of cerebrovascular disease can be difficult to pinpoint. In thrombotic and embolic stroke, minor symptoms are often dismissed by patients and it is not until a significant symptom presents that the patient seeks medical help. Earlier symptoms, e.g. tingling and weakness of a limb, are the result of mild transient interruptions of neurological function. Major episodes requiring medical intervention include loss of consciousness, speech difficulties and hemiplegia, which may be accompanied by loss of vision on the affected side.

Subarachnoid haemorrhage typically causes sudden, severe headache, often accompanied by vomiting. The patient may be alert and orientated and may feel intense fear at what they are experiencing. Alternatively, there may be loss of consciousness, seizures and evidence of neurological deficits such as IIIrd nerve palsy, hemiplegia or hemiparesis (Lindsay & Bone 2004). Many of these symptoms are related to the effects of raised ICP (see p. 408).

The patient may still have a residual headache and neck stiffness which may be confirmed by passive neck flexion. This indicates meningism, caused by the presence of blood in the subarachnoid space irritating the sensitive tissue of the meninges. Kernig's sign, demonstrated by extending the knee to stretch the nerve roots, will cause the patient some pain and is an indicator of meningism.

Conscious level may be depressed and there may be evidence of seizures. Other findings will include hypertension and pyrexia. Signs and symptoms will depend on a variety of factors and can occur according to the area of the brain affected (see Fig. 9.5).

9.7 Think of two patients you have cared for, who have had a stroke. For each patient, write a short word picture of how you recall them, then compare your notes with the common presenting symptoms you have just read about. How similar were they?

MEDICAL MANAGEMENT

Investigations will be as follows:

A CT scan may be performed to determine the location and type of stroke and to ensure that there is no other, potentially treatable, lesion to account for the stroke. If a subarachnoid haemorrhage is diagnosed and the patient is alert, obeying commands and has no focal neurological deficits, a lumbar puncture is indicated (Jamieson et al 2002). Confirmation of the subarachnoid haemorrhage will result when examination of the CSF reveals uniform bloodstaining or, if 6 h have elapsed since the original bleed, straw-coloured CSF, called 'xanthachromia', is apparent. This colour is due to the breakdown of haemoglobin.

If the patient is displaying signs of raised ICP, e.g. is in coma or has a neurological deficit, lumbar puncture is contraindicated because of the risk of coning (see p. 407). The safe alternative of CT is used, which may reveal the presence of blood in a variety of locations such as the surface of the cerebral hemispheres or in the ventricular system.

Angiography If blood is detected, either by lumbar puncture or CT scan, angiography is indicated (see Appendix 1). The presence and location of aneurysms and other blood vessel anomalies such as stenosis will be demonstrated. Angiography is not without risk and its performance may be delayed if the patient is in a vulnerable clinical condition. Electrocardiography may be performed to exclude or confirm cardiac disease.

Treatment Approaches to stroke management vary widely because of the variety of presentations. They will depend on:

- the site of the occlusion or aneurysmal rupture
- the degree and extent of the ischaemia or haemorrhage
- the effectiveness of medical and nursing intervention
- the patient's response.

The aims are to prevent further brain damage, reduce the risk factors, provide supportive care and regain functional independence.

Treatment can be conservative or surgical.

Conservative management is as follows.

- Anticoagulant therapy is often used in an attempt to halt further deterioration and to improve the patient's recovery. However, some doubt has now been cast on its usefulness, as a risk of further haemorrhage into the infarcted brain has been identified (Lindsay & Bone 2004). One example of an anticoagulant is warfarin.
- The use of thrombolytic agents, especially recombinant tissue plasminogen activator (rTPA), has been investigated. Early indications are that its use within a few hours of infarction produces a sustained, significant neurological improvement (Lindsay & Bone 2004).
- Calcium antagonists, e.g. nimodipine, have been used in patients following subarachnoid haemorrhage and their use has been shown to reduce the incidence of cerebral infarction.
- Antiplatelet agents. The use of aspirin as an antiplatelet agent is now well established practice, with the recognition that the sooner treatment is commenced the better. Other factors. Pre-existing contributory disorders may be treated with medication, e.g. antihypertensive agents and diuretics may be used in the patient with raised blood pressure.

Surgical management uses two techniques (Lindsay & Bone 2004):

- carotid endarterectomy, which involves the removal of stenosing or ulcerating atheromatous lesions at the bifurcation of the common carotid arteries
- a superficial temporal to middle-cerebral artery anastomosis (ST–MCA bypass), which provides an artificial collateral blood supply to the affected part of the brain.

Aims of treatment in subarachnoid haemorrhage The main aim of treatment is to avoid a potentially fatal recurrence of bleeding. In untreated patients, 30% will bleed again within 28 days, and 70% of these will die.

Preventing rebleeding An effective way to prevent rebleeding is to place a metal clip across the neck of the aneurysm. This entails a craniotomy, a major neurosurgical procedure. This procedure is not suitable for all patients, either due to their general condition or to the location of the aneurysm. Alternative surgical procedures include wrapping, which involves the application of muslin gauze around the fundus of the aneurysm. Wrapping may be combined with clipping in some patients. A third technique, known as 'trapping', may be indicated. This involves clipping the feeding vessels supplying a large aneurysm. Another technique involves the insertion of helical platinum coils into the aneurysmal sac to induce thrombosis (Nichols et al 2002).

The timing of surgery is crucial and opinions vary with regard to this. When surgery is carried out as soon as possible to avoid the risk of rebleeding, there are higher morbidity and mortality rates during the operation. Delayed surgery decreases the operative risks but increases the risk of rebleeding. Antifibrinolytic therapy may be used in an attempt to prevent this (Lindsay & Bone 2004).

There are now well-established grading systems to identify the patient most at risk from deterioration after subarachnoid haemorrhage. The best known of these is the Hunt and Hess scale which is described in Hickey (2002). A critical review of scales is provided by Cavanagh and Gordon (2002).

Complications of subarachnoid haemorrhage that may influence treatment are as follows.

Rebleed This is a risk which peaks between days 7 and 10 following the original bleed, due to the process of fibrinolysis, which dissolves the clot that formed over the ruptured vessel (Lindsay & Bone 2004).

Cerebral ischaemia Reduction of the blood supply to any part of the brain can have serious consequences for the patient. The extent of its effects will depend on the site and extent of the ischaemia. About half of the patients who develop ischaemia will be left with a permanent deficit.

Box 9.10

Hydrocephalus

This is a condition in which there is a progressive dilatation of the cerebral ventricular system due to a production of CSF which exceeds the absorption rate. This may be brought about by an obstruction of one of the pathways by, for example, a tumour. Other causes include congenital stenosis and infection.

It can occur at all ages; it may be congenital in the newborn or secondary to some other intracranial pathology in the older child and adult.

Treatment is by insertion of a ventriculoperitoneal shunt. This is a long narrow plastic tubing, valve and reservoir device. One end is inserted into the lateral ventricle and the other end is sutured into the patient's peritoneum via a subcutaneous route. The excess CSF is now 'shunted' from the ventricles into the peritoneum, from where it then returns to the bloodstream.

Arterial narrowing (vasospasm) is common following subarachnoid haemorrhage and can have similar results (Kirkness et al 2002). A case study on the use of drugs to control vasospasm is provided by Le Strange (2003).

Hydrocephalus The normal drainage of cerebrospinal fluid may be impaired by the presence of a haematoma pressing on the narrow pathways or by haemorrhage into the CSF impeding the flow of the normally clear fluid. About one-fifth of patients are affected, although only one-third require treatment (see Box 9.10).

Intracerebral haematoma Bleeding during a subarachnoid haemorrhage may result in a localised collection or haematoma. This will contribute to a rise in ICP and may demand treatment.

Epilepsy Seizures may occur, necessitating treatment with anticonvulsants (see p. 427).

NURSING PRIORITIES AND MANAGEMENT: Stroke

Prevention

One of the most important aspects of stroke management is prevention, by identifying at-risk individuals and dealing with early predisposing factors such as hypertension.

Transient ischaemic attack (TIA)

A TIA is caused by insufficient blood reaching the brain, for a brief period. It is similar to a stroke but the pathology is transient, symptoms lasting for only a few minutes. These are:

- weakness of one side of the body
- tingling and twisting of the mouth
- loss of speech
- disturbance of vision (www.stroke.org.uk).

If an individual or their relative notices the symptoms of a mild TIA, they should contact a doctor immediately, as TIAs can be treated.

Reducing the risk of stroke

Although action can be taken to reduce the likelihood of stroke occurring, the following factors put people at greater risk.

High blood pressure Using medication to reduce high blood pressure does reduce the risk of a stroke. Ideally blood pressure should be checked periodically, e.g. every 4 years until the age of 40, and every 2 years after that. Drinking alcohol raises blood pressure. The consistent consumption of four or more units of alcohol per day for men and three or more for women is not advised (NHS Health Scotland 2003).

Cigarette smoking In people who smoke 20 cigarettes a day or more, the risk of having a stroke is three times greater than that for people who do not smoke (www.stroke.org.uk). Smokers should therefore be encouraged to stop smoking, and young people discouraged from starting to smoke (see Ch. 3).

High blood cholesterol may lead to coronary heart disease. Patients with high blood cholesterol can reduce the amount of cholesterol-rich foods they take, by the following measures:

- using spread which is high in polyunsaturates rather than saturates, and using vegetable oil for cooking
- using skimmed milk, rather than full-cream milk
- avoiding cream and cheese, and cutting down on the number of eggs eaten
- choosing lean cuts of meat or removing the fat.

Being overweight may increase the likelihood of high blood pressure, so at-risk patients should try to control their weight.

Diabetic patients are more likely to have a stroke, so the level of glucose in the blood and urine should be checked regularly (see Ch. 5, Part 2).

The contraceptive pill increases the risk of stroke in younger women, particularly if there is a family history of arterial disease. Other forms of contraception should therefore be recommended.

Nursing care following a stroke

Often the immediate priorities and follow-up care overlap, and they are separated here for the purposes of explanation only. An optimal outcome is more likely when appropriate techniques and resources are utilised, encompassing every member of the multidisciplinary team, and when the rehabilitation process commences as soon as possible. NHS Education for Scotland (2005) provide a framework of core competencies for all health care professionals involved in the care of individuals with or at risk of a stroke, in acute and primary care settings.

Immediate priorities

Airway Techniques for maintaining a patent airway and adequate ventilation, outlined in Box 9.6, are a priority (see Ch. 28).

Safety and comfort Hemiplegia often results from stroke, so the care of paralysed limbs and avoiding the hazards of immobility are axiomatic.

Similarly, the patient with a decreased level of consciousness will require to have their safety needs met (see Ch. 28). Raised intracranial pressure will pose a number of dangers for the patient (see interventions outlined on p. 412 for care of a patient with a head injury).

The patient who has experienced a haemorrhage will be assessed for headache and an analgesic such as codeine phosphate or dihydrocodeine, which do not mask conscious level, prescribed. Patients often have a stiff neck which can be alleviated by cold packs and a position in bed which avoids extreme flexion or sudden movement of the neck. A quiet darkened room will also relieve discomfort, particularly if the patient is photophobic. An antiemetic may also be prescribed for nausea and vomiting.

Patient safety and comfort are greatly enhanced when consideration is given to the patient's ability to communicate and to their emotional well-being, as well as that of their family.

Communicating Speech impairment or loss can be a frightening experience for the patient and their family. Early referral to a speech and language therapist (SALT) is important, so that an expert assessment can be performed and an appropriate strategy identified. It is crucial to ascertain the type and nature of the speech deficit, e.g. whether the patient's difficulties are related to expression or to comprehension. The nurse should encourage and help the patient to perform the exercises prescribed by the speech and language therapist.

Powerful emotions are often displayed by the patient following stroke (Hickey 2002). Many of these patients display anger at or frustration with the frightening situation in which they find themselves. This can be vented onto the nurse and can manifest itself as lack of cooperation or physical abuse. Patients who are unable to communicate their feelings verbally may feel trapped inside a body that refuses to do as they want. Some patients are convinced that their words are properly formed and fail to realise that what the nurse or family is hearing is indistinct or jumbled. The patient needs to be repeatedly reminded of what has happened to them and why they feel the way they do, in order to try to reassure them. Patients and their friends and family can become very distressed when they meet and this needs to be handled with sensitivity. Some patients experience denial (see Research Abstract 9.1).

Mobility Patients with mobility difficulties require a clutter-free environment. The nurse should ensure that any obstacles likely to pose a danger are removed and that the patient is wearing appropriate clothing and footwear, e.g. outdoor shoes rather than loose-fitting slippers.

Visual impairment may also be dangerous for the patient (see Box 9.9). Simple interventions that may help include providing an eye patch to eliminate double vision and approaching the patient with homonymous hemianopia, i.e. loss of vision in the same half (right or left) of the visual field in both eyes, from the side with the intact field of vision. These interventions should also be explained to the patient's family, who should be advised about basic safety precautions at home following discharge, e.g. removal of loose rugs and any necessary rearrangement of furniture.

RESEARCH ABSTRACT 9.1

During the first few months after a stroke, family caregivers must learn how to care for the stroke survivor in the home setting. Although there are some studies that address the needs and concerns of stroke caregivers during the early post-stroke period, there are very few caregiver studies that report strategies used by caregivers to deal with their needs and concerns. Studies are also lacking that report the advice that caregivers would offer to others. The purpose of this study was to determine the self-reported needs, concerns, strategies and advice of family caregivers of stroke survivors during the first 6 months after hospital discharge. Using open-ended questions, 14 female family caregivers of stroke survivors (8 African–American, 6 white) were interviewed to identify their needs and concerns, strategies they used to deal with stroke and advice they would offer to other stroke caregivers. Findings revealed five major categories of caregiver needs and concerns: information, emotions and behaviours, physical care, instrumental care and personal responses to caregiving. Based on the findings, an initial needs and concerns checklist was developed. This checklist, as well as the list of strategies and advice, may help to identify relevant areas for caregiver intervention.

Bakas T, Austin J K, Okonkwo K F, Lewis R R, Chadwick L 2002 Needs, concerns, strategies and advice of stroke caregivers the first 6 months after discharge. Journal of Neuroscience Nursing 34(5): 242–251

Differences of opinion exist with regard to mobility following subarachnoid haemorrhage. One approach advocates that patients should have strict bed rest and that their visitors should be restricted; however, this approach can heighten the patient's anxiety, particularly when they feel well. An alternative approach is to allow the patient up to the toilet provided they are symptom-free (Hickey 2002). The patient with a neurological deficit or alteration in conscious level should be nursed in an easily observable bed with side rails as required. Seizure precautions should also be adopted as outlined on page 427.

Eating and drinking Initially the patient's fluid intake is likely to be via an intravenous infusion and the nurse will be responsible for maintaining this accurately. A patient who has had a subarachnoid haemorrhage may be prescribed a fluid regimen of 2.5–3 L/day. This helps to maintain arterial blood pressure, which encourages adequate cerebral perfusion and, in turn, prevents cerebral ischaemia and infarction. As the patient progresses, an oral diet may be introduced gradually, providing that swallowing and cough reflexes are intact. The patient may need help with feeding, or can be given adapted eating utensils which allow them to feed themselves. Being spoon-fed can be embarrassing and sensitivity is required to preserve the patient's dignity and self-esteem. The nurse should determine the patient's capability; for example, hemiplegia may prevent them from cutting up their own food but, once this is done, they can feed themselves. The patient with a facial paralysis should be encouraged to chew food on the unaffected side only.

Dysphagia may hinder progress. If the patient experiences swallowing difficulties, these should be assessed to determine the extent of the difficulty before attempting oral feeding. A combined assessment may be performed by the dietitian and speech and language therapist. Recommendations may include the use of nasogastric feeding with a prescribed proprietary liquid diet, and the use of specialised exercises and techniques to aid swallowing. Increased oral hygiene is important in both instances. The patient with dysphagia receiving nasogastric feeding will be more prone to a dry mouth and the patient who is managing to take an oral diet may leave food debris in the affected side of their mouth. Regular oral inspection and oral hygiene are essential (see Ch. 15).

Eliminating Interruption of the patient's usual elimination pattern is due to loss of consciousness and enforced immobility. Urinary incontinence is best resolved by retraining the patient to use bedpans or urinals at specified intervals, rather than resorting to catheterisation. Condom-type urinary appliances may be suitable for male patients, but these are not without practical problems. No successful female equivalent is yet available.

Kwan et al (2004), in a before-and-after study, evaluated the introduction of an integrated care pathway for acute stroke, and found evidence that the use of the pathway improved the quality of documentation and process of care, and reduced the risk of certain post-stroke complications; for example urinary tract infections were significantly less frequent.

CASE HISTORY 9.1

Mrs F

Mrs F had her stroke on May 21st. She was completely paralysed on the right side and had lost all power of speech. A CT scan on May 22nd showed a large area of ischaemic damage on the left side. By June 1st her speech was normal, but she still could not walk at all or use her right arm. She took her first steps on June 21st, and 1 month later was walking alone using a tripod. A little movement returned in her right arm 6 weeks after her stroke. She was discharged on July 16th, and by early November she was walking to the local shops, talking normally and was able to use her right hand and arm for holding cans.

Mrs F's story is not unusual, and illustrates several points:

- There was a rapid recovery over the first month, when her speech returned and leg movements started
- Her recovery continued, although slowly, for about 6 months
- This happened despite the fact that the scan appeared to suggest that Mrs F had lost a lot of brain function.

Processes of recovery

1. Reduction of brain swelling around the stroke area
2. Possible growth of nerve axons
3. Use of other parts of the brain
4. Learning new ways of coping
5. Adaptation in behaviour by others towards the person who has had a stroke.

Behind this success story must be close collaboration between community nurses and other members of the health care professions.

Rehabilitation

The overall aim of rehabilitation, as outlined in Chapter 34, is the active promotion and restoration of independence, and this applies equally to all patients following a stroke, whether they are at home, in hospital or in a rehabilitation centre (see Case History 9.1).

Lindsay & Bone (2004) describe the common complications following a stroke and provide advice on how to deal with these.

Therapy Different types of therapy can aid rehabilitation. These are not necessary immediately, as many people recover spontaneously, but can be of help once it is apparent that specific problems remain. Clear evidence exists of the value of a multidisciplinary approach to managing the patient.

Physiotherapists can assist people to walk again and suggest suitable aids such as canes, Zimmer frames or foot splints. They can also help the patient to regain movement in paralysed arms.

Occupational therapists can help patients learn adaptive ways to dress and cook for themselves, and can suggest suitable home aids.

Speech and language therapists (SALTs) help patients to overcome problems with speech, often involving the patient in attending speech therapy sessions at the hospital.

The nursing interventions identified during the acute period will often be continued during the rehabilitative phase, e.g. care of the paralysed limbs must be maintained. Other areas of nursing will include attention to speech difficulties and sensory deficits and preparing the patient for discharge home with adequate support and advice as reflected within a well-constructed care package. Involvement of the patient's family in the recovery phase is crucial as their cooperation can result in the increased likelihood of success (see Box 9.11).

The patient will have been referred to the local primary health care team for assessment and support. Once home, the patient's ability to live independently can be enhanced by aids such as hand rails in the bathroom and adapted cutlery. Advice on rearranging the patient's furniture at home may facilitate easier mobility and reduce the likelihood of an accident. The use of information from the Stroke Association (see 'Useful websites') should be considered along with help and support from appropriate community groups.

Box 9.11

Some do's and don'ts for home carers of individuals recovering from stroke

- Do not overprotect the individual
- Do encourage them to exercise
- Do not accuse them of 'not trying'
- Do not pull their weak arm
- Do encourage friends to visit
- Do not become gloomy and pessimistic
- Do think twice before selling the double bed
- Do continue a normal sex life

9.8 With the help of your community nurse mentor, try to find an example of such a multidisciplinary approach in support of a patient and their family from your own placement experience of nursing in the community.

9.9 How many people in the UK suffer from stroke every year? Have you looked after a stroke patient with severe physical and behavioural problems? If not, ask a fellow student to help you with this question. How many different members of the hospital and primary care teams do you think were involved in the patient's care? Consider each team member's role, then try to draw a circle with the patient and their spouse, partner or main carer in the middle, surrounded by each team member. What might be their feelings about having to meet so many people?

INTRACRANIAL TUMOURS

Approximately 2250 people in the UK die from a brain tumour every year. The cause of primary brain tumours is unknown, but they are the most commonly known disorders affecting the nervous system, and occur in 6 per 100 000 of the population (Lindsay & Bone 2004).

Astrocytoma, a malignant tumour of star-shaped astrocytes, occurs twice as often in males as in females and is most common in the 40–60 year age group. Up to 50% of brain tumours occur in more than one location. Some appear to be congenital in origin while others are related to hereditary factors (Hickey 2002).

There are two age peaks for intracranial tumours: the first decade of life, and the 50s and 60s. There is a slight male preponderance, except for meningiomas and neurilemmomas (Lindsay & Bone 2004).

PATHOPHYSIOLOGY

Intracranial tumours can be classified according to their pathology, as outlined in Table 9.4, but the presence of a benign tumour in a crucial location, such as a confined space, can prove equally serious. Intracranial tumours can grow in one of two ways: they may encapsulate, or spread and infiltrate surrounding tissue. Their rate of growth can be very slow or extremely rapid.

The pathological features of tumours are:

- cerebral oedema
- raised ICP
- focal neurological deficits
- seizures
- altered pituitary function
- hydrocephalus.

Common presenting symptoms are extremely variable. Presentation will be determined by the location, type, size and speed of growth of the tumour and its effect on surrounding structures.

The neurological symptoms of brain tumours may occur alone or in combination. There may be general symptoms, e.g. epilepsy, focal symptoms, dependent on location, such as hemiparesis or cranial nerve deficits, and signs of raised ICP such as headache.

MEDICAL MANAGEMENT

Investigations CT scanning is likely to be the investigation of first choice. Other investigations may include MRI scanning and cerebral angiography. Additional investigations include measuring the ESR and taking a chest X-ray to establish the possible presence of metastases. If a pituitary tumour is suspected, endocrine studies and visual field testing will be performed. If acoustic neuroma is suspected, audiometric studies will be performed.

Exploratory surgical procedure Burr hole biopsy, in which a small piece of tissue is removed for pathological examination, may confirm the diagnosis. This technique relies upon the ability of the operator to remove a specimen of tumour tissue which reflects the true extent and pathology of the growth.

Treatment This may be with surgery, radiotherapy and/or chemotherapy.

Surgery The tumour is removed (if possible) using one of four different approaches, as outlined in Box 9.5, and a combination of radiotherapy and surgery may be indicated where surgery alone cannot remove all of the tumour.

Chemotherapy has been used for some time, but the clinical benefits remain uncertain (Lindsay & Bone 2004). Armstrong and Gilbert (2002) provide an update on new approaches in chemotherapy (see Ch. 31).

NURSING PRIORITIES AND MANAGEMENT: Intracranial tumours

As a priority, assessment should be made of the patient's and family's understanding of the reason for admission. Someone with an intracranial tumour can usually carry out their normal daily activities, unless there is a rise in ICP caused by swelling or by tumour enlargement. The onset of symptoms can be slow and progressive or almost immediate, in which case the person's condition deteriorates rapidly.

Immediate priorities

The patient should be assessed for increasing ICP, primarily through the assessment of conscious level, and the nurse should observe for any deterioration in the patient's condition. If the patient has experienced seizures before admission, this should be carefully noted and the nurse should be prepared should a seizure occur.

If the patient has speech problems, e.g. dysphasia, time should be taken to ensure they have communicated their needs, possibly drawing on information from relatives.

Subsequent considerations

After physical and neurological assessment, the speech and language therapist, physiotherapist and occupational therapist should be involved in assessing the patient, offering advice and assistance.

Support during investigations

The patient will be anxious to know the results of investigations and worried about the diagnosis. The investigations can confirm the diagnosis and/or identify the type of

Table 9.4 Classification of tumours

Tumour	Description	Usual site	Incidence (% of total)	Remarks
Tumours of neuroepithelial tissue				
Astrocytoma Grade I	Well differentiated, insidiously invasive, relatively benign	Cerebral hemispheres of adults; most commonly the frontal lobes followed by the temporal and parietal sites (occipital lobe astrocytoma is rare)	10	A cystic type of astrocytoma is sometimes located in the cerebellum. A childhood tumour of the first decade of life
Intermediate astrocytoma Grades II & III	Will possess some of the characteristics of grade I astrocytomas but cell differentiation less well defined			
Glioblastoma multiforme (anaplastic astrocytoma) Grade IV	Rapidly growing, undifferentiated cells, extremely malignant and highly vascular. Infiltrates brain tissue extensively. Peak age is 48–52 years with a male bias. Can produce extensive brain swelling while still relatively small in size	Grade IV shown to spread into the white matter of both hemispheres via the anterior corpus callosum	18	
Oligodendroglioma	Rare, slow-growing tumour, age of onset 40 years. Relatively benign — minor signs and symptoms can be present for a number of years before diagnosis is confirmed. Shows a marked tendency to calcify (may be seen on skull X-ray)	Demonstrates a predilection to grow in close proximity to the ventricular wall and commissural midline structures in the frontal region of the cerebral hemispheres. Can also be found in the temporal lobes	4	Can 'mimic' a meningioma upon presentation. Unlike many tumours, raised ICP is a late sign in the patient with an oligodendroglioma. Sudden deterioration can occur, thought to be due to spontaneous haemorrhage and cystic degeneration within the tumour body
Ependymoma	Rare, undifferentiated, slow-growing glioma. Often seen in childhood and young adult	Arises from the ependymal layer of the ventricular system; therefore may be found in any of four lobes	5	Due to involvement of the CSF pathways, hydrocephalus and raised ICP are early common features
Optic nerve glioma	Occurs mainly before the age of 20 years. Follows a relatively benign course, remaining localised to the optic nerve and chiasma	Optic nerve and chiasma	4	Approximately 60% of patients have an associated neurofibromatosis called a spongioblastoma
Medulloblastoma	Rapidly growing, malignant tumour of childhood. Composed of round, undifferentiated cells. Commonest intracranial neoplasm of childhood. Usually occurs before the age of 10 years	Cerebellar vermis or fourth ventricle roof	3	Can 'seed' throughout the subarachnoid space. Slight male bias. Hydrocephalus is common
Tumours of nerve sheath cells				
Neurilemma/ Schwannoma	Slow-growing, benign tumour. Well encapsulated. Usually unilateral, predilection for females, occurs in the middle years of life	The Schwann cell sheath of cranial nerves VIII, V and VII located within the confined cerebellopontine angle		A tumour of the sheath of the VIIIth nerve. Referred to as an acoustic neuroma. Other tumour types may be seen in this location, e.g. meningioma, but a differential diagnosis may not be made until surgery
Neuroma (neurofibroma)	A complex familial disorder characterised by widespread benign tumours throughout the nervous system. Inherited as an autosomal dominant trait. Known as Recklinghausen's disease. Manifests itself in young adulthood	The neurilemma of nerves; therefore tumours may appear intracranially, i.e. VIIth nerve, acoustic neuroma, or extracranially, i.e. spinal roots and peripheral nerves	10	Patient will present with cutaneous pigmentation of the skin termed 'café au lait' spots. Some of these patients will also have a meningioma or glioma

Continued

Table 9.4 Classification of tumours *(Continued)*

Tumour	Description	Usual site	Incidence (% of total)	Remarks
Tumours of meningeal and related tissues				
Meningioma	Benign, slow-growing tumour arising from the arachnoid cells of the arachnoid villi. An irregular single mass usually well encapsulated	Intracranial venous sinuses — most common, superior sagittal sinus known as a parasagittal meningioma. Other sites include sphenoid ridge convexity of hemispheres and suprasellar region and olfactory groove	15	Can become very large before signs and symptoms appear. Predilection for females in 40–60 year age group. Do not show any malignant change
Tumours of blood vessel origin				
Haemangioblastoma	Slow-growing, vascular tumour of developmental origin. Single or multiple lesions occur. Manifests in children and young adults, male bias. May be familial	Cerebellar hemisphere	2	May be associated angiomatosis of the retina or abnormal organs. von Hippel–Lindau disease
Germ cell tumours				
Teratoma	Rare tumour of childhood and young adulthood	Pineal parenchymal cells; therefore located around the pineal gland		The terms pinealoma and teratoma are often interchanged
Local extensions from regional tumours				
Chordoma	Soft tumour with a jelly-like consistency	Arise extradurally at the base of the skull		
Metastatic tumours				
Metastatic tumour	Well defined, usually multiple secondary deposits of a primary growth elsewhere in the body. Common primary sites are bronchus and breast	As lesions are often multiple, can occur anywhere in the cerebrum or cerebellum	12	The symptoms and signs of a secondary intracranial growth may precede those of the original growth
Other malformative tumours				
Craniopharyngioma	A tumour of developmental origin, may be cystic or solid. Does not usually present until adolescence. May calcify	Arises from embryological remnants of the craniopharyngeal duct (Rathke's pouch) into the suprasellar region and the posterior fossa	3	Sometimes referred to as cholesteatoma
Epidermoid cyst	Congenital fluid-filled cyst of the ectodermal layer. May contain keratin and cholesterol. Occurs in childhood	Posterior fossa		
Dermoid cyst	Similar to epidermoid cyst; arises from the ectodermal layer but contains more solid material such as hair, sebaceous glands or even teeth	Posterior fossa		Difficult to differentiate from other posterior fossa tumours until direct visualisation at surgery
Colloid cyst of the third ventricle	Rounded cystic tumour of childhood	Choroid plexus within the third ventricle		Often presents with an acute, sometimes intermittent hydrocephalus
Vascular malformations				
Angioma	Arterial and/or venous congenital abnormality comprising enlarged and tortuous vessels. Usually have a 'feeder' artery and a 'draining' vein	Anywhere in the cerebral cortex, most commonly in the region of the middle cerebral artery		A unilateral capillary-venous malformation and the presence of a facial naevus is termed the Sturge–Weber syndrome. Hamartomas are small vascular malformations

Table 9.4 Classification of tumours *(Continued)*

Tumour	Description	Usual site	Incidence (% of total)	Remarks
Angioblastoma	Cystic tumour comprised of angioblasts	Cerebellum		The patient may also exhibit an angioblastoma of the retina
Tumour of the anterior pituitary				
Pituitary adenoma	Benign, slow-growing, well encapsulated tumour. Classified by the clinical syndrome, i.e. the hormone produced. Three types of hypersecreting adenomas: prolactin-secreting (prolactinoma); excess growth hormone (acromegaly); ACTH-secreting (Cushing's disease). Hyposecreting tumours are very rare	Anterior lobe of the pituitary gland	8	Hyposecreting tumours will produce panhypopituitarism and chiasmal compression

Adapted from Hickey (2002).

tumour, and the patient should be encouraged to discuss their fears and anxieties. An excellent account of the problems encountered by patients can be found at news.bbc.co.uk/1/hi/health/3636697.stm and news.bbc.co.uk/1/hi/health/4193093.stm. This diary was maintained by Ivan Noble, a BBC reporter who had a malignant tumour and in it he spoke honestly of his feelings and concerns. He died, aged 37, early in 2005, but his account of his personal journey and comments from people worldwide who read the diary provide a remarkable insight into one person's experience of cancer and the impact his sharing of the experience has had for people in several countries (see Research Abstract 9.2). The nurse should be aware of the reality of a grieving process should the diagnosis be life limiting and accept the patient's reactions. Some fears and anxieties may be unfounded and can be alleviated by sensitive nursing interactions.

RESEARCH ABSTRACT 9.2

The purpose of this study was to describe the experience of being a patient with a brain tumour in the neurosurgery clinic of a university hospital. Eight brain tumour patients volunteered to participate. The data were collected by interviewing the participants on the day preceding brain surgery and 3–7 days postoperatively. The interviews used open-ended questions and the responses were analysed according to themes.

Preoperatively, some patients had a fearless and calm attitude towards their illness, whereas others were fearful and depressed. Postoperatively, the patients' body images changed, and they were concerned about the future. They perceived their care as matter-of-fact and friendly, both before and after the surgery, and they thought their basic needs were met. Some patients would have wanted more psychological support, especially after the surgery, whereas others found the psychological support adequate.

The patients were willing to participate in decision making about their care, and they trusted the professional skill and competence of the nurses. Suggested improvements in care were to minimise the atmosphere of urgency and hurry, appoint a primary nurse for each patient, and give more attention to after-care.

Lepola I, Toljamo M, Aho R, Louet T 2001 Being a brain tumor patient: a descriptive study of patients' experiences. Journal of Neuroscience Nursing 33(3): 143–147

Non-surgical interventions

Medication Steroids, particularly dexamethasone, are prescribed once a tumour is diagnosed, to reduce swelling around the tumour, and therefore ICP. The patient can feel better almost immediately after commencing steroids, finding relief from headache, nausea, vomiting and the effect of neurological deficits. However, there are established side-effects from steroid medication:

- irritation of the lining of the stomach — H_2 antagonists, e.g. cimetidine and ranitidine, are routinely prescribed to counteract this
- glycosuria — urine is routinely tested for glucose and ketones
- adrenal insufficiency, which will occur if medication is withdrawn suddenly (see Ch. 5).

Radiotherapy The radiotherapist can assess the patient in the ward or as an outpatient. If the patient requires urgent radiotherapy, this will be discussed by the radiotherapist, and the nurse should also be available to discuss with the patient their feelings and reactions to the treatment (see Ch. 31).

Inoperable tumours

A tumour may be inoperable due to inaccessibility or because of its type and size. Surgery could involve great risk of neurological deficits postoperatively. This situation

offers a considerable challenge to all members of the multidisciplinary team to be able to communicate effectively and offer adequate support (see Chs 31 and 33). Sherwood et al (2004) highlight the needs of bereaved caregivers and identify the work of caring, informal and formal support, information and dealing with symptoms as key issues in achieving optimal end of life care.

Ongoing care

Major deficits

The provision of care at this stage will be dependent upon the patient's condition. Advice from specialists in palliation may be sought and the involvement of relatives will be crucial, as evidenced by the findings of Sherwood's work outlined above.

Preparation for discharge

The patient may have no neurological deficits or only slight deficits, such as limb weakness. If this is so, they should be encouraged to maintain their previous lifestyle.

If the patient has severe neurological deficits and requires considerable assistance with daily living, the situation should be discussed with both patient and family.

If the family members are anxious to have the patient at home, their wishes should be discussed with the ward team, community nurses and the patient's GP in order to ensure adequate support is available and in place prior to the patient's discharge. A home visit by the occupational therapist or physiotherapist may be advisable to assess the patient's requirements when at home.

Hospice care should be discussed prior to discharge and, if the patient and family wish, further information can be obtained from the palliative care team.

EPILEPSY

Epilepsy can be a symptom of an identifiable cause, such as head injury, or a disorder with no identifiable cause. Five per cent of the population will have a seizure in their lifetime, but with recurrence in only 0.5% (Lindsay & Bone 2004). The occurrence of an isolated seizure does not mean that the person is 'epileptic'. Box 9.12 shows causes at different stages of life. For some the cause will prove to be psychogenic, i.e. not of organic origin. Epileptic seizures can occur at any age, although the age of onset can often provide a clue as to the cause, e.g. in early childhood it may be due to pyrexia, whereas in the middle years of life, a brain tumour is more likely (Hickey 2002). Thomas (2002) describes the particular problems of epilepsy in older people.

PATHOPHYSIOLOGY

An intermittent, uncontrolled discharge of neurones within the central nervous system results in a seizure. It can range from a major motor convulsion to a brief period of lack of awareness and can occur in any individual at any time, even in an apparently healthy nervous system. Each individual is susceptible to seizure if the threshold level, which is different for everyone, is breached. In some instances, the cause is obvious, e.g. a seizure can be secondary to structural damage to the brain; in others, no apparent cause can be detected and it is described as an 'idiopathic' or 'primary' seizure.

Box 9.12

Causes of epilepsy at different stages of life

Newborn
- Hypocalcaemia
- Hypoglycaemia
- Asphyxia
- Hyperbilirubinaemia
- Water intoxication
- Inborn errors of metabolism
- Trauma
- Intracranial haemorrhage (vitamin K deficiency, thrombocytopenia)

Infancy
- Febrile convulsions
- Inborn errors of metabolism
- Congenital defects
- CNS infection

Childhood
- Trauma
- Congenital defects
- Arteriovenous malformation
- CNS infection

Adolescence and adulthood
- Trauma
- Neoplasm
- Withdrawal from drugs or alcohol
- Arteriovenous malformation
- CNS infection

Late adult
- Trauma
- Neoplasm
- Drug/alcohol withdrawal
- Vascular disease
- Degenerative disease
- CNS infection

Common presenting symptoms depend on when the person is examined. During certain types of seizure, the patient may be unconscious, apnoeic and incontinent of urine, whilst in others, changes are barely noticeable. Between seizures, the patient may show no neurological impairment or deficit. Seizures are classified as outlined in Box 9.13.

MEDICAL MANAGEMENT

Investigations Electroencephalography (EEG) will be performed (Louden 2004). Other investigations such as CT scanning and MRI may also be considered in order to identify possible organic causes.

The most dependable diagnostic tool is a reliable eyewitness account of the seizure.

Treatment The mainstay of therapy is medication, which is effective in keeping many people free from seizures. A range of anti-epileptic medication is available and guidance is provided by NICE (2004) on their use.

Box 9.13

Classification of seizures

I. Partial (focal, local) seizures
- A. Simple partial seizures (consciousness is not impaired)
  1. With motor symptoms
  2. With somatosensory or special sensory symptoms
  3. With autonomic symptoms
  4. With psychic symptoms
- B. Complex partial seizures (with impairment of consciousness)
  1. Beginning as simple partial seizures and progressing to impairment of consciousness
     — with no other features
     — with features as in I.A.1–4
     — with automatisms
  2. With impairment of consciousness at the start
     — with no other features
     — with features as in I.A.1–4
     — with automatisms
- C. Partial seizures evolving to secondarily generalised seizures
  1. Simple partial seizures evolving to generalised seizures
  2. Complex partial seizures evolving to generalised seizures
  3. Simple partial seizures evolving to complex partial seizures to generalised seizures

II. Generalised seizures (convulsive or non-convulsive)
- A. Absence seizure
  1. Absence seizures
  2. Atypical absence seizures
- B. Myoclonic seizures
- C. Clonic seizures
- D. Tonic seizures
- E. Tonic-clonic seizures
- F. Atonic seizures

III. Unclassified epileptic seizures
Includes all seizures that cannot be classified because of inadequate or incomplete data.

For those patients who have an identifiable focus amenable to surgery, this option will be offered. The most commonly employed technique is resection of the specific cortical area, e.g. temporal resection. Over half of the patients treated become free from seizure or acquire easier control.

NURSING PRIORITIES AND MANAGEMENT: Epileptic seizures

Most individuals with seizures live independently, with regular monitoring by their GP or at an epilepsy outpatient clinic. However, occasionally treatment loses its efficacy and the patient requires to be admitted to hospital for reassessment.

Immediate priorities

Once notification is received at the ward that a patient is to be admitted due to a worsening of seizures, the following essential equipment should be assembled and be readily available:

- oxygen and suction in good working order
- a selection of various sizes of artificial airways
- charts for recording neurological status, vital signs and seizures
- side rails should be in place and may be padded for additional safety
- anticonvulsant medication, particularly in the intravenous or intramuscular form.

If the patient is having a seizure, the following actions must always be carried out:

- ensure privacy is provided for the patient
- use suction if necessary to prevent aspiration of secretions
- ensure side rails are in place, using pillows as padding if required
- ensure safety by removing any objects or furniture likely to cause harm
- loosen any restrictive clothing
- insert an airway only when teeth have unclenched (after the tonic stage); any attempts to insert objects into the patient's mouth prior to this serve no purpose and may cause harm to the nurse (bitten fingers) or to the patient (broken teeth)
- record pupillary activity — pupils will begin to react as the patient recovers.

Immediately following a seizure the nurse should:

- place the patient in the recovery position, to facilitate the drainage of secretions
- allow the patient to sleep with minimal disturbance
- allow time for the patient to wake up and provide gentle reassurance and assistance to encourage reorientation
- record a description of what happened on the seizure observation chart.

The nurse should record:

- the time at which the seizure occurred
- what the patient was doing at the time
- any aura or crying out prior to the seizure
- any loss of consciousness
- which parts of the body were affected
- any stiffening or jerky movements
- any urinary or faecal incontinence
- the length of each phase
- the length of the recovery period
- the patient's behaviour after the seizure
- any weakness in part of the limbs.

Prescribed anticonvulsant medication should be administered and, where appropriate, medical staff informed.

For further helpful information on caring for patients at risk of seizure, see Lanfear (2002), Pena (2003) and Wehrle (2003).

Further considerations

The patient should be allowed to express their feelings and fears and they and their family should be given adequate

explanations and support. Explanation about the medication, its effects and side-effects, will encourage the patient's adherence to prescribed regimens. Monitoring of medication serum levels should be carried out, as this test will indicate if there is an adequate or inadequate dosage of the medication, or if the blood levels are too high. If too high, the patient may experience side-effects; if too low, seizures may recur. Common side-effects of anticonvulsant medications are:

- drowsiness
- dizziness
- gastric upset
- diplopia
- ataxia.

The patient must be allowed time to come to terms with the diagnosis of epilepsy. They may experience feelings of anger, grief and/or disbelief, and the nurse should discuss with both the patient and family the realities of epilepsy, but encourage a positive outlook. This should stress the full life that can be led, despite the diagnosis.

The patient may note the experience of an aura prior to a seizure and the nurse can advise how to use the time available to ensure personal safety. Advice should be given prior to discharge about safety in the home (see Box 9.14) and the possible involvement of the primary care team (Bingham 2004).

Box 9.14

Safety measures at home

- Fireguards are essential and should be securely fixed to the wall.
- Smokers should consider and understand the dangers of smoking in an armchair or in bed.
- Cordless kettles and irons are safer than trailing flexes.
- Pot handles should point to the back of the cooker. Hot food or liquid should not be carried.
- Sharp corners can be covered by rounded plastic pieces; these are available from supermarkets, children's departments and ironmongers.
- Glass doors should either use safety glass or be covered in safety film; available from children's departments.
- If seizures are frequent and unpredictable, the patient should let someone know when they are taking a bath or shower. The water should not be very hot and the depth should only be a few inches. The patient should turn the taps off before getting in. A shower is more suitable, particularly if the patient can sit, unless the shower tray has a high lip where water can gather.
- If the toilet door can be hung to open outwards, the person will not block it if they fall. Locks should not be used, except for special safety locks that can be opened in an emergency. An 'engaged' sign can be used instead.
- Soft pillows can be dangerous. It is best to avoid pillows or to obtain special safety pillows.
- In a small proportion of people with epilepsy, a seizure may be triggered by flickering light. These people should place the television set at eye level, at least 3 m away, with a small, lit lamp on top.
- An epileptic parent should ensure that garden gates have locks, so that, should the parent have a seizure, their children cannot wander off.

9.10 What information does your local library have about self-help groups for people with epilepsy?

Equally, 'triggers' that may induce a seizure should be discussed, such as:

- lack of food and sleep
- excessive heat
- constipation
- menstruation
- alcohol
- anxiety or stress.

Medical opinion varies as to whether someone with epilepsy should drink alcohol, as it can interfere with anti-epileptic medications, preventing them from effecting the intended seizure control. Large amounts of any liquid are known to trigger a seizure, but significant alcohol intake is also often associated with late night, irregular eating habits and forgotten tablets. However, whether or not to drink alcohol is an individual decision, bearing in mind medical advice on the particular case.

It may be suggested to the patient that they carry a card or wear a MedicAlert to inform about their condition should a seizure occur.

Employment

The patient's employment situation should be discussed, especially if it entails driving or operating machinery. The patient must be told of the requirement to inform the DVLA of their liability to have seizures and should be advised to stop driving in the meantime. This may present major problems to the patient, who may have to look for alternative employment; this may affect self-esteem or outlook for the future.

It must be recognised that some employers may not be prepared to employ someone with epilepsy and that their current position may have to be reviewed. Epilepsy is common in adolescents. They may experience a change in outlook for the future and have to consider a change to their hoped-for career structure.

Physical activity

The patient should be encouraged to continue normal physical activities, with some emphasis being placed on the need to take adequate precautions, e.g. when swimming. It should be suggested that the patient lets someone know or takes a friend who could deal with a potential seizure.

Involving the patient's family

The patient's family should be given time and the opportunity to express their perceptions and concerns, and the nurse should be prepared to provide advice and explanations. The nurse should explain about the type of seizure the patient is experiencing, e.g. a generalised seizure, and family members should be told what to expect if a seizure occurs, e.g. that the patient will have sudden uncontrolled movements and will appear to be holding their breath. They should know exactly what to do and why they are doing it. Epilepsy Action provides helpful advice through their website (see 'Useful websites'). Consideration must be

CASE HISTORY 9.2

Miss S

I am 22 years of age, and was diagnosed with epilepsy 4 months ago. I had previously thought epilepsy was something that became apparent at birth or in early childhood. Now I understand that the particular type of epilepsy that I have, juvenile myoclonic epilepsy, is commonly diagnosed in the late teens and early twenties.

At first the diagnosis did not seem to worry me. It was a novelty, both to me and to my family and friends. However, 2 or 3 months later, the novelty wore off, and the long-term aspects of epilepsy became more apparent. It was only then that the reality of having epilepsy began to sink in.

Being a student and living away from home has meant that my friends have carried most of the burden of supporting me. It has been of immense comfort to know that I can trust those around me and I have not encountered many negative reactions. On the contrary, my family and friends have shown an interest in all aspects of epilepsy, not only in what they should do if someone has a seizure. I have also found, however, that living away from my parents has made it difficult for them. Whilst they have supported me completely, they have never seen me have a seizure. I think that this has made it difficult for them to accept that I do have epilepsy.

I have found that there are a number of ways in which epilepsy impacts upon my life. It has become necessary for me to lead an organised life, so that I get enough sleep and am able to take my medication at the appropriate times. The biggest impact I have found involves challenging the stigma that, for some people, still surrounds epilepsy. It is sometimes difficult to combine maintaining my privacy with informing the appropriate people. I feel that if I am not open about having epilepsy, then I am contributing to a belief that epilepsy is something which should not be talked about, or that people should be ashamed of being associated with. For this reason I decided to be entirely open about having epilepsy from the start.

I have found that there is a very fine line between being sensible and letting epilepsy take over my life. In reality there are very few restrictions placed upon me, but at the same time, this does not mean that epilepsy is not always at the back of my mind.

With thanks to Sarah Canning, student nurse, Edinburgh University, for her Case History 9.2.

RESEARCH ABSTRACT 9.3

A feasibility study of a psycho-educational family intervention — 'Be Seizure Smart' — aimed at improving attitudes and increasing family functioning was conducted. The intervention was individually tailored for each family member by:

- providing information about epilepsy, treatment and seizure management according to the individual's knowledge base
- addressing unique concerns and fears
- providing emotional support.

Participants were 10 families of children with epilepsy, aged 7–13 years. Data were collected about 2 weeks before and after the intervention, which was delivered over 3–4 months, by using structured interviews. One-tailed paired t tests were used to determine changes from pre-test to post-test. Participants were also asked to evaluate the intervention and make suggestions about how the intervention could better meet their needs. Results generally indicated that the intervention had the anticipated effects. Knowledge scores increased for both parents and children. Children had fewer concerns and were more satisfied with family relationships.

Information and support needs decreased for both children and their parents. Information need reductions were statistically significant for both parents and children; support need reductions were significantly reduced only for parents. Although child and parent attitudes were more positive after the intervention, this finding was not statistically significant. Moreover, parents indicated overall satisfaction with the programme and appreciated the convenience of in-home telephone interactions with the nurse and receiving information specific to their needs in the mail. It was concluded that the 'Be Seizure Smart' intervention had strong potential to help children with epilepsy and their families and that the intervention should be developed further and piloted on a larger sample.

Austin J K, McNelis A M, Shore C P, Dunn D W, Musick B 2002 A feasibility study of a family seizure management programme: Be Seizure Smart. Journal of Neuroscience Nursing 34(1): 30–37

given to meeting the needs of children whose parents have epilepsy. Advice should include the following:

- Ensure the safety of the individual, which can involve removing harmful objects and ensuring that all restrictive clothing is loosened
- After the seizure, place them on their side, in the recovery position, and allow them to sleep, giving them adequate time to wake up and reorientate to time and place
- Ensure that the family knows to seek medical advice if a seizure lasts longer than usual or if seizures continue without time for the individual to recover
- Ensure that the family is aware that the individual may have feelings of shock, anger and lack of self-esteem and that time should be allowed for them to come to terms with these feelings (see Case History 9.2).

Greenhill and Betts (2003) provide useful advice on the lifelong care of women with epilepsy.

The multidisciplinary team should work together to give the individual and their family encouragement and advice about being at home. Bingham (2004) highlights the provision of support for people in the community who have epilepsy. It may be helpful to explain that one person in every 200 has epilepsy, so that they can recognise that they are not alone. Involvement in groups for people with epilepsy provides advice and support (see Research Abstract 9.3).

9.11 Discuss with your fellow students what may be some of the social implications of epilepsy (see Case History 9.2). Try to find out whether someone with epilepsy is permitted to drive a car.

MULTIPLE SCLEROSIS

Multiple sclerosis is a chronic neurological disorder and is the most common cause of neurological disability in young adults in the UK (MacLean 2004). The age of onset is 20–50 years and it is slightly more common in females. The cause is unknown and the disorder typically follows a pattern of relapses or exacerbations and remissions (Lindsay & Bone 2004).

The occurrence of multiple sclerosis varies significantly in different parts of the world. Its incidence in the Orkney and Shetland Islands of the UK is 309 per 100 000, whereas in Italy it is 13 per 100 000 (Lindsay & Bone 2004). It is therefore described as a disorder of temperate climates. However, those who move from an area of high risk to one of low risk do not lessen the chance of the disease occurring. Multiple sclerosis is not hereditary, but the risk of a child developing multiple sclerosis where a parent is afflicted is approximately 15 times greater than in the unaffected population (Lindsay & Bone 2004).

A definitive diagnosis is usually difficult because demyelination develops over a varying period of time. To be conclusive, there must be dissemination over a period of time and in several locations within the nervous system.

PATHOPHYSIOLOGY

According to Lindsay and Bone (2004), it is thought that a viral infection affects the white matter of the brain and spinal cord, producing demyelinated lesions that prevent normal conduction of nerve impulses. The demyelination results in scarring or sclerotic patches, and the remission, typical in multiple sclerosis, is the result of healing of these areas. However, in time, these lesions degenerate to a point where recovery is unlikely and the resultant disruption of function becomes permanent.

Common presenting symptoms Clinical features vary considerably, depending on which nerves are affected, but may include:

- blurring of vision or double vision — an early and common symptom; a patient presenting to their GP or practice nurse with this particular symptom is always investigated with a view to diagnosis of multiple sclerosis
- weakness and dragging of limbs and extreme fatigue
- slurred speech
- nystagmus — a disturbance in the normal balance of the eye in which a slow drift in one direction is followed by a fast corrective movement
- loss of sensation in a specific area of the body, e.g. part of the arm
- difficulty in determining the position of limbs in space
- 'stiff limbs'
- intention tremor
- clumsiness/difficulty with movement
- incontinence/retention of urine or hesitancy with urinary flow.

Sometimes fatigue will override all these symptoms.

MEDICAL MANAGEMENT

Investigations

Lumbar puncture Examination of the CSF may reveal:

- a mild rise in cell count
- an elevated total protein and gamma globulin fraction (in 60% of cases)
- oligoclonal bands in the gamma globulin in 80% of cases (Lindsay & Bone 2004).

Visual evoked responses A delay in conduction is noted in the pathways.

RESEARCH ABSTRACT 9.4

The purpose of this study was to describe the experiences of patients with relapsing multiple sclerosis (MS) who are being treated with interferon beta-1a. MS patients often experience fear and uncertainty about their future and derive benefit from understanding their diagnosis, as well as learning about their anticipated disease course. Interferon beta-1a treatment can delay the accumulation of physical disability that naturally occurs over time in patients with untreated relapsing MS and thus offer hope for their future. However, patients may be afraid to start interferon beta-1a because they do not know what to expect.

To answer the question, 'What is the patient's experience on interferon beta-1a', we used Heideggerian phenomenological and Colaizzi's qualitative data analysis techniques to interpret serial interviews of 15 patients with relapsing MS. Interviews were audiotaped, transcribed verbatim and analysed using the Martin qualitative data analysis computer program. The theme clusters that emerged were learning, feelings, adaptation and interferon beta-1a issues.

An exhaustive description of the phenomena that were derived illustrates the patients' process of learning about their illness and adapting to changes in their lives. Starting a new treatment requires coping and challenges use of resources. Social support is vital to patients, particularly those who have difficulty injecting themselves. Most of the patients expressed a sense of improvement in their condition since starting on interferon beta-1a treatment and considered it crucial to their hope for the future.

Miller C, Jezewski M A 2001 A phenomenologic assessment of relapsing MS patients' experiences during treatment with interferon beta-1a. Journal of Neuroscience Nursing 33(5): 240–244

MRI identifies areas of demyelination.

CT scan may be required to exclude other disorders (see Appendix 1).

Treatment There is still no specific treatment. Steroid therapy may be helpful in acute exacerbations to manage symptoms and physiotherapy is helpful in the rehabilitation of numb, affected limbs. The use of interferon has been tried in some patients; however, clinical outcomes have not conclusively proved its usefulness. Outcomes continue to be assessed as part of a national surveillance scheme (Lindsay & Bone 2004) (see Research Abstract 9.4). Many complementary therapies exist and are used with varying degrees of success, e.g. special diets and hyperbaric oxygen.

Essentially, care consists of supporting the patient and their family and alleviating symptoms.

NURSING PRIORITIES AND MANAGEMENT: Multiple sclerosis

The extensive tests involved in obtaining a diagnosis may necessitate admission to hospital or attendance at an investigation unit on an outpatient basis.

Many patients with multiple sclerosis lead a normal life at home, requiring admission to hospital only if they

CASE HISTORY 9.3

Multiple sclerosis: a carer's view

'It's the "not knowing" what I'll be like tomorrow that I find so difficult to cope with,' was the heartfelt cry of one MS sufferer. Caught up in the turmoil of wanting desperately to make plans for the following day, she was weary of the continual conflict between her desire to be independent and her body's limitations. The uncertainty and unpredictability of MS make it particularly wearing and difficult to come to terms with. As both a nurse and the relative of an MS sufferer, it would appear to me that coping with frustration becomes a major part of everyday life:

- frustration at having to rely heavily on family and friends
- frustration at loss of bodily function
- frustration at some members of society who don't seem to understand
- frustration at feeling a burden.

Coming to terms with limitations is only one aspect of living with MS; making the most of life within the confines of such restrictions is another. When caring for someone with MS, whether in hospital or in the community, the most important part we can play is in helping the patient to maintain their integrity and to adapt to changes imposed by further degeneration.

experience deterioration in their condition. Lisak (2001) provides an overview of the symptomatic management of multiple sclerosis, and comprehensive guidelines on the management of patients in both primary and secondary care have been issued by NICE (2003b).

For the patient who is experiencing difficulties, hospitalisation will not only provide an opportunity for nursing and other health care staff to help the patient and their family to deal with problems that are disrupting the patient's daily life, but also enable the nurse to learn more from the patient about the experience of living with multiple sclerosis (see Case History 9.3). Courts et al (2004), in a small qualitative study, explored both the lived experience of multiple sclerosis and their participants' perspective of their needs, the most poignant of which was the need for someone to listen and to help them to learn about their condition. Williams (2004) reviews the evidence for current practice in the management of patients during a relapse or exacerbation of their condition and evaluates how the evidence can be incorporated into patient care.

Immediate priorities

Communicating

The patient admitted for investigations is likely to be fearful and will require adequate explanation about the tests and examinations to be carried out. Frequently, the nurse is asked about these tests and should be prepared to answer questions or, if unable to do so, should find the answer for the patient. It is important that there is an awareness of the patient's knowledge regarding the condition, as the patient will either fear the worst, often with only a partial understanding of what the diagnosis may be, or may not be aware of the possibility of having multiple sclerosis until the diagnosis is confirmed. Increasingly, patients are well informed from use of the internet.

It is advisable for the nurse to be present when the doctor is speaking to the patient, so that the nurse knows what information the patient has received. Often the patient wishes to discuss certain points and will find it reassuring to seek supporting advice and information from the nurse after the doctor has left.

The patient will need time to consider the condition and what effects it will have on their outlook for the future. Patients often experience a range of feelings and emotions related to the loss of self-esteem and body image and may worry about how the condition will eventually affect them. Expressed feelings may include shock, denial, depression and anger. The nurse must accept these feelings and provide adequate support to facilitate the patient's coping mechanisms. Providing information about support groups, e.g. the Multiple Sclerosis Society (see 'Useful websites') is often helpful. Normally, the patient's family should be included and they will require explanations about their relative's condition. They too should be provided with opportunities to discuss their feelings and fears.

Deterioration in the patient's physical condition can cause major psychological and social problems. Family members and/or carers may experience difficulties in coping and may require help and advice.

Admission to hospital during the course of the disease progression can cause considerable stress, especially for the patient who has a set routine at home that allows maintenance of independence. The nurse should encourage the patient to continue to be independent and to follow their daily routine as far as possible when in hospital. People often have well-developed coping mechanisms, and if nurses indicate that they think they know best, this may cause patients frustration and anger (Hickey 2002). They can then seem difficult to look after and a vicious circle develops, where patients dread even more having to come into hospital.

Subsequent considerations

Problems with communication

Communication impairment in the patient with multiple sclerosis can include difficulties in pronouncing words, slow and/or slurred speech and poor concentration. This can create major problems with everyday communication for the patient. People may not understand that, although the patient has speech problems, their intellectual capabilities are not affected, and reactions towards the patient may cause them to lose confidence in their ability to communicate.

The speech and language therapist should be involved and can give advice on how to improve the patient's ability to communicate. Useful techniques to help the patient include:

- ensure that an erect posture is maintained, as this aids breathing and assists with speech
- reduce background noise as much as possible
- encourage the patient to express the most important points at the beginning of a sentence, when energy and concentration are greatest
- use communication aids such as picture boards or computer boards.

Maintaining a safe environment

The patient with multiple sclerosis can experience difficulties with:

- movement, e.g. ataxia, unintentional tremors or paralysis
- vision, e.g. diplopia
- sensory disturbance, e.g. detection of pain and temperature.

Account needs to be taken of the patient's immediate environment, both at home and in hospital, in order to avoid accidents. The patient may already be aware of the potential dangers at home and may take care to avoid them, or may be experiencing a deterioration and realise that adaptations are required in order to maintain safety.

Some patients may be unable to accept that their condition is deteriorating and that they are not able to perform certain tasks safely. When in hospital, an accurate assessment of the patient's condition, level of understanding and, if necessary, home conditions should be made. This will involve assessments by the community team, including the community nurse, occupational therapist, physiotherapist and social worker.

In hospital, the nurse should involve the patient in making any necessary changes to their new surroundings, as they will know best what suits them, e.g. the location and height of the bed, depending on their mobility. Ensure there is adequate space to manoeuvre a wheelchair properly. The nurse-call system should be within easy reach and the patient should be instructed in its use. The patient with clumsiness of movement or tremor may require assistance with some activities, e.g. at mealtimes, when there is a risk of spilling liquid and food, possibly risking a burn.

Mobility

Maintaining mobility plays a large part in being independent. A problem for the patient with multiple sclerosis is the uncertainty of the rate at which deterioration in mobility will occur. The patient's family should be aware of any limitations that are necessary and also encourage the proper use of any mobility aids required when at home.

The attitude of the ward team is very important; the members should work together to encourage a positive outlook for the patient, while making time to understand the patient's and family's feelings and fears.

If the patient uses mobility aids at home, they should also be used when admission to hospital is required. This enables the patient to maintain independence and also allows the physiotherapist to assess the effectiveness of any aids. For example, if the patient's mobility is deteriorating, is use of a walking stick sufficient to maintain safety? Common problems may include ataxia, limb weakness and lack of coordination. Techniques which may be useful in helping these problems are:

- maintaining a good posture
- when walking, making contact with the ground with the heel of the foot first
- taking care to place feet firmly in the direction of travel
- looking straight ahead rather than down at the ground
- relaxing and trying not to feel self-conscious.

The physiotherapist may suggest exercises to maintain the function of a limb and to prevent muscle wastage, and the nurse and the patient's family can give encouragement for the exercises to be practised. Rietberg et al (2005), in a systematic review of exercise therapy, concluded that, for those patients not experiencing a relapse, exercise can be beneficial.

Skin care

The patient and family should be taught the importance of regular skin inspection, e.g. to observe the sacrum and heels closely and to look for redness or blanching of the skin. If this occurs, the patient should be aware of the importance of relieving the pressure from the problem area, e.g. by lying on their side in bed.

Using a wheelchair

The physiotherapist and occupational therapist may advise that the patient requires a wheelchair in order to maintain mobility. It can be very distressing for the patient to realise that this stage has been reached. It must be emphasised that this does not mean that the patient becomes totally reliant on the wheelchair and is unable to maintain independence. The patient may need to use the wheelchair outside the house only if required to walk a long distance, or around the house only when feeling tired.

The patient may have become unable to stand and be able to weight-bear for short periods only. In this case, they are dependent on the wheelchair for mobility, but should be encouraged to continue to perform tasks involving their hands, e.g. shaving and washing, in order to maintain a degree of independence.

If the patient requires physiotherapy when at home, advice and support can be obtained from the community physiotherapist. Some local multiple sclerosis societies also offer a physiotherapy service.

Advice should be given to the patient about when to use the wheelchair, what in particular to look for, and why:

- The wheelchair should be used only when necessary, so that the patient utilises any residual walking ability, thus helping to prevent muscle weakness.
- The importance of relieving pressure, especially on the sacral area, should be discussed, as the immobile patient may lie or sit in the same position for a period of time.
- Careful positioning of limbs should be ensured, taking into account any weakness or paraesthesia.
- The footrest on the wheelchair should always be used; care should also be taken that no part of the foot or ankle is rubbing against the footrest or wheel.
- The legs should be placed in proper alignment and the patient should check regularly that the limbs are safely in position on the footrest (www.mssociety.org.uk).

Balance of rest and exercise

The patient should be advised about the importance of rest periods to avoid becoming overtired or overstressed, which will exacerbate the condition. Relaxation techniques and a specific rest/exercise programme may be beneficial and should be discussed with the patient and their family.

Fatigue is a significant symptom of multiple sclerosis and can enforce changes in the patient's lifestyle. The patient may have to learn to ask for help when feeling tired and

this can be difficult for someone who may normally have led an active, independent life. Although rest is very important, exercise is also vital to maintain muscle strength and help reduce the risk of spasticity. It will also improve circulation and prevent pressure ulcers and joint stiffness. Exercise will contribute to maintaining the patient's independence.

Employment

If the patient's current employment involves physical exertion, this may prove problematic with regard to returning to work. The patient may have to consider how their disorder will affect current employment and think about finding alternative work, although in many cases this may prove impossible.

Eliminating

The patient may experience bladder dysfunction, which can vary in severity, including incontinence, urinary frequency or urine retention. Problems with constipation are also of concern. The urinary problems are due to the reflex action of the bladder having been disturbed due to sites of demyelination in the lower spine, particularly the cauda equina.

The social implications of incontinence can be enormous and some patients will avoid going out for fear of embarrassment (see Ch. 24). The patient should be encouraged to take time when passing urine and to ensure that the bladder is completely empty. Journeys can be planned to take account of the availability of toilets and this will reassure the patient. If a urine infection is suspected, a specimen should be sent to bacteriology for culture and sensitivity. It may be necessary to use aids such as protective pants and pads (see Ch. 24).

Urinary catheterisation may be required if persistent urinary retention is experienced. Some patients will prefer self-catheterisation at set intervals and many become very competent at performing this procedure. Adequate instruction on hygienic technique can facilitate this (see Ch. 8). Advice from a continence advisor may also be useful (see Ch. 24).

Some patients will require an indwelling catheter, and support should be provided to enable them to come to terms with this alteration to body image.

The importance of an adequate fluid intake of 2.5–3 L/day should be stressed. Many patients mistakenly think that if they stop drinking they will no longer be incontinent.

The immobile patient will be especially prone to constipation, which will aggravate coexisting urinary problems. The patient and the family should be advised as to how constipation can be avoided by taking an appropriate diet, an adequate fluid intake and maintaining as much mobility as possible. Regular aperients may be required and the occasional use of enemas and suppositories may be indicated.

Expressing sexuality

The patient may experience a change in body image, and the nurse should try to encourage a positive attitude in order to improve the patient's self-esteem.

Sexual counselling may be beneficial for both partners.

Men may experience impotence and women diminished libido, due to neurological damage. The patient may be too embarrassed or worried to discuss such difficulties with a nurse or doctor, and external services such as Outsiders (see 'Useful websites') and marriage guidance services may be a helpful alternative (see also Ch. 34).

Advice on contraception may be required, especially by women, as some oral contraceptives may interfere with existing medication. Pregnancy should be avoided during active stages of the disease as this may exacerbate the symptoms, although successful pregnancy may be achieved.

9.12 Find out where the marriage guidance and sexual health counselling services are in your area.

Eating and drinking

There has been some research into the link between diet and multiple sclerosis, and a number of specialised diets have been identified (www.mssociety.org.uk). It has been demonstrated that people with multiple sclerosis have higher levels of saturated fats and lower levels of poly-unsaturated fats in the myelin sheath and the dietary advice outlined below may be useful to patients. They should:

- decrease the intake of saturated fats and increase the intake of unsaturated fats
- try to include more chicken and white fish in the diet
- ensure that when cooking red meat, visible fat is trimmed off prior to cooking
- note that liver contains vitamin B_{12} and arachidonic acid, an essential fatty acid (see Ch. 21)
- use semi-skimmed or skimmed milk
- ensure a high-fibre content, i.e. wholemeal and wheaten bread, pulses and cereals, and eat plenty of fruit and fresh vegetables.

The speech and language therapist and dietitian may be able to offer assistance and advice if the patient has swallowing difficulties. The nurse can assist by encouraging the patient to:

- sit up straight with the head supported, if necessary
- eat in a quiet, relaxed atmosphere and not speak while eating
- take time when eating, to avoid choking
- eat certain types of food that are easier to swallow, e.g. semi-solid or liquidised foods.

Personal cleansing and dressing

In hospital and at home, the patient should be encouraged to maintain independence with regard to washing and dressing. It may seem to the patient, and at times to the nurse or to the patient's family, that it would be quicker and easier for the nurse to do these activities for the patient. The patient may feel under stress to hurry in order to release the nurse to go and attend to other patients. The nurse should explain that there is no hurry to have everything finished for a set time.

The carer should be encouraged to allow the patient to perform these activities at home, so that they have some degree of independence. The occupational therapist can assess the patient when in hospital and give advice regarding washing and dressing, offer a range of dressing aids and suggest specially adapted clothing, e.g. with Velcro

instead of buttons and zips. The patient can be referred to the community occupational therapist if further difficulties are anticipated, due to the possible deterioration in the patient's condition.

9.13 Many people with multiple sclerosis develop particular patterns of behaviour over the years. Have you or any of your fellow students observed this in such patients, either at home or in hospital? If so, can you describe them? How did you adapt your work to fit in with these routines?

Patient education

The patient and the family should be as well informed as possible about the diagnosis of multiple sclerosis and should be aware of the most successful methods of maintaining independence. They should know their primary care team and understand that they can increasingly call on the community services, e.g. the community nurse, physiotherapist, GP, as the patient's condition worsens. They should also be aware of the possibility of the occurrence of behavioural and mood changes. Euphoria, depression, apathy and emotional lability are common.

Preparation for discharge

Episodic hospitalisation may become necessary as the multiple sclerosis condition becomes more widespread, and the patient and family should be given the opportunity to voice any worries or fears to allow adequate preparation for discharge on each occasion. A comprehensive assessment of the patient's home situation should be performed, if possible well before there is any mobility problem, and should involve all members of the multidisciplinary team in order to gauge the suitability and likely success of discharge.

In cases where there is decreasing ability to perform activities of living, a home visit for the patient involving the nurse, occupational therapist, social worker and physiotherapist may be indicated. Assessment of the home situation, layout and the patient's ability to adapt, while maintaining safety and maximal independence, can be carried out. Some adjustments may be required in the house, e.g. bath aids and rearrangement of furniture. If the patient depends on a wheelchair for mobility, the doorways may have to be widened, cupboards lowered, and a shower may be required instead of a bath.

The patient may have to be rehoused at ground floor level in order to accommodate access to and from the house in a wheelchair. This involves major changes not only for the patient but also for the family and can be very traumatic, especially if they have to leave a district they have lived in for a long time, and to leave good friends and neighbours.

Advice regarding income and benefits available, e.g. mobility and attendance allowance, can be given by the social worker. Outpatient appointments can be arranged for physiotherapy, occupational or speech therapy, if necessary.

Some doctors advocate discussing the possibility of relapse so that the patient is better prepared when it occurs. On the other hand, some patients may not have a period of relapse for up to 20 years and may worry unnecessarily if the subject is broached too soon. As indicated, some patients may benefit from being informed of the availability of support groups, and it may be possible for the patient to be seen by a member of a support group prior to discharge. Such groups offer a range of services, including general advice, physiotherapy and ongoing counselling.

For further information on the experiences and health concerns of people with multiple sclerosis as they grow older, see Finlayson et al (2004).

PARKINSON'S DISEASE

Parkinson's disease is a chronic neurodegenerative disorder of the basal nuclei, with a slow onset that progresses gradually, often resulting in premature death (Lindsay & Bone 2004). It has an annual incidence of approximately 0.2/1000 and a prevalence of 1.5/1000 in the UK (Haslett et al 2002). Both incidence and prevalence increase with age, with the majority of those diagnosed aged over 60, and it affects both genders; however, McCall (2003) observes that one in seven will be under 50 years. A syndrome indistinguishable from Parkinson's disease is seen in some substance abusers. Some 'designer' drugs contain a substance called MPTP (1-methyl-4-phenyl-1,2,3,6,tetrahydrapyridine) which can cause typical Parkinsonian features. It is thought that research which seeks to understand this syndrome may lead to further developments in the treatment of Parkinson's disease (Lindsay & Bone 2004).

PATHOPHYSIOLOGY

The patient with Parkinson's disease (or syndrome) is known to have degenerative changes in the substantia nigra which forms part of the basal nuclei. Depletion of the dopaminergic neurones in the substantia nigra results in a decrease in the levels of the neurotransmitter, dopamine, essential for the control of movement, coordination and posture. As a result, the balance between dopamine and acetylcholine is lost and the acetylcholine effects exaggerated. Several forms of Parkinson's disease have been identified, including medication-induced Parkinsonism. For example, the use of phenothiazines such as chlorpromazine in mental health disorders may lead to the development of tardive dyskinesia (Cortese et al 2004, Houltram & Scanlan 2004). Another unusual form was an outbreak of encephalitis lethargica in 1916–28, and those afflicted, now in their late 80s or 90s, developed Parkinson's disease. No new such outbreaks have occurred in the UK. However, although viral, ischaemic and ageing processes have been implicated, for most of those who have Parkinson's disease, no specific cause can be identified.

Common presenting symptoms The clinical features may include:

- a triad of symptoms: tremor, muscle rigidity and dyskinesia, including slowness in initiating or repeating movements and impairment of fine movements; in addition, there are the excessive cholinergic effects, e.g. excessive gastrointestinal secretions
- cramps
- expressionless face
- disturbance in free-flowing movement, particularly on initiating movement or changing direction (see p. 436)
- loss of postural reflexes
- autonomic manifestations, e.g. excessive perspiration
- general weakness and increased fatigue.

For further information, see Haslett et al (2002).

9.14 With reference to your chosen physiology text, e.g. Marieb (2004), consider how the basal nuclei regulate the groundwork for the fine control of movement, not under voluntary control. Think how any disturbance of the function of the basal nuclei in general, and the substantia nigra in particular, can result in the symptoms seen in disorders known as the dyskinesias, such as Parkinson's disease/ syndrome.

MEDICAL MANAGEMENT

Investigations such as CT scanning may be considered in order to eliminate other disorders. There is no specific diagnostic test for Parkinson's disease. Diagnosis is usually based on clinical presentation.

Treatment Medication is the mainstay of treatment and the aim is to maintain the patient at the lowest effective level of medication (McGuire 1997). Treatment is symptomatic and does not halt the pathological process. Medicines can be divided into different categories and their prescription and use in particular combinations, or on their own, requires careful management and monitoring.

Dopaminergic preparations such as levodopa are administered to replace the depleted dopamine. In older people, levodopa with a decarboxylase inhibitor is often used; however, it is only used once the symptoms of the disease compromise the individual's normal functioning. In younger patients, dopa-agonists, e.g. pergolide, are given to stimulate the surviving dopamine receptors in the basal ganglia. Anticholinergic agents such as trihexyphenidyl may be considered to treat the cramps, tremor and rigidity associated with Parkinsonism, but their use does appear to be receding (McGuire 1997). The enzymes monoamine oxidase A and B play a key role in the breakdown of dopamine. Selegiline is a medication which inhibits this process and appears to have a symptomatic effect. Amantadine acts by allowing the dopamine to stay longer at its site of action without being used up by other cells. It may be useful in the control of tremor but helps only a small proportion of patients.

Patients who experience sudden fluctuations in their symptoms in spite of careful management of their medications may be prescribed apomorphine. This is a potent dopa-agonist and is sometimes given as a 'rescue' medicine in advanced states. It produces a direct effect at the sites where dopamine is active in the brain. It is usually given by intermittent subcutaneous injection, but continuous infusion may be considered (Hagell & Odin 2001).

Many of the medications have variable side-effects and accurate titration usually necessitates admission to hospital. Another curious aspect is an 'on–off' phenomenon, whereby, at certain times of the day, the patient loses the benefit of the dopamine and becomes rigid and immobile for a period of time. It is important to recognise this, as alteration to the medication regimen can reduce the likelihood of this happening.

Surgery may be indicated for some patients. This comprises, for example, bilateral subthalamic nucleus stimulation (Eriksen et al 2003) or specific neurosurgery for movement disorders (Tornqvist 2001).

NURSING PRIORITIES AND MANAGEMENT: Parkinson's disease

Parkinson's disease has an insidious onset. Some of its effects may be attributed by the patient and their family to old age. The progressive nature of the disease, combined with the potential embarrassment of many of its symptoms, can result in a patient who is aware of what is happening but at a loss to know how to obtain help (see Case History 9.4).

The importance of the role of the patient's family or carer, and of the community nurse and primary health care team in supporting them, cannot be overstressed. The family's or carer's ability to cope with the mobility and other problems associated with Parkinson's disease can make the difference between a level of independence, with the patient living in their own home, and enforced, frequent hospitalisation or long-term care with total dependence on others for everything. Mobility aids may be of limited use. The use of self-assessment in the earlier stages of the disease, while the patient is still able to articulate their needs, is helpful, both for the accurate evaluation of needs and to facilitate empowerment of the patient in sharing in decision-making about their care.

Immediate priorities

Typically, many of the early symptoms of Parkinson's disease may be treated by the family doctor, with the patient and their family making necessary adjustments to their home, e.g. removal of rugs and other obstacles over which the patient may trip.

The progress of the disease can vary, but should the patient's condition worsen, admission to hospital may become necessary. Hospitalisation will provide an opportunity for nursing and other health care staff, such as the physiotherapist, speech and language therapist and occupational therapist, to advise the patient and the family on how to deal with the problems which are interfering with the patient's daily life.

CASE HISTORY 9.4

Parkinson's disease: the family's perspective

We are 7 years into living with father's Parkinson's disease. There have been so many challenges for him and for us over the years, and the challenges keep changing as the disease progresses. Here are just three of them:

- *'They didn't know him as he was.'*
  With each new admission to care, we are having to work harder to make sure that staff understand that the painfully slow speech from an expressionless face still conveys humour, awareness of world events, kindness and insight.
- *'Food goes everywhere, from face to shoelaces.'*
  It is hard to accept that it is probably now right to use that large bib at mealtimes. It lets him enjoy his meals independently and keeps his clothes clean, which matters a lot to him … but I still don't like it.
- *'He's changing.'*
  We knew it would happen, but it's been a shock to watch the first signs of mental change. It is painful to listen patiently to his attempts to sort out delusion from reality.

Once stabilised, and if the home circumstances permit, the patient will be discharged. Re-admission to hospital will only become necessary should further problems arise, such as worsening of symptoms. Much of the care and advice which the patient receives while in hospital is directed towards maintaining independence, dignity and self-esteem in what is a profoundly distressing disorder.

Mobility

Problems can include difficulty in starting to walk or stopping walking, shuffling, tottering, impaired balance when turning and ongoing stiffness, interrupted by a 'freezing' of movement. Many of the techniques employed to assist the patient can be used by the relatives in the patient's home. The patient's strength and range of motion need to be improved in conjunction with the medication therapy programme. Warm relaxing baths and passive and active range of movement exercises are a good starting point. Relatives should be advised to continue this activity at home. Effort should also be directed towards improving the patient's gait, with the assistance of the physiotherapist. Useful tips to consider are given in Box 9.15.

If the patient experiences difficulty in rolling over in bed or getting in and out of bed, they can be advised to use a low bed with a firm mattress or to place a board under their existing mattress. Additional techniques are given in Box 9.15 and additional suggestions inspired by patients themselves can be found at www.parkinsons.org.uk (see 'Useful websites').

Exercise

Some patients may benefit from an exercise programme to assist mobility and improve posture. It is important that this programme is performed under supervision initially, until the patient and their helper are conversant with the techniques. Again, the importance of continuing these at home should be stressed to both patient and family.

Eating and drinking

The person with Parkinson's disease may have difficulty with eating and drinking due to abnormal posture, tremor, poor swallowing and excessive saliva. There may be embarrassment about their untidiness when eating, and the length of time it takes to eat often results in food going cold. People will often choose to eat alone rather than endure the social embarrassment of seeing others watching them eat. Families may adapt mealtimes creatively; for example, two small servings may mean that food stays hot and portion

Box 9.15

Useful tips for the nurse or carer to encourage a frail older man with Parkinson's disease to move

General tips

- Gently rocking the patient to and fro encourages initiation of walking when he 'freezes'.
- Advise the patient to consciously lift each foot as he is walking and to place his heel on the ground first. To encourage this, tell the patient to think that he has a series of imaginary steps to climb. These techniques help to counteract the usual propulsive movement.
- Remind the patient to swing his arms when walking.
- Teach the patient to broaden his stance to provide a more stable base.
- Remind the patient to think about his posture and to stand erect.
- If the patient starts to shuffle, tell him to stop and start again.
- Tell the patient to adopt the habit of taking small steps when he is turning and to turn only in a forward direction.

Rolling over in bed

1. The patient is advised to bend his knees so that his feet are flat on the mattress and then swing the knees in the direction that he wishes to turn.
2. The next move involves the patient clasping their hands and lifting them straight up, straightening the elbows as they do so, then turning the head and swinging the arms in the same direction as the legs.
3. The patient then grips the edge of the mattress and adjusts his position until comfortable.

To turn in the opposite direction, the process is reversed.

Some patients find a 'monkey pole' helpful. Whilst this is easy to attach to a hospital bed, it is not usually possible in the home; however, an alternative the patient may consider is tying a stout rope to the bottom of the bed and ensuring that the free end of the rope is within reach. This may allow the patient to alter his position in bed without help.

Getting into and out of bed independently

1. To get into bed, the patient sits on the edge of the bed near the pillow so that when he lies down, his head is in the correct position on the pillow.
2. Once this manoeuvre has been mastered, the patient only has to lift his legs onto the bed and then adjust himself into a comfortable position.

Finding the correct spot to sit on the mattress may take some practice, but once mastered the patient will find this a convenient way to get into bed.

Getting out of bed is more complicated and several techniques can be suggested. One example is as follows:

1. The patient lies on his back with his arms at his side.
2. He then lifts his head, tucking his chin into his chest, and sits up supported by the elbows.
3. The patient then sits up, pushing the trunk so that he is leaning forward, bent at the hips.
4. Support is now achieved by using his outstretched arms behind him.
5. He should now move his legs towards the edge of the bed until he is sitting up and ready to stand up.

Rising from a chair

The patient should avoid low chairs, choosing instead firm, high-backed chairs. In the home, the height of a low chair can be increased with blocks under the legs and it will help to raise the back of the chair slightly higher than the front. Cushions or a spring-ejector seat will also help. Placing a sturdy armchair in a frequently used location within the home is ideal. The patient can use the arms of the chair to assist him to rise from it.

size is less daunting. Staff in some restaurants, following discussion, may be sensitive to such difficulties and very helpful.

The speech and language therapist may be asked to assess the patient's swallowing ability and to draw up a programme of swallowing management. This could include facial exercises and techniques to encourage swallowing, e.g. taking a sip of iced water to stimulate the swallowing reflex.

The dietitian's advice should also be sought. It is usual to establish what kind of foods the patient likes best. A review of their current dietary intake will alert the nurse to any deficiencies or inappropriate foods; for example, it is easier to swallow semi-solid food than lumpy food. If tremor is a problem, the patient can be taught to hold their arm close in to their body, using their elbow as a pivot. Bendable straws could be used and cups containing hot liquids should only be filled halfway to avoid spillage or scalding.

It is important for the patient's self-esteem to resist the temptation to feed them before this is absolutely necessary. Many patients may still be able to feed themselves if their food is cut up for them. Feeding the patient for the convenience of speed is unacceptable.

Some of the swallowing difficulties which may be experienced are as follows:

- coughing within a few seconds of the act of swallowing
- food sticking in the throat
- nasal regurgitation
- fear of swallowing
- drooling
- food which remains in the mouth once the meal is completed.

If the patient wears dentures, these should be checked frequently to ensure that they fit properly. The importance of good oral hygiene should be emphasised. Patients should check their body weight weekly and keep a record of this, as weight loss may occur. Some hospitalised patients need to have suctioning equipment readily available while they are eating, in case they choke.

9.15 Work out how many day-to-day abilities need to be considered in helping a person with advanced Parkinson's disease to continue to enjoy watching television.

Communication

The communication impairment seen in the patient with Parkinson's disease includes a loss of facial expression, which may lead to the assumption that the patient is cognitively impaired and, due to the abnormal stooping posture, there may be loss of normal eye contact and body language. The speech and language therapist should be involved in the care of the patient at an early stage and, should communication problems arise, a programme of exercises and therapy will be instituted. Facial exercises encourage the patient to pronounce sounds more clearly, e.g. by mouthing words slowly and clearly. Imagining that someone else is trying to lip read their words can often help the patient. There are also exercises for breathing, strengthening the voice and controlling the speed of speech, many of which can be continued in the patient's home. Other simple measures include reading out loud or singing, for example in the bath. Alternatively, the patient can stand in front of a mirror, watching their lips as they talk.

Eventually the voice may become so weak that meaningful communication is impossible and an alternative means of communication becomes necessary. Communication aids must be appropriate to the patient's needs, and advice regarding their use should be taken from the speech and language therapist. Aids can range from using a simple picture board through to sophisticated computer devices.

More simply, it may be possible for the patient to write down messages using pen and paper. However, the ability to write also deteriorates progressively and the writing becomes smaller and smaller (micrographia) as muscle stiffness increases. An alternative device, which may be useful for some patients, is a portable amplifier which will make a weak voice sound louder. However, this will not improve slurred speech. Reading books and newspapers also becomes difficult when muscle rigidity interferes with the ability to hold them and to turn pages.

For further advice and support for patients with Parkinson's disease, see www.parkinsons.org.uk.

Elimination

The impairment of mobility in conjunction with urinary frequency or hesitancy can lead to embarrassing episodes of incontinence. This can be difficult to deal with and initially the patient is encouraged to visit the toilet regularly. The use of continence aids may be indicated (see Ch. 24) and the advice of a continence advisor should be sought. It is important that patients are encouraged to maintain a fluid intake of 2.5–3 L/day.

Eventually catheterisation of the bladder may be unavoidable. Many patients and their families reach a stage where they would prefer to have a catheter inserted rather than suffer the continual embarrassment of incontinence and odour. For some, the increasing expense associated with laundering clothes and sheets may become overwhelming.

Constipation is a common problem in Parkinson's disease, so the patient and family should be taught preventive action. A high-fibre diet and plenty of fluids will encourage regular bowel motions. Failing this, it will be necessary to administer faecal softeners or bulking agents regularly and, when required, an enema.

Personal cleansing and dressing

The oily skin and excessive perspiration seen in patients with Parkinson's disease, due to excess parasympathetic activity, demand more frequent washing and bathing. If tremor is present, men will find an electric or battery-operated shaver easier to use.

Slowness in performing voluntary movement (bradykinesia) can make daily activities such as dressing difficult for the patient. For example, buttoning clothes and tying shoelaces may become impossible. Adaptations to clothing, e.g. replacing buttons and other types of fastening with Velcro, and the use of appropriate aids will allow the patient to continue to dress independently for as long as possible, thus maintaining independence. Cardigans are sometimes easier to take off and on than pullovers.

A change of clothing style may be indicated, e.g. pull-on tracksuit trousers, slip-on shoes, elastic shoelaces and

front-opening skirts with an elasticated waistband are also easier to manage.

Discharge

Every opportunity should be taken to advise the patient and family about the best way to manage the disorder at home. Each of the areas already outlined should be included in the discharge plan.

Additional points to consider following discharge from hospital are as follows:

- The names and times of the medicines to be taken should be written down. The importance of maintaining the correct dosage is emphasised and some indication of the medicine's action and possible side-effects should be given.
- A daily exercise programme should be devised for the patient, along with instructions about how much the patient should do.
- Contact should be established with the appropriate community services, such as nursing, social services, physiotherapy, occupational therapy and speech and language therapy, who may be providing the patient and family with support at home.
- Advice on dietary aspects along with sample menus should be provided.
- Advice on safety should be provided. The removal of loose rugs and identification of other similar dangers in the home should be highlighted.

The patient should be encouraged to remain as active as possible for as long as possible, but should also be warned to pace their activity. Each individual will approach this situation in their own unique way and this has to be taken into account when proffering advice. The attitude and approach of the family, where appropriate, can be crucial to the patient's progress towards maintaining independence for as long as possible. A helpful account of the psychosocial impact of late stages of the disease is provided by Calne (2003).

For further information on palliative care for people with Parkinson's disease, see Thomas & MacMahon (2004a,b).

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

There are many infections of the central nervous system, of which the following are considered: bacterial meningitis, i.e. infection of the meninges, viral encephalitis, i.e. infection of the cerebral tissue, and cerebral abscess.

A serious outbreak of bacterial meningitis occurred in Stroud, Gloucestershire, in 1985 (Cartwright et al 1986) and since then sporadic outbreaks have occurred in other parts of the UK. Many of the victims are young children and teenagers. It is estimated that there are about 5000 cases per year in England and Wales, with 500 deaths and approximately 1000 patients being left permanently disabled (Lindsay & Bone 2004). Approximately 10 000 people contract viral meningitis annually. As a result of this, the Meningitis Trust (see 'Useful websites') was set up with the following aims:

- to raise funds for research into all aspects of meningitis
- to provide help and support for the victims and families
- to educate the public about the disease and its symptoms in the hope that awareness and early diagnosis will save lives.

PATHOPHYSIOLOGY

In bacterial meningitis, purulent exudate is found in the subarachnoid space. The most likely route of entry is via the bloodstream, which can carry microorganisms from, for example, an infected middle ear. Other routes of entry include direct extension from a skull or facial fracture, via the CSF, and extensions along cranial and spinal nerves. The circulating CSF acts as an effective means of spreading the microorganisms. Causative organisms in adults include *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*.

Viral encephalitis may accompany viral infections elsewhere in the body, e.g. the respiratory tract. The commonest virus in the UK is the herpes simplex virus. Some viruses, such as in Creutzfeldt–Jakob disease, appear to be latent for many years and are called 'slow viruses' (Lindsay & Bone 2004).

Cerebral abscess most commonly occurs following middle ear and mastoid infections. Pus accumulates in the cerebral tissue, its location depending on the source and method of spread of infection. Other related conditions are extradural abscess, where pus accumulates in the extradural space, and subdural empyema, where pus accumulates in the subdural space. The offending organisms include the *Streptococcus* and *Staphylococcus aureus*. Once formed, the abscess comprises a mature capsule containing necrotic tissue, inflammatory cells and necrotic debris. The presence of an intracranial abscess can result in raised ICP (Lindsay & Bone 2004).

Common presenting symptoms Infections of the central nervous system affect all age groups. Common symptoms are described in Box 9.16. A patient with meningitis may have had some predisposing infection and be receiving treatment for it, e.g. antibiotics and ear drops for an ear infection, or may have experienced a head injury and have a compound skull fracture, a fractured base of skull or a facial fracture (see 'Head injury', p. 406). In the last case, the patient may not have realised the extent of the injury, initially deferring medical attention after the accident, but may begin to feel unwell over a period of time. Their GP may suspect a serious problem as the patient's condition deteriorates. Admission to hospital will be necessary and, if the patient's condition is serious, referral to a neurosurgeon will be made, as the condition can rapidly become fatal, especially in children.

MEDICAL MANAGEMENT

Examination Typically, the patient is pyrexial, complains of headache and may be disorientated and drowsy. They find all external environmental stimuli, such as strong light (photophobia), painful (see Box 9.16) and their reaction to interference is often aggressive.

Investigations The patient with any focal neurological signs, or presenting with a Glasgow Coma Scale of <7, should have a CT scan performed to exclude an intracranial mass,

Box 9.16

Features of presentation in CNS infections

Bacterial meningitis (abrupt onset)

Infants

Non-specific:
- Drowsiness
- Irritability
- Off feeds
- Distress on handling
- Vomiting or diarrhoea
- Fever

More specific:
- Neck stiffness
- Tense or bulging fontanelle
- Purpuric or petechial rash that does not blanch under pressure

Late:
- High-pitched or moaning cry
- Coma
- Neck retraction
- Shock
- Widespread haemorrhagic rash

Older children and adults

Non-specific:
- Vomiting
- Fever
- Back or joint pains
- Headache

More specific:
- Neck stiffness
- Photophobia
- Confusion
- Purpuric or petechial rash that does not blanch under pressure

Late:
- Coma
- Neck retraction (in severe cases this, in combination with spasm, causing the heels to bend backwards, produces opisthotonos)
- Shock
- Widespread haemorrhagic rash

Viral encephalitis (insidious onset)
- Headache and fever are both present
- Conscious level deteriorates gradually. Confusion is common
- Moderate neck stiffness
- Seizures can occur
- ICP may be elevated as a result of cerebral oedema
- Cranial nerve deficits and focal neurological signs may be present.

Cerebral abscess (insidious onset, 2–3 weeks or more)
- Headache is recurrent and fever is usually present
- Patient becomes confused and drowsy
- Neck stiffness is indicative of circulating CSF infection
- Partial or generalised seizures occur in 30% of patients
- ICP is elevated as abscess expands
- Cranial nerve deficits occur and focal neurological signs include speech disorders, motor and sensory deficits and ataxia

such as an abscess. A lumbar puncture may be performed to identify the offending organism. A moderate increase in lumbar CSF pressure may be noted. The changes seen in the CSF are outlined in Table 9.5.

Other investigations include blood cultures and X-rays to detect the source of infection. In the patient with a cerebral abscess, there may be a rise in the ESR. This may be confirmed by the identification of the organism on CSF analysis, or of a lesion, such as an abscess, on CT scanning. Brain biopsy guided by CT scan may be helpful. When an abscess is suspected, the CT scan should be enhanced with contrast medium to highlight small lesions which may otherwise be missed.

Treatment The patient with bacterial meningitis or a cerebral abscess should commence antibiotics as soon as possible. Penicillin is the antibiotic of choice and is usually given intravenously in high doses, such as penicillin 24 million units over 24 h, but it should be remembered that a significant proportion of the population is allergic to penicillin and so other antibiotics may be used.

Surgery will be performed if the presence of a cerebral abscess is confirmed and adequate explanations should be given to the patient and family of what is involved in this course of treatment (see Hickey 2002 for complications). This may involve burr hole aspiration (repeated, if necessary), primary excision of the whole abscess or evacuation of the abscess contents leaving the capsule intact. This avoids damaging the surrounding brain.

When there are signs of high ICP, the patient requires immediate surgical intervention to drain the abscess. This will relieve the ICP and will prevent coning and herniation of cerebral contents (see 'Head injury', p. 407). The patient may have a focal neurological deficit or be in a coma (see Ch. 28).

NURSING PRIORITIES AND MANAGEMENT: Infections

For those patients who require surgery, the general pre- and postoperative care is as given in Chapter 26. The nurse should observe the patient for signs of the abscess re-collecting: this will present as raised ICP. The patient's family will require explanations, support and comfort.

Immediate priorities

Neurological status and vital signs

Because the patient with an intracranial infection may have a decreased conscious level and because this may deteriorate rapidly, observations should be recorded and any change in condition reported immediately. Vital signs are very important as the patient may be pyrexial, and as the infection continues, the patient's temperature can increase further. Pulse, blood pressure and respirations may be high when recorded, owing to infection: any changes in these observations should be reported. There may be signs of raised ICP (see p. 408).

Breathing

The respiratory pattern should be observed for rate, depth and frequency, as a change may indicate a rising ICP.

Any respiratory distress should be reported immediately. Oxygen may already have been prescribed and the nurse should encourage the patient to tolerate it, giving explanations when necessary. Nursing the patient in a bed with a head-up tilt of 30° will not only help to decrease ICP, but also encourage lung expansion. The nurse should be aware of the risk of a chest infection developing.

Controlling body temperature

In order to reduce pyrexia, the patient's temperature should be recorded frequently and any further rise reported immediately, as this may indicate that the antibiotics are not controlling the infection and that the patient's condition could deteriorate. Each 1°C increase in temperature increases the body's demand for oxygen by 10%, which encourages vasodilatation and increases ICP. Nursing measures to reduce pyrexia may include tepid sponging, use of a fan and the administration of paracetamol, either per rectum or orally. The effects of these measures should be evaluated.

Seizure activity

If seizures are observed, they should be recorded, noting the type of seizure, its duration and exactly what happened (see section on 'Seizures', p. 427). An airway, oxygen and suction should be at hand.

Communication

Communication can be difficult, as the patient may be experiencing severe headache, nausea and vomiting, have photophobia and be disorientated and drowsy. A calm darkened environment will comfort the patient, who will be distressed about their condition and what is happening to them.

Explanations should be given to the patient about what is happening and why, and the patient should be given time to ask questions and express their feelings.

The family will also require reassurance and explanations, but they should be advised not to overstimulate the patient, although touch could be suggested as this can be comforting.

Maintaining a safe environment

Side rails should be placed in position to prevent the patient falling out of bed due to restlessness or confusion.

Medication

In order to give the patient adequate relief from pain, analgesics should be administered.

The nurse should ensure that prescribed antibiotics are given or taken at the correct time by the patient, to ensure maintenance of the medication at a therapeutic level in the bloodstream. An accurate fluid balance chart should be maintained as the patient can become dehydrated due to pyrexia, nausea and vomiting. Signs of dehydration include dry skin or mouth or a diminishing urinary output and these should be reported. Intravenous fluids will be prescribed until the patient is able to tolerate adequate oral fluids.

Personal cleansing and dressing

Once an assessment of the patient's needs has been carried out, assistance should be given with personal cleansing and dressing. If the patient has a decreased conscious level, care should be exercised in meeting their needs and, as their condition improves, independence should be encouraged.

Mobility

The patient should be as mobile as their condition allows. Initially, bed rest may be necessary and all care should be taken to ensure that their position is changed 2-hourly. Examination of the skin should be carried out at frequent intervals in order to detect signs of pressure, such as redness.

Preparation for discharge home

If the source of the infection has been identified, it will be treated or, if necessary, further investigations carried out. If it has been treated successfully, e.g. in sinusitis or an ear infection, the patient should be advised to contact their GP if there is a recurrence of the infection. The need to continue medication on discharge should be fully explained, with emphasis on the importance of completion of the course of antibiotics.

If the reason for the introduction of the infection was an injury, such as a skull or facial fracture, further investigations may be required to ensure proper healing. While rehabilitating in the ward, the patient will have been assessed by the ward team. Maintenance of optimum function of the patient is a priority, both physically and mentally, and

Table 9.5 Changes in cerebrospinal fluid which is infected

CSF	Acute bacterial meningitis	Viral encephalitis
Appearance	Yellow	Clear
Cells	Polymorphs 1000–2000 per cubic mm or more	Mononuclear 50–1500 per cubic mm
Protein	Increased 1.0–5.0 g/L	Mildly elevated
Chloride	110–115 mmol/L	Normal
Glucose	Much reduced or absent	Normal
Organisms	Present on culture	Absent on culture. Require specialist virological testing to identify
Pressure	Increased	Increased

outpatient appointments may be required, e.g. for physiotherapy. The patient's family should be involved in the patient's planned discharge and rehabilitation programme at home. Advice and encouragement for this should be given by the ward team. Advice should also be given about employment, driving and other activities, especially if the patient has experienced seizures (see p. 428).

Coping after meningitis

The Meningitis Trust (see 'Useful websites') offers a comprehensive support system for those affected by meningitis. This includes a 24-h support and information line, home and hospital emotional support visits, provision of financial support, grant funding and a rehabilitation advisory service. The Trust emphasises that complete recovery takes time and they provide guidance on how to deal with a range of minor after-effects, e.g. general tiredness, headaches and difficulty in concentration.

Care of the dying patient

The patient's condition may deteriorate rapidly after admission, if medication and surgery have not treated the cause of the infection successfully. In these circumstances, all of the patient's needs should be attended to. Adequate pain relief should be given and the patient should be comforted (see Ch. 28).

INTRODUCTION

A fully functioning musculoskeletal system is fundamental to optimal health in the normal active human being. Injury or disease involving this system can have a profound effect on an individual's ability to perform the activities of daily living and can result in either temporary or permanent disability, one of the main problems usually being the degree of decreased mobility. The overall aim of nursing care is to prevent further injury, reduce the risk of complications, promote healing, maximise independence within individual constraints of the existing condition and promote optimal rehabilitation.

This chapter will describe some of the more common disorders of the musculoskeletal system that are caused by either trauma or disease and will outline relevant principles of nursing management.

Epidemiology

The main causes of musculoskeletal trauma or disease in the UK include road traffic collisions (RTCs), industrial and other work-related accidents, sporting accidents and damage due to underlying disease.

Road traffic collisions

In 2002 there were 314 519 road casualties in the UK (National Statistics 2004) and many of these will have sustained musculoskeletal injuries. It should be emphasised that it is often the immediate treatment of injury or suspected fracture that determines the ultimate outcome of an RTC; this applies particularly to injuries of the spinal column and fractures of major long bones.

Work-related injuries

In the UK in 2001/2002, 251 workers died as a result of injuries sustained at work, 28 940 sustained major injuries and 130 572 sustained injuries which resulted in sickness of more than 3 days' duration (National Statistics 2004). As with RTCs, many work-related injuries result in broken bones, damaged joints or torn ligaments/tendons.

In many countries low back pain is the most common cause of long-term disability in middle age (Guzmán et al 2004). Repetitive strain injuries (RSI) or cumulative trauma disorders (CTD) are also increasing, possibly due to the increased use of computers in the workplace (Winzeler & Rosenstein 1997).

Sporting injuries

With increased leisure time and facilities and the many health campaigns promoting the benefits of exercise, more time is being spent in sporting activities, with a resultant increase in sporting injuries. In many cases these are minor, but they can also be serious and result in permanent disability: diving into shallow water can cause serious injury to the cervical spine; knee and lower limb injuries are common in football and skiing; and shoulder, upper limb and spinal injuries often result from horse riding accidents.

Damage due to underlying disease

Relatively minor trauma may also highlight a previously undiagnosed underlying disease process. For example, osteoporosis in a postmenopausal woman may only be diagnosed when she presents with a fractured wrist or neck of femur (see p. 460).

Osteoarthritis, i.e. degenerative arthritis, is the commonest condition to affect joints in humans (Hakim & Clunie 2002) and is mainly due to wear and tear on the articular cartilage of the larger weight-bearing joints and to the degenerative changes associated with the ageing process.

Rheumatoid arthritis is a chronic or subacute disease of the musculoskeletal joints and affects 34/100 000 women and 14/100 000 men (Hakim & Clunie 2002). It usually affects more than one joint (polyarthritic) and can be extremely disabling.

The contribution of the science of bioengineering

Musculoskeletal conditions involve, or are caused by, disruption of the mechanics of the human body. Through research, bioengineers are making vital contributions to the understanding of these mechanics and, with the availability of more biologically compatible materials, are able to design a wider and more refined range of replacement joints and limbs. Joint replacement surgery is now a common procedure and has revolutionised the quality of life for thousands of post-injured or older people. This chapter provides examples of these and other bioengineering developments such as endoprosthetics following bone tumour excision.

ANATOMY AND PHYSIOLOGY OF THE MUSCULOSKELETAL SYSTEM

This section gives a brief overview of the anatomy and physiology of the musculoskeletal system. For detailed information, refer to anatomy and physiology textbooks and become familiar with the model skeleton in your classroom.

For further information, see Marieb (2004).

The skeletal system

The skeleton can be divided into the axial skeleton (the bones of the head and trunk, excluding the pectoral and pelvic girdles) and the appendicular skeleton (the bones of the limbs, including the bones of pectoral and pelvic girdles).

The main functions of the skeleton are:

- support for the body
- protection for internal organs
- movement — bones and muscles act as levers to produce movement through joints
- mineral storage — minerals such as calcium and phosphorus
- blood cell formation — red bone marrow produces red and white blood cells and platelets (Knight et al 2004).

Structurally, the skeletal system consists of two types of connective tissue: bone and cartilage.

Bone

10.1 Look up the factors involved in the development and growth of healthy bone. Describe them.

Unlike other connective tissue, bone contains large amounts of mineral salts, mainly tricalcium phosphate and calcium carbonate, which, when deposited on the collagen fibres, results in hardening. There are two types of bone tissue: compact and cancellous.

The hard outer layer of a bone is compact bone tissue, cortical bone, while cancellous tissue fills the inside. Cancellous tissue is spongier in appearance and the larger spaces contain the highly vascular red bone marrow and the fatty yellow bone marrow. The thickness of each type of tissue varies, depending on the type and function of the particular bone. In long bones such as the femur, the shaft, diaphysis, is enclosed by a thick layer of cortical tissue which gives strength for weight-bearing, while at each end, the epiphyses, the cortical tissue is thinner and encloses a greater mass of cancellous tissue.

Flat bones, such as the sternum and the pelvis, have a thinner layer of cortical tissue and a relatively greater amount of cancellous tissue. This is the reason why they are chosen for bone marrow biopsy.

Tissue renewal

Like the skin, bone tissue is constantly being replaced, but at variable rates in different parts of the body. The cancellous bone at the epiphyses, e.g. in the upper end of the femur, is replaced about every 4 months in an adult, in contrast to the compact bone in the shaft of the femur which will never be completely replaced during a lifetime. This process of growth and repair is dependent on balanced activity between the three types of bone cell: osteoblasts, osteocytes and osteoclasts (see Fig. 10.1).

10.2 Referring to an anatomy and physiology text, define the function of each type of bone cell.

For further information on bone, see Knight et al (2004).

Cartilage

This is a form of connective tissue which is tough, flexible, avascular and devoid of nerve fibres. It forms part of the support mechanism of the body.

There are three types of cartilage:

- hyaline cartilage — firm yet pliable and forms the articular cartilage that covers the articulating surfaces of synovial joints

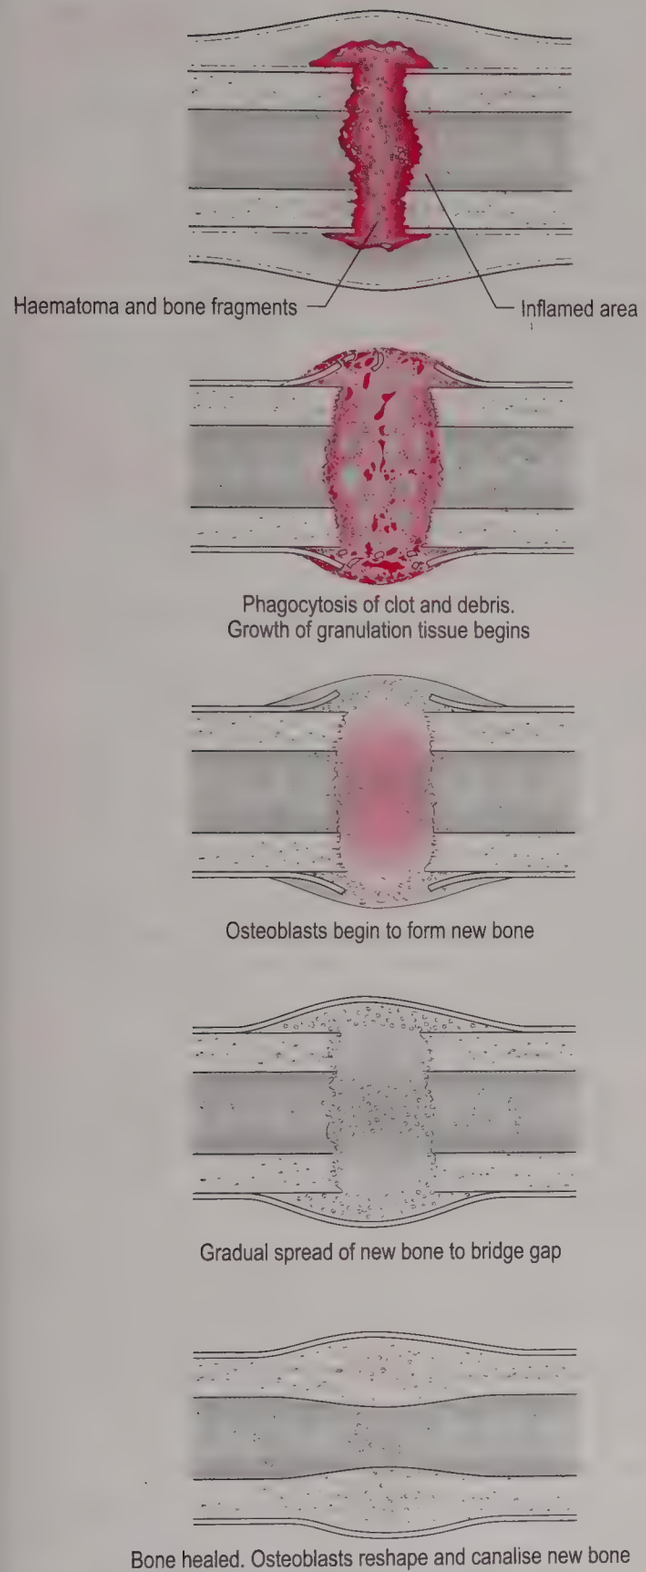

Fig. 10.1 Stages in bone healing.

- fibrocartilage — strong, compressible and tension-resistant and is found in areas such as the intervertebral discs
- elastic cartilage — contains more elastin fibres than the others and therefore has a greater ability to stretch whilst retaining its strength; it is found in the external ear and the epiglottis.

The axial skeletal system

The skull and vertebral column form the central axis of the skeletal system. It is a strong, flexible column of 33 bones,

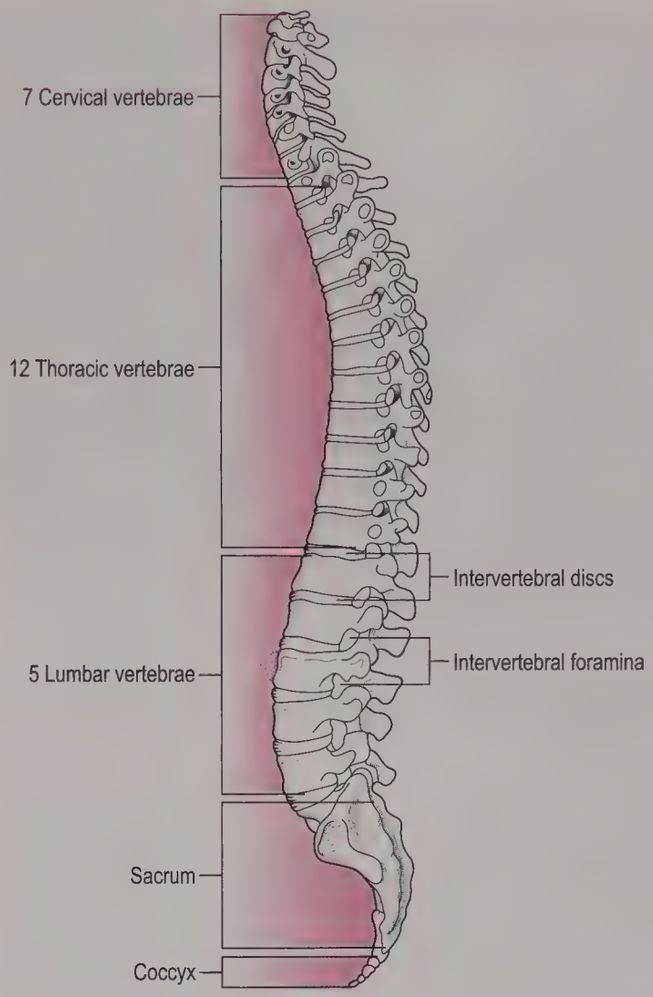

Fig. 10.2 The vertebral column — lateral view.

24 of which are 'true' vertebrae — the cervical, thoracic and lumbar — the remainder being fused to form the sacrum and coccyx (see Fig. 10.2). Between each of the vertebrae from C2 to S1 is a strong joint created by the fibrocartilaginous intervertebral discs, which allow flexibility and act as shock absorbers when the spine is exposed to vertical forces.

The spinal column functions to protect the spinal cord, to support the skull and to act as a point of attachment for the ribs and muscles of the back.

The appendicular skeletal system

The bones of the upper and lower limbs and their girdles are the main parts of the appendicular skeletal system and are characterised by the presence of synovial joints which connect the articular surfaces of adjoining bones (see Fig. 10.3). The bones that make up the joint are held within a fibrous capsule, which consists of two layers:

- an outer layer of dense connective tissue which allows movement but resists dislocation
- an inner layer lined with synovial membrane which secretes synovial fluid; this provides nourishment and lubrication.

The articular surfaces of the bones involved are covered in hyaline cartilage — articular cartilage.

Ligaments

Ligaments attach bone to bone and are vital in maintaining the stability of a joint. They are made of dense connective

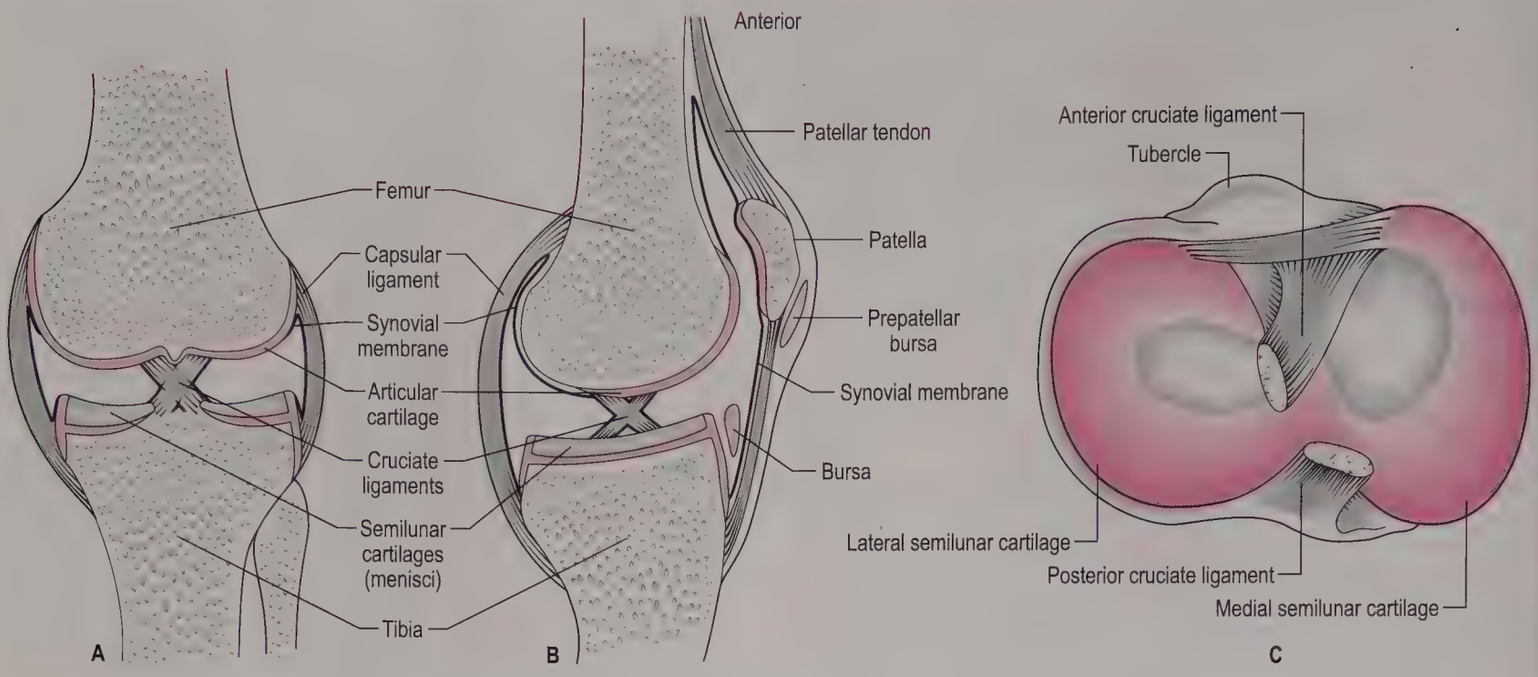

Fig. 10.3 The knee joint. A: Section viewed from front. B: Section viewed from side. C: Superior surface of the tibia showing the semilunar cartilages and cruciate ligaments.

tissue and have a relatively poor blood supply. A joint may have many ligaments, such as the knee which has the cruciate ligaments to prevent the femur and tibia moving forwards on each other and the medial and lateral collateral ligaments which prevent side to side movement (see Fig. 10.3). Damage to ligaments can result in an unstable and painful joint, common in football injuries.

The muscular system

Skeletal muscle tissue is composed of multinucleated muscle cells which are long and cylindrical in appearance. Each muscle is made up of muscle fibres and connective tissue. A good blood and nerve supply is essential for muscle function and the mechanics of movement.

10.3 Find a chart or model of the muscular system. Identify and name the main muscle groups.

For further information, see Kneale & Davis (2004).

Tendons

Tendons attach muscle to bone and allow movement of joints to take place. As with ligaments, tendons too have a relatively poor blood supply. Damage to tendons can therefore be as serious as bony injury and prevent movement in an individual.

GENERAL PRINCIPLES OF NURSING MANAGEMENT OF MUSCULOSKELETAL DISORDERS

Nursing assessment

This will involve a holistic assessment of the patient, as musculoskeletal disorders can have profound effects on a patient physically, psychologically and socially. In addition, visual inspection, palpation, measurement, and other investigations such as radiological/imaging studies (see Box 10.1) and blood tests in rheumatoid arthritis for example, are necessary.

In particular the nurse should assess for:

- the patient's description of pain and other symptoms
- abnormal position or appearance of limbs or affected part, with loss of function (compare with contralateral side)
- abnormal posture or gait
- use of walking aids or prostheses
- concurrent health problems, allergies and medications
- the patient's perception of the cause of the primary problem
- the patient's knowledge and understanding of the condition
- the impact on activities of living (ALs) (Roper et al 2000), especially relating to impaired mobility
- the patient's and the family's expectations and coping strategies.

Problems and strengths (actual and potential) are identified in the following categories:

- life-threatening problems such as shock
- pain
- impaired mobility
- knowledge deficit
- potential for further injury — physical safety and neurovascular complications, especially compartment syndrome (see p. 450) and deep vein thrombosis (DVT)
- psychosocial consequences
- rehabilitation
- patient and family strengths — these should be defined and used constructively.

Box 10.1

Investigations for musculoskeletal abnormalities

Radiological and imaging studies

- X-ray — to detect abnormal position, fractures, bone density and presence of fluid or abnormalities in joint capsules
- Computed tomogram (CT scan) — makes use of the fact that different tissues have varying radiodensities. A series of radiographs are made at different angles and planes and the computer integrates the information to produce pictorial slices (sometimes 3D) which can be used to detect soft tissue injuries or tumours and inflammatory or metastatic skeletal disease or fracture
- Magnetic resonance imaging (MRI) — magnetic fields used to show the difference in hydrogen density of various muscle and soft tissues, indicating the presence of abnormalities
- Dual energy X-ray absorptiometry (DEXA) scan — scan for bone density
- Arthrogram — injection of a radio-opaque substance or air into a joint followed by X-ray to identify abnormalities of joint structures. Largely superseded by arthroscopy and MRI scan, where available
- Myelogram — a contrast medium is injected into the subarachnoid space of the lumbar spine in order to visualise disc herniation or tumours. Largely superseded by MRI scan, where available

Joint examination

- Arthroscopy — endoscopic visualisation of structures inside a joint. May also involve withdrawal of synovial fluid for analysis, and treatments such as washout of the joint to remove debris or the trimming of any damaged structures, e.g. the menisci in the knee joint

Muscle and nerve studies

- Electromyography (EMG) — measures electrical potential of muscle during rest and activity
- Nerve conduction velocities (NCVs) — measures speed of nerve impulse conduction

Other tests

- These include bone biopsy, densimetry, total body calcium and various haematological studies for hormone and mineral levels

Nursing interventions

- Treat life-threatening problems — ABC of resuscitation (see Chs 2 and 27) and treatment of shock (see Ch. 18)
- Relieve pain
- Maintain an appropriate degree of therapeutic restriction and mobility
- Constantly monitor and reduce the risk of neurovascular complications such as compartment syndrome and DVT
- Maintain a safe environment
- Explore the patient's and family's understanding of the condition and provide support and education based on individual needs
- Coordinate multidisciplinary intervention for psychosocial problems
- Facilitate rehabilitation

SKELETAL DISORDERS

FRACTURES

PATHOPHYSIOLOGY

Fractures, which patients often refer to as a 'broken bone', are a break in the continuity of a bone (Langstaff 2000) as a result of direct or indirect trauma, underlying disease (pathological fracture) or repeated stress on a bone (stress fracture).

Classification of fractures A simple or closed fracture is one where there is no communication between the external environment and the fracture site. When direct contact between the fracture site and the external environment occurs, it is known as a compound or open fracture.

A fracture may be described as 'stable' when the bone ends are lying in a position from which they are unlikely to move, or as 'unstable' when the bone ends are displaced or have the potential to be displaced.

Common fracture patterns are shown in Figure 10.4.

MEDICAL MANAGEMENT

Priorities of treatment If a fracture has been sustained following trauma it is important to follow the principles of trauma treatment (see Ch. 27). Once the patient's physical condition has been stabilised, specific treatment for the fracture will continue. For all fractures there is a risk of the edges of the broken bones damaging soft tissues or blood vessels/nerves, either at the time of injury or subsequently, due to poor handling of the affected limb.

Whether the fracture is a major life-threatening injury, such as an open shaft of femur fracture, or one where the physical damage is relatively slight, such as a phalangeal fracture, the principles of treatment remain the same, i.e. reduction of the fracture, maintenance of the reduced position, and restoration of function (rehabilitation).

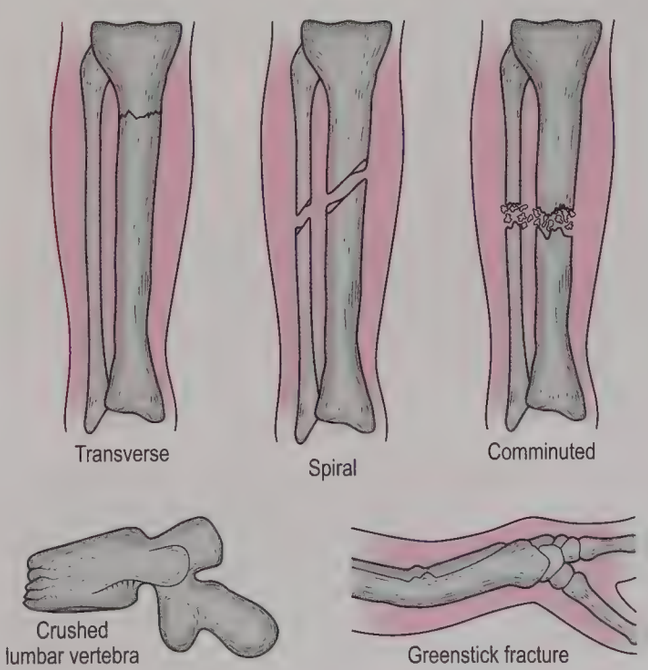

Fig. 10.4 Patterns of fracture.

Reduction of fractures Fractures are said to be reduced when displaced bone fragments are pulled into their normal anatomical position. In many cases, a general anaesthetic will be necessary to overcome the protective muscle spasm and severe pain.

Maintenance of position It is important, following reduction, that the fracture is held in the correct anatomical position until bony union occurs. Various methods are used, depending on the site and the type of fracture. These include external splintage using an orthosis, i.e. a removable splint, plaster of Paris (POP) or synthetic (resin/plastic based) casts, skin or skeletal traction, or an external fixator frame. Operative reduction with internal fixation by metal pins, plates, screws or nails may also be used to hold the bony fragments in position. When the blood supply is grossly affected, it may be necessary to implant a prosthesis to replace the affected bone, e.g. in some cases of fractured neck of femur.

Restoration of function When one part of a limb is immobilised, there is a tendency for related joints and muscles to become stiff and weak; for example, during splintage of a wrist fracture, the finger and shoulder joints can be affected. Appropriate physiotherapy is therefore essential.

Patients require varying degrees of rehabilitation, involving a multidisciplinary team approach (see Ch. 34). It should be remembered that even when the physical damage is slight, the psychosocial impact may be considerable.

Traction

Orthopaedic traction occurs when a pulling force is applied to a part or parts of the body, and counter-traction, a pulling force in the opposite direction, is also applied (Lucas & Davis 2004). Counter-traction is most usually supplied by the body weight of the patient. It is used in the following circumstances:

- to reduce and immobilise fractures/dislocations and maintain normal alignment of all injured tissues
- to prevent and correct deformity
- to reduce muscle spasm
- to relieve pain
- to immobilise an injured or inflamed joint
- to keep joint surfaces apart.

Traction is less used than in the past as alternative methods, in particular internal fixation, enable patients to become mobile more quickly and therefore avoid the problems of bed rest. However, it still has its place in treatment and nurses must know the principles of its use.

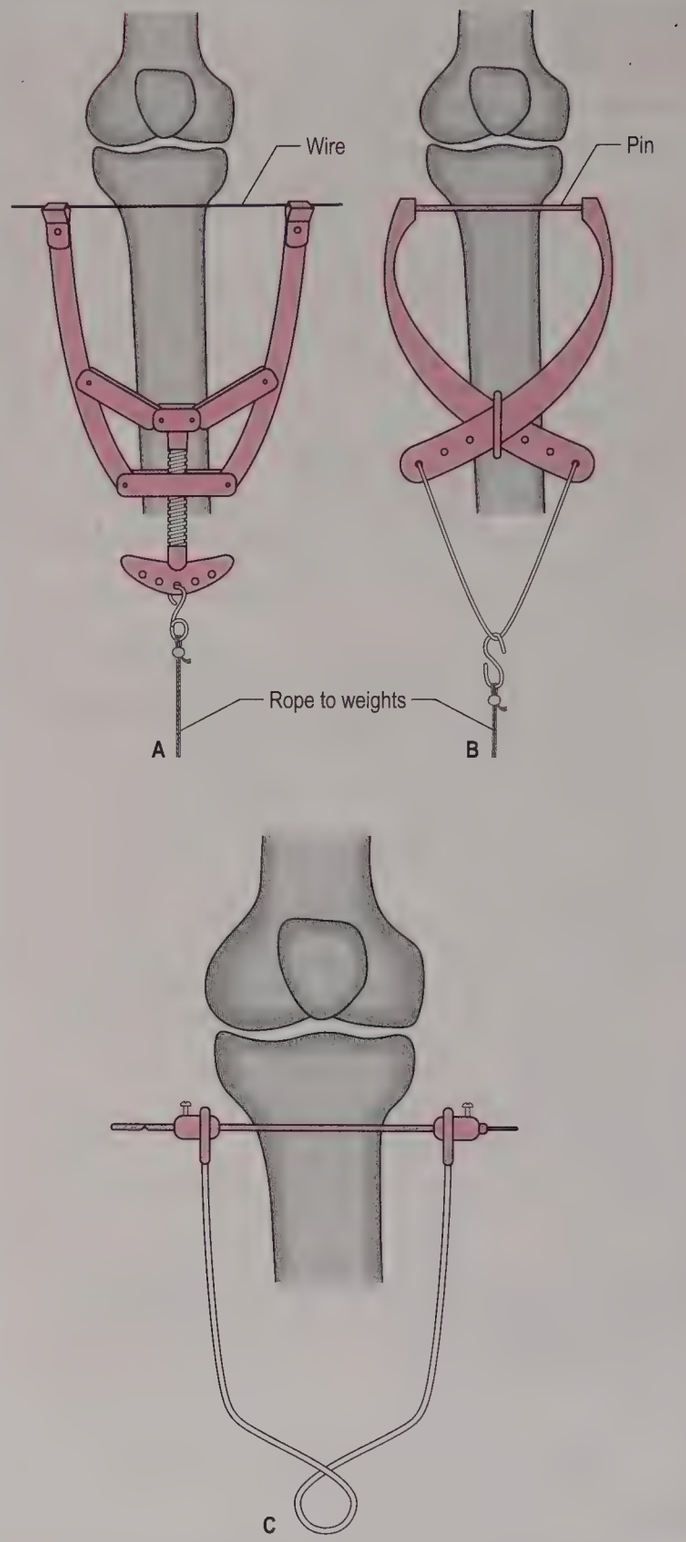

Fig. 10.5 Skeletal traction may be applied by — A: a Kirschner wire and traction stirrup; B: a Steinmann pin and traction stirrup; or C: Steinmann pin and Böhler stirrup.

Types of traction

Balanced or sliding traction This relies on the patient's own body weight to produce the necessary counter-traction, usually by tilting of the bed. Skeletal pins may be used to provide a firm point of attachment (see Fig. 10.5), but the most common type of balanced traction uses skin traction. This is Buck's traction which is used as a temporary measure for pain relief in patients with a fractured neck of femur (see Fig. 10.6). However, a Cochrane Review (Parker & Handoll 2004) could find no evidence which conclusively demonstrated the benefit of such traction for the outcome measures of pain relief or ease of fracture reduction at the time of surgery.

Fixed traction This is the application of counter-traction acting through an appliance which obtains purchase on a part of the body. The most common is a Thomas splint,

Fig. 10.6 Buck's traction for femoral neck fractures.

used for restricting movement of a fractured shaft of femur when transferring a patient, e.g. between hospitals, or in the treatment of fractures of the shaft of femur in children (Lucas & Davis 2004). Skin or skeletal traction may be used (see Fig. 10.7). Methods used to apply skin traction for balanced or fixed traction are outlined in Box 10.2.

For further information, see Kneale & Davis (2004).

PRINCIPLES OF NURSING MANAGEMENT: Traction

In addition to the general principles outlined earlier for management of musculoskeletal injuries, the following are specific to a patient in traction.

Traction equipment and purpose

The nurse should have a thorough understanding of the type and purpose of the particular traction in use and explain these simply and clearly to the patient in order to obtain their active participation in overall treatment, rehabilitation and prevention of complications. All patients in traction should be assessed by the nurse for their moving and handling needs with particular reference to the equipment required. Patients are taught how to lift themselves up using the overhead lifting aid and also which movements are safe.

All parts of frames, pulleys, ropes and slings should be inspected at regular intervals every day to ensure that they are correctly positioned and in good working order; this is especially important when the patient has been moved, e.g. after using a bedpan.

Observation of neurovascular status and prevention of complications

Observation of colour, sensation and movement (CSM) of the injured limb must be carried out throughout the patient's stay in hospital. The patient should be helped and encouraged to describe changes in sensation and levels of pain, and any complaint of discomfort, pain or paraesthesia must be thoroughly investigated (Lucas & Davis 2004).

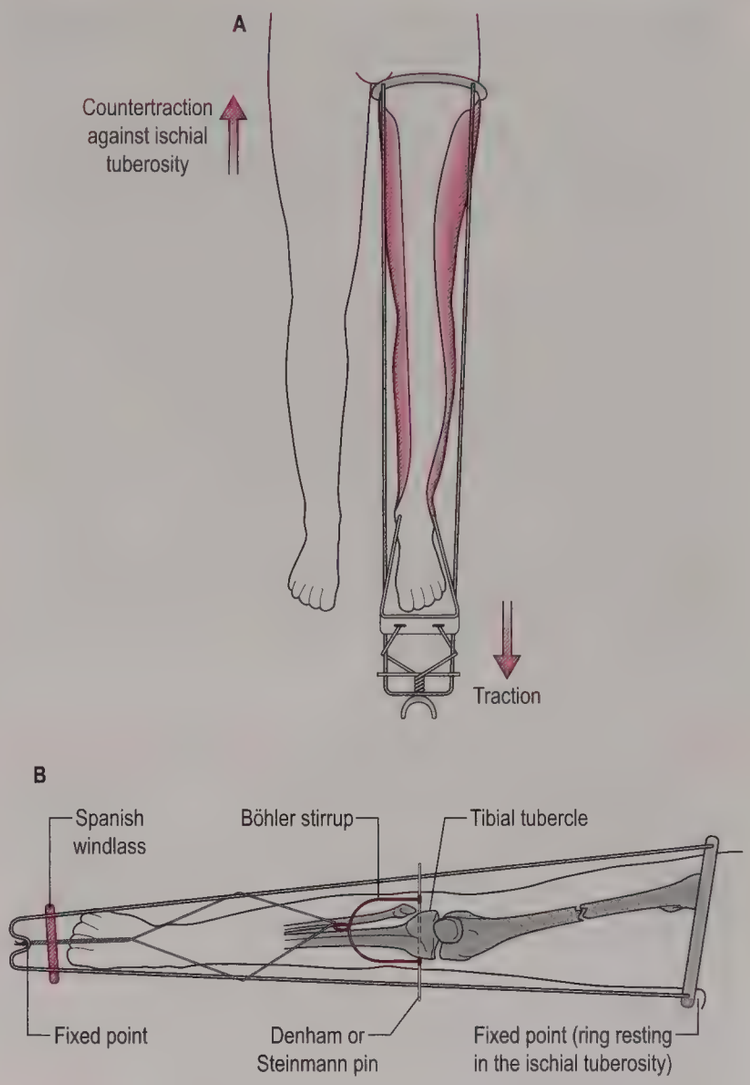

Fig. 10.7 A: Fixed traction using skin traction and Thomas' splint. B: Fixed traction using skeletal pin and Thomas' splint.

Box 10.2

Application of skin traction

Skin traction can be applied using a ready-prepared skin traction kit made of either Venfoam (non-adhesive) or Elastoplast (adhesive). Elastoplast is very rarely used, both because of its potential for damaging skin and also because skin traction is nowadays used only in the short term, before surgery or application of external fixation. Non-adhesive skin traction is adequate for short-term use.

Venfoam kit

Made of non-adhesive, soft foam padding, this can be applied directly to the skin and held in position with a crepe bandage. It will take approximately 2–3 kg of weight. It must be reapplied twice a day because of loss of bandage pressure. Avoid bandaging over the joint, such as the knee, and ensure that the foot of the bed is elevated to provide traction counterbalance.

External pressure can come from any part of the traction or be caused by restricted movement; internal pressure may be the result of tissue damage and swelling.

Nursing staff must be alert for:

- increased risk of pressure ulcers and skin reactions due to the patient's reduced mobility and/or the traction equipment
- drop foot caused by excessive pressure on the common peroneal nerve located around the head of the fibula
- compartment syndrome (CS) — a compartment consists of muscles surrounded by inelastic fascial tissue. CS occurs when there is increased tissue pressure resulting in inadequate tissue perfusion and anoxia within the compartment (Tucker 1998). This results in tissue death and permanent loss of function can occur within 6–8 h.

It is vital to be aware that compartment syndrome is a hazard of the complex nature of musculoskeletal trauma, surgery and immobilisation (Maher et al 2002) that can occur even when a pulse is present and there is capillary refill (see Box 10.3).

Prevention of infection at skeletal pin sites

A Cochrane Review (Temple & Santy 2004) concluded that there is little evidence as to which pin site care regimen best reduces infection rates. However, a consensus conference has produced best practice guidelines based on the available literature and expert opinion (Lee-Smith et al 2001). These indicate that:

- pin sites do not need to be cleaned if there is no exudate present. However, when necessary, cleaning should be done using normal saline
- pin-site crusts should be removed as it allows visualisation of the wound and free drainage of exudate
- pin sites may be left exposed if there is no exudate, otherwise woven gauze should be used.

Purulent discharge, redness or inflammation suggests infection and a wound swab should be taken to identify the causative organisms. The appropriate antibiotics should be commenced and the pin sites cleaned with normal saline and dressed with woven gauze, the frequency of dressing change depending on the amount of exudate (Lee-Smith et al 2001).

Maintaining normal body system functions

Traction, with its accompanying degree of restriction on movement and positioning, can create particular problems and the following interventions are important:

- Assessment and planning of care together with a physiotherapist, to coordinate and encourage breathing exercises, active and passive exercises to maintain joint mobility and prevent muscle wasting and deep vein thrombosis (DVT). In particular, regular dorsiflexion of the foot to counteract foot drop should be carried out. Local policy may determine the prophylactic measures to be implemented with the aim of preventing the complication of DVT.

Box 10.3

Impending compartment syndrome — dialogue between student (S) and mentor (M)

S You've explained what compartment syndrome is but how do I know that it is actually happening, especially when I can still feel a pulse and the capillary refill appears to be normal?

M Well, the first thing to keep in mind is that there is always a possibility of it happening where there is fairly extensive musculoskeletal trauma and constricting devices or traction are in use. Also, don't depend solely on observation of capillary refill and pulse — they can give a false sense of security. Obviously, degree of swelling, colour, pulse and capillary refill are very important and you may be able to feel a tight and tense muscle mass on palpation — but what the patient feels and can describe to you will be the deciding factor.

S I've noticed that you spend a lot of time talking to the patients about how things feel and really pursuing their answers — but what are the critical clues that you're looking for?

M I get red alerts when they describe deep throbbing pain inappropriate to the injury and a persistent sensation of pressure or pain on stretch, or if they complain of abnormal sensations such as numbness, tingling, loss of sensation, increased sensitivity or weakness.

S How can we prevent compartment syndrome?

M Attention to all the basic principles of treatment such as correct tissue alignment, splinting the affected part but encouraging normal movement of other parts, elevation, keen and constant observation of neurovascular status, assessment of major nerve function such as in the peroneal, ulnar and median nerves, prompt action to relieve constriction from bandages, slings and plaster casts, educating the patient to detect adverse signs and symptoms and possibly anticipating fasciectomy, i.e. surgically opening the skin and fascia to allow the tissues to expand and relieve pressure.

S What action should we take if we suspect impending compartment syndrome?

M Report signs and symptoms immediately to a member of the surgical team and take any necessary nursing action, such as reassuring the patient and stopping elevation, which can increase the compartment pressure, checking and possibly reapplying the traction, relieving the constriction and continuing to monitor changes. It is possible to measure tissue pressure with a direct needle measurement device — and anything above 30 mmHg needs action.

- Ensure adequate fluid intake (2 L or more daily) and a balanced diet with plenty of fibre.
- Assess and plan care to prevent constipation; treat if present.
- Deal sympathetically with the awkwardness of using bedpans and urinals and fear of soiling the bed.
- As normal sleep position and pattern will be disturbed, every attempt should be made to make the patient

comfortable and relaxed before resorting to the use of hypnotic medication.
- Often patients are in traction for a long time and will feel the need for close physical contact with their partners. Ensure undisturbed privacy for them.
- Be creative in finding ways to alleviate boredom which is a hazard of lengthy hospitalisation, particularly when movement is restricted.

10.4 Discuss ways in which you can help relieve the boredom of a patient who is in traction. Which other health professionals could you call upon to help in this respect?

10.5 Ask the physiotherapist in your clinical area to show you how to measure a patient for crutches and how to use them. Try walking with crutches yourself.

10.6 How many different kinds of walking aids can you identify in your clinical area? Discuss each with the physiotherapist.

Casts

A cast is a splinting device consisting of layers of bandages impregnated with plaster of Paris (POP), fibreglass or resin, some of which are applied wet and solidify as they dry out. Their main uses are to immobilise and hold bone fragments in reduction and to support and stabilise weak joints.

The advantages and disadvantages of the main categories of casting types are summarised below.

Plaster of Paris POP has better moulding properties, can be split or windowed if tension increases due to swelling and is cheaper. However, it takes 48 h to dry, and interferes with visualisation of bony detail on X-ray, making it more difficult to assess if a fracture is healing. It can be heavy and deforms permanently when it becomes wet. It is usually used for new injuries as a backslab, i.e. half a plaster held in place with a bandage, which allows for any potential swelling to take place. It has been suggested, however, that backslabs are no better than a full cast in allowing for pressure due to swelling in an acute injury (Younger et al 1990).

Synthetic casts These casts set within 20 min and allow early weight-bearing. They are stronger than POP due to the fibreglass content; thus, fewer layers are required and they are lighter. As they do not accommodate swelling, this material is infrequently used as the initial method of cast immobilisation following trauma, but if used, regular assessment of the neurovascular status of the limb is required. Synthetic casts are ideal for use in older patients, because they are lightweight and allow early mobilisation. A disadvantage is that they are more expensive than POP.

Adjustable focused rigidity primary casts These were developed in the 1990s and are adjustable to accommodate swelling or atrophy (wasting), reducing the risk of neurovascular impairment or insufficient support for a limb (Petty & Wardman 1998).

Cast bracing

A cast brace is applied closely to the limb and fitted with hinges to allow joint movement; this stimulates articular cartilage nutrition (Dandy & Edwards 2003). It allows early weight-bearing but needs specialist skills to apply correctly.

PRINCIPLES OF NURSING MANAGEMENT: Casts

In addition to the general principles of nursing management for musculoskeletal disorders (p. 446), the following will also apply.

Potential for neurovascular problems

Although padding such as Velband will allow for some swelling within the restricting cast, tissue pressure may build up and result in pain, tingling and discoloration. Unexplained pain is an important indicator that something is wrong, and therefore careful assessment and investigation of the cause, while alleviating the patient's discomfort, are essential. If not attended to immediately, pressure could lead to tissue necrosis and nerve palsy, the signs and symptoms of which include severe pain, odour and discoloration on the cast.

Prevention of neurovascular complications

- Elevate the limb above the level of the heart on cloth-covered pillows, unless compartment syndrome is suspected when elevation can exacerbate the condition and should be stopped (Love 1998).
- Avoid denting a moist cast by handling it only with the palms of the hands and not allowing it to rest on a flat, hard or sharp surface.
- Ensure that physiotherapy is carried out regularly.
- Have plaster cutting equipment ready and bivalve the cast, i.e. split it down both sides into two halves if signs and symptoms of neurovascular compromise do occur. Spread it enough to relieve pressure and remember to cut the padding, which may have shrunk due to drying blood and exudate.
- Cut an inspection and treatment window if pressure ulcer symptoms occur. The window must be replaced so that swelling does not rise into the space and cause more problems.
- Use an appropriate bed aid, such as a bed cage, to allow adequate air circulation, which aids in the drying process.

Care of the cast

Avoid getting the cast wet. Do not cover a plaster for any prolonged period with plastic or, in the case of a leg plaster, with rubber boots, because of condensation; however, synthetic protective covers can be used to permit the patient to take a shower. Teach the patient how to protect the cast when washing and when using bedpans and urinals. Casts can be cleaned by wiping with a damp cloth.

Many patients will go home wearing casts, so be sure to give them clear verbal and written instructions specific to their cast (see Box 10.4).

Removal of a cast

Application of a cast should be carried out only by experienced nurses or other health professionals, but all nurses

Box 10.4

Advice to patient with hand to elbow plaster

The plaster holds all the broken bones firmly in place to allow them to heal in the correct position. To prevent your fingers swelling, support your arm in the sling provided during the day and on pillows at night. It is important that you exercise the finger, elbow and shoulder joints of your injured arm at regular intervals, otherwise they will become stiff and painful to move.

The following exercises should be carried out at least four times each day:

- make a firm fist then stretch the fingers as wide as possible
- try to touch each fingertip with the thumb of that hand
- bend and stretch the elbow joint
- lift your arm high above your head — use the other arm to help
- move your arm behind your back as if you wanted to scratch between your shoulder blades.

Do not wet, heat or otherwise interfere with the plaster and do not insert sharp objects between the plaster and the skin to scratch — this could cause skin damage and infection.

Report to the doctor or Emergency Department AT ONCE if:

- the plaster cracks, becomes loose or uncomfortable
- there is pain
- the fingers become numb or difficult to move
- the fingers become more swollen, blue or very pale
- there is discharge
- you have any other problems.

need to be aware of the procedure for removal of a cast, to be familiar with the equipment used and to know where it is located.

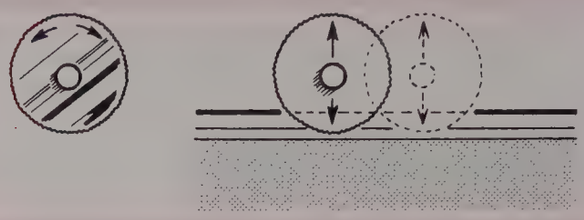
Casts may need to be removed and renewed if they become loose or are damaged in any way. Where serious signs and symptoms of neurovascular complications have developed, splitting and removal will be required as an emergency procedure.

Guidelines for removal of a cast are given in Box 10.5.

External fixation

Bone fragments are held in position by skeletal pins inserted into the bone on either side of the fracture and held in alignment by a scaffold or a ring fixator (see Fig. 10.8). They are used for the treatment of some closed fractures, e.g. the pelvis, to stabilise open fractures with extensive soft tissue loss until the soft tissue has healed, for fractures that have not united by other methods, and for reconstructive surgery such as leg lengthening. Depending on the reason for their use they can be in place for as little as 6 weeks, e.g. for treatment of a closed fracture, or up to 1 year, e.g. in non-union of a tibial fracture.

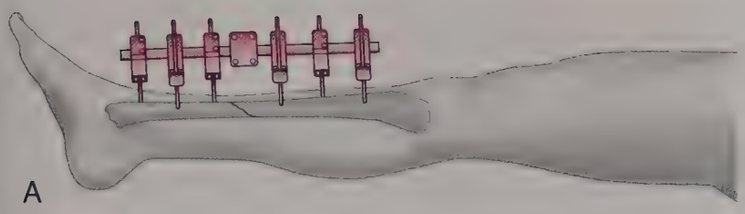
PRINCIPLES OF NURSING MANAGEMENT: External fixation



In addition to the general principles relating to altered neurovascular status, positioning and potential for pin site

Box 10.5

Guidelines for removal of a cast



Equipment

- Plaster cutter — a small electric saw with a circular oscillating blade (with an integral dust extractor)
- Plaster spreader
- Large flat-bladed bandage scissors
- Plaster shears
- Plaster knife
- Protective eyewear such as goggles

Procedure

- Explain to the patient what the procedure entails and, if the cast is padded, demonstrate the plaster cutter by turning it on and explaining its action (the electric cutter is not used on plasters that are not padded). Shears will be used on unpadded casts. Instruct the patient to shield the eyes as the saw could throw off fragments of plaster. Give reassurance that the saw will not cut the skin because of its oscillating action and the depth of padding.
- Mark where the cutting line will be with a felt pen and dampen it to reduce plaster dust. This line should avoid bony prominences; it is usually in front of the lateral malleolus and behind the medial malleolus in the lower limb, and along the ulnar or flexor surface in the upper limb.
- Grasp the electric cutter.
- Dust extractor apparatus and goggles should be used by plaster room personnel to comply with health and safety regulations.
- Turn on the cutter and push the blade firmly and gently through the cast, at the same time allowing the thumb to contact the cast as the blade oscillates. When you feel a 'give' or lack of resistance, you know you are through.
- Lift the cutter blade up a degree but not out of the groove and repeat until the line of cut is complete. The movement is one of alternating pressure on the oscillating blade and lifting slightly, at right angles to the plaster within the groove of the cut. It is wise to get the 'feel' of this by practical experience with discarded plasters and then in actual practice under the guidance of an expert.
- Cut the cast down both sides.
- Insert the blades of the plaster spreader at several sites along the line of cut then separate the cast with the hands.
- Cut the padding with the bandage scissors.
- Lift the limb carefully out of the posterior portion of the cast, maintaining the same position.
- After removal of the cast, wash the skin gently with pure soap and water, pat dry and apply skin cream. Expect a scaly appearance, some muscle atrophy, pain and stiffness, but reassure the patient that prescribed exercise will help to regain normal feeling, appearance and function in a relatively short period of time.

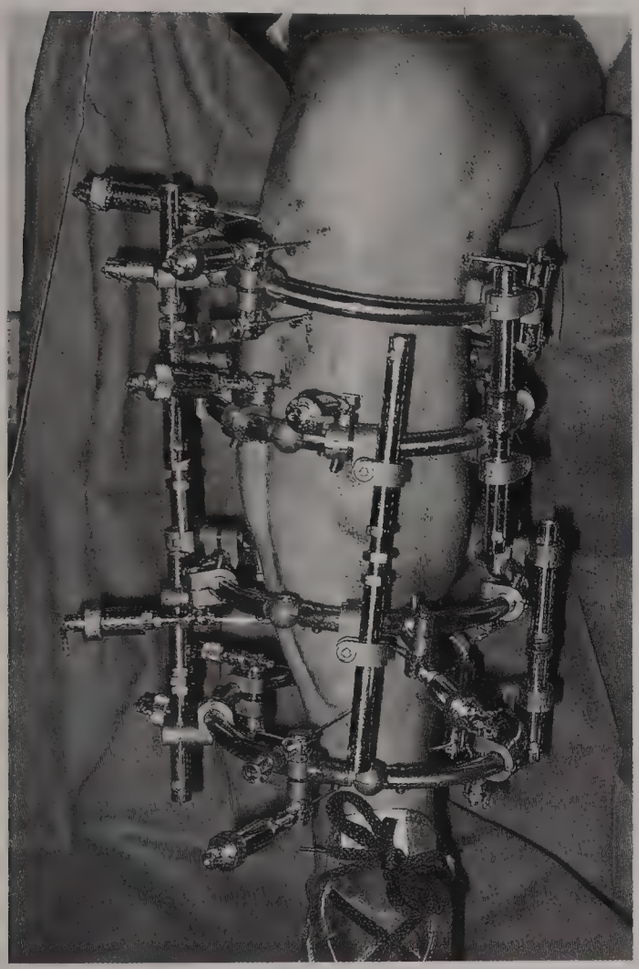


Fig. 10.8 Types of external fixation. A: External fixation of the tibia. B: External ring fixator in position on the tibia.

infection that have already been discussed, the following is specific to external fixation. As this device allows for early discharge of a patient, the nurse must ensure that the patient, carers and community staff are familiar with and confident in the care required (Sims et al 1999).

Appearance

The appearance of the appliance may cause the patient concern. In hospital, patients with an external fixator may be nursed with other patients having the same treatment and may therefore feel comfortable. On discharge, however, they may be exposed to the gaze and curiosity of the public. Limb (2004), in a survey of 60 patients with external fixators, found that they had below-average mean scores on a self-concept scale, with particularly low scores related to body image. He suggests that individual or group discussions may help patients through the process of treatment.

For further information, see Dandy & Edwards (2003).

Internal fixation

Fractures may also be stabilised by surgical intervention where nails, plates, wires, screws or rods hold the bone fragments in place (see Fig. 10.9). Again this permits earlier mobilisation and reduces the potential for complications. All perioperative principles of nursing management apply in this instance (see Ch. 26).

FRACTURES OF SPECIFIC SITES

Fracture of the femoral shaft

Femoral shaft fractures are most commonly seen in young people following motorcycle or car accidents.

MEDICAL MANAGEMENT

Following X-ray to confirm the diagnosis:

- operative treatment may consist of either internal fixation, usually the preferred option, or rarely, external fixation.
- the fracture may be reduced under general anaesthetic and skeletal traction applied. Any accompanying wounds are debrided or sutured at the same time. If there is adequate callus formation within 2–6 weeks, a cast brace may be applied.

NURSING PRIORITIES AND MANAGEMENT: Fracture of the femoral shaft

In addition to the principles of management relating to a fracture, operative intervention and traction, the following are specific to fracture of the shaft of femur.

Haemorrhage

An early complication may be damage to the femoral artery from bone fragments, in addition to bleeding from other

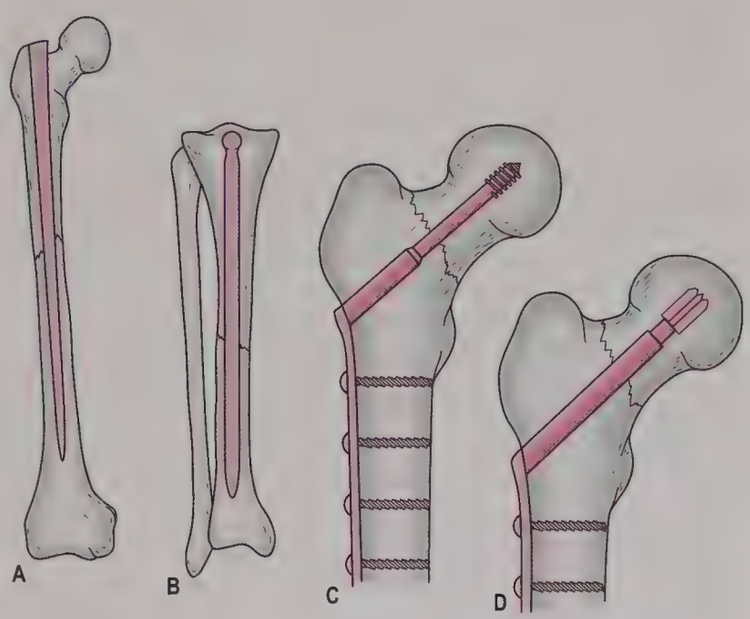

Fig. 10.9 Types of internal fixation. A, B: Intramedullary nails. C: Compression nail for fixation of femoral neck. D: Sliding nail fixation of the femoral neck.

damaged tissues and the bone marrow. As much as a litre of blood can be contained within the thigh, and this hidden haemorrhage can result in hypovolaemic shock (see Ch. 18).

The nurse must be alert for signs of haemorrhage and shock and ensure that i.v. replacement therapy is ready and that blood is sent for cross-matching.

Fat emboli

Fat emboli are a particular hazard following fracture of the shaft of the femur but can also occur following fracture of any long bone. There are two theories relating to the cause: one is that fat cells from damaged tissue migrate into ruptured veins; the other is that catecholamines released through the stress of trauma mobilise lipids from fatty tissue. In the lung, these droplets are converted into free fatty acids which are toxic to lung tissue and disrupt alveolar function. Additionally, the droplets may become enmeshed in the capillary network of the alveoli and disrupt gas exchange. This can lead to cerebral hypoxia and, if large vessels in the pulmonary system are involved, to respiratory failure and death. Early signs of fatty emboli are increased respiratory rate, anxiety, transient petechial haemorrhage and confusion. The last two are the classic and most important clinical signs.

The nurse must be alert for early signs of altered mental status — anxiety, irritability and especially confusion. Report this immediately and be prepared to deal with respiratory failure and arrest and to transfer the patient to intensive care. Equipment should be ready for immediate blood gas analysis.

Collaborative care

The nurse has an important role in coordinating the care provided to ensure that all physical and psychosocial issues are addressed.

Fracture of neck of femur

There are over 69 000 fractures of the femoral neck, commonly known as a hip fracture or fractured neck of femur, in the UK each year (Shire Pharmaceuticals 1998) and 1.66 million worldwide (Santy 1998). They are most common in older people, particularly women who may have osteoporotic bones. There is much evidence to show that preventive methods can be useful in reducing the risk (see Research Abstract 10.1).

It is also recognised that successful care of a patient with a fractured neck of femur depends on a coordinated approach throughout the patient journey from initial injury to long-term rehabilitation (SIGN 2002a). This means the involvement of the multidisciplinary team as well as the nursing and medical staff. The physiotherapist will help to ensure that the patient can walk and get out of a chair and bed safely. The occupational therapist will ensure that the patient can manage activities such as eating and bathing, providing adaptations as necessary. If a patient needs additional support at home after discharge, or needs to find alternative accommodation, the social worker can help. Other health care professionals will be involved following individual patient assessment; for example, some patients may require a chiropodist if they cannot bend to attend to their pedicure.

RESEARCH ABSTRACT 10.1

Hip fracture: the SIGN guidelines

The Scottish Intercollegiate Guidelines Network have examined the evidence for the prevention and treatment of hip fractures, and graded this to provide nurses and other health care workers with a basis for evidence-based practice. Included in their recommendations are:

- Assessment of the risk of hip fractures and falls should be carried out and those at increased risk should be offered multiple interventions — an exercise programme, balance training, modification of identified hazards, treatment with calcium and vitamin D, and hip protectors.
- For patients who have sustained a hip fracture the routine use of traction preoperatively is not recommended.
- Prophylaxis against deep vein thrombosis should be considered; mechanical means (foot pumps or intermittent pneumatic compression) and aspirin, and heparin for high-risk patients.
- Discharge planning should begin within 48 h of admission and is a multidisciplinary team effort.

Scottish Intercollegiate Guidelines Network (SIGN) 2002a Prevention and management of hip fractures in older people No. 56. Online. Available: www.sign.ac.uk

MEDICAL MANAGEMENT

History and examination The patient may have been found on the floor following a fall and, if living alone, could have been there for some time and be suffering from hypothermia and dehydration. Careful assessment to identify other reasons which may have led to the fall, such as a cerebrovascular accident or myocardial infarction, should be made. The patient will complain of severe pain in the hip or knee and there will be visible shortening and external rotation of the affected leg. Diagnosis will be confirmed by X-ray.

Treatment Depending on the site of the fracture, and the age and condition of the patient, the treatment will be either internal fixation with a plate and screws or replacement of the head of femur with a metal prosthesis. Intracapsular fractures high in the neck of the femur have a serious effect on the blood supply to the femoral head (see Fig. 10.10) which would certainly need operative replacement.

NURSING PRIORITIES AND MANAGEMENT: Fracture of neck of femur

In addition to the general principles relating to musculoskeletal injury and fractures, the following priorities need to be addressed.

Potential complications As a result of age and general physical condition when found, the patient may be confused and fearful and need a great deal of comfort and reassurance. Measures will be taken to reverse any hypothermia and dehydration. Risk assessment of the patient for skin

Fig. 10.10 Blood supply of the femoral head via the capsule. Intramedullary vessels and ligamentum teres.

breakdown using an approved scale such as the Waterlow scale (see Ch. 23) should be recorded and the patient may be nursed on a therapeutic bed. Vital signs will be monitored at 4-hourly intervals to detect early signs of complications.

Pain With an extracapsular fracture there is often extensive bruising which adds to the severe pain. When the cause has been established, this may be treated by repositioning and supporting the body and limbs, and administering prescribed analgesics. Pain assessment and pain relief measures should be implemented (see Ch. 19).

Increased risk of multisystem complications For an older patient, such acute trauma and associated surgery may lead to multisystem failure (see Ch. 18).

Rehabilitation Discharge planning should commence within 48 h of admission (SIGN 2002a). The use of an integrated care pathway (ICP) can help to improve the standard of overall care by ensuring that each member of the multidisciplinary team knows the best available evidence for care and when that care should be carried out (Tarling et al 2002) (see Table 10.1). Early supported discharge schemes, often led by nurses, can help to ensure that patients are discharged rapidly but safely to their home environment (Renton & Brown 2001).

10.7 Discuss with your mentor how an ICP differs from a nursing care plan, and what are the advantages and disadvantages of each.

Fracture of the tibia and fibula

Fracture of the tibia and fibula is one of the most common injuries dealt with by orthopaedic surgeons. These fractures usually result from direct impact to the limb, and extensive skin and soft tissue damage may be present. RTCs and sports injuries are common causes.

MEDICAL MANAGEMENT

Treatment There are three choices of treatment.

Cast immobilisation This is the treatment of choice for closed, stable injuries. If the fracture requires manipulation, the patient will receive a general anaesthetic which will necessitate a stay in hospital; otherwise the patient may be discharged home from the Emergency Department. Following reduction of the fracture, a long leg plaster cast will be applied and plain radiographs taken to confirm the position of the fracture. Repeat X-rays will be taken at 1 week, 2 weeks and then at monthly intervals following reduction. The patient will not be allowed to bear weight on the injured leg for at least 1 month following injury. At this stage a Sarmiento type plaster, patellar tendon bearing, may be applied (McRae & Esser 2002) and the patient allowed to bear weight through the injured limb. The average length of stay in plaster for this type of injury is 12–16 weeks.

Internal fixation Fractures which are closed but unstable will benefit from internal fixation using a nail, but some patients may be placed in a plaster cast for 6–8 weeks

Table 10.1 Extract from the integrated care pathway of a patient with a fractured neck of femur — postoperative day 1 (nursing part only)

Patient problem/need	Nursing intervention	Expected outcome
Recovery from anaesthetic	4-hourly monitoring of vital signs	Vital signs within normal limits
Wound care	Check wound site dressing Check and record wound drainage	Dressing dry and intact Drain to be removed at 24 h after surgery as further drainage minimal
Neurovascular status of limb	Monitor neurovascular status of affected limb	No neurovascular deficit
Relief of pain	Use pain score with patient 4-hourly Administer analgesics as prescribed	Pain relief at level acceptable to patient
Risk of deep vein thrombosis (DVT)	Ensure anti-embolic stocking in situ Thromboprophylaxis injection as prescribed Monitor for signs of DVT	Reduction in risk and early detection of problem
Reduced mobility	Ensure patient understands correct way to transfer and mobilise	Patient to sit in chair Patient to walk to end of bed with aid of Zimmer frame

following surgery. Routine postoperative care as discussed in Chapter 26, and cast care (see p. 451) will be required. The patient will be able to use crutches once fully recovered from the effects of surgery.

External fixation If there is skin loss or a contaminated wound at the fracture site, the choice of treatment is more commonly an external fixator. This enables frequent observation of the wounds and easy access for wound dressing changes. An external fixator is applied under a general anaesthetic in an operating theatre.

This type of fixator holds the fracture in position and the patient can be walking, weight-bearing or not, dependent on the injury and the stability of the fixation of the injured limb, and discharged home to allow the community nurse and general practitioner (GP) to attend to the wounds. The patient is reviewed at regular intervals at the outpatient clinic (see Case History 10.1).

CASE HISTORY 10.1
Mr K

Mr K is a 40-year-old man who lives alone. He sustained a compound fracture to his left tibia and fibula while skiing with friends in the Highlands of Scotland. One friend stayed with him on the mountainside while the other alerted the emergency services, who arrived within an hour. The paramedical team applied a clean dressing over the open wound and splinted his leg.

On arrival at the hospital, Mr K was in obvious pain, although he had been using the analgesic gas Entonox, so the doctor administered an intravenous analgesic.

In the Emergency Department, the named nurse, Bill, noted Mr K's temperature, pulse, blood pressure and respirations, and the colour, sensation and movement of the injured limb, all of which were within normal limits. A clean sterile dressing was applied to the wound following inspection by the doctor.

Confirmation of the diagnosis was made by radiography and it was decided to take Mr K to the operating theatre for application of an external fixator to his left leg. This was explained to him and a picture of an external fixator in position was shown to him and the two friends who had accompanied him. His first reaction was revulsion at all the metal pins and scaffolding, but as his friends joked about his 'bionic parts' his anxiety subsided.

After an uneventful postoperative period, Mr K was allowed to sit in an armchair on day 1 with his leg elevated on a stool to reduce the swelling. The wound had been dressed in theatre following the local dressing policy of the institution. The physiotherapist gradually assisted Mr K to walk with the help of crutches without bearing weight on his left leg, and showed him how to manage the awkward appliance to avoid injuring himself. He was helped to widen two pairs of trousers below the knee so that he could cover the external fixator.

As Mr K lived on his own, the social worker made arrangements for a home help to be provided on discharge. His two friends agreed to visit him and provide him with food and other provisions at the weekends. Mr K was shown how to dress the pin sites himself and educated to be aware of the warning signs of infection or other complications. It was arranged that a community nurse would visit weekly to bring fresh supplies of dressings and to check the pin sites. He was given a contact name and number if he required advice between visits.

Mr K was discharged home 6 days after his accident with a return appointment for 2 weeks later.

NURSING PRIORITIES AND MANAGEMENT: Fracture of the tibia and fibula

The principles of nursing management for each type of treatment are given on pages 451, 452 and 453.

10.8 Jot down the complications associated with fractures. Discuss with colleagues the causes of each complication and say how you can prevent it. Check your findings with Table 10.2.

Fracture of neck of humerus

Fracture of the neck of the humerus commonly occurs in older adults with osteoporosis after a fall on an outstretched hand. Often the bone is not displaced or badly impacted and normally heals well, depending on its stability. The major complication is of shoulder and elbow stiffness.

MEDICAL MANAGEMENT

Treatment This injury can usually be treated at home following the initial visit to the Emergency Department, providing there is no gross displacement or neurovascular complications. The arm is supported in a shoulder immobiliser, broad arm sling or collar and cuff for approximately 2 weeks. Movement is gradually introduced, followed by outpatient physiotherapy, in order to avoid the major complication — development of a stiff shoulder joint. If the fracture does not heal, internal fixation may be required.

NURSING PRIORITIES AND MANAGEMENT: Fracture of neck of humerus

Assessment of ability to carry out normal activities of daily living This is done before the patient is discharged home from the Emergency Department. Home nursing and home help are arranged accordingly, or a supported discharge scheme may be in place (Renton & Brown 2001).

Skin care of injured arm If a supported discharge scheme is not available, it is wise to have the community nurse attend to washing the injured arm two or three times a week, taking particular care of the axilla. The sling is reapplied and neurovascular status and degree of mobility monitored. Case History 10.2 outlines the continuing care of an older lady with fractured neck of humerus.

10.9 After initial instruction from your tutor or mentor and with a fellow student, practise applying a broad arm sling, a high sling and a collar and cuff.

Colles' fracture

This is one of the most common fractures seen at the Emergency Department and usually involves the lower end of the radius within 2.5 cm of the wrist joint. There may be an associated fracture of the ulnar styloid. The obvious feature of a Colles' fracture is the classic 'dinner fork' deformity (see Fig. 10.11). It is commonly found in middle-aged and older women after a fall on an outstretched hand.

Table 10.2 Prevention of complications of fractures

Complication	Cause	Prevention
Damage to soft tissue — neurovascular compromise	Trauma Sharp fragments/edge of bone	Monitor neurovascular function regularly — report abnormalities
Complications associated with immobility:		
Diminished function of all body systems Muscle atrophy — decreased range of movement — contractures	Decreased physical stimulation Lack of normal exercise	Encourage active and passive exercise Coordinate physiotherapy programme
Altered psychological processes	Decreased social stimulation	Provide social and mental stimulation
Pressure ulcers	Casts — prolonged pressure	Regular pressure area care and position change
Infection	Open wound postoperatively Skeletal pin sites	Apply principles of infection control
Malunion	Mal-apposition of bony fragments Inadequate mobilisation (e.g. swelling subsides — cast becomes loose)	Meticulous and regular monitoring of cast fit and traction alignment
Delayed union	Unstable fracture Poor blood supply	Maintain adequate circulation and splintage
Non-union	Infection Soft tissue intrusion	Infection control
Fat embolus — emergency	Fat globules released into circulation from bone marrow at fracture site — usually associated with fractured femur or multiple fractures	Early reduction and splintage Report confusion, chest pain, dyspnoea immediately (see p. 454)

CASE HISTORY 10.2

Mrs L

Mrs L is a 70-year-old lady living alone in sheltered housing. She was admitted to the Emergency Department following a fractured neck of humerus, which was treated with a sling. The supported discharge scheme sister undertook a multidisciplinary assessment of Mrs L, who was discharged home after a stay of 2 h in the Emergency Department. The social worker within the supported discharge team arranged a suitable social care package to provide the support Mrs L would require.

The supported discharge scheme staff nurse visited Mrs L at home to wash and dry the skin around her injured shoulder, inspecting it for any signs of friction or pressure. Extensive bruising was noted over the shoulder region. The sling was reapplied. The nurse checked that Mrs L was moving her joints as advised and that no joint stiffness was present. It was established that no neurovascular deficit was present and Mrs L was educated to look for any developing signs of tingling or numbness of the fingers, change in finger colour or warmth, and/or reduced ability to move the arm.

The team's occupational therapist carried out an assessment and suggested changes to the environment, such as removing the bath mat on which Mrs L had slipped and replacing it with a non-slip one. Mrs L attended the hospital outpatient department 10 days later where she was seen by an orthopaedic specialist. The supported discharge team completed their package of care at this point, but social services continued to provide social care, including help with hygiene needs.

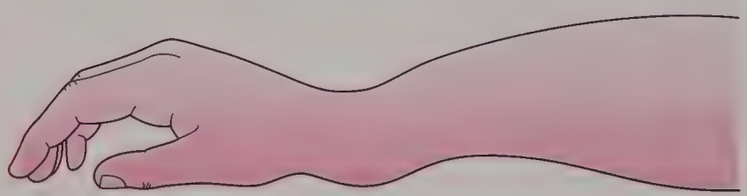

Fig. 10.11 The 'dinner fork' deformity of Colles' fracture.

MEDICAL MANAGEMENT

Examination Diagnosis will be confirmed by the appearance of the patient's wrist and by plain X-rays.

Treatment Manipulation of the joint is required to reduce the fracture and for this anaesthesia is required. This may be a haematoma block, i.e. the blood clot around the fracture is injected with a local anaesthetic, intravenous regional anaesthesia, i.e. Bier's block, or general anaesthesia. A Cochrane Review (Handoll et al 2004) concluded that there was insufficient evidence to establish the relative effectiveness of different methods of anaesthesia but that a haematoma block provides poorer analgesia than intravenous regional anaesthesia. After successful reduction, the position is maintained by a backslab for 2–3 days to allow for any swelling, and then by a complete hand to below elbow cast. Internal or external fixation may be necessary if closed reduction is unsuccessful.

Prevention This fracture is more often seen in the winter months, and older people should be advised to avoid slippery surfaces. Osteoporosis investigation and advice should also be initiated, to ensure that the risk of future fractures is minimised (see p. 461).

NURSING PRIORITIES AND MANAGEMENT: Colles' fracture

In addition to the management principles already discussed which relate to musculoskeletal trauma, fractures and plaster casts, the following priorities should be noted.

Removal of rings Marked swelling of the fingers is likely to occur and it is important to remove all rings and bracelets from the injured hand as soon as possible. If swelling has already made this impossible, it will be necessary to obtain the patient's permission to cut the rings off using the special ring cutter found in all Emergency Departments. The arm should be kept elevated to reduce swelling.

Advice Ensure that the patient is given written and verbal advice for a hand to elbow plaster as described in Box 10.4 (p. 452). Advice is equally as important after the plaster cast has been removed, usually after 6–8 weeks, as the wrist joint will be stiff and weak due to lack of use. Nursing staff in fracture clinics should educate patients about the rehabilitation exercises they should perform and encourage them to do these regularly. A removable splint, futura splint, can be provided to give some support. In some areas, nurse-led clinics are being developed so that this patient group can receive holistic care from an experienced orthopaedic nurse practitioner (Wardman 2002).

SPINAL INJURIES

Injury or damage to the vertebral column which protects the spinal cord may be confined to bony and/or ligament injury or may be accompanied by damage to the cord itself. This spinal cord damage can happen at the time of injury or be the result of poor handling of the patient by health care professionals. It is estimated that 500–700 people per year in the UK sustain traumatic injury to the spinal cord (Harrison 2000) but many more sustain vertebral fractures or ligament damage with no spinal cord damage. Common reasons for spinal cord injury (Smith 2004a) are:

- road traffic collisions
- falls, such as falling downstairs
- industrial injuries, mainly building site falls
- sports injuries, e.g. rugby, skiing and diving.

PATHOPHYSIOLOGY

The resultant damage can involve transection, compression, contusion or interference to the spinal cord, accompanied by varying degrees of paralysis and sensory deficit below the level of the lesion (see Fig. 10.12). There is hope, however, that research can find ways of reversing this damage (see Research Abstract 10.2).

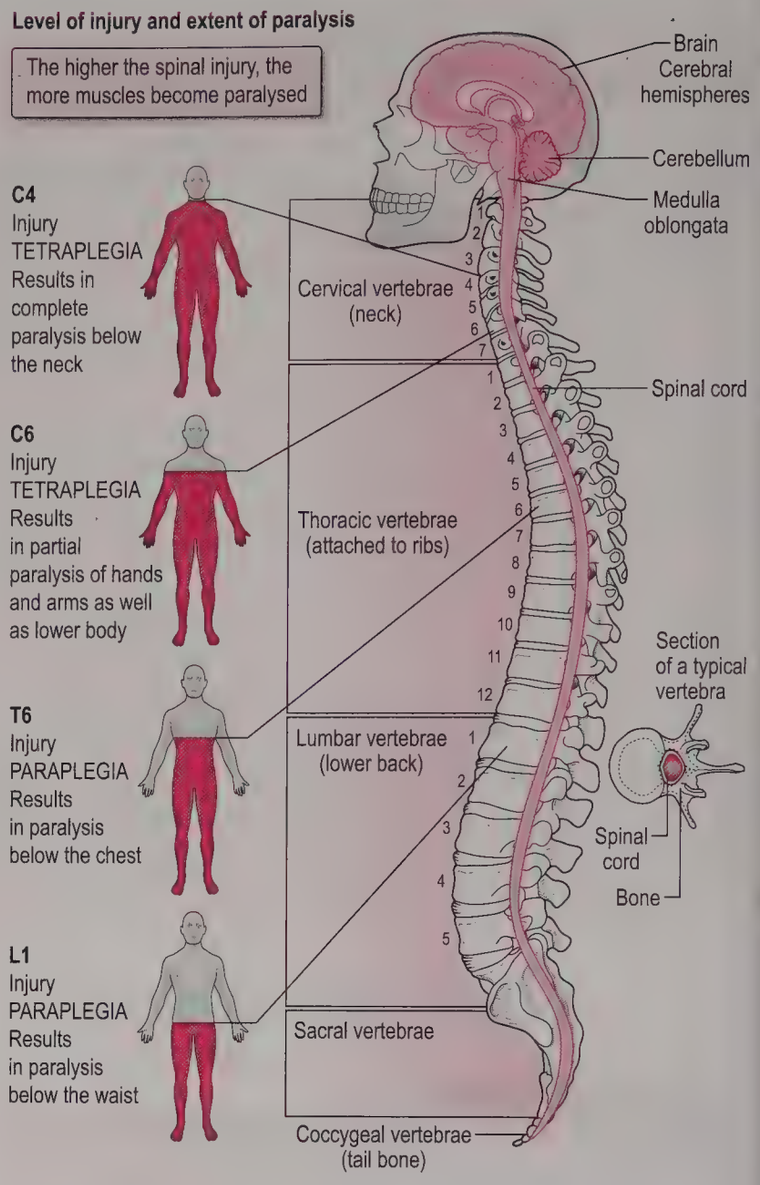

Fig. 10.12 Level of injury and extent of paralysis. (Reproduced with permission from the Spinal Injuries Association 2000; see 'Useful websites' and addresses.)

MEDICAL MANAGEMENT

The three principles of management (Smith 2004a) are:

- *Preserving existing neurological function*, which includes correct moving and handling of the patient. Vertebral fractures may be stabilised with halo traction (see Fig. 10.13) which facilitates early mobilisation in patients with intact neurological function. Some stable fractures, especially lower thoracic and lumbar fractures, can be treated by bed rest on a firm base.
- *Physiological resuscitation*, i.e. attending to the potential life-threatening respiratory and cardiovascular effects related to spinal cord injury, e.g.:
  — ineffective airway clearance
  — ineffective breathing pattern
  — hypotension
  — bradycardia
  — hypothermia.

RESEARCH ABSTRACT 10.2

International Spinal Research — the 4 cm future

A registered charity, Spinal Research, is working on research trials with the hope of finding ways of regenerating 4 cm of spinal cord in a paralysed person. These 4 cm could potentially help a seriously paralysed person to breathe unaided or to regain use of the arms. A number of possibilities are being explored.

- *Neuroprotection.* Most spinal injuries do not completely sever the spinal cord but the neurones that do die send out signals to nearby uninjured neurones and these also die a few hours after the original injury. Research is examining how this early secondary damage can be reduced.
- *Chondroitinase treatment.* Chondroitinase is an enzyme that partially removes the barrier formed by scar tissue around a spinal cord injury, thus allowing regenerating nerve fibres to pass through.
- *Combating blockers.* Antibodies have been developed to counteract the effects of Nogo, a family of protein molecules that prevent the regrowth of spinal cord nerve fibres.
- *Filling the gap.* Biocompatible materials have been developed which can form a bridge across the damaged region so that nerve fibres, blood vessels and supporting tissues can regrow.
- *Nurturing regrowth.* Olfactory glia are cells that guide and protect newly forming nerve fibres. They are present in the olfactory system but researchers have transplanted them into spinal cord injuries in the laboratory and some regenerative effect has occurred.
- *Replacing stem cells.* Stem cells have the potential to develop into any type of cell in the body and thus could replace all the damaged tissue in the spinal cord. Stem cell research using embryonic stem cells has ethical issues and is still in its early stages. Scientists do not yet understand how to control stem cells and make them turn into the required cell types, and those transplanted into spinal injuries tend to turn into cells that make cell tissue.

A combination of some or all of these methods could mean that spinal cord injuries may be successfully reversed, or at least the patient's clinical condition improved.

Spinal Research 2004 Spinal cord repair. Online. Available: www.spinal-research.org

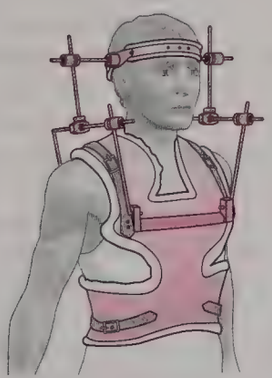

Fig. 10.13 'Halo-vest' traction. A halo fixed to the skull — attached to bars mounted on the chest.

The last three are caused by spinal shock, i.e. the cessation of conduction within the spinal cord neurones. This results in a loss of voluntary movement and sensation below the level of the injury and progressive loss of sympathetic and parasympathetic activity, which can last for up to 6 weeks.

- *Prevention of secondary complications*, which may be physical or psychological (see p. 460).

It is accepted practice in the UK and Eire that any patient with an actual or potential spinal cord injury is transferred to one of 12 specialist spinal injury units (SIUs) (Harrison 2000). Ideally this should occur immediately but may be delayed due to patients being unfit to travel or a bed not being available. All nurses in general hospitals should therefore understand the principles of caring for a patient with a confirmed spinal cord injury, and that every patient with spinal trauma should be treated as a potential spinal cord injury patient until investigations such as MRI or X-rays have provided a firm diagnosis. Patients who have damaged the ligaments supporting the vertebral column (see Fig. 10.14) may have a potentially dangerous unstable spine.

NURSING PRIORITIES AND MANAGEMENT: Spinal injuries

Basic principles of positioning and moving patients with spinal injury All nurses should be aware of the importance of maintaining anatomical alignment of the vertebral column in patients with suspected spinal cord injury, both before patients reach hospital and once they are admitted, to avoid scenarios such as that outlined in Case History 10.3. Manoeuvres such as log rolling the patient (see p. 951) (for thoracolumbar injuries), pelvic twists (for cervical injuries) and using special beds (e.g. an electric turning bed) are carried out under the guidance of an experienced nurse.

10.10 What do you suspect are the main reasons for such different outcomes for the accident victims described in Case History 10.3?

CASE HISTORY 10.3

First aid for accident victims — the effect on outcome

Two 18-year-old men were brought into the Emergency Department on the same night. They had both sustained multiple injuries to the head and body in similar road traffic collisions — P had been moved from his overturned vehicle by well-meaning people at the scene of the accident whilst waiting for the ambulance to arrive, whereas T was supported in the position in which he was found until the ambulance team arrived. They applied a neck collar and maintained skeletal alignment whilst transferring him to the ambulance and at all times subsequently. Spinal X-rays showed that the men had identical injuries to the cervical spine.

Two months later, T walked out of the spinal injuries unit; many months later, P was wheeled out of the same unit as a quadriplegic.

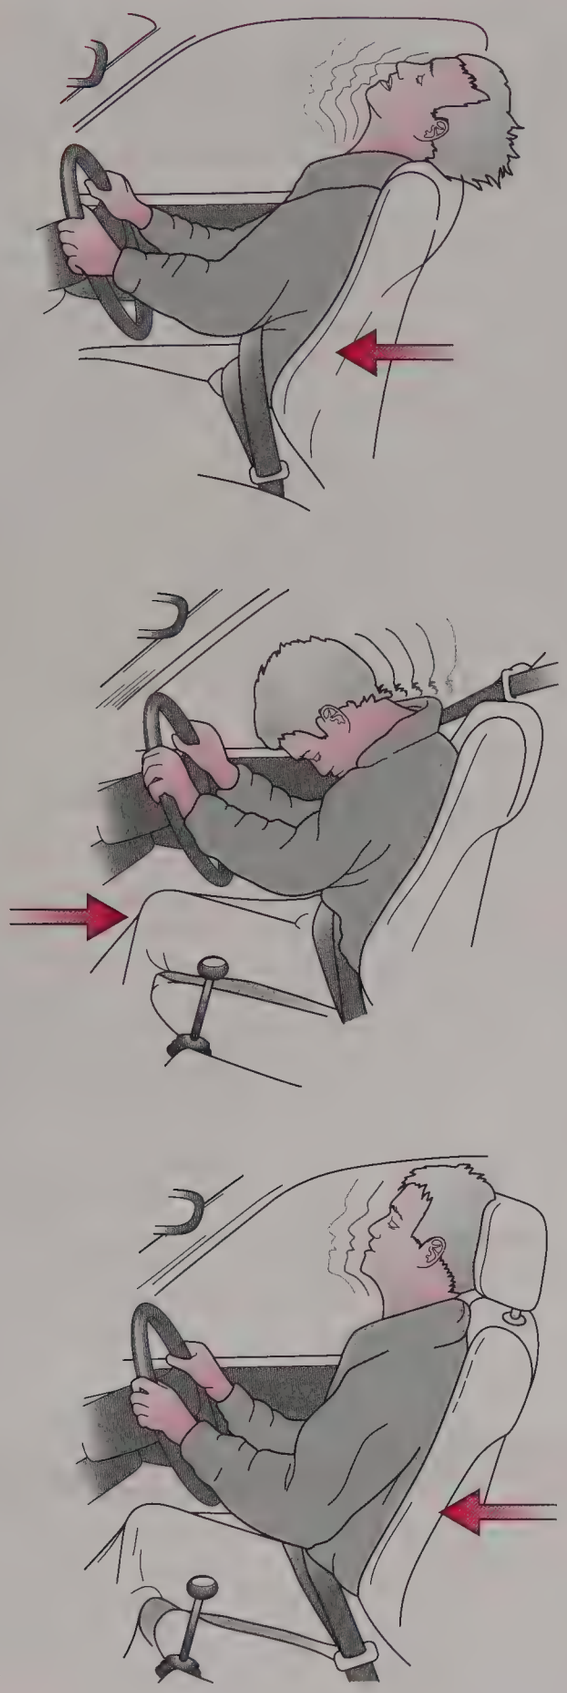

Fig. 10.14 Combined flexion/extension (whiplash) injury of the cervical spine. Movement of the head is limited by a head restraint.

Respiratory and cardiovascular monitoring This is a vital nursing responsibility, to detect any deterioration in the functioning of these systems. Depending on the level of injury, patients may be ventilated. Deep vein thrombosis is a potential complication and prophylaxis should be carried out according to local policy.

Additional physical care Patients with a spinal cord injury have the potential to develop additional physical problems, in particular paralytic ileus, gastric ulceration and pressure ulcers. During the acute stage the patient will have a flaccid bowel and bladder, and therefore urinary catheterisation will be necessary and manual evacuation of faeces will be undertaken by a suitably qualified practitioner.

Psychological care Spinal cord injury is a life-changing event, not only for the patient but also for the family. The experience of SIU staff is that two of the most important interventions nurses can perform are to be truthful at all times, ensuring all staff are providing the same information, and to reduce the effects of sensory deprivation through the use of therapeutic touch and aids such as mirrors (Harrison 2000). Long-term support and adaptation will be necessary and organisations such as the Spinal Injuries Association (see 'Useful websites and addresses') are vital in this.

10.11 You are on placement with a community nurse who has been asked to teach the principles of first aid in spinal injury. Ask if you can accompany her to the teaching session or, if this is not possible, ask her to share her teaching plan with you.

OSTEOPOROSIS

Osteoporosis is 'a progressive systemic skeletal disease characterised by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture' (World Health Organization 1994). It is estimated that 1 in 3 women and 1 in 12 men in the UK will develop clinically significant osteoporosis (Allsworth 2004).

PATHOPHYSIOLOGY

The characteristic overall reduction in bone mineral density (BMD) is caused by both uncontrollable and modifiable factors (Howard 2001). Eighty per cent of BMD is determined by genetically determined risk factors such as race, gender and stature. The remaining 20% is influenced by non-genetic factors which can be modified to enhance BMD (see below). Patients become susceptible to fractures, with the wrist, e.g. Colles' fracture, vertebrae and neck of femur as the most common sites.

MEDICAL MANAGEMENT

Prevention is aimed at ensuring that patients have as high a BMD as possible. Modifications to diet, e.g. increased calcium, and exercise, ensuring sufficient weight-bearing exercise, are key in this. Peak BMD is reached during a person's mid-30s and therefore such modifications should ideally be made before this, although there are benefits in all age groups.

Early identification is also key. It has long been recognised that a low-impact or fragility fracture, i.e. one sustained by falling from standing height or less, especially a distal radial fracture, is suggestive of osteoporosis and merits further investigation and patient education (Royal College of Physicians 1999). In particular, women under 50 with a low-impact Colles' fracture should have their bone density measured and appropriate treatment initiated by their GP or local osteoporosis unit (Royal College of Physicians 1999).

In the presence of osteoporosis, medication therapy is instituted to inhibit bone resorption by osteoclasts and therefore slow down the rate of bone loss. A group of drugs known as the bisphosphonates are widely prescribed and are designed to bind calcium to bone; in the UK, etidronate, alendronate and risedronate are licensed for use (Allsworth 2004). Vitamin D and calcium supplements are also prescribed, as vitamin D is required for the absorption of calcium, and calcium supplementation is vital in the prevention and treatment of postmenopausal osteoporosis (James 2000).

Hormone replacement therapy (HRT) was widely prescribed for the prevention and treatment of osteoporosis but questions about long-term safety, in particular the increased risk of breast cancer, have led to a change in thinking. A review of the evidence (Lookinland & Beckstrand 2003) concludes that HRT should not be used for the primary prevention of chronic diseases such as osteoporosis, and if it is used to control menopausal symptoms it should be limited to 2–3 years at the lowest dose (see Ch. 7).

NURSING PRIORITIES AND MANAGEMENT: Osteoporosis

Prevention Nurses can play a key role in education of the population about the importance of diet and exercise in the prevention of bone problems later in life. Community nurses, school nurses and health visitors are specific groups that can contribute, but all nurses can use time spent with patients as a health promotion opportunity.

Early detection and treatment A number of hospitals are developing schemes whereby patients identified as at risk of osteoporosis, especially patients who have had a Colles' or femoral neck fracture, are screened for osteoporosis and treated appropriately. Many of these schemes are nurse led (Content et al 2003).

BONE TUMOURS

A patient with a bone tumour usually requires complex care which is interprofessional, multi-agency and comprises many types of treatment. A key nursing role is therefore the coordination of care and specialist nurses with a knowledge of orthopaedic and oncology care are invaluable in this and in supporting patients through their journey.

Primary bone tumours can be benign or malignant, although some benign tumours may become malignant. Bone tumours are usually classified according to the cell type from which they originate (see Table 10.3). Metastatic bone disease is malignant bone disease due to secondary deposits in bone tissue from a primary neoplastic site elsewhere (see Ch. 31).

For further information, see Kneale & Davis (2004).

PATHOPHYSIOLOGY

Primary bone tumours are known to occur in specific age groups and in certain sites of bone tissue. Osteosarcoma, for example, is most often seen in people under the age of 30 and usually occurs in the metaphyseal region of the distal femur, proximal tibia and proximal humerus.

Table 10.3 A classification of bone tumours

Tissue of origin	Benign tumour	Malignant tumour
Bone	Osteoid osteoma Osteoblastoma Aneurysmal bone cysts	Osteosarcoma
Cartilage	Osteochondroma Chondroma Endochondroma	Chondrosarcoma

Reproduced with permission from Henry (2004).

As the bone tumour grows, eruption into the surrounding tissues can occur which may be noted as a warm swelling of the affected area. The tumour will originate from a specific cell type within the bone tissue, but may then involve a variety of bone cells.

Approximately 30–70% of all new cancers develop skeletal metastases and, of these, 80% arise from carcinomas of the breast, prostate and lung, with those of the kidney and thyroid to a lesser degree (Dupuy & Goldberg 2001). Bony metastases are usually transmitted by the blood and tend to occur in sites where red bone marrow is present, the commonest sites being the femur, humerus and acetabulum.

MEDICAL MANAGEMENT

History Patients most commonly present with pain, due to stretching of the surrounding tissue by the tumour and/or its impingement on nerves and blood vessels. Pain at night and pain not relieved by rest are indications of malignant tumours. Other symptoms include swelling, reduction in movement of the affected limb and reduced sensation (Henry 2004).

Investigations There are three main investigations:

- Blood tests — raised serum alkaline phosphatase may be present, due to increased osteoblastic activity, and a raised ESR or white cell count can occur in certain tumours due to the necrotic nature of the tumour (Henry 2004)
- Imaging — plain X-ray may reveal the presence of a tumour, but other forms of imaging may be used to provide more detail, especially MRI and CT scans
- Biopsy — in order to determine histopathology and microbiology.

Treatment is usually dependent on the type of bone tumour.

Benign bone tumours Osteochondroma, the most common type, is managed by wide excision. Osteoclastoma, common in the femur and tibia, may require excision and

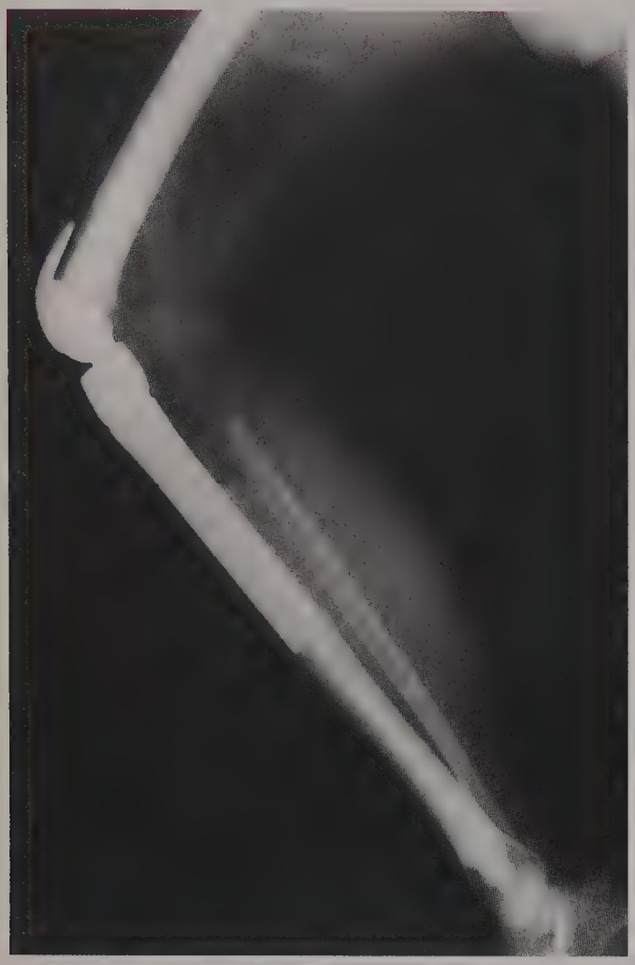

Fig. 10.15 Endoprosthetic replacement of the proximal tibia (lateral view) with distal femoral component and excision of head of fibula.

insertion of an endoprosthesis (see Fig. 10.15). Prostheses are now being used which are extendable, allowing for growth in skeletally immature patients.

Malignant bone tumours The most common type, osteosarcoma, which affects young people up to 30 years of age, is usually treated with chemotherapy followed by surgery, either limb sparing, with endoprosthesis, or amputation. The second most common, chondrosarcoma, occurs in people aged 40–60 and is usually treated by wide excision (with endoprosthesis) or amputation.

Metastatic bone disease The treatment of a patient with metastatic bone disease tends to be symptomatic. The major problem for the patient is pain, which can be severe and debilitating. Pain assessment is crucial in facilitating good pain control which may be achieved by analgesics, radiotherapy, chemotherapy and/or surgery (see Ch. 31).

NURSING PRIORITIES AND MANAGEMENT: Primary bone tumours

Once the patient has seen their GP, immediate hospitalisation will ensue. The care of a patient undergoing chemotherapy and/or radiotherapy is described on pages 1041–1059.

The care of a patient who has a custom-built prosthetic implant will be specific to the implant but the principles of postoperative care are similar to the care of a patient following joint arthroplasty (see p. 472).

Psychological care is paramount for patients with bone tumours, as treatment can last for several months and be very debilitating, e.g. chemotherapy followed by major surgery. Concerns about body image may arise and there will be many fears, including fear of the unknown and of dependence (Henry 2004).

AMPUTATION OF A LIMB

With the development of new treatments amputation is becoming less common, but can still be necessary in some instances. The most common reasons are:

- primary malignant bone tumour, where limb salvage is not possible
- trauma, such as a crushing injury
- vascular insufficiency, such as peripheral vascular disease
- congenital anomaly
- severe infection, such as chronic osteomyelitis with systemic manifestations.

It has been estimated that a large number of the patients who undergo amputation of a limb, or part of a limb, in the Western world do so due to the effects of peripheral vascular disease, while trauma remains the most common reason in the developing countries.

NURSING PRIORITIES AND MANAGEMENT: Amputation of a limb

Coping with loss Loss of a limb through amputation is like any other major loss. As the majority of amputations are carried out as elective procedures, the nurse will be able to make physiological, psychological and social assessments of the patient, and therefore plan care which will assist in the adjustment and adaptation process for the patient (Donohue 1997). This may include arranging for the patient to visit the local prosthetic department or to meet a patient who has had an amputation and is coping successfully.

Occasionally a patient may undergo an amputation as an emergency procedure following a severe crushing injury. In this case, the psychological preparation of the patient and family can only be very limited. They are very likely to require extra support and understanding during the postoperative period.

Wound dressing A stump bandage is used for the first few days and then replaced with a special shrinker sock, which has better elastic properties and is lighter than a crepe bandage. It maintains uniform compression on the wound, thereby reducing oedema, promoting wound healing and beginning to shape the stump, which eases the fitting of the prosthesis.

Phantom sensation (phantom limb) is the name given to the painful sensation experienced by some patients following an amputation and can develop into a form of non-malignant pain, the causal mechanism of which is still not fully understood (McCaffery & Pasero 1999). If it becomes a chronic problem, treatment in the form of transcutaneous electrical nerve stimulation (TENS), ultrasound, local nerve

blocks, relaxation therapy or medication, such as the adjuvant analgesic carbamazepine, has been shown to be effective (Judd 1997).

For further information, see Ramachandran & Hirsten (1998).

Pneumatic post-amputation mobility aid Some centres use a prosthesis known as a pneumatic post-amputation mobility (PPAM) aid to help the patient regain balance, reduce oedema of the stump and encourage early walking after lower limb amputation. The aid consists of an inflatable plastic tube which is placed around the patient's stump. The tube is encased in a metal frame with a rocker foot. The use of the PPAM aid can help the patient adjust to the change in body image as the time without an artificial limb is reduced.

BONE INFECTIONS

Over the last century there have been dramatic reductions in the numbers of bone infections, largely due to the development of antibiotics and improved infection control. However, antibiotic resistance, the re-emergence of tuberculosis (TB) in Western countries, and the increased use of metallic implants in orthopaedic surgery all mean that the potential for orthopaedic infections is ever present. This section will outline the three most common types: osteomyelitis, septic arthritis and TB.

Osteomyelitis

PATHOPHYSIOLOGY

Acute osteomyelitis is most commonly caused by *Staphylococcus aureus* and the bacteria usually accumulate in the metaphyseal plate where they proliferate (Burden & Kneale 2004). As the infection spreads, the patient develops pyrexia and severe pain and the affected part is hot and swollen (Dandy & Edwards 2003). If untreated, the infection spreads through the marrow, erodes the cortex and the periosteum and an abscess forms, which will eventually discharge through the skin. By this stage it has become chronic osteomyelitis. If the infection is close to a joint it may track into the joint, causing septic arthritis; this most commonly occurs at the hip, knee, shoulder, elbow and wrist joints (Dandy & Edwards 2003).

MEDICAL MANAGEMENT

History Patients may have had recent trauma affecting the bone or an infection elsewhere in the body. Local signs of infection will be pain, heat and redness, and systemic symptoms of pyrexia, nausea, sweating and malaise may also be present.

Investigations Blood cultures, wound swabs or needle biopsy samples are taken to identify the causative organism and thus ensure the appropriate antibiotic is prescribed. White cell count, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) (see Appendix 1) will all be raised in the presence of infection.

A plain X-ray will exclude any other causes for the symptoms, and a CT scan will highlight bony abscesses or sinus tracks. An MRI scan may also be carried out to detect any soft tissue or bone marrow involvement.

Treatment Antibiotic therapy is the first line of treatment. This can include instillation of the antibiotics directly into the medullary canal of the bone via an irrigation tube (Sims et al 2001). If this is not successful surgical intervention, involving removal of infected material and clearing of the area, may be necessary. This may result in wide excision requiring bone grafting or external fixation in order to remedy the resulting bone deficit. In severe cases amputation may be necessary.

NURSING PRIORITIES AND MANAGEMENT: Osteomyelitis

Early detection All nurses need to be alert to the condition so that early referral and treatment can be instituted to prevent progression.

Elevation of the affected part This will reduce pain and may be accompanied by the use of traction, splints or casts to rest the affected area.

Pain and comfort Rest, gentle handling, use of bed cradles to relieve pressure of bedclothes, prompt administration of analgesics and antipyretics, reassurance and distracting activity will all help to relieve pain to some extent.

Antibiotic therapy Initially, antibiotics will be administered intravenously. Increasingly this is being carried out in the community by appropriately skilled nurses, thereby reducing the need for prolonged inpatient stay. If antibiotics are instilled directly into the bone the patient will remain in hospital (Sims et al 2001).

Chronic osteomyelitis Patients with chronic infection may have many hospital admissions and treatments and be anxious about the long-term prognosis. Nurses can help by ensuring patients are kept fully informed of their condition and its treatments, and by referring them to appropriate agencies such as social services or occupational therapy.

Joint infection

Septic arthritis

PATHOPHYSIOLOGY

Septic arthritis can be caused by osteomyelitis, infection from a penetrating wound or bacteraemia from a distant focus of infection. Most commonly the organism is *Staphylococcus aureus*, but gonorrhoea infections affect sexually active teenagers and young adults (ARC 2004). It should be suspected in systemic conditions, especially diabetes mellitus, which may present with swollen and painful joints.

MEDICAL MANAGEMENT

History Septic arthritis usually presents as a hot, swollen, red and painful joint which the patient is reluctant to move.

Investigations Blood cultures, blood tests and aspiration of the joint will confirm the presence of infection and identify the causative organism. Imaging, such as X-rays, CT and MRI, will help to identify the extent of the problem.

Treatment The joint is drained by needle aspiration, arthroscopic washout or open surgery, depending on the joint involved. Antibiotic therapy is instituted, usually intravenously at first. If treatment is not successful, patients may be left with long-term arthritic changes and reduced mobility.

NURSING PRIORITIES AND MANAGEMENT: Septic arthritis

The priorities are similar to those for patients with osteomyelitis. Infection in a joint can be exquisitely painful and patients with lower limb infections may require a walking aid as it will be too uncomfortable to weight-bear.

Tuberculosis

Rates of tuberculosis (TB) declined during the 20th century in developed countries due to improved living conditions and the availability of specific medication, but towards the end of the century the incidence increased for a number of reasons, including movement of unvaccinated people between countries and susceptibility to infection of immunosuppressed patients such as those with HIV (see Ch. 16).

PATHOPHYSIOLOGY

TB usually occurs in the lungs and may spread to the skeletal system, especially the vertebral column, where half of all cases of skeletal infection occur (Burden & Kneale 2004). The course of the disease is similar to that of osteomyelitis, although the pace is much slower. It can cause vertebral fractures and in some cases paraplegia. Surgical treatment may be necessary once the active disease has been controlled, including vertebral fusion to prevent further collapse of vertebrae, or joint replacement.

MEDICAL MANAGEMENT

History Symptoms usually develop slowly with little redness or heat initially. Localised tenderness sometimes occurs.

Investigations Blood tests, sputum/urine tests, X-rays and MRI are all used to aid diagnosis.

Treatment is by antitubercular drugs, such as rifampicin, and by addressing the symptoms.

NURSING PRIORITIES AND MANAGEMENT: Tuberculosis

Management involves implementation of the principles of infection control (see Ch. 16), health education and comfort measures to alleviate symptoms. It may take up to 2 years to successfully treat skeletal TB and patients require support, for example, regular supervision and monitoring of medication regimen for side-effects to ensure completion of the treatment. In some areas specialist TB teams have been set up for this reason.

The journal *Tuberculosis* is a useful source of additional information.

DISORDERS OF JOINTS

This section gives examples of the management of disorders of the lumbar spine, osteoarthritis and rheumatoid arthritis.

DISORDERS OF THE LUMBAR SPINE — BACK PAIN

Lumbar spine disorders or 'back pain' account for more lost working hours than any other medical condition and up to 25% of referrals to some orthopaedic clinics are for this condition (Dandy & Edwards 2003).

PATHOPHYSIOLOGY

Damage or trauma to the vertebrae, ligaments or intervertebral discs can result in instability and potential impingement on the spinal cord. Figure 10.16 highlights the major causes of low back pain. In the lumbar spine mechanical causes are the most common, i.e. abuse, overuse or underuse of the back (Smith 2004b). This section will focus on management of acute back strain, recurrent back strain and management of prolapsed intervertebral disc.

Acute back pain/strain

This is associated with a sudden sharp movement or an attempt to lift a heavy object from an extended position, or it may occur when people with sedentary occupations indulge in bursts of excessive exercise. It may be manifest by sudden severe pain in the lumbar region, due to an acute muscle or ligament strain in the lumbar spine.

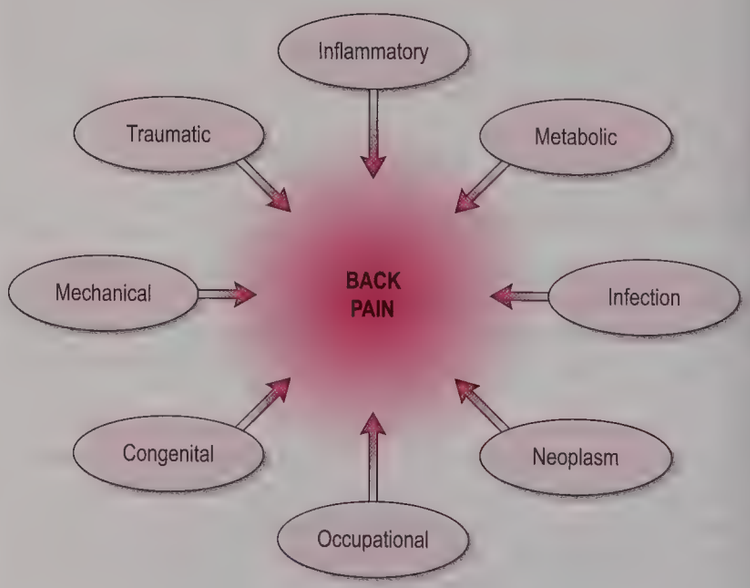

Fig. 10.16 Causes of back pain.

MEDICAL MANAGEMENT

Treatment

- Rest for 24 h maximum in the most comfortable position and then resume activity (Hilde et al 2004)
- Analgesics, non-steroidal anti-inflammatory drugs (NSAIDs) and/or antispasmodic medication (Van Tulder et al 2004).

NURSING PRIORITIES AND MANAGEMENT: Acute back pain/strain

Prevention through health education

Nurses have many opportunities in the workplace, community and hospital to teach people how to organise their environment and activities in order to avoid acute back strain. Much research has gone into the ergonomics of correct lifting techniques and many teaching aids such as videos and leaflets are available (see Disabled Living Foundation in 'Useful websites and addresses').

Nurses are themselves a high-risk group for back injury and a code of practice has been published by the RCN Advisory Panel for Back Pain in Nurses (2002). Both employer and employee responsibilities are set out and there are specific guidelines for assessment and planning of patient care (see Box 10.6).

For information about lifting practices, see Jamieson et al (2002) and Royal College of Nursing (2002).

10.12 Find out what moving and handling aids are available in the clinical area to which you are currently attached. How often are they used? What different techniques for moving and handling patients have you personally used?

Box 10.6

Moving and handling of patients/clients

Assessment and planning

1. Particularly heavy patients, or helpless patients with no ability to assist nurses, need to be individually assessed by a competent patient handling team. Student nurses and support workers should not be expected to undertake these assessments without competent supervision.
2. The care plan or profile should include the following information:
   - The current weight of the patient
   - The extent of the patient's ability to assist and weight-bear, and any other relevant information
   - The technique to be employed to handle that particular patient which should be consistent with the activity undertaken. This should be based upon:
     — the task
     — the patient
     — the environment
     — the equipment
     — the patient handlers.
3. The Manual Handling Operations Regulations and Guidance (UK Government Health and Safety Executive 1992) do not contain any weight limits and state that there is no threshold below which handling may be regarded as safe. All patient handling should be assessed looking at all risk factors, not just weight.
4. Mechanical handling devices or equipment should be used for moving totally dependent patients from bed to chair, trolley, toilet, etc. Sliding equipment should be used for moving totally dependent patients in bed.

From the RCN Advisory Panel for Back Pain in Nurses (2002).

Recurrent back pain/strain

A patient who suffers recurrent back pain or strain should be fully investigated to rule out any other causes, such as a spinal tumour or a prolapsed intervertebral disc.

MEDICAL MANAGEMENT

Treatment Physiotherapy, medication and strategies for dealing with chronic pain are the mainstays of treatment. Specific medication may include tricyclic antidepressants and gabapentin (see Ch. 19). Patients are often referred to a chronic pain clinic where an interprofessional team aims both to relieve pain and to enable patients to live with their pain (Hansson et al 2001). This involves supporting the patient's ability to manage pain by improving self-efficacy, a measure of how confident an individual is to engage in a specific behaviour (Oliver & Ryan 2004). This is achieved by helping patients to understand the reason for their pain, and by teaching behavioural techniques that can help to reduce it, such as pacing activities over time and learning to use relaxation techniques (Oliver & Ryan 2004).

Osteopathy or chiropractic treatment may also be of benefit (Currie 2000), although a systematic review found no evidence on the short- or long-term effectiveness of osteopathy, chiropractic or spinal manipulation for people with non-specific chronic low back pain (Patterson 2004).

NURSING PRIORITIES AND MANAGEMENT: Chronic back pain/strain

The nursing role within a chronic back pain management programme can encompass case management, administration and monitoring of analgesics, education and, with an appropriate qualification, counselling (Smith 2004b).

Prolapsed intervertebral disc

PATHOPHYSIOLOGY

The intervertebral discs consist of a firm nucleus pulposus surrounded by a ring of fibrocartilage and fibrous tissue which links two vertebrae together. Age-related loss of water content and an increase in collagen content leads to stiffening of the discs (Smith 2004b). The disc space becomes narrowed and distorted, leading to increased stress on the spine and intervertebral discs. Eventually the disc may rupture and the soft contents, the pulposus, will prolapse, causing compression and stretching of nerve roots or fibres. Dandy and Edwards (2003) state that 90% of lumbar disc protrusions involve L4–5 or L5–S1 (see Fig. 10.17).

MEDICAL MANAGEMENT

History The classic presentation is of a patient with acute lumbar pain radiating down the thigh and lower leg;

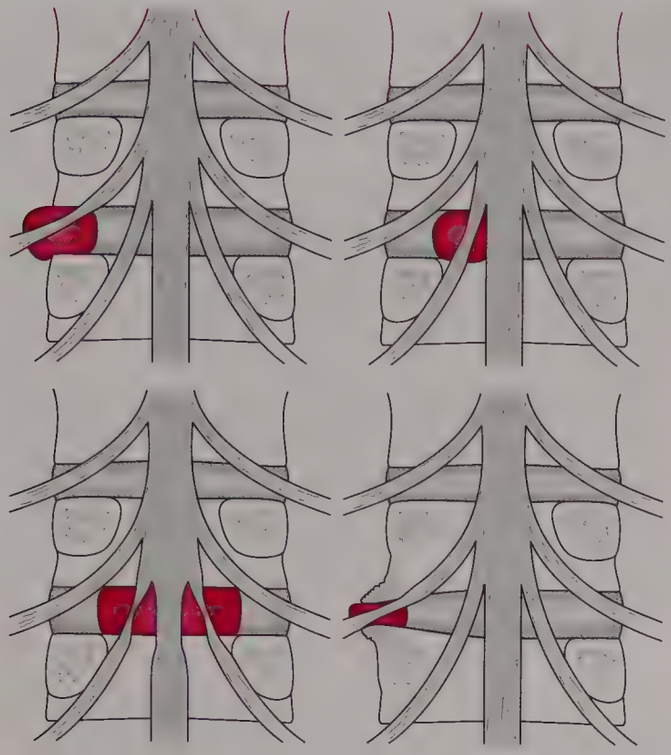

Fig. 10.17 Disc prolapse and root compression in the lumbar spine. A laterally placed prolapse may compress the L4 root, a more central prolapse will compress L5, and a central prolapse will compress the cauda equina. Osteophytes in the lateral canal will also produce root compression.

the precise position is dependent on the spinal nerve root affected, but a few patients may present with only leg symptoms. The patient may also be 'locked' in the classic bent position. There may be a history of dull lower back pain.

Examination Muscle spasm and an intense focal area of pain may be identified. The straight leg raising test will indicate restriction of movement well below 90° of hip flexion and there may be neurological signs such as numbness, tingling or diminished motor function. If necessary, an MRI scan will confirm the diagnosis.

Treatment Conservative treatment for acute back pain as outlined above should be tried first, although manipulation of a spine with acute disc prolapse is said to be dangerous as it could lead to a spinal cord injury (Dandy & Edwards 2003). Localised epidural steroid injections may prove beneficial (Smith 2004b).

The indication for disc excision is when there is proven disc protrusion with accompanying neurological signs and no improvement after 6 weeks of conservative treatment, or if any neurological deficit worsens. Intervention will comprise either of the following:

- Disc excision involves excision of the ligamentum flavum and inferior portion of the lamina (laminectomy) overlying the affected nerve root. The herniated portion of the disc and all disc material is excised, relieving the pressure on the nerve root. Surgery can also be performed in the day case procedure of a microdiscectomy (Cox & Boswell 2000).
- Chemonucleolysis is injection of an enzyme (chymopapain) into the prolapsed disc which breaks down the disc material, thus relieving pressure on the nerve root. This procedure is performed under image intensifier control and appropriate analgesic cover to prevent/relieve the accompanying pain which can be severe.

A Cochrane Review of surgery for lumbar disc prolapse (Gibson et al 2004) found that chemonucleolysis is more effective than placebo but less effective than surgical discectomy. As in both procedures some disc tissue will have been removed, there will be a reduction in its shock-absorbing function, and unnatural stresses may trigger degenerative reactions, with the result that between 30 and 60% of patients may suffer permanent, though varying, degrees of stiffness and back pain (Dandy & Edwards 2003).

NURSING PRIORITIES AND MANAGEMENT: Prolapsed intervertebral disc

A patient who presents with a central disc prolapse is an orthopaedic emergency as the prolapsed disc causes pressure directly on the spinal cord. Without prompt surgical decompression, the presenting neurological manifestations will result in permanent disability. For all patients it is important that they are part of the decision-making process with regard to their treatment — see Case History 10.4 for an example of this.

CASE STUDY 10.4

A patient with a prolapsed intervertebral disc

Ms G, a 54-year-old lady, sustained an injury to her back whilst carrying concrete blocks during home renovation. For 2 months she had pain but attempted to continue with her normal activities, including full-time work as a nurse lecturer. Eventually, when the symptoms did not improve, she saw her GP. He suggested an MRI scan and told her that she probably had a herniated disc which would require surgery.

Ms G did not accept this and refused the MRI scan; instead she arranged to see a chiropractor. However, this did not help and she asked her GP to refer her for physiotherapy; she also agreed to have the MRI scan. This revealed herniation and rupture of the intervertebral disc at L5/S1. Ms G was still 'afraid of undergoing the knife' and decided to persevere with physiotherapy. However, by 4 months after the original injury, her symptoms had worsened and she agreed to see a neurosurgeon. Conventional surgery would require up to 5 days in hospital, but Ms G was adamant that she did not want a general anaesthetic or to stay in hospital. It was agreed therefore that she would have a microdiscectomy as a day case with an epidural anaesthetic, a new treatment at the time. After this was performed Ms G used a number of complementary therapies, including aromatherapy, herbal medicine and meditation, to manage her postoperative care and she returned to work 8 days after surgery.

Cox C L, Boswell G M 2000 Integrating complementary health care in outpatient surgery for discectomy: the patient's perspective. Journal of Orthopaedic Nursing 4(4): 179–184

Conservative treatment

As most of the conservative treatment can be carried out at home, it is the community nurse who will have responsibility for advising and supporting the patient and family in all comfort measures. The care that might be given by the community nurse is described in Nursing Care Plan 10.1. Case History 10.5 provides background information about the patient.

Operative treatment

In addition to the general principles for perioperative care, the following points are specific to postoperative management of patients having a discectomy/laminectomy and chemonucleolysis.

Pain This can be expected to be severe following chemonucleolysis, but it may be complicated by the development

Nursing Care Plan 10.1 Community nursing care of patient with prolapsed intervertebral disc (see Case History 10.5)

Problem A, actual; P, potential	Goal	Nursing intervention	Evaluation
Communication • **Pain (A) related to disc prolapse**	Improvement and control	Advise on: • Self-administering medication • Self-assessment on pain chart	Significant reduction in level of experienced pain
• **Anxiety (A) related to children's welfare and reduced mother role**	Reduce anxiety by addressing causes	• Define problems – discuss with Mrs S and husband • Neighbour willing to help Mon./Wed./Fri., husband at weekend • Arrange nursery care for Emma Tues. and Thur. (social worker)	Mrs S will report satisfaction with arrangements Enquire daily Children and husband adapting and appear happy
Reduced mobility related to rest (A)	Maintain Mrs S in limited mobility – ensure comfort	• When lying in bed, advise to lie supine on a well supported mattress • Mr S to assist with shower • Ensure radio, TV, telephone, magazines available	Mrs S states she is more comfortable Adequate diversional therapy observed
Maintaining a safe environment (P)	Prevent accidental ingestion of Mrs S's medication by children Prevent other accidents	• Discuss problem with Mrs S, husband and neighbour • Locate safe place • Ensure child-proof medication cap • Discuss potential home accidents – give Royal Society for Prevention of Accidents (RoSPA) leaflet	There are no preventable incidents or accidents Family and friends demonstrate raised awareness of safety – discuss leaflet
Nutrition (P)	Maintain balanced diet to prevent constipation	• Arrange friend to assist with food preparation • Home help Tuesdays and Thursdays • Mrs S to sit well supported when eating	Mrs S will report no constipation
Neurological impairment (P)	Early detection and reduction in risk	• Educate Mrs S and her husband in signs and symptoms of deterioration in colour, warmth, sensation, movement of lower limbs. • Provide advice about what to do if deterioration occurs	Any neurological deterioration will be detected and dealt with promptly and appropriately

CASE HISTORY 10.5
Mrs S

Mrs S is 30 years old and married to a builder. The couple have two children, 7-year-old Tim and 4-year-old Emma. Mrs S is being treated at home for a prolapsed intervertebral disc, her prescribed treatment being pain control and neurological assessment. The community nurse plans to visit Mrs S until her condition begins to improve. She has already ascertained that Mrs S's next door neighbour is also a friend.

of neurological deficit. Neurological status should therefore be monitored carefully. The use of patient controlled analgesia (PCA) or of epidural analgesia following spinal surgery will help to ensure that the patient's pain is well controlled.

Positioning and mobilising Frequent position changes should be encouraged, always maintaining spinal alignment. Normal movements can be gradually resumed as soon as the patient's general condition permits. Minimal flexion of the knees, using the knee rest or a pillow for support while in the supine position, will allow spinal muscles to relax. A pillow between the knees will provide comfortable alignment when in the lateral position.

Early mobilisation is usually prescribed. The bed should be lowered and the patient taught to roll to the edge, swing the legs to the floor and stand up in one smooth movement.

DEGENERATIVE AND INFLAMMATORY JOINT DISORDERS

There are over 200 conditions that can affect synovial joints and tissues. This section focuses on two common joint diseases: osteoarthritis and rheumatoid arthritis (see Fig. 10.18).

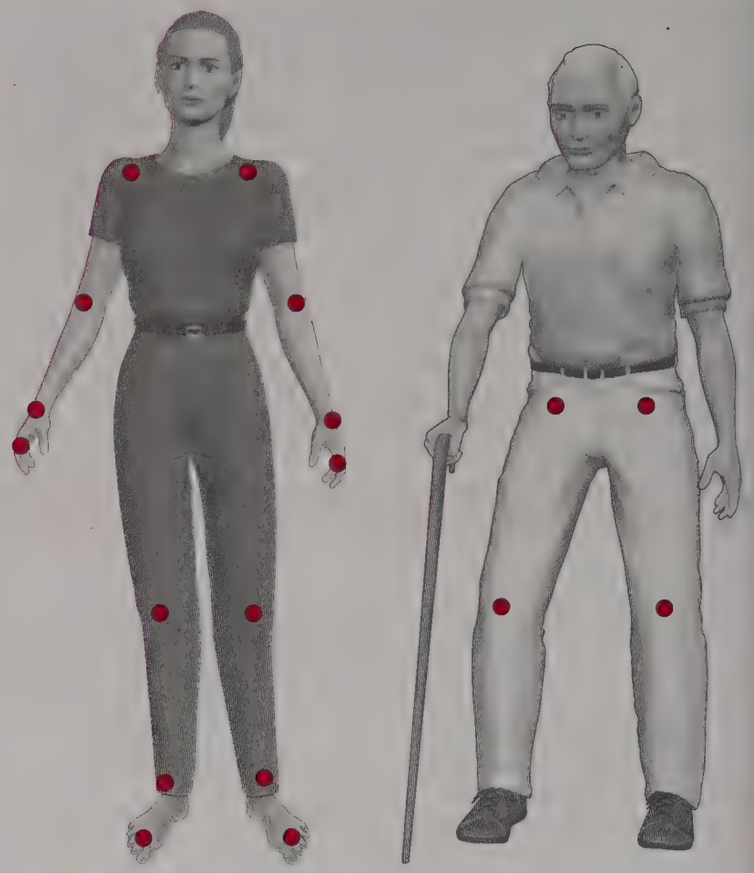

Fig. 10.18 Some differences between rheumatoid arthritis and osteoarthritis. Rheumatoid arthritis affects small joints, is symmetrical and is more common in young women. Osteoarthritis mainly affects the weight-bearing joints and is more common in older and heavyweight people.

Rheumatoid arthritis

PATHOPHYSIOLOGY

Rheumatoid arthritis (RA) is a systemic disease of connective tissue which affects approximately one million people in the UK (Hill & Ryan 2000). It is an autoimmune disease, i.e. the body's immune system attacks its own tissues and becomes self-destructive. The cause of this is not yet known and research continues, but it is thought that factors such as infection, stress and trauma might act as initiating factors in people with a genetic disposition (Ryan & Oliver 2002). The joints are acutely inflamed due to inflammatory changes in the synovial membrane. The synovium becomes thicker, very vascular and the site of increased cell infiltration which may cause an effusion within the joint that manifests as a swollen joint. As the proliferative tissue spreads as a 'pannus' over the articular cartilage, the cartilage is slowly eroded.

Systemic inflammatory changes can affect many of the body's organs and lead to pericarditis, pleuritis and bowel vasculitis, as well as general malaise and anaemia. It is therefore potentially a very debilitating chronic disease. Life expectancy is reduced by approximately 7 years in men and 3 years in women, mainly due to infections, renal or respiratory disease, or the RA itself (Hakim & Clunie 2002). However, there is no one path of RA progression and some patients have permanent remission whilst others have severe relentless deterioration in symptoms; each patient must therefore be assessed individually.

MEDICAL MANAGEMENT

History The disease most commonly starts when a person is in her 30s or 40s with a gradual onset of pain and stiffness, particularly in the morning, affecting the small joints of the hands and feet. The person may also present to their GP complaining of loss of appetite and weight, mild pyrexia, and characteristics of anaemia. As the RA progresses, other joints may become involved, with inflammation, swelling and progressive loss of function. Commonly the wrists, elbows, shoulders, cervical spine, temporomandibular joints, knees and ankles are affected.

For some patients the onset of RA is acute, with multiple joint involvement from the onset, with rapid progress to loss of function.

Examination The affected joints will appear swollen, be warm to the touch, and the patient will complain of pain when the normal range of movement is attempted. If the joint is severely affected, some crepitus may be heard. With

time, joints often become deformed, especially in the hands and feet.

Investigations X-rays of both hands and feet will usually be sufficient to confirm the diagnosis. A blood specimen will be taken for assessment of the level of haemoglobin, number of white blood cells, ESR, CRP and the presence of rheumatoid factor.

Diagnosis The American Rheumatism Association criteria for classification of RA provide a diagnostic guideline (Arnett et al 1988). The seven criteria are:

- morning stiffness
- arthritis in three or more joints with swelling
- arthritis of the hand joints
- symmetrical arthritis
- subcutaneous nodules
- presence of rheumatoid factor
- joint changes on X-ray.

The first four criteria must have been present for at least 6 weeks and a patient must have four or more of the seven criteria to be diagnosed as having RA.

Treatment There is no known cure for RA, and therefore intervention is directed towards relieving pain, modifying the level of disease activity and maintaining optimal functional ability for each individual (Ryan & Oliver 2002).

The aims of medical treatment are to:

- reduce the patient's pain with the use of analgesics, e.g. NSAIDs
- reduce joint destruction with the use of disease-modifying antirheumatic drugs (DMARDs) such as methotrexate, and/or early short-term use of local or systemic steroid therapy. Newer treatments, 'biologics', are being tested. These alter the normal immune response by blocking the normal inflammatory process. They are administered intravenously (infliximab) or subcutaneously (etanercept) (Ryan & Oliver 2002)
- prevent or minimise deformity of a joint by splinting damaged or painful joints (see Fig. 10.19)
- assist the patient to adapt their lifestyle
- correct anaemia.

The main surgical treatments are:

- synovectomy — removal of excess synovial membrane from within the joint capsule of the affected joint. This is less frequently performed because the synovial inflammation recurs. However, tenosynovectomy, removal of synovial membrane from around tendons within joints, is a quick and safe method of relieving nerve entrapment (Hakim & Clunie 2002)
- osteotomy — division of a bone and removal of a piece so that the joint can be realigned. This alters the weight distribution within a joint, most commonly of the metatarsal bones of the feet
- arthroplasty — remodelling of an affected joint using synthetic materials and/or metal, most commonly of the hip and knee joint
- arthrodesis — surgical fusion of a joint, which will reduce or eliminate the joint pain but create a stiff immovable joint, most commonly performed on the ankle.

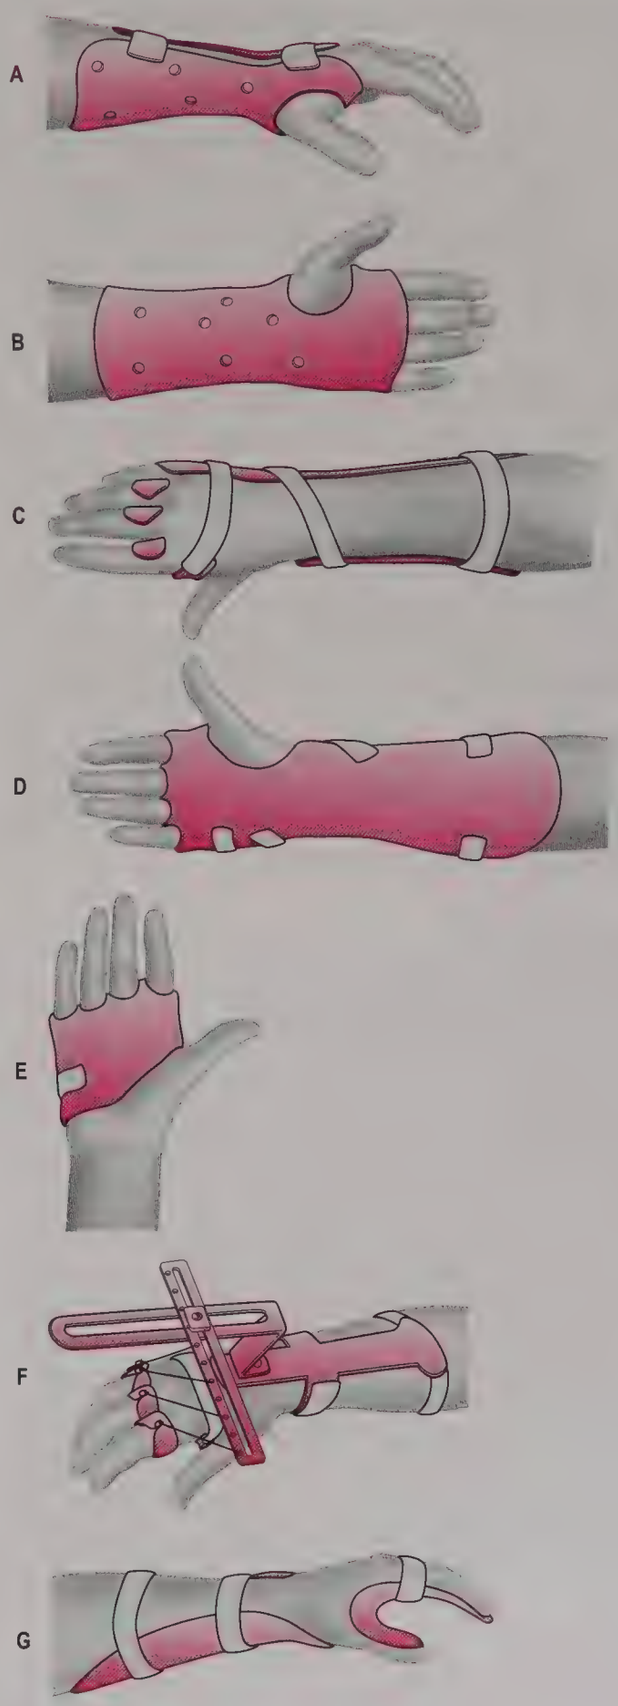

Fig. 10.19 Different types of splint. A–E: Resting splints. F: Functional splint used to stabilise a joint during activity. G: Corrective splint to immobilise a joint, realign soft tissue or correct contracture or deformities.

NURSING PRIORITIES AND MANAGEMENT: Rheumatoid arthritis (RA)

The aim of care is to relieve symptoms and to maintain and, if possible, improve quality of life. A multidisciplinary approach is essential, but coordination of care and therapeutic interventions such as joint injections often fall within the remit of rheumatology nurse specialists. Nurse-led clinics have been shown to be popular with patients (Hill 1997).

Patient involvement/empowerment

As a chronic disease, the key to successful treatment of RA is patient involvement and empowerment, as these increase the likelihood that a person will cope with the treatment regimen and necessary lifestyle adaptations (Mulligan & Newman 2003). There is an increased focus on the concept of the expert patient and on self-management programmes. The Chronic Disease Self-Management Program (CDSMP) is a generic programme which has been adapted for rheumatoid arthritis patients and, in the UK, the Expert Patient Programme, which is being funded and implemented through the National Health Service, includes RA (Mulligan & Newman 2003). These programmes address crucial issues such as family and personal relationships, adaptation of the home, and work and leisure activities.

Controlling pain

A range of analgesics may need to be considered, from paracetamol/aspirin, compound analgesics such as co-codamol, to NSAIDs. NSAIDs can cause gastrointestinal side-effects and the National Institute for Clinical Excellence (2001) advocates the use of the cyclo-oxygenase (Cox) II group of NSAIDs, such as celecoxib, as these reduce the risk of side-effects. Corticosteroids are usually used in the short term in acute episodes of pain/inflammation. When they are used for long-term therapy, abrupt withdrawal must be avoided as the body may not have sufficient glucocorticoids to deal with stress (see Ch. 5). Herbal therapy is tried by many patients and a Cochrane Review (Little & Parsons 2004) suggests that one herbal therapy — gamma-linolenic acid (GLA) — may potentially relieve pain, morning stiffness and joint tenderness, although the evidence is not conclusive.

Local pain control can be achieved in some joints by other methods, such as splints for the hand and wrist joints (see Fig. 10.19).

Maintaining independence and fostering well-being

Exercise and mobility The principles of joint protection should be explained to the patient, such as respecting pain and not being fearful or ignoring it, balancing work and rest, using the larger or stronger joints rather than small ones, and reducing the effort to a joint (Maher et al 2002).

Adaptation of living space The muscle power of the patient with RA is reduced, and therefore the use of aids such as a variable-height bed, raised or ejector chair and raised toilet seat may be of assistance.

Walking aids, such as a stick or elbow crutches, may help to retain the patient's level of mobility by reducing the weight load placed on specific joints. The hand pieces of the aids may need to be adapted to accommodate the finger and wrist deformities that are common features of the disease.

Diet The patient with RA may require assistance in maintaining nutritional status due to anorexia and/or difficulty in using eating and drinking utensils. Frequent, light, appetising meals should be served. The occupational therapist can supply a variety of utensils, such as large-handled cutlery and a tilting kettle stand, which will help the patient to retain independence. A patient with RA is likely to develop anaemia due to the chronic inflammatory process of the disease and medication therapy and iron supplements may be prescribed.

Sexual activity Counselling regarding sexual activity may be required. The Arthritis and Rheumatism Council and the Association to Aid the Sexual and Personal Relationships of People with a Disability (SPOD) have both produced booklets containing useful information for RA patients and their partners (see 'Useful websites and addresses').

Osteoarthritis

PATHOPHYSIOLOGY

Osteoarthritis (OA) is by far the most prevalent joint disorder, with knee and hip OA together affecting up to 10–25% of people in retirement (Doherty & Dougados 2001). It is characterised by a relatively slow deterioration of the articular cartilage that covers the joint surfaces. Although not primarily an inflammatory disease, there is some inflammation in the joint due to the presence of cartilage debris and some synovitis (Maher et al 2002). The disease may be classified as primary or secondary, the former being a progressive condition of unknown origin, more common in the older person, especially females. Secondary osteoarthritis can affect people of any age or gender and is usually associated with a previous injury/condition of the joint, such as a previous fracture or a childhood hip condition such as Perthes disease. It can also develop following repeated high impact joint movements in sport or occupation, e.g. professional footballers are particularly prone to hip and knee OA.

MEDICAL MANAGEMENT

History and examination Pain on movement and stiffness at rest are the most common early symptoms, and may have been present for up to a year before a patient consults a health professional (Peat et al 2001), who will confirm that the normal range of movement of a joint is reduced.

Investigations Plain radiographs of the affected joint will be taken, although the degree of destruction of the joint space does not always correlate to the degree of pain and disability a patient is experiencing.

Diagnosis is confirmed by the patient history and the appearance of the joint on the X-ray, showing narrowing of

Box 10.7

Treatment of the patient with osteoarthritis

Non-operative
- Education
- Glucosamine sulphate, analgesics and NSAIDs
- Physiotherapy
- Walking aids
- Occupational therapy
- Shoe raise
- Modification of activities

Surgical (see Fig. 10.20)
- Debridement/joint washout — removal of osteophytes and washing out of joint debris
- Osteotomy — removing parts of a bone to correct line of weight-bearing
- Arthrodesis — fusion of a joint
- Arthroplasty — creation of a joint
- Total joint replacement — creation of a joint

the joint space and possible formation of bony outgrowths at the bony margins, known as osteophytes.

Treatment The goals of care are pain control, improvement of function and health-related quality of life, and avoidance of side-effects where possible (Barlow 2001). Treatment can be classified as non-operative or surgical (see Box 10.7).

Non-operative treatment Many patients do not require, or want, surgical intervention and for these patients education and support are vital — interventions that nurses are ideally placed to provide. These may be formal OA education and support groups or more informal support for individuals or groups given by practice or community nurses. Arthritis Self-Management Programme (ASMP) Groups may be led by health professionals or by people who themselves have OA (Barlow 2001). These programmes combine advice about medication and lifestyle changes, including appropriate physical exercise such as walking or swimming. Research Abstract 10.3 considers the experience of patients living with OA.

As well as prescription medication, patients should be advised to try glucosamine sulphate, a biological compound which is said to have pain-reducing effects and may also slow down the rate of cartilage damage; a Cochrane Review concluded that it was safe and effective in OA (Towheed et al 2004). For knee arthritis, intra-articular injections of hyaluronic acid or steroids have been shown to be effective in relieving symptoms (Ayral 2001).

Surgical treatment Patients with knee OA may benefit from arthroscopic washout and removal of osteophytes. There is some evidence that drilling exposed bone in the knee joint to make it bleed will cause a clot to form, and that from this a fibrocartilaginous tissue will develop which mimics to some extent the destroyed articular cartilage. This procedure is available in a few centres only (Esteve-de-Miguel 2003). Other operative procedures are shown in Figure 10.20. Of these, joint replacement, particularly of the hip and knee joints, is now the most common.

RESEARCH ABSTRACT 10.3

Living with osteoarthritis: insiders' views

A small-scale American study (Kee 1998) examined 20 patients' individual perspectives and experiences of living with osteoarthritis (OA). The patients were over the age of 60, living in the community and had had OA for at least 1 year.

Four themes emerged — refusing to give up, pragmatism towards treatment strategies, staying in charge, and tangible caring:

- 'Refusing to give up' was attempting to limit the negative effects of OA by emphasising the more positive aspects of lives and lifestyles.
- 'Pragmatism towards treatment strategies' was concerned with receiving advice about treatment for OA from various sources and trying them but stopping if they were not effective; this included advice from health professionals.
- 'Pragmatism' was linked to the third theme 'Staying in charge' where patients reported adjusting medication dosages, such as 'My doctor told me to take aspirin regularly but I only take it when I need it because of what I've been reading about stomach ulcers'. The patients used the conventional health care system on their own terms so that they could continue to maintain control of their lives.
- 'Tangible caring' referred to caring demonstrated by friends and families, such as providing helpful devices ordered from catalogues.

The research suggests that nurses can play an important part in helping OA patients to view their illness as something with which they can live, to recognise that they do have ultimate control over their treatment, and to know that others care for them and are sources of practical assistance. In order to do this, nurses need extensive knowledge of important matters such as appropriate self-help organisations, assistive devices and gadgets, and therapy options, including alternative therapies.

Kee C C 1998 Living with osteoarthritis: insiders' views. Applied Nursing Research 11(1): 19–26

Joint replacement Figure 10.21 illustrates types of prostheses used in hip replacement (see Case History 10.6). Joint replacements are very successful and it is not uncommon for research studies to report 95% survivorship of the prosthesis at 10 years (e.g. Font-Rodriguez et al 1997).

A new type of surgery is hip resurfacing, where the arthritic surfaces are debrided and a short stem metal prosthesis to cover the femoral head is inserted, preserving the femoral neck; at the same time a metal cup is inserted into the acetabulum. The femoral head prosthesis and cup are usually made of cobalt chrome. These are used in younger patients and those who are particularly active. The theory is that when the prostheses wear out it will be easier to replace them with a conventional hip replacement, because more bone has been left intact; however, as yet, there is a lack of long-term follow-up studies to support the theory (Vale et al 2002).

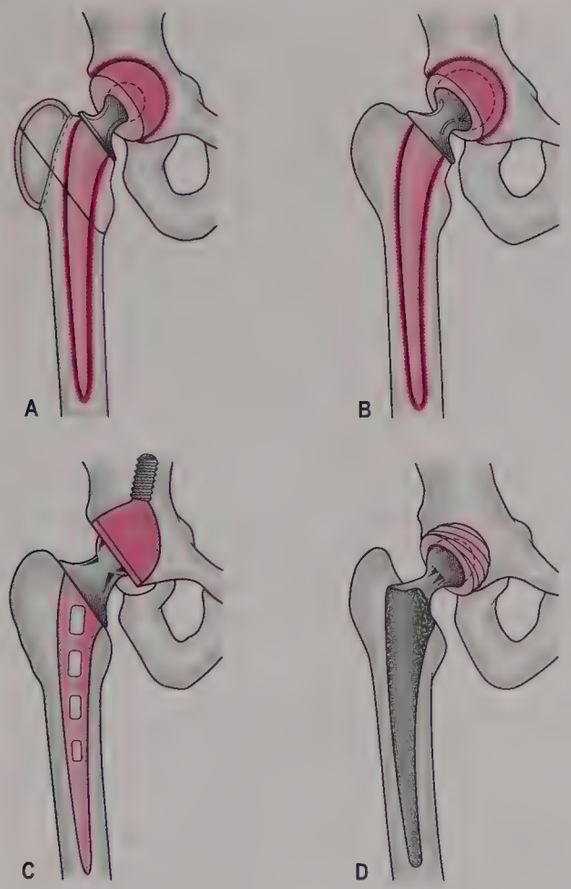

Fig. 10.21 Types of total hip replacement. A: Charnley hip replacement with greater trochanter reattachment. B: Müller-type replacement with larger femoral head. C: Ring-type replacement using a long threaded acetabular component, without cement. D: Uncemented prosthesis with sintered surfaces and screw-in acetabular prosthesis.

Postoperative complications — total hip replacement (THR)

Dislocation of the femoral component One of the risks of a THR is dislocation of the prosthesis, i.e. the femoral component comes out of the acetabular cup. It is common for patients to have to follow certain restrictions for the first 6 weeks postoperatively to reduce this risk, namely not crossing their legs, sleeping on their back, and not getting into a bath, although a study examined 499 patients on whom no restrictions on postoperative mobilisation were imposed and only three suffered dislocation (Talbot et al 2002). To help prevent dislocation during the inpatient stay, some orthopaedic surgeons request that the patient is nursed sitting with no more than 45° of flexion at the hip joint. A Charnley wedge or foam troughs in which the patient's lower legs rest may also be used to reduce excessive adduction which can increase the incidence of dislocation of the hip joint replacement. The femoral bone tissue has an excellent blood supply; therefore, compared with other forms of surgery, blood drainage can be excessive. Accurate recording of the drainage volume is essential and, if excessive, the patient may need a blood transfusion. If a wound drain is used the nurse must ensure that contamination of the drainage system does not occur when emptying the collecting chamber(s). Autotransfusion is becoming a more frequent practice within orthopaedic surgery (see Ch. 18).

NURSING PRIORITIES AND MANAGEMENT: Joint replacement

Preoperative care

As with any surgery, the key to success is planning and early patient involvement. It is increasingly being advocated that such planning should begin as soon as a patient is listed for surgery, with an initial health check to ensure that the patient does not have surgery postponed at preoperative assessment due to ill health (DH 2002). Patients may also attend a group information session where they can find out more about the surgery and rehabilitation ('Hip and Knee Club'). Preparing patients for surgery is an ideal role for an orthopaedic nurse practitioner.

Postoperative care

Postoperative care will follow the basic principles outlined in Chapter 26 with the following additions.

Prevention of infection Bacterial infection of the bone around the prosthesis can have a severe debilitating effect and, if this occurs, the prosthesis may have to be removed, leaving a grossly unstable joint; therefore prophylactic therapy is essential. In addition to basic attention to infection control, especially when undertaking invasive procedures, and attention to clearing up any septic foci, i.v. antibiotic therapy is commenced perioperatively and continued postoperatively, i.e. one dose perioperatively and two doses postoperatively.

Deep vein thrombosis (DVT) Hip and pelvic surgery have the highest incidence of DVT, and therefore local policy to

CASE HISTORY 10.6

A patient's perceptions of an experience surrounding total hip replacement

Two months after an operation for hip replacement I am trying to record my experiences, but one thought predominates to such an extent that everything else fades into insignificance. I can think of nothing other than the fact that I have no pain: no pain walking, no pain sitting, no pain lying in bed, no pain at all. Two ideas arise from this: one, that it does not seem at all healthy to be so conscious of the absence of pain. The hope must be that sooner or later being pain-free will become the normal unobserved fact of life. The other is a retrospective awareness of the debilitating effect of continuous chronic pain, the insidious way in which everything developed. People now keep exclaiming that I look so well, that my colour has improved so much. They never in the past told me that I looked old and grey. This must have been as unremarkable to others as the experience of continuous pain was to me.

There were many different kinds of pain. The worst in intensity was probably the pain on weight-bearing, but somehow it did not bother me so very much. I felt I could anticipate it, control it by leaning on a stick or furniture, or by refraining from walking altogether. There were sudden and very acute bouts of pain, sharp like toothache, on sudden movements or jolts, but these passed and did not matter much. There was the impossibility of ever sitting or lying in comfort — much less severe pain, but the most difficult to bear. It was when that particular pain suddenly got much worse that I first told the GP how I felt. When, in spite of anti-inflammatory painkillers, even the weight of the sheet became intolerable and lack of sleep became difficult to cope with, an appointment was made with the orthopaedic specialist services. The nature of the worst of the continuous pain, however, was none of these; it was almost not experienced as pain at all. It was a deep nagging, dragging, twisting sensation which was nauseating and depressing, not responding to analgesics at all, analgesics which I took in maximal dosage and which added to the feeling of nausea, depression and apathy. Neither the GP nor I myself was keen on the thought of surgery: the GP no doubt because he was conscious of obesity being a contraindication for surgical intervention; I myself because I knew of many cases when no great improvement followed hip replacement. As soon as my friends had heard that I had been put on the waiting list, example after example was related to me of how wonderful Mr or Mrs X, Y or Z was as a result of this operation — 'a new lease of life', 'years younger', 'never looked back'. But my own attention focused, not on their reassurance, but on those people I had met who had developed infections, whose prosthesis had broken down, who had to have a second operation. It was no help to see a television programme and read a newspaper article about the inferior quality of the prostheses which were coming on the market at that time.

Now, after the operation, I have joined the ranks of those who extol its virtue, but even the most enthusiastic supporters had not prepared me for the speed with which it would be possible to lead a normal life: walking within 48 h, discharged from hospital within 2 weeks, fully independent by the time of the follow-up outpatient appointment 6 weeks after operation. Here, in summary, are the events which I now believe made the whole experience entirely positive: on first appointment at the orthopaedic outpatient clinic the thorough examination, the fact that the surgeon appeared to understand how much pain I had — perhaps even better than I did — and did not belittle what I was saying. The fact that he arranged immediately, before the operation, to start physiotherapy and that he promised an operation as soon as possible. I was on the waiting list for only 6 months. A week before the operation there was a day of tests and examinations in the ward to which I was to be admitted, giving a good opportunity to allay anxiety. I was glad that I had explanations of the operation, the anaesthetic and the possible risks. I appreciated the time taken to answer my questions and the sensitivity of the staff, though I do not think I could have entered into any decision making in spite of the explanations. My anxiety about the postoperative phase, about living alone, upstairs, in a relatively large flat was well understood and arrangements were made by the occupational therapist, at that early stage, for various pieces of helpful equipment to be delivered to the house. I was assured that I would be fully rehabilitated by the time of discharge which was anticipated to be after about 7 days, but I found this difficult to believe.

On admission I was immediately aware of the cordiality and friendliness of the nursing staff and of the community spirit of the patients who made me feel welcome and who augmented the very adequate information given to me by the staff, both in print and in discussion.

Preoperative relief of anxiety and postoperative pain control were superb; after the initial intravenous analgesic cover, painkillers were offered every 4 h, but not really needed, except before physiotherapy, after the first few days. It was interesting to observe that all patients who had hip operations went through the same progression of skill acquisition and setbacks, learning how to get in and out of bed, how to turn in bed, how to walk, first with a Zimmer frame, then with two sticks, and later one stick, how to pick things up off the floor, to put on stockings and shoes, to shower independently, to dress and undress, to climb stairs and to get in and out of a car. It was evident that all the nurses knew exactly what each patient was capable of doing. All were willing to help but clearly expected and encouraged independence. The nurses' awareness of patients' progress and the supervision of the activities of less highly qualified staff were always in evidence. It was reassuring to notice that there was vigilance in case deep vein thrombosis arose and to see the speed with which one patient was advised to go to bed, the foot of which was raised, and how speedily support stockings were offered. With the emphasis throughout on what one can do by oneself and encouragement to get moving, it was a boost to self-confidence to know that nurses were vigilant for complications and setbacks. I found it helpful to have been shown the X-ray of the new hip as it makes it possible to visualise what the joint is doing during various activities, and to understand why one is advised never to cross the legs, to get on all fours or to pick things up off the floor from the sitting position. A pillow between the legs during sleep helps prevent crossing the legs accidentally.

There were 12 women in the ward, most of them in for hip or knee operations. The impression gained on admission of a friendly, supportive group spirit was reinforced throughout. What a wealth of experience, what a reservoir of knowledge, what abundance of empathy, goodwill and helpfulness. There was also a tremendous amount of fun and humour, perhaps enhanced by the experience all had of being pain-free all of a sudden. On discharge I was part of a supported discharge scheme, which meant that a physiotherapist and nurses visited me during my first few weeks at home to check that I was continuing to make progress. It was reassuring to have this support when I got home.

I learned a lot, not only about health and illness, but also about emotional, social and economic stress, and about coping strategies. The importance of the patient community and its therapeutic potential is seldom recognised in general nursing but it should never be underestimated.

prevent this complication should be implemented (SIGN 2002b, Davis 2004). There is much debate as to the most appropriate method of prevention and the evidence is controversial (Love 1999). Common methods used are thrombotic/embolic deterrent (TED) stockings, foot pumps, which reduce venous stasis, and chemical prophylaxis using heparin injections.

Urinary retention is a potential problem. If all nursing measures, such as helping patients to the toilet or commode rather than using a urinal or bedpan, fail then intermittent catheterisation may be advised. The insertion of a self-retaining catheter should be avoided because of the risk of creating a septic focus (see Ch. 8). In some orthopaedic centres, oral or i.v. antibiotics may be administered prior to and after catheterisation, but the research evidence to support this is inconclusive.

Mobility and rehabilitation The patient may begin to mobilise as soon as their condition permits, which is usually on the first day postoperatively. This will be supervised by the physiotherapist and the nurse. A hydraulic bed is essential for correct manoeuvring, as care must be taken not to flex the hip more than 45° when helping the patient out of bed or while sitting; therefore a high armchair should be used.

A walking frame may be used at first and the physiotherapist will re-educate the patient to use a normal walking gait. Depending on progress, the patient should practise using crutches or walking sticks before discharge.

Aids to living The occupational therapist will provide aids for dressing, such as a stocking applicator, and any other aids found to be necessary after an assessment of the home environment and the patient's capabilities.

Discharge planning

Discharge planning should begin preoperatively, and in some centres patients will be identified as suitable for an early supported discharge scheme where a hospital at home environment is provided. It is essential, however, that the patient accepts this and is not forced into early discharge (Jester 2003). Support after discharge may be continued by a telephone helpline and nursing advice service (O'Brien et al 1999). Where such services do not exist, the community nurse will provide care, such as wound suture removal, and will liaise with the hospital team as necessary.

10.13 From the information provided above, write a concise discharge plan for a patient who has undergone an uncomplicated total hip replacement.

SOFT TISSUE INJURIES

LIGAMENT INJURIES

PATHOPHYSIOLOGY

Excessive extension, flexion and/or rotation of a joint may result in a partial or complete rupture of a ligament. Whiplash injury is the term used to describe a ligamentous injury to the cervical spine area often occurring after a RTC (see Fig. 10.14, p. 460). This injury is due to excessive flexion and extension movements to the neck. The knee is heavily dependent on its ligaments for stability and they are susceptible to injury, particularly the anterior cruciate ligament which limits forward movement of the tibia on the femur. Injured ligaments never heal soundly or regain their former strength as the scar tissue that forms at the site is never as strong as the original tissue (Dandy & Edwards 2003).

MEDICAL MANAGEMENT

History and examination People who suffer these injuries are often young and will complain of severe pain around the injured area after feeling or hearing something snap or tear. Pain may be increased when the person's body weight is exerted through the injured limb. Limitation of normal joint movement may be found with swelling of the injured part. Joint instability may be noted during the physical examination.

Investigations Plain radiographs are taken to rule out a bony injury to the area. An MRI scan or examination of the joint under general anaesthesia may be undertaken.

Treatment If bleeding into the injured joint (haemarthrosis) has occurred, this may be aspirated under local anaesthesia. The injured area will be supported, e.g. using a cervical collar for a whiplash injury (see Fig. 10.22) or a POP cylinder/knee brace for a knee injury. Physiotherapy is instituted in order to build up muscle groups that surround the joint which the injured ligament normally supports. Surgical intervention is usually needed only when the injury affects the knee joint or where there is damage to more than one ligament and/or gross instability of the joint. Repairing ruptured ligaments is generally not successful, because the repaired ligament will not have the same 'stretchiness' as the original, and therefore they are usually replaced with a length of tendon or prosthetic material (Dandy & Edwards 2003).

Fig. 10.22 Cervical collar.

NURSING PRIORITIES AND MANAGEMENT: Ligament injuries

The patient may arrive at the Emergency Department within a few hours of injury (see Ch. 27). In other cases, the patient may present 12–24 h after injury when the pain and swelling have greatly increased. If no other injury has been sustained, the patient may be treated and discharged to attend as an outpatient.

Pain This will be the major patient problem on presentation at hospital. Such pain should be assessed (see Ch. 19, p. 745) and an effective analgesic prescribed. As ligamentous injuries are sustained following severe trauma to the body part, the surrounding soft tissues will also be involved, causing further bleeding which will increase the swelling and irritate the surrounding tissues, thus increasing the patient's pain. The use of NSAIDs will be of value to reduce the inflammatory process.

Muscle spasm This is a common sign of soft tissue irritation and, if severe, the patient may need to be prescribed a mild antispasmodic as well as an analgesic.

Support/immobilisation Refer to priorities and management of patients in casts (see p. 451). In addition, when a cervical collar is worn, it can usually be removed to allow daily skin care. Following anterior cruciate ligament repair a patient usually wears a knee brace for the first 6–8 weeks, which prevents flexion greater than 90°, and nurses should ensure that the patient can correctly apply the device.

Psychosocial care Ligamentous injury may take up to a year to heal completely, and work and financial status, as well as social interaction, can be affected (Smith 2004c).

MUSCLE AND TENDON INJURIES

PATHOPHYSIOLOGY

These injuries are most often caused either by direct trauma at the site of the injury, i.e. an in-site injury, or by a sudden sharp movement of the joint associated with sports such as tennis and squash, i.e. a shearing injury. The large tendons and muscles of the lower limbs, such as the Achilles tendon, are the most common sites of injury, with a reported incidence of 18 per 100 000 persons (Bhandari et al 2002).

MEDICAL MANAGEMENT

History and examination The patient will experience a distressing tearing sensation or a kick at the site of the injury and possibly an inability to put the foot down. Swelling and tenderness will develop within a few hours following the injury. Bruising will appear later and may be extensive and alarming for the patient. On examination, a gap between the ends of the muscle or tendon may be felt in superficial muscle injuries. MRI or ultrasound may be used to determine the extent of the injury.

Treatment For muscle injuries the principles of RICE — Rest, Ice, Compression and Elevation — should be followed in order to control haemorrhage and haematoma. Early mobilisation within pain limits is important, as muscle healing occurs through aerobic metabolic pathways and therefore needs adequate circulation. Surgery may be necessary if there is a large intramuscular haematoma or if there is a large muscle tear affecting movement of a joint.

Tendon injuries are usually treated conservatively, with a cast or splint holding the ends together until healed. Surgery may be required for a complete tendon rupture, particularly of the Achilles tendon; however, a systematic review of surgical versus conservative treatment of Achilles tendon injury concluded that whilst surgery reduced the risk of re-rupture, it significantly increased the risk of infection (Bhandari et al 2002).

NURSING PRIORITIES AND MANAGEMENT: Muscle and tendon injuries

Comfort The nurse has a key role in helping the patient to institute and maintain RICE.

Mobility Once activity is commenced, the physiotherapist will teach the patient to use the most appropriate walking aid, usually a pair of crutches. Assessment of the patient's home circumstances with regard to mobility will be required.

Following surgery, routine postoperative care will be necessary. The use of a cast or brace will necessitate education of the patient in their care and management.

PERIPHERAL NERVE INJURIES

Nerves can be damaged due to underlying disease or following trauma. In this section, the focus will be on injuries following trauma.

PATHOPHYSIOLOGY

A single nerve or group of nerves may be damaged depending on the site of injury. Nerve injuries can be due to either direct or indirect force and can be divided into three types (Wellington 2004).

- Neuropraxia — intact nerves with temporary damage usually due to compression
- Axonotmesis — divided axons with maintenance of the endoneural tubes, usually due to severe blow or traction, a pulling injury; prognosis is good
- Neurotmesis — the whole nerve is divided, usually from a penetrating wound such as a stabbing. No recovery is possible without surgical repair.

MEDICAL MANAGEMENT

History and examination Following an accident, a patient may become aware of tingling (paraesthesia), numbness and/or loss of movement of the affected part. Examination of the distribution of the loss of sensation and movement will aid diagnosis as to the extent of the injury.

Investigations Plain radiographs are useful to assess bony injury and for the presence of any foreign material, such as glass fragments, which may have caused the injury.

Diagnosis is confirmed by the absence or alteration of neurological function and sensation of the affected part. Nerve conduction studies, which involve stimulating a nerve with a wave pulse to evaluate the sensory and motor responses along the course of the peripheral nerve, may be carried out (Dandy & Edwards 2003). Electromyography (EMG), which records motor activity at rest and on attempted muscle contraction, may also be used (Wellington 2004).

Treatment Primary surgical repair is indicated only when a nerve has been cleanly divided. Secondary repair may include suturing and grafting of nerve tissue from a less important nerve within the patient's body. Non-operative management involves immobilisation of the affected part in the anatomical position, using a lightweight cast or splint. Peripheral nerves are capable of regenerating at a rate of 1–2 mm/day (Wellington 2004). It is possible to calculate roughly the length of time to recovery although there is no guarantee that each nerve cell will heal.

NURSING PRIORITIES AND MANAGEMENT: Peripheral nerve injuries

Complete recovery may occur but take a few weeks, months or years. However, the patient may need to adapt to permanent and severely disabling physical, psychological and social changes (Wellington 2004).

In the short term, as the patient will have been involved in some form of trauma, nursing care as outlined in Chapter 27 will apply.

Should the patient require surgery, general perioperative care will be as described in Chapter 26.

Preventing further injury

The patient will have partial or complete loss of the protective mechanisms of touch and pain, and care must be taken to prevent further injury to the affected part. Movement of the injured limb must be through the normal range of passive joint movements, otherwise joints, muscles, tendons, ligaments and other nerves could be damaged further. To prevent the development of joint contracture and deformity, the patient may be fitted with a lightweight splint which holds the joints in their anatomical position. This may be needed for a long period. Exposure to extremes of temperature should be avoided, to prevent a skin burn.

Subsequent considerations

Pain Sharp shooting pain and a constant tingling sensation can be very troublesome and the patient may need prolonged use of analgesics. Antidepressant medication, such as amitriptyline and adjuvant analgesics, are known to be beneficial as a supplementary medication in the relief of neuropathic pain (see Ch. 19). The nurse may also wish to suggest, as an adjunct, the use of one of the many complementary therapies that are widely available (Wellington 2004).

Washing and dressing The patient will need advice and information to assist in adapting their usual mode of personal cleansing and dressing. For example, a patient with a median nerve injury due to a laceration of the wrist of the dominant hand may have difficulty in brushing their teeth or combing their hair. The occupational therapist can provide advice and appropriate aids.

Splints If a splint is used, the patient will need information and advice about the correct method of application and removal. The patient with sensitive skin has to be taught to inspect it for signs of pressure by removing the splint at regular intervals throughout the day.

Exercise The physiotherapist will exercise the joints of the injured limb passively to prevent stiffness and muscle wasting. The patient may be able to use their own hands to exercise the joints, or a relative can be taught the skill of passive exercises. Not only will this assist physical recovery but it can also be of psychological benefit.

Support As recovery from a peripheral nerve injury may be prolonged, the patient will require support and understanding from family, friends and the members of the health care team to relieve boredom and prevent the development of depression. Group sessions for patients with similar injuries who are receiving physiotherapy, occupational therapy and/or diversional therapy can be an excellent psychological support mechanism. The social worker can assist with social and/or financial problems which may develop due to the possible lengthy absence from employment.

Permanent disability If the nerve injury prevents return to the previous occupation, it will be necessary to ensure that the patient has access to specialist advice about retraining and new employment opportunities. In some instances, alteration to body image could have a severe psychological effect. Nurses should be aware of this and provide support and counselling as needed by the patient.

CONCLUSION

This chapter has outlined the basic principles of nursing management that relate to the more common musculoskeletal disorders and has focused on some of the critical factors that influence management and care in specific disorders. It has stressed that the focus of care is the patient and family, and that the challenge to nursing increases with changing trends in therapeutic interventions, early supported discharge schemes, care in the community, and an ageing population whose lifestyle has been revolutionised by joint replacement surgery and multidisciplinary care and support.

Trauma is a constant in human societies and musculoskeletal injuries will always be a fact of life. However, continuing research and more attention to health screening and health promotion have shown that many accidents and conditions are preventable and many diseases amenable to treatment.

A wide knowledge of musculoskeletal disorders is essential for both hospital- and community-based nurses, to enable them to respond to the needs of patients and their families, to work actively to prevent accidents and complications, and to give appropriate information, advice and care.

INTRODUCTION

Blood is a vital body fluid which, via the cardiovascular system, reaches all body organs and tissues. It has three primary functions:

- to transport oxygen, nutrients and other substances
- to protect the body against microorganisms and other foreign materials
- to regulate homeostatic systems.

Disorders of the blood are diverse and may be acute or chronic. All age groups may be affected, although some disorders are more common in certain age ranges than in others. Some disorders, such as haemophilia, are sex-linked; others, such as sickle cell disease and thalassaemia, are more prevalent among certain ethnic groups. Still others, such as nutritional anaemia, occur worldwide.

Causes of blood disorders

Contributing factors in the development of blood disorders can be divided into nine types:

- *Developmental.* Infants and older people can be predisposed to anaemia, the former group because of increased nutritional requirements for growth and development, and the latter because of poor nutrition resulting from factors such as depression or inability to get out to shops.
- *Genetic.* Inherited disorders include:
  — abnormalities of the red blood cells, e.g. spherocytosis
  — haemoglobin abnormalities, e.g. thalassaemia and sickle cell anaemia
  — lack of a clotting factor, e.g. haemophilia and von Willebrand's disease.
- *Dietary.* Nutritional deficiencies can be related to poverty, lack of knowledge about nutrition and healthy cooking methods, and to overriding political and economic circumstances.
- *Sociocultural.* Dietary habits leading to nutritional deficiency may be related to values and beliefs. Strict vegetarians, for example, may develop vitamin B_{12} deficiency anaemia. Lifestyle factors, such as a reliance on fast foods or a habit of skipping meals, can also lead to nutritional anaemias. Other social factors such as homelessness and unemployment can contribute to poor nutrition, leading to the development of blood disorders.
- *Environmental.* Exposure to industrial chemicals — benzene, lead, sodium chlorate — and to ionising radiation has been linked to the development of blood disorders such as aplastic anaemia, agranulocytosis and leukaemia.

- *Pharmacological.* Some over-the-counter and prescription drugs are known to cause specific blood disorders (Craig et al 2002). Agranulocytosis can be caused by dapsone, used to treat leprosy, and by some medications to reduce excessive thyroxine production, e.g. carbimazole. Quinine, quinidine and heparin can cause thrombocytopenia by damaging the platelets. Prolonged use of aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) can lead to iron deficiency anaemia. Most cancer chemotherapy agents cause myelosuppression and thus anaemia, neutropenia and thrombocytopenia.
- *Iatrogenic.* Surgical interventions that cause blood disorders include the use of prosthetic heart valves, which can damage red blood cells, and total gastrectomy which, through the resulting lack of intrinsic factor, leads to vitamin B_{12} anaemia, i.e. pernicious anaemia.
- *Pathological.* Diseases which can cause blood disorders, particularly anaemia, include inflammatory diseases, malabsorption syndromes, cancers and infections.
- *Idiopathic.* In some cases of anaemia, especially aplastic anaemia, no cause may be identified.

The nurse's role in the treatment of blood disorders

The nurse's role in caring for patients with blood disorders in a community, hospital or occupational setting will include the following functions:

- promoting health, e.g. by encouraging good dietary habits
- detecting early signs of illness such as pallor, fatigue and frequent absence from work
- assisting with medical investigations, e.g. bone marrow aspiration, dietary history-taking
- explaining tests, diagnoses, treatments and prognoses to patients
- educating patients about lifestyle, diet and medication
- providing emotional support to patients and their families
- referring patients to other professionals such as genetic counsellors.

Depending upon their work setting and specialism, nurses will play a variety of roles in the care of patients with blood disorders. Primary health care nurses may be involved in health screening and may be the individual's first point of contact with the health care team. Hospital nurses may care for anaemic patients in all types of wards and units. Specialist nurses may work as sickle cell disease counsellors or in a haemophilia centre. Macmillan nurses may provide care at home for patients with malignant haematological disorders.

The particular needs of patients with blood disorders will vary in accordance with the nature of their illness. Some patients may present with one very acute episode of illness, e.g. massive haemorrhage because of, for example, trauma or disseminated intravascular coagulation (DIC), and then return to full health after treatment. More commonly, patients are diagnosed with blood disorders after a prolonged period of malaise.

ANATOMY AND PHYSIOLOGY

Blood is red viscous fluid which is pumped from the heart via the arteries to the capillaries in the tissues and returns via the veins to the heart. Its central role is to help maintain an optimal environment for the functioning of the body cells. It fulfils this role by performing the following functions:

- transporting oxygen, essential nutrients and other important substances, e.g. hormones, enzymes, chemicals to all cells
- removing carbon dioxide and other waste products from the cell
- haemostasis
- protecting the body from microorganisms and antigens
- regulating water, electrolyte and acid–base balance
- regulating body temperature.

The total volume of blood circulating in an average 70 kg male adult is 5 L. Blood consists of cellular and fluid components. The main constituents of plasma, the fluid component, are:

- water
- plasma proteins
- electrolytes
- nutrients
- hormones
- enzymes
- waste products.

Cellular components of blood

There are three different cellular components of blood:

- erythrocytes
- leucocytes
- thrombocytes.

These cellular components are developed in the active bone marrow found in the medullary cavity of certain bones in the adult. The sites of the active bone marrow are:

- ends of the long bones, e.g. humerus
- ilia of the pelvis
- vertebrae
- ribs
- skull
- sternum.

These sites can be extended when there is an increased demand for blood cells. All types of blood cell are derived from a common pluripotent stem cell.

Erythrocytes (red blood cells)

Red blood cells are biconcave discs. Haemoglobin, the oxygen carrying molecule within the erythrocyte, makes up 33% of the red cell weight and gives blood its characteristic red colour. The thin cell membrane allows gaseous exchange between the cell and surrounding tissues. The cell is also soft and pliable, allowing it to pass along the capillary lumen easily. During maturation, the red blood cell extrudes its nucleus. The mature cell therefore has no capacity to reproduce, repair, grow or make haemoglobin.

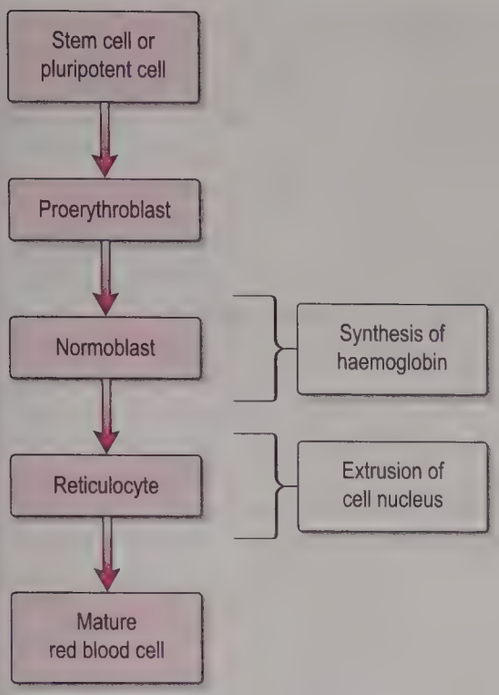

Fig. 11.1 Maturation of red blood cell.

Function Oxygen is carried in the form of oxyhaemoglobin by the red blood cells from the lungs to the tissues. Carbon dioxide, as carboxyhaemoglobin, is transported from the tissues to the lungs.

Maturation (see Fig. 11.1) The total number of circulating red blood cells remains fairly constant at $3.9–6.5 \times 10^{12}$ cells/L (there is a slight variation between men and women) to ensure that the optimum amount of oxygen is available to the tissues. To ensure this number, the body has to maintain a balance between the number of cells produced and the number broken down.

The reticulocyte numbers are increased when there is a greater demand for red blood cells. Therefore, a reticulocyte count can be used as a measure of response to treatment for anaemia (a deficiency of haemoglobin in the blood due to a lack of red blood cells and/or haemoglobin content). Treatment should stimulate production of more reticulocytes.

The essential factors required for red cell production are:

- erythropoietin produced by the kidney
- iron — part of the haemoglobin molecule (see below)
- amino acids
- vitamins B_{12} and folic acid (both for DNA synthesis)
- vitamins B_6, thiamine, riboflavin, C and E
- intrinsic factor — for absorption of vitamin B_{12} from the gut
- thyroxine
- androgens
- adrenocortical steroids
- human growth hormone.

Haemoglobin is a complex molecule of haem and globin. The haem fraction is a combination of porphyrin and iron. The globin complex is composed of four polypeptide chains.

Life span The average life span of a red blood cell is 120 days. At the end of its life span, the cell is broken down in the bone marrow, spleen and liver by macrophages. The haemoglobin molecule is split into its major components: haem and globin. The globin is further split into amino acids, which are then stored in the body's amino acid pool. The haem is split into iron (which is stored in the liver and reused by the marrow) and porphyrin (which is converted to bilirubin). The bilirubin (insoluble in water and bound to albumin) is transported to the liver, converted into soluble bilirubin and excreted into the small intestine as a constituent of bile. From there, some is reabsorbed and excreted by the kidneys as urobilinogen. The majority of the bilirubin is excreted in the faeces as stercobilirubin.

Leucocytes (white blood cells)

There are three types of white blood cell:

- granulocytes
- lymphocytes
- monocytes.

Granulocytes are characterised by the presence of granules in the cytoplasm and are divided into three subtypes: neutrophils, eosinophils and basophils. Lymphocytes are subdivided into T lymphocytes and B lymphocytes.

Normal numbers and percentages of each type and subtype are given in Table 11.1.

Function White blood cells are involved in the defence of the body against microbes and other foreign antigens (see Ch. 16).

Maturation All white blood cells develop from the pluripotent stem cell in the bone marrow and mature

Table 11.1 Normal number of different subtypes of white blood cells

Type	Subtype	Normal value (cells/L)	Percentage of total	
Granulocytes		$2.5–8.0 \times 10^9$	40–75	
	Neutrophils	$2.0–7.5 \times 10^9$	40–70	Percentage of total white blood cell count
	Eosinophils	Up to 0.4×10^9	1–6	
	Basophils	$<0.1 \times 10^9$	<1	
Lymphocytes		$1.5–4.0 \times 10^9$	20–50	
	B lymphocytes		15–30	Percentage of total lymphocytes
	T lymphocytes		40–80	
Monocytes		$0.2–0.8 \times 10^9$	2–10	

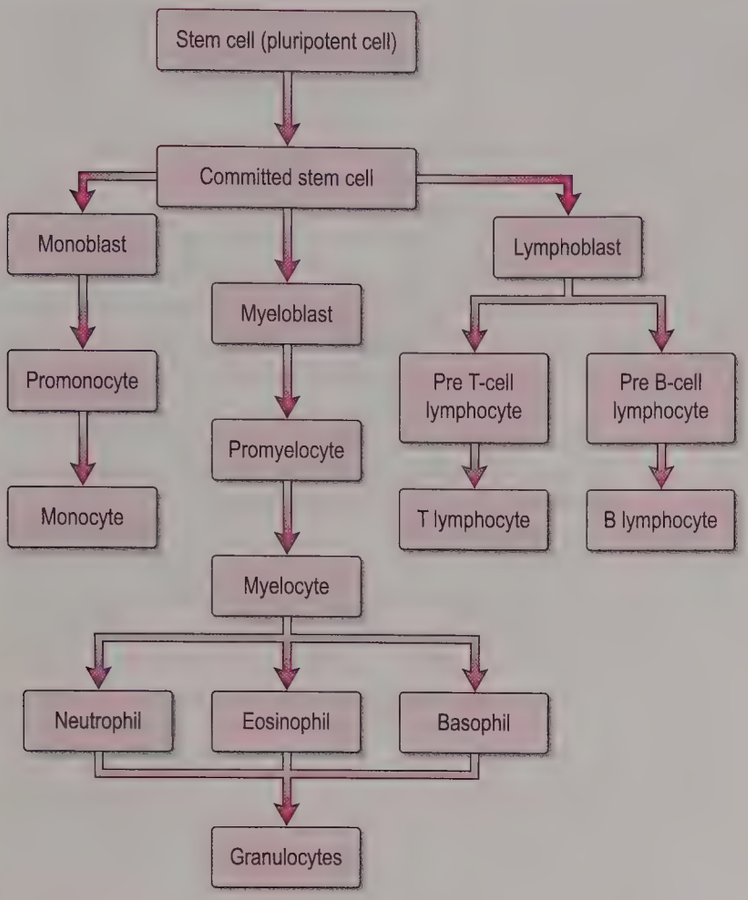

Fig. 11.2 Development of different types of leucocyte, each stage controlled by a specific growth factor.

through several stages as illustrated in Figure 11.2. Maturation is regulated by specific haemopoietic growth factors, e.g. granulocyte colony stimulating factor (GCSF), at each stage of maturation. Lymphocytes mature in either bone marrow (B lymphocytes) or the thymus (T lymphocytes) (see Ch. 16). Monocytes enter the tissues from the blood and mature into macrophages (scavenger cells in different tissues).

Life span The different types of white blood cell have variable life spans. Neutrophils, once they enter the blood, circulate for about 7 h and then migrate into the tissues, where they die after a few days. Lymphocytes have a variable life span, ranging from 100 days to several years. Monocytes, as macrophages, can survive for many years.

Thrombocytes (platelets)

Platelets are small, granular, non-nucleated blood cells that play a vital role in haemostasis (the arrest of bleeding). The normal concentration of platelets is 140–400 $\times 10^9$/L.

Function Platelets are involved in the first three phases of haemostasis:

- phase 1 — vasoconstriction of an injured vessel
- phase 2 — formation of platelet plug
- phase 3 — formation of fibrin clot.

The fourth and final stage — fibrinolysis, the dissolution of the fibrin clot — does not involve platelets.

During phase 1 of haemostasis, narrowing of the damaged blood vessel occurs in response to the release of powerful vasoconstrictors — serotonin and thromboxane A — by the platelets. This reduces blood flow and thus decreases the likelihood of the platelet plug being sloughed off. In phase 2, platelets adhere to the site of the damage and release adenosine diphosphate (ADP), which causes the platelets to adopt a spherical shape conducive to aggregation. In phase 3, a fibrin clot is formed. This involves the conversion of prothrombin to thrombin, which then acts on the plasma protein fibrinogen to form fibrin. This fibrin clot is soluble at first but becomes insoluble in the presence of calcium and clotting factor XIII (fibrin-stabilising factor).

The formation of fibrin in phase 3 is made possible by two cascades of events known as the extrinsic pathway, events outside the damaged blood vessel, and the intrinsic pathway, events inside the vessel (see Fig. 11.3). The extrinsic pathway is activated by the tissue damage. The intrinsic pathway is activated by exposed collagen. Each stage in the intrinsic pathway is regulated by a particular clotting factor. Together, the two cascades act on clotting factor X, which then activates the prothrombin.

Vitamin K, a fat-soluble vitamin, is required for the synthesis in the liver of the following clotting factors (Summerton et al 2002):

- factor II (prothrombin)
- factor VII
- factor IX (Christmas factor)
- factor X (Stuart factor).

Maturation Platelets arise from the pluripotent stem cell and mature into megakaryocytes, mainly regulated by thrombopoietin. The megakaryocyte then fragments into many platelets.

Life span Platelets circulate for 7–10 days before being destroyed.

Plasma

Plasma is the straw-coloured fluid part of the blood which is left after the cellular components are removed. It contains blood clotting factors. Serum is the term for the fluid which separates from blood when it coagulates. It contains none of the blood clotting factors. The main constituents of plasma are shown in Figure 11.4.

For further reading on the anatomy and physiology of blood see Waugh & Grant (2001) and Tortora & Derrickson (2006).

Blood groups

ABO blood groups

Red blood cells have specific antigens, agglutinogens, on the red cell membrane. These agglutinogens are referred to in terms of the ABO blood group system. A person can have either the A or B agglutinogen on the red blood membrane, or neither, or both. Agglutinogens are inherited and are present from birth.

The importance of these agglutinogens is apparent when one person is given blood from another person. A person

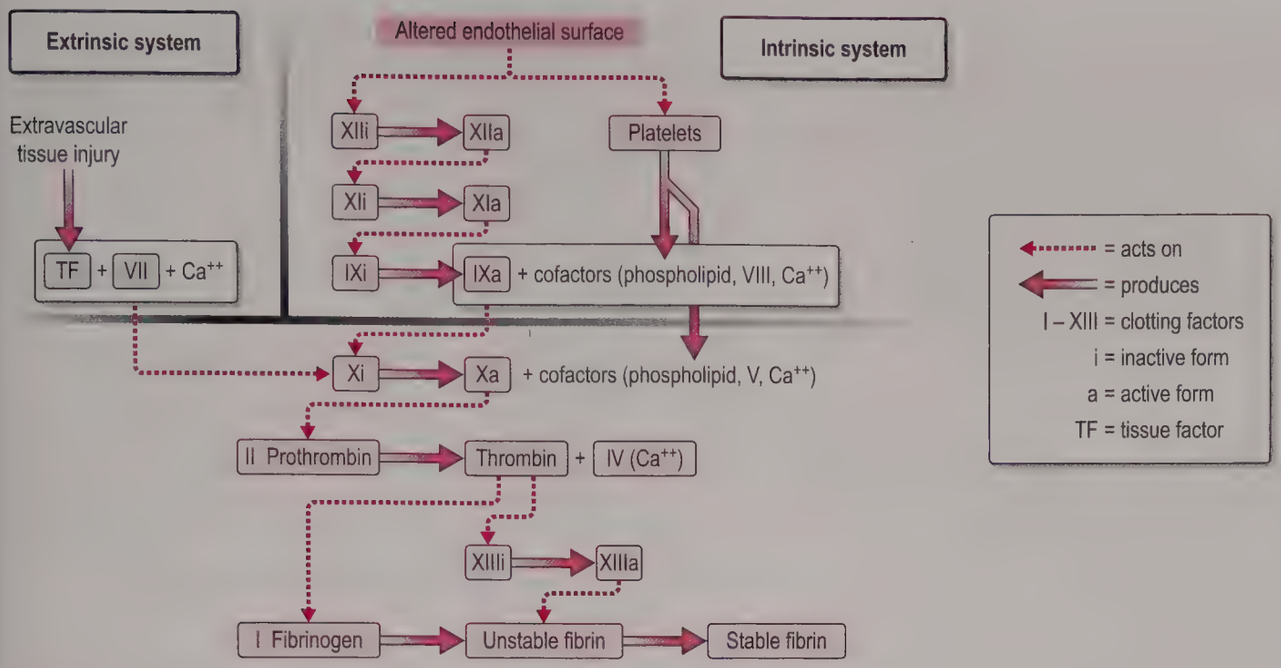

Fig. 11.3 Blood coagulation.

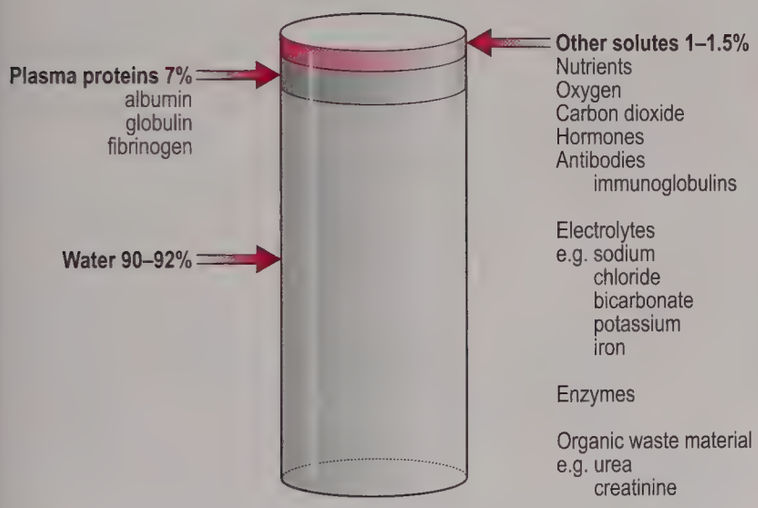

Fig. 11.4 The main constituents of plasma.

with the agglutinogen A (blood group A) has anti-B antibodies in the serum (antibodies are substances that cause clumping to occur when attached to particular antigens). A person with agglutinogen B (blood group B) has the anti-A agglutinin (or antibody). A person with both agglutinogens A and B (blood group AB) has no agglutinins, whilst a person with neither A nor B agglutinogens (blood group O) has both anti-A and anti-B agglutinins (see Table 11.2). Therefore, if a person is given a transfusion of blood from a different group, the red cells will clump together and haemolyse (break down). In a blood transfusion, it is the reaction between the donor's red cells and the recipient's serum, i.e. between the introduced agglutinogen and the agglutinin already present, which causes an adverse reaction which can be fatal. Thus, if the recipient's serum has anti-B agglutinin present, the donor's cells must be either blood group A or O.

Not only the red cells but also the white blood cells and platelets have ABO agglutinogens. Therefore, if a patient is to receive a transfusion of other cellular components, the correct blood group should be used.

Table 11.2 Antigens and antibodies present in different blood groups

Blood group	Agglutinogen present on red cell membrane	Agglutinin present in serum
A	A	Anti-B
B	B	Anti-A
AB	AB	None
O	O	Anti-A and anti-B

The Rhesus factor

In the UK, 85% of the population have a second important class of antigen present on their red cells: the Rhesus (Rh) factor (Craig et al 2002). A person is either Rh-positive or Rh-negative. The antibody, anti-D, does not occur naturally in the plasma of Rh-negative blood, but stimulation to produce it can occur if a person receives a Rh-positive blood transfusion or if, during childbirth, red blood cells from a Rh-positive baby cross the placental barrier into the circulation of a Rh-negative mother. If the person is later exposed to Rh-positive red blood cells, agglutination and haemolysis of the red blood cells will occur. Blood to be transfused must therefore be carefully cross-matched for the Rh factor.

The Rh factor is only carried on the red blood cells.

Other blood groups

The ABO and Rh factor blood groupings are the most important blood classifications, but there are more than 12 other blood group systems which normally do not cause agglutination unless the patient requires multiple blood

Box 11.1

The importance of checking blood component compatibility

SHOT (Serious Hazards of Transfusion) annual report 2001/2002 warns that 71.7% of incidents reported involved the transfusion of wrong blood; 35% of these incidents occurred during bedside administration (SHOT 2003).

transfusions, e.g. patients who have had a massive haemorrhage or who have leukaemia; in such cases it may be necessary to ensure the donor's blood is compatible with other known antibodies in the recipient's serum.

Blood transfusion

A blood transfusion is the administration to one individual of blood donated by another individual. The practice of blood transfusion makes it possible to save lives when severe haemorrhage has occurred, when major surgery is required or when there is failure of the bone marrow to produce blood cells. Transfusion does, however, expose patients to the risk of potentially fatal complications, e.g. infection, haemolytic reactions (see p. 491) or receiving a mismatched unit of blood (see Box 11.1).

For further guidelines about safe transfusion of blood, see Gray & Illingworth (2004).

Under some circumstances, patients may need blood products to be cytomegalovirus (CMV) negative. CMV is a herpes viral infection which causes few symptoms in the healthy person. However, for patients who are immunocompromised, and especially those undergoing bone marrow/stem cell transplantation, exposure to the virus may lead to potentially fatal complications such as pneumonitis, liver dysfunction and graft failure.

Transfusion of blood products carries the risk of transfusion-associated graft-versus-host disease (TA-GVHD) whereby transfused lymphocytes engraft in the recipient — a very rare possibility in immunocompetent patients, but may occur in the immunocompromised patient, especially those with haematological diseases. Irradiating blood products will prevent this potential complication.

For further information and guidelines to indicate which patients should receive irradiated blood products, see Wilkins (2000).

Blood transfusion products readily available are given in Table 11.3.

Cross-matching

Before a unit of blood or blood component is transfused into another person, the blood from the donated unit must be cross-matched with that of the recipient's serum, i.e. the blood from the donated unit is mixed in the laboratory with a sample of the recipient's serum. The donor's blood should be of the same ABO blood group to prevent a potentially fatal agglutination reaction.

A Rh-negative recipient should receive Rh-negative blood. Details of the results of the cross-matching are recorded along with the blood unit number on the documentation sent with the unit of blood when the blood transfusion is given. This documentation is retained after the unit of blood has been used in case of any transfusion reaction (see p. 491 for the nursing care of patients receiving transfusions). Patients may be able to donate their own red cells prior to elective surgery, i.e. autologous transfusion, to avoid the risk of receiving an allogeneic blood transfusion.

11.1 Attend a blood donor session to find out about:

(a) the categories of people who are allowed to donate blood
(b) the screening process for blood donations
(c) the process of donating a unit of blood
(d) the care of the donor before, during and after the procedure
(e) how the blood is stored after donation.

DISORDERS OF RED BLOOD CELLS

These disorders can be divided into:

- disorders in which there is a deficiency of haemoglobin in the blood due to lack of red cells and/or reduced haemoglobin content
- disorders due to blood loss
- disorders due to excessive production of red blood cells.

ANAEMIAS

Anaemias are those disorders in which there is a reduction in the haemoglobin concentration in the blood. There are three main types of anaemia (see Fig. 11.5):

- anaemia due to decreased red cell production, resulting from:
  — reduced bone marrow function
  — lack of essential factors for cell maturation
- anaemia due to blood loss
- haemolytic anaemia — due to excessive destruction of the red cells.

Anaemia is extremely common worldwide; the overall incidence of iron deficiency affects 30% of the world population (Parker-Williams 2000). Anaemia is defined as a haemoglobin level of less than 13.5 g/dL blood for men and less than 11.5 g/dL for women (Hoffbrand et al 2001).

The anaemias are a complex group of red blood cell disorders, which may be:

- primary, i.e. the presenting illness
- secondary to another disease, e.g. infection, cancer, gastrointestinal malabsorption syndrome, chronic renal failure, or an inherited disorder of haemoglobin synthesis or formation
- acquired:
  — iatrogenic, e.g. medication-induced
  — environmental, e.g. benzene exposure
  — nutritional, e.g. iron, protein, vitamin B_{12} or folate deficiency.

Table 11.3 Blood transfusion products available

Product	Indications for use	Special points
Whole blood	Acute, severe bleeding requiring replacement of red blood cells and plasma and clotting factors	Stored at 4°C Remains viable for 35 days Platelets and clotting factors have much reduced viability
Fresh whole blood	As above	Blood <24 h old, therefore more likely to contain viable clotting factors
Red cell concentrate	Replacement of red blood cells only. Therefore used when haemoglobin level is low	Up to 200 mL plasma removed per 500 mL blood
Washed red cells	As for red cell concentrate. Specially prepared to remove antigens	Prevents anaphylactic transfusion reactions
Frozen red cells	As for red cell concentrate	Storage life span lengthened, therefore useful for rare blood groups
Platelet concentrate	Patients with platelet count $<20 \times 10^9$ cells/L but not actively bleeding	Platelet units from blood banks contain platelets from many units of blood, therefore there are frequent reactions. Patient may require i.v. hydrocortisone + i.v. chlorphenamine prior to transfusion. Stored at 20°C. Viability of platelet concentrate only 24 h. Never place in fridge
Other blood components:		
Fresh frozen plasma	Hereditary or acquired bleeding disorder Volume replacement Liver disease Disseminated intravascular coagulation	Frozen within 6 h of cell separation and viable for 1 year. Once thawed, use within 30 min
Cryoprecipitate (factor VIII, fibrinogen)	Haemophilia	From fresh frozen plasma. Last part to thaw is cryoprecipitate
Factor VIII	Haemophilia A	From fresh frozen powder (half-life 12 h)
Factor IX	Christmas disease	
Human immunoglobulin	Passive immunity, especially immunosuppressed patients	
Albumin solution	Hypoproteinaemic oedema, ascites, acute volume replacement	

Anaemia is found in all age groups. At each developmental stage there are potential dietary reasons for the occurrence of anaemia, as follows (Craig et al 2002):

- In infancy, anaemia can occur if a poor diet is provided, especially at the time of weaning
- In adolescence, a growth spurt may cause anaemia, particularly if during this period 'fad eating' leads to an inadequate intake of the essential nutrients for red cell formation (see Ch. 21)
- Women of child-bearing age may become anaemic due to menstrual blood loss for which inadequate dietary compensation is made
- In pregnant women, extra demands for red cell synthesis may lead to the development of anaemia
- In older people, poor eating habits resulting from difficulty in shopping, reduction in income, depression, poor dental hygiene or badly fitting dentures can all lead to a reduced intake of essential nutrients for red blood cell formation.

Many people are diagnosed as anaemic only by chance when they seek medical advice for an unrelated symptom or attend a health clinic, e.g. antenatal or occupational health, for a routine medical examination. It is therefore likely that nurses working in any area of community or hospital nursing will care for people with anaemia.

11.2 In a group, discuss the social, cultural and environmental factors which might contribute to the development of anaemia.

PATHOPHYSIOLOGY

Anaemia occurs when the oxygen-carrying capacity of the red blood cells is reduced. Its symptoms all stem from a lack of oxygen in the tissues. Their severity depends on two main factors:

- haemoglobin concentration, i.e. oxygen-carrying capacity of the red blood cell
- ability of the person to adapt to lower oxygen concentration. Some patients with chronic anaemia live

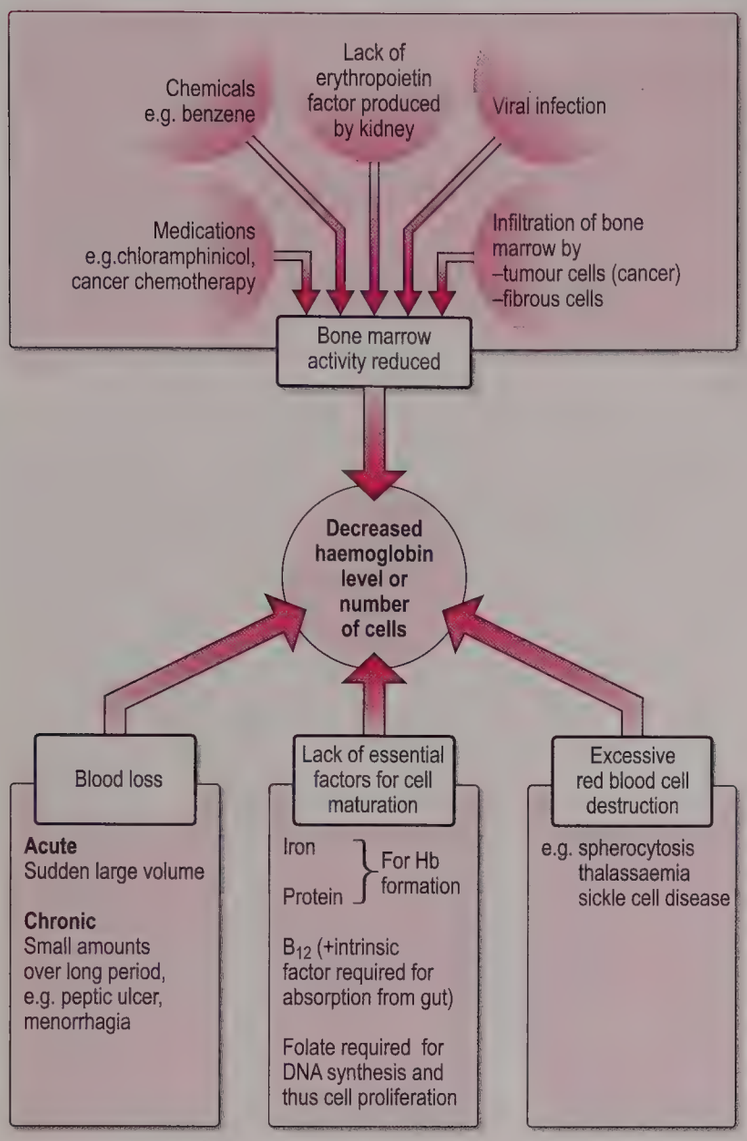

Fig. 11.5 Main types of anaemia.

very active lives with a haemoglobin level that in other people would cause severe symptoms.

Common presenting symptoms The clinical features of anaemia are diverse and may depend on other factors, e.g. the underlying cause of the anaemia. Each type of anaemia has specific clinical features but there are common presenting symptoms, as follows:

- *Tiredness and lethargy* — a very subjective symptom for which the person is unlikely to consult a general practitioner (GP). Some people have a variety of explanations for tiredness, e.g. the season, social life, stress and workload
- *Breathlessness* — a compensatory mechanism to overcome low oxygen concentration, which may be present only on exertion. The person may dismiss this symptom, thinking they are just 'not fit'
- *Palpitations* — due to the heart increasing its rate to increase blood flow to tissues
- *Loss of appetite* — often an unexplained feature but may be due to dysphagia, sore mouth due to epithelial lining fragility, or sheer fatigue
- *Dysphagia* — difficulty in swallowing, and sore mouth
- *Oedema* of ankles, especially at the end of the day — due to a degree of heart failure
- *Dizziness, fainting and dimness of vision* — due to lack of oxygen to the brain
- *Headache and lack of concentration* — resulting from insufficient oxygen supply to the brain
- *Angina and/or intermittent claudication* — because of impaired blood flow to peripheral and/or coronary arteries; this is especially likely in older people
- *Bleeding* — rectal bleeding, haematuria, haemoptysis or menorrhagia.

MEDICAL MANAGEMENT

To diagnose anaemia and establish its cause, it is necessary to clarify the patient's symptoms and discover if there are any other symptoms that the person may not consider significant or may not wish to volunteer.

History and examination Careful questioning about the patient's state of health in the present and recent past and about the use of medication, e.g. aspirin, which may cause bleeding, or phenytoin, which causes folate deficiency, may help to uncover the cause of the anaemia. A determination of the person's social circumstances and dietary intake may also be important.

An accurate and detailed dietary history is often difficult to obtain but may reveal deficiencies in iron, folic acid or vitamin B_{12}. This history may be taken by the GP, practice nurse or dietitian. Questioning about social background should include consideration of:

- financial circumstances
- home circumstances
- work environment, including exposure to harmful substances.

Clinical examination may reveal:

- paleness of skin which may be difficult to assess as many people are pale but not anaemic
- paleness of mucous membranes, e.g. conjunctiva, palms of hands, buccal cavity
- signs of underlying disease, e.g. cancer, hypothyroidism or infection
- signs of complications of anaemia, e.g. cardiac failure, glossitis, stomatitis, jaundice due to haemolytic breakdown (see p. 497)
- signs of pregnancy.

Investigations used in the diagnosis of anaemia include the following:

Blood tests Not all of the following will be relevant for all patients:

- *Full blood count* — to establish total number of red cells, white cells and platelets. The result is compared with normal values (see Appendix 2)
- *Haemoglobin concentration* — a level 10% below normal is usually considered a sign of anaemia
- *Haematocrit or packed cell volume (PCV)* — proportion of total blood volume which consists of red cells. Dehydrated patients have a high PCV as the plasma volume is reduced

- *Reticulocyte count* — a small percentage of reticulocytes are normally present in blood. A larger percentage may indicate increased bone marrow activity if the red blood cell count is low (see p. 481 on maturation of red cells)
- *Mean corpuscular volume (MCV)* — measures the average red cell volume
- *Mean cell haemoglobin (MCH)* — measures the average concentration of haemoglobin. A low MCH may be found when haemoglobin is low
- *Blood film* — examination of blood cells under the microscope to detect any abnormality in size or shape
- *Erythrocyte sedimentation rate (ESR)* — measures the speed at which red cells settle in uncoagulated blood left standing for 1 h. The height of the plasma column above the sedimented blood cells is measured (in mm) and compared with normal height. ESR may be raised because of an underlying problem causing the anaemia, e.g. infection.

Bone marrow aspiration This is the removal with a special needle of a small quantity of bone marrow which can then be mounted on slides and stained for examination under a microscope. This is not done routinely but is indicated if the anaemia is severe or has no apparent cause, or if there is evidence of another blood disorder such as aplastic anaemia or leukaemia (see Box 11.2).

Treatment The type of treatment given for anaemia will depend on the cause and severity of the condition. A few patients will need to be hospitalised but most can be treated in the community by their GP. The treatment may involve medication and health education. Blood transfusions may be needed either initially or repeatedly over a period of time. Intervention will also include treatment of the underlying cause of the anaemia.

Treatment may be short term (a few weeks), long term (months or years) or, as in the case of pernicious anaemia, lifelong. Follow-up care for all anaemic patients is important to encourage adherence to the medication regimen and to prevent recurrence and long-term effects. This care may be provided by the GP or at an outpatient clinic.

NURSING PRIORITIES AND MANAGEMENT: Anaemias

As the anaemias are such a diverse group of disorders, nursing intervention can take a variety of forms. It is vital that the patient is considered as an individual and that psychological, social and environmental concerns are taken into account along with the medical considerations pertinent to the specific form of anaemia.

Certain nursing interventions will be common to all patients. The first task to be carried out is an assessment of the patient's background, illness, needs and goals. Following assessment, a treatment plan will be agreed between the patient and the health care team.

Life-threatening complications

The patient may present with any of the following potentially life-threatening problems:

- cardiac failure
- breathlessness
- shock.

These complications may arise if there has been severe blood loss over a short period of time or if a chronic condition suddenly enters an acute phase. This is more likely to occur in individuals who have other conditions such as hypertension, chronic obstructive airways disease (COAD) and/or pre-existing chronic blood loss (see Chs 2, 3 and 18).

Box 11.2

Bone marrow aspiration

Purposes
- Diagnosis — to examine cell populations and thus determine type of anaemia, leukaemia or lymphoma
- Monitoring — to assess progress of disease and response to treatment

Sites
Red bone marrow is found in the cavities of the flat bones of the adult, e.g. skull, clavicle, scapula and iliac crest. The site usually chosen (for ease of access to minimise trauma to nearby structures) is the iliac crest — left and right, anterior and posterior.

The nurse's role
The patient may be anxious about this investigation, especially if there is awareness that the results may show a malignant condition. This anxiety may be heightened if the patient has been talking with others who have undergone the procedure.

Providing the patient with information on all aspects of the test — the use of premedication and local anaesthetic, the site to be used, the degree of discomfort to be expected, the time that it will take, and when the results will be reported — will help to reduce anxiety.

It is the policy of some doctors, especially where repeated aspiration will be required, to give a sedative such as lorazepam or a light general anaesthetic.

The individual may undergo the procedure as an outpatient, inpatient or in a day ward. Whatever the setting, the nurse's role will include:

- Assessing the patient's understanding of the test and providing more information if necessary
- Preparing the equipment
- Ensuring that the patient is comfortable and is positioned correctly
- Observing the patient throughout the procedure and drawing attention to any change in condition
- Assisting the doctor
- Applying a pressure dressing and making the patient comfortable after the procedure
- Inspecting the aspiration site frequently for haemorrhage or haematoma formation
- Documenting the patient's response to the procedure
- Preparing the patient for discharge by explaining care of puncture site, what discomfort may be expected, who to contact if ill-effects arise, when results will be available and timing of the next appointment.

Possible complications
- Haemorrhage — patient's platelet count should be checked before aspiration
- Infection

Major problems of nursing anaemic patients

Tiredness

Anaemic patients will tire easily because of poor oxygenation of cells and tissues. Patients with severe anaemia will be exhausted after even the slightest exertion. It is important that their daily routine in hospital or at home ensures periods of rest. If cardiac failure is evident, they may need to be nursed in bed or in a chair. The nurse should be aware of the potential problems of immobility, paying particular attention to pressure areas. Such patients may require assistance with personal hygiene and dressing. They should be reassured that their tiredness is not imaginary but is part of the anaemia and that it will lessen as treatment progresses.

Breathlessness (see Ch. 3)

The breathlessness may be mild, arising only on exertion, or it may be a major problem causing great distress. The most important aspects of nursing the breathless patient are to ensure maximum perfusion of oxygen to the tissues and to reduce the patient's distress. This can be achieved by nursing the patient in an upright position (to allow maximum lung expansion and use of accessory respiratory muscles), administering oxygen as prescribed, explaining to the patient the reason for the breathlessness and giving reassurance that it will lessen as the anaemia improves.

Breathlessness, if incapacitating, will require the nurse to assist the patient with personal hygiene, changing position in bed and mobilisation.

Nutrition

The anaemic patient will require a high-protein diet which includes all the nutrients necessary for red cell production (see p. 481). Breathlessness, a lack of energy to shop and prepare food, a sore mouth and dysphagia may all contribute to anorexia. A sore mouth can be especially distressing and the nurse will need to carry out an initial evaluation using an assessment tool such as that described in Beretta (2003). Care should include not only that which will improve and heal the mouth but also relevant health education about oral hygiene and care of dentures, e.g. use of a soft toothbrush, regular mouthwashes and prevention of dry and cracking lips (Jamieson et al 2002) (see Ch. 15).

It will be necessary for anaemic patients who have a low income and/or a poor understanding of nutrition to receive guidance in budgeting and the components of a balanced diet as well as advice about social security allowances. The multidisciplinary team may therefore include a dietitian and a social worker.

Other important considerations include dietary restrictions deriving from the patient's cultural background and/or spiritual beliefs. Dietary restrictions may also be imposed by a pre-existing medical disorder such as diabetes mellitus. Older patients may have ill-fitting dentures which may lead to reliance on a poorly balanced 'soft' diet. In such cases, referral to a dentist may be appropriate.

Safety

Giddiness, faintness, light-headedness and sensitivity to cold may make the anaemic patient prone to injury. Since the body responds to poor oxygenation by preserving the blood supply to the essential organs, anaemic patients will have poor peripheral circulation and, consequently, fragile skin. The reduced attention span typical of anaemic patients will also make them vulnerable to falls, minor injuries and hypothermia. Anaemic patients should be warned against changing position suddenly, especially from lying to standing, and should be given instruction on first aid for minor injuries and on the prevention of hypothermia (see Ch. 22).

Skin integrity (see Chs 12 and 23)

The anaemic patient's reduced oxygen and nutrient supply to the skin increases the risk of pressure ulcers. Hypoxic skin will not necessarily break down quickly, but if damaged it will take longer than usual to heal. When the patient's mobility has been impaired, either as a result of the anaemia or because of a concurrent condition, e.g. arthritis, the nurse must be alert to the importance of maintaining skin integrity. An initial and continuing assessment of all pressure points should be made using such tools as the Waterlow scale (see p. 851). Once the patient's level of risk of developing pressure ulcers has been determined, an appropriate intervention should be planned. Prevention of pressure ulcers is likely to include ensuring that the patient's position is changed 2-hourly, the use of appropriate pressure-relieving devices and instructing the patient about the importance of regularly changing position.

Communication

Anxiety and fear may present a barrier to communication by preventing the patient from asking for information about diagnosis, prognosis and treatment. The patient's physical condition, e.g. breathlessness and sore mouth, may also impede communication. The nurse caring for anaemic patients must be aware of these potential difficulties and of the effect that they can have upon patient–staff relationships.

The nurse should assess actual and potential communication difficulties and help the patient and the health care team to anticipate and overcome obstacles. The patient should be encouraged to voice fears and should be given the appropriate reassurance and information. Here, the nurse should try to involve other relevant members of the team. The nurse should be receptive to the patient's non-verbal as well as verbal messages and, in doing so, anticipate those times when support and reassurance will be needed.

Anxiety

Prior to diagnosis, the anaemic patient may fear the presence of a life-threatening illness, particularly if symptoms such as breathlessness, palpitations and chronic headaches have been experienced. The disorientation, confusion and general slowing of intellectual responses arising from cerebral hypoxia can be especially distressing. Explanation of the causes of these symptoms and reassurance that they should improve as the anaemia responds to treatment will help to reduce the anxiety suffered by both the patient and the family.

Iron deficiency anaemia

Iron deficiency anaemia is the most common anaemia worldwide. It affects an estimated 600 million people (Craig

et al 2002) and is recognised as one of the most prevalent diseases of nutritional origin in developing countries (Mehta & Hoffbrand 2000). The onset of this form of anaemia is usually insidious, taking place over a period of months. This is explained by the fact that iron stored in the body is usually reused after the breakdown of red blood cells and only a very small proportion is lost (less than 1 mg/day) through hair, urine, faeces and sweat (Mehta & Hoffbrand 2000).

PATHOPHYSIOLOGY

Iron is part of the haem component of the haemoglobin molecule: each haemoglobin molecule is composed of four molecules of haem with one ferrous ion, which is the oxygen carrier that transports oxygen from the lungs to the tissues (Tortora & Derrickson 2006).

A typical Western diet contains 10–15 mg of iron/day, but only 5–10% is absorbed (Mehta & Hoffbrand 2000). The ferrous form is more soluble than the ferric form; a low pH in the duodenum maintains iron in ferrous form, the form in which it can be absorbed from the gut. Vitamin C, present in fresh fruit and vegetables, enhances absorption.

Iron deficiency anaemia may be caused by:

- inadequate intake, i.e. poor diet
- increased iron requirement, e.g. in pregnancy
- lack of gastric acid, e.g. following total gastrectomy or gastric atrophy
- duodenal or jejunal malabsorption.

Common presenting symptoms As the onset of iron deficiency anaemia is usually very gradual, the patient may not consult their doctor until some time after symptoms have begun to appear. The most common presenting symptoms are tiredness and pallor, but any of the other general symptoms of anaemia (see p. 486) may be apparent. Symptoms specific to iron deficiency anaemia may include:

- painless glossitis — smooth, raw tongue
- angular stomatitis
- koilonychia — brittle, spoon-shaped nails
- dysphagia and glossitis; with the formation of a pharyngeal web (5–15% of cases), also called Paterson–Kelly syndrome (Palmer & Penman 2002)
- atrophic gastritis and achlorhydria
- pica — a strong desire to eat unusual substances, e.g. coal.

MEDICAL MANAGEMENT

History and examination The patient may give a history suggestive of chronic blood loss, e.g. menorrhagia, and examination may reveal general signs of anaemia.

Investigations Blood samples will be taken for such tests as full blood count, haemoglobin level, blood film, MCV, MCH, serum iron and total iron-binding capacity (TIBC) (see Appendix 1). Estimates of ferritin, an iron storage protein, distinguish iron deficiency anaemia from that caused by chronic blood loss. These tests can be done in a GP's surgery. Other investigations, e.g. faecal occult blood and endoscopy, may be undertaken to establish the cause of the deficiency. Such tests will be selected according to the patient's symptoms and medical history. Bone marrow aspiration is rarely performed if iron deficiency anaemia is present, but will show a bone marrow with no iron stores (see p. 487).

Treatment If dietary adjustment is insufficient to correct the anaemia, medication is given and, in very severe cases, blood transfusion is carried out.

Medication Iron supplements will be prescribed, usually in the following forms:

- *Oral iron supplements* — usually ferrous sulphate 200 mg three times a day before food. Medication should be continued for 3–6 months after the haemoglobin level has returned to normal to build up iron stores (Craig et al 2002). Side-effects, which include constipation, nausea, abdominal pain and diarrhoea, often lead to poor compliance. Alternative iron preparations which may be better tolerated, but which are more expensive, include ferrous gluconate and ferrous fumarate.
- *Intramuscular iron injections*. These are given only where there is proven malabsorption syndrome or poor compliance. Administration of i.m. iron via the 'Z track' technique prevents or minimises back-tracking of iron and skin discoloration (Skinner 1998).

Blood transfusion If the anaemia is very severe (less than 7 g/dL), a slow infusion of red cell concentrate will be administered. However, there is a danger, particularly in older or very young patients, of blood volume overload leading to cardiac failure.

NURSING PRIORITIES AND MANAGEMENT: Iron deficiency anaemia

Many of the general nursing considerations for the care of anaemic patients (see pp. 487–488) are relevant to the treatment of iron deficiency anaemia. Patients with this condition will most likely be cared for by a community nurse.

Nursing considerations

Blood transfusions

A few patients with iron deficiency anaemia will require a blood transfusion (see Case History 11.1). This measure may be interpreted by the patient and family as a sign that the condition is very grave; therefore, it is important that the nurse clarifies the reason for the transfusion, explains what is involved, and gives reassurance that the procedure is safe. Many people fear being infected with a transmittable disease, especially AIDS, or hepatitis C, and it may be necessary to explain the screening procedures performed on all blood donations. Practising Jehovah's Witnesses will refuse blood transfusions (see Box 11.3). Some Muslims may be reluctant to accept a blood transfusion and may wish to consult their families or a religious leader before agreeing to the procedure.

The nurse must be familiar with local policies for prescribing and checking blood products prior to transfusion to minimise the risk of administering incompatible blood. Any doubt about the unit of blood to be given should be referred to the haematology laboratory medical staff.

CASE HISTORY 11.1
Mrs B

Mrs B, a frail lady aged 82 years, has been admitted to hospital as an emergency after collapsing at home. She used to enjoy an active social life until her husband died a year ago. Since then her family and friends have noticed that she has become withdrawn and depressed and rarely goes out except to shop.

Mrs B has always enjoyed good health, until recently. On admission to hospital she admitted that over the past few months she has become increasingly tired and breathless when she climbs stairs or walks uphill. She has noticed that her ankles tend to swell, especially in the evening. She also finds that she has become forgetful; her neighbours have noticed that she appears confused at times.

A blood test has revealed that Mrs B has a haemoglobin level of 7 g/dL blood, and other blood test results have proved that she has an iron deficiency anaemia. Mrs B has been prescribed three units of red cell concentrate to be given prior to any further investigations of the iron deficiency anaemia. Her nursing care is outlined in Nursing Care Plan 11.1.

Box 11.3

Jehovah's Witnesses and blood transfusions

Devout Jehovah's Witnesses believe that it is against God's law to receive transfusions of blood or blood products. This belief is based on three biblical references: Genesis 9: 4; Leviticus 17: 14; and Acts 15: 28–29 (Jehovah's Witness 2003).

If a Jehovah's Witness requires a blood transfusion as an urgent or essential part of treatment, they or their next of kin will need to be approached by the medical practitioners and informed of the gravity of the situation. If the treatment is refused, this must be documented. Alternative ways of supporting the patient should be considered, e.g. autologous transfusion or drugs.

Each unit of blood must be administered at the prescribed rate and correct temperature. Close observation of the patient in the first 15 min of each unit is essential as this is when transfusion reactions are most likely to occur (see Nursing Care Plan 11.1).

Patient education

By helping the patient to understand the nature of the disorder and come to terms with the fact that, although the anaemia is not a life-threatening illness, it may become very severe if left untreated, the nurse will encourage acceptance of treatment.

The patient will need to learn which foods are rich in iron and may need advice on budgeting for a well-balanced diet. By assessing the patient's perception of the problem, level of knowledge and sociocultural background, the nurse can ensure that the advice offered is relevant and comprehensible. Referral to a social worker, e.g. for advice about social security benefits, may be appropriate.

Careful and clear instruction should be given to reinforce the doctor's and pharmacist's directions regarding medication. Important points to emphasise are:

- how frequently the medication should be taken
- that it is to be taken before food
- the possible side-effects of constipation and indigestion and how to overcome them; to avoid undue alarm, the patient should be warned that oral iron supplements will turn the stools black
- safe storage
- the importance of the continuation of medication and the importance of follow-up.

In certain circumstances when the patient is unable to take oral iron preparations, daily administration of i.m. iron may be necessary for a period of about a week. The patient needs to trust both the value of this short-term therapy and the skill of the practitioner, as the possible side-effects of an unpleasant taste in the mouth, palpitations and potential pain on administration could easily result in reluctance to continue treatment.

Discharge planning

If the person has been hospitalised for treatment, the following considerations should be discussed before discharge:

- socioeconomic conditions at home
- social services available, e.g. home care assistants and lunch clubs, if family members are unable to help
- the importance of a follow-up appointment with the consultant or GP
- the importance of taking the prescribed medication.

In older people, there is often a link between recent bereavement (i.e. in the last 6–12 months) and the onset of iron deficiency anaemia, as loneliness, grief and depression may lead to self-neglect. This problem may be accentuated if the bereaved person also has difficulty with personal care. Care needs to be taken that such patients are not returned to their former social circumstances without the necessary follow-up and support by the GP, health visitor, social worker or grief counsellor.

11.3 A 72-year-old widower is admitted to hospital with general tiredness, breathlessness and mild congestive heart failure. He is diagnosed as having iron deficiency anaemia. His wife died 6 months ago and his only daughter, who is married and has two young children, lives a considerable distance away.

With regard to the patient's discharge:

(a) identify potential problems
(b) discuss how these might be resolved
(c) identify what community services might be required.

Megaloblastic anaemias

These anaemias stem from a lack of one or more of the essential factors for the synthesis of DNA, resulting in a reduction in red blood cell proliferation. There are two types of megaloblastic anaemia (see Table 11.4):

- folate deficiency
- vitamin B_{12} deficiency.

Nursing Care Plan 11.1 Care of Mrs B during blood transfusion (see Case History 11.1)

Nursing considerations	Action	Rationale	Expected outcome
1. Anxiety (a) About cause of anaemia	• Reduce anxiety and stress of receiving blood transfusion by explaining and clarifying information given	Information given about procedures and care reduces anxiety and discomfort	Appear calm, not anxious
(b) About safety of blood transfusion	• Reassure Mrs B by explaining screening and cross-matching of blood	Mrs B may fear receiving infection from donor, especially HIV, AIDS or hepatitis B virus. Fear of receiving wrong blood group	Accept blood transfusion
(c) About possibility of complications	• Reassure Mrs B she will be observed and monitored frequently for any signs of complications. Tell her she must inform nurses of any new symptoms		
2. Correct blood given to correct patient	• Check blood unit details against blood transfusion cross-matching form, prescription and patient's details with a registered nurse as per local policy. Document blood unit transfused	Prevention of wrong blood being given to wrong patient, with possible incompatible reaction	Correct blood given to correct patient as detailed on prescription sheet
3. Condition of blood to be transfused is optimal	• Ensure blood stored at correct temperature prior to commencing transfusion. Blood transfusion is commenced within 30 min of removal from special refrigerator. Blood is not artificially warmed (unless directed by doctor because of special antibodies)	Blood not stored at correct temperature may undergo haemolysis (red cell breakdown) Risk of microorganism contamination increased	Blood is given at correct temperature
4. Early detection of acute haemolytic transfusion reaction	• Record Mrs B's temperature, pulse and BP *before* starting and 15 min after start of each unit of blood and then as per local policy until completion of each unit	Signs and symptoms of blood transfusion incompatibility usually occur within 15 min of starting the unit of blood	Any symptoms or signs of incompatibility are detected immediately
	• Observe Mrs B for any restlessness		
	• Record and report any nausea or vomiting		
	• Observe and record any complaints of: – flushing – burning sensation in arm above cannula – chest tightness, headache or pain – dyspnoea – loin pain – lumbar pain

Nursing Care Plan 11.1 Care of Mrs B during blood transfusion (see Case History 11.1) *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
4. Early detection of acute haemolytic transfusion reaction (*Continued*)	• Report any signs or symptoms to doctor	Symptoms of pain in arm, chest, lumbar region and loin and dyspnoea are due to agglutination of red blood cells in blood vessels, causing obstruction to blood flow	
	• Summon doctor immediately if Mrs B develops circulatory collapse		
	• Stop blood transfusion if any signs or symptoms of incompatibility occur	Incompatible blood transfusion rarely causes sudden collapse	
	• Keep unit of blood and infusion-giving set if incompatibility occurs		
	• Return both to haematology laboratory	Blood will be further tested for cause of incompatibility. Mrs B's unit of blood may have been wrongly cross-matched or labelled or her red blood cells may have other rare antibodies which require special cross-matching	
5. Circulatory overload	• Monitor Mrs B's pulse, respiratory rate and blood pressure. Report any abnormal measurements		
	• Observe and report to medical staff any dyspnoea or wheezing		
	• Ensure transfusion is regulated at prescribed rate		
	• Measure urinary output		
	• Give furosemide as prescribed and monitor urinary output	Mrs B has developed some cardiac failure due to her anaemia and the transfusion could increase her blood volume to a level at which the cardiac failure deteriorates. It is important that signs of cardiac failure and pulmonary oedema are detected early. Furosemide, as a diuretic, will increase fluid output and thus reduce circulatory volume	Any signs of cardiac overload are detected immediately

Nursing Care Plan 11.1 Care of Mrs B during blood transfusion (see Case History 11.1) *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
6. Pyrexia	• Monitor temperature and pulse as in 4		
	• Report any abnormal temperature and pulse recordings to doctor	Fever can occur for unknown cause at start of each unit. Temperature falls if transfusion slowed. May occur 1.0–1.5 h after transfusion. Subnormal temperature which rises later may be a sign of infection	All episodes of abnormal temperature are recorded and reported. Any further action requested by doctor is implemented immediately
	• Report any chest pain or sign of infections		
	• Ensure blood used has been out of special blood fridge for maximum 30 min	To prevent blood temperature rise with the increased risk of growth of organisms. Greater risk of contamination by microorganisms	Blood unit always commenced within 30 min of removal from special blood fridge
	• Do not continue transfusion of a unit of blood after 4 h		
	• Report if transfusion rate becomes slow		
	• Administer any medications as prescribed, e.g. antipyretics, antibiotics		
7. Allergic reactions	• Observations of temperature and pulse as in 4	Allergic response to protein in the plasma	Any signs of allergic reaction are detected immediately and the appropriate action implemented
	• Observe for any skin rashes		
	• Observe for any oedema around eyes		
	• Observe for any signs of laryngeal oedema (see Ch. 3)		
	• Observe for shortness of breath		
	• Record and report any of above signs to doctor immediately. If symptoms are mild, slow transfusion. If severe, stop transfusion, treat patient for shock (see Ch. 18)		

Table 11.4 Causes of the megaloblastic anaemias

Type	Causes
Folate deficiency	Inadequate dietary intake Disease of upper small bowel, malabsorption or extensive surgical resection of small bowel Increasing body demands because of: • very active cell proliferation, e.g. in haemolytic anaemia or leukaemia (see pp. 496 and 501) • pregnancy Interference with folate metabolism by medications, e.g. methotrexate (see Ch. 31) Unexplained mechanisms, e.g. ingestion of alcohol and anti-epileptic medications, e.g. phenytoin and primidone
Vitamin B_{12} deficiency	Inadequate vitamin B_{12} in diet (especially vegans), pernicious anaemia Gastric surgery, gastric atrophy or intrinsic factor deficiency Disease of terminal ileum where vitamin B_{12} is absorbed, e.g. Crohn's disease (see Ch. 4)

Deficiencies of these two vitamins account for most cases of this type of anaemia. Vegans are at particular risk of vitamin B_{12} deficiency as B_{12} is only found in meat products. However, the commonest cause of vitamin B_{12} deficiency (80%) is pernicious anaemia (Hoffbrand & Provan 1997) due to a lack of intrinsic factor in gastric parietal cells. One in 100 people over the age of 60 have pernicious anaemia.

PATHOPHYSIOLOGY

Red blood cells are produced continually and have a life span of approximately 120 days (see p. 481). Folate and vitamin B_{12} are essential factors for the synthesis of DNA required by each cell (see Figs 11.6 and 11.7). If DNA synthesis is reduced (because of lack of folate or vitamin B_{12}), the cell nucleus is abnormal and this results in the normoblasts (see Fig. 11.1) becoming larger than normal (macrocytic). While macrocytes may contain a greater amount of haemoglobin than normal red cells, the total amount of haemoglobin will be reduced as the total number of red blood cells is reduced. There may also be large, primitive nucleated red cells (megaloblasts) in the peripheral blood.

For further reading on the role of folate in health, see Fox & Cameron (1995).

Common presenting symptoms Vitamin B_{12} and folic acid are required by all dividing cells. Therefore a deficiency of these factors not only affects red blood cells but also the gastrointestinal epithelium, giving rise to glossitis, anorexia, diarrhoea and malabsorption. It also causes spinal cord and peripheral nerve damage which can give rise to the following symptoms:

- paraesthesia (pins and needles or tingling)
- coldness or numbness in limbs
- ataxia (lack of coordination of movement, staggering)
- paralysis.

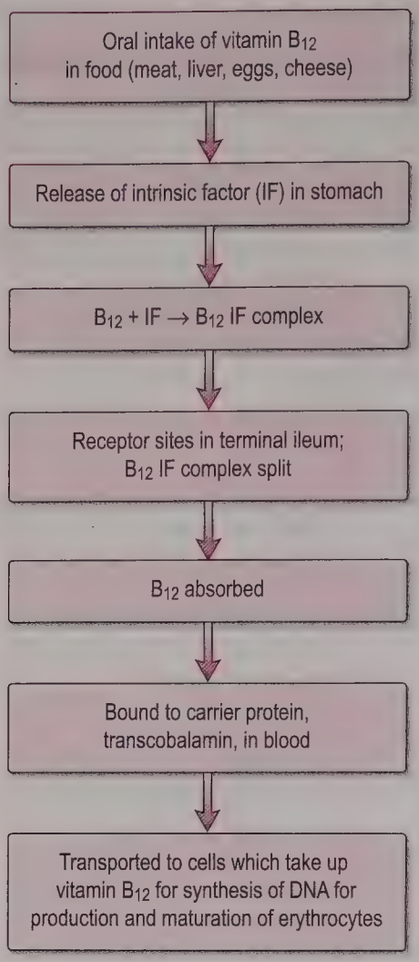

Fig. 11.6 Vitamin B_{12} absorption and transport.

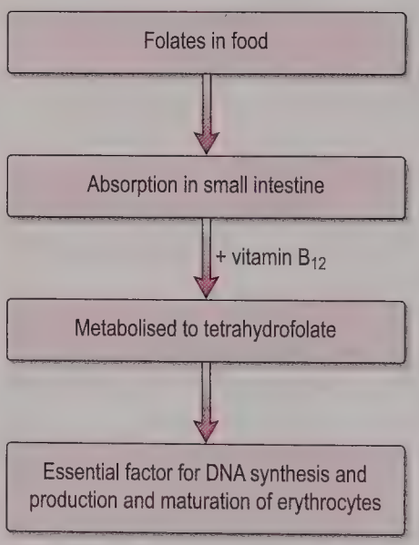

Fig. 11.7 Absorption and utilisation of folates.

For further reading on role of folate in prevention of neural tube defects in pregnancy, see Hoffbrand et al (2001).

MEDICAL MANAGEMENT

History and examination Medical investigation is similar to that for anaemia (see p. 486). However, in suspected

megaloblastic anaemia the doctor will be alert to the following specific features:

- glossitis
- angular stomatitis
- mild jaundice (lemon yellow skin pallor because of increased fragility of red cells)
- excess urobilinogen (due to excessive red cell breakdown)
- mild symptoms of malabsorption and weight loss
- evidence of possible increased need for either factor, e.g. pregnancy or vegan diet.

If a lack of vitamin B_{12} intrinsic factor (pernicious anaemia) is suspected, patients may present with the following neurological symptoms:

- paraesthesia, especially in toes
- symptoms of subacute combined degeneration of the spinal cord causing muscular weakness, loss of muscular coordination and paralysis. These symptoms are apparent in approximately 10% of all cases of pernicious anaemia and these neurological features may arise before other symptoms.

Investigations Specific diagnostic blood tests for megaloblastic anaemia include serum B_{12} levels and red cell folate level. Other investigations include:

- assessment of gastric parietal cell antibodies
- Schilling test (see Appendix 1)
- endoscopy
- bone marrow aspiration (see p. 487)
- neurological examination (see Ch. 9)
- past medical history for gastric or intestinal surgery, alcohol abuse or epilepsy
- possible pregnancy.

Treatment for megaloblastic anaemia is as follows:

- Folate deficiency — 5 mg folic acid daily for 4 months
- Vitamin B_{12} and intrinsic factor deficiency:
  - — injection of hydroxycobalamin 1000 mcg (1 mg) i.m. twice during the first week, then weekly until blood count is normal
  - — maintenance dose of hydroxycobalamin 1000 mcg (1 mg) i.m. every 3 months for life.

11.4 Reflect on the implications for the patient of the lifelong necessity for 3-monthly injections.

NURSING PRIORITIES AND MANAGEMENT: Megaloblastic anaemias

Folate deficiency

Individuals with folate deficiency are usually diagnosed and treated by a GP or at an antenatal clinic and are referred to a haematology outpatient department only if further tests are necessary, e.g. bone marrow aspiration. The setting for nursing intervention will therefore be a community health centre or the patient's home. Patient education with regard to diet and acceptance of medication will be the most important aspect of nursing care.

A patient with folate anaemia will need to know which foods contain folic acid, how to budget for these if income is low and how to avoid destroying folic acid in food preparation. The patient will also need to understand how to take folic acid supplements correctly. The nurse should also emphasise the importance of follow-up checks with the consultant or GP.

Nurses must be on the alert for patients who may be susceptible to folic acid deficiency, i.e. those whose diet is inadequate, those with extensive disease of the small intestine and those with increased folic acid requirements, and advise them as to how to prevent its occurrence.

Vitamin B_{12} and intrinsic factor deficiency

Patients may need to be admitted to hospital for diagnosis and treatment in the initial stages but most will be diagnosed by their GP. If the anaemia is not yet acute, treatment can be started immediately by a community or practice nurse, who will administer prescribed vitamin B_{12} injections. The nurse should bear in mind that the patient may be very breathless at first and will need some degree of assistance with personal care tasks (see p. 488) and support in adjusting to a regimen of regular injections. The patient and family should be encouraged to participate in the management of the anaemia, possibly by learning how to administer the hydroxycobalamin injections themselves.

Patients in the advanced stages of pernicious anaemia are rarely seen today. If cardiac failure and severe neurological problems do develop, major nursing interventions will be required (see Chs 2 and 9).

Aplastic anaemia

This form of anaemia results from the failure of bone marrow stem cells to mature and proliferate. In 20–50% of all cases of this very rare disease, onset can be connected with exposure to one of the following:

- chemical compounds, i.e. industrial chemicals, especially benzene
- medications, for example chloramphenicol and certain cytotoxic chemotherapeutic agents, e.g. busulfan, phenothiazines and anti-epileptic medication
- ionising radiation, whether therapeutic or industrial
- viral infection, notably hepatitis
- rarely bone marrow infiltration by disease, e.g. multiple myeloma, metastases from primary tumours.

The remaining 50–70% of cases are idiopathic, having no detectable cause.

PATHOPHYSIOLOGY

There is considerable reduction in the number of blood stem cells causing:

- lack of red blood cells: anaemia
- lack of white cells: leucopenia
- lack of platelets: thrombocytopenia.

These three conditions together are referred to as pancytopenia. In aplastic anaemia, the degree of anaemia, leucopenia and thrombocytopenia, and therefore the severity of the disorder, is variable.

Common presenting symptoms The onset of aplastic anaemia is often insidious: 1 or 2 months may elapse

between the individual's exposure to the causal agent and the development of symptoms. The presenting symptoms are the result of pancytopenia and include:

- general symptoms of anaemia
- infections, e.g. throat, upper respiratory tract
- bleeding, e.g. in the skin and mucous membranes, especially the gums.

MEDICAL MANAGEMENT

History and examination Medical investigation may uncover no abnormality other than the presenting symptoms; for example, careful examination may reveal no enlarged liver or spleen. However, questioning might bring to light the patient's exposure to chemicals or the use of over-the-counter medication. It may require very careful and extensive questioning to uncover the causative factor, which may have seemed trivial to the patient at the time. The recollections of family and friends may be of help.

Investigations will include:

- blood film and blood count to reveal pancytopenia
- bone marrow aspiration to reveal the degree of stem cell failure. This procedure gives a definitive diagnosis.

Treatment If the patient is not admitted to hospital on presentation, immediate admission to hospital occurs once a diagnosis of aplastic anaemia is made.

In mild to moderately severe cases, supportive therapy with blood and platelet transfusion may be given. Antibiotic therapy will be essential to treat any infections. Androgens are thought to stimulate bone marrow cell synthesis, e.g. oxymetholone orally or high-dose methylprednisolone, and may be tried (see Ch. 5). Other possible medications are antilymphocyte or antithymocyte globulin, ciclosporin and haemopoietic growth factors. However, the side-effects of these medications may cause problems, e.g. pyrexia, rashes, hypo- or hypertension, and nephrotoxicity (Howard & Hamilton 1997).

If the aplastic anaemia is severe or the above treatment is unsuccessful, allogeneic bone marrow transplantation will be considered as an urgent treatment.

NURSING PRIORITIES AND MANAGEMENT: Aplastic anaemia

Life-threatening complications

The nurse must be on the alert for the development of grave complications of aplastic anaemia. The nurse's role will therefore include:

- prevention of infections
- early detection of infections
- immediate implementation of nursing care of septic patients when infection is confirmed
- prevention and early treatment of bleeding.

Nursing considerations

Psychological state

The patient, the family and friends may experience feelings of guilt if and when the causative agent of the anaemia is identified; they may believe that they were to blame for the patient's contact with the toxin. The nurse must be sensitive to the patient's concerns as information is assimilated about diagnosis and prognosis and as the need for sudden transfer to hospital and, possibly, being nursed in protective isolation becomes evident (see Ch. 16). Some patients will not survive a year.

Patient education

It is vital to inform the patient how to prevent overexertion and to detect the signs of injury, bleeding and infection. The teaching programme will depend on the severity of the disorder and the patient's response to treatment and should include the family, friends and carers.

The nurse should also assess the patient's understanding of the reason for and importance of all medication, what action to take if medication is accidentally omitted and how to get new supplies in good time. A patient prescribed steroids, e.g. prednisolone, should understand that it is most important to continue taking them even if feeling ill. The patient should also be advised to inform any doctor or dentist about prescribed steroids and always to carry a card giving details of their medication.

The nurse will also need to advise the patient, family and any members of staff unfamiliar with caring for pancytopenic patients about reducing the risk of infection and haemorrhage. Information leaflets are invaluable in reinforcing all details given, as patients and carers will find it hard to remember everything.

Test coordination

The nurse will act as coordinator in the programme of diagnostic tests and will prepare the patient for stem cell bone marrow graft if this is to be performed. Further details on caring for profoundly pancytopenic patients are given in the section on nursing management of acute leukaemia (p. 505).

Rehabilitation

Rehabilitation begins even before the patient's discharge from hospital and must be planned in response to the potential for recovery, motivation and needs (see Ch. 34). The multidisciplinary team involved may include a physiotherapist, occupational therapist, dietitian, social worker, district nurse, health visitor, counsellor and psychologist.

Realistic goals must be set in discussion with the patient. Consideration must be given to avoiding the causative agent of the anaemia in the future. It may be necessary for the patient to change their job. This may require liaison between medical staff, the patient's employer and a social worker.

Discharge planning

Before discharge it will be important to discuss with the patient any fears or apprehensions to clarify details of who to contact if there are any further episodes of illness and to go over any written information provided.

Haemolytic anaemias

These anaemias result from the premature destruction of red blood cells, in response to either an inherited or an acquired

Box 11.4

Causes of haemolytic anaemias

Inherited
- Red cell membrane fragility, e.g. spherocytosis
- Haemoglobin defects
  - — structure: sickle cell
  - — synthesis: thalassaemia
- Red cell metabolism defect, e.g. glucose-6-phosphate dehydrogenase deficiency

Acquired
- Antibody attack, e.g. mismatched blood transfusion
- Direct cell injury
  - — traumatic, e.g. prosthetic heart valve
  - — chemical or medication-induced, e.g. sodium chlorate, vitamin K analogues, sulfasalazine (Salazopyrin), nitrates
  - — infection, e.g. bacterial, disseminated intravascular coagulation
- Paroxysmal nocturnal haemoglobinuria

defect. Many of the haemolytic anaemias are rare or very rare. The most common inherited anaemias are sickle cell disease and thalassaemia. The most common acquired forms result from direct cell injury following infection or medical treatment. Causes of haemolytic anaemias are listed in Box 11.4.

PATHOPHYSIOLOGY

In this type of anaemia, the life span of the red blood cells is reduced because of red blood cell fragility, leading to excessive breakdown. This results in a reduced oxygen-carrying capacity in the blood and thus hypoxia in the tissues. This causes stimulation of the production of erythropoietin, a growth factor which stimulates the bone marrow to increase erythropoiesis (see p. 481). A healthy person with mild haemolytic anaemia will not experience symptoms. However, if the red cell life span is greatly reduced (<15 days) the bone marrow will not be able to compensate adequately and the person will experience symptoms of haemolytic anaemia. This will occur more quickly if for any reason the bone marrow is not healthy. The resulting haemolytic anaemia gives rise to increased bilirubin and urobilinogen (see Fig. 11.8).

MEDICAL AND NURSING MANAGEMENT

The medical and nursing care provided will vary according to the specific type of haemolytic anaemia. This chapter will discuss only the management of sickle cell anaemia.

11.5 (a) What is the difference between sickle cell disease and b-thalassaemia?
(b) How is b-thalassaemia treated?
(c) What are the possible complications of this disorder and how can these complications be minimised?

Sickle cell anaemia

The sickle cell anaemias are a group of haemolytic anaemias in which there is an inherited structural abnormality in the haemoglobin molecule (HbS). This abnormality is the result of the substitution of one amino acid in the globin molecule for another in the haemoglobin. The abnormal haemoglobin causes a characteristic sickle-like shaping of the red blood cell when it is in the deoxygenated state (Mehta & Hoffbrand 2000). It is a recessively inherited blood disorder of which there is a homozygous and a heterozygous variant (see Ch. 6). In the heterozygous variant, the person inherits the abnormal haemoglobin gene (HbS) from one parent and the normal (HbA) gene from the other parent. This person has the sickle cell trait (HbSA) and usually will be unaware of the abnormality unless tested for the trait or develops symptoms when exposed to hypoxic conditions, e.g. anaesthesia or unpressurised aircraft. The trait will be passed on to any children. In the homozygous variant, the abnormal gene is inherited from both parents and the person will suffer from sickle cell anaemia.

A crucial factor in diagnosing this haemolytic anaemia is a knowledge of the patient's racial origin and family history. This inherited sickle cell trait or sickle cell anaemia

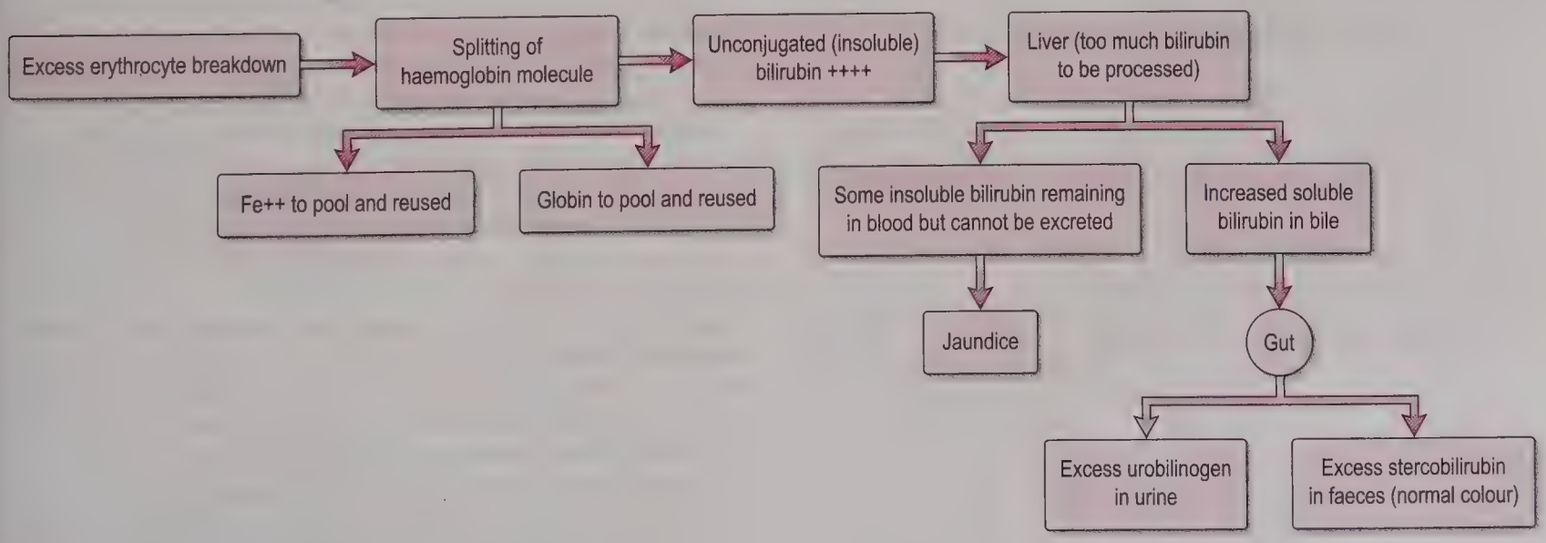

Fig. 11.8 Development of symptoms of haemolytic anaemia.

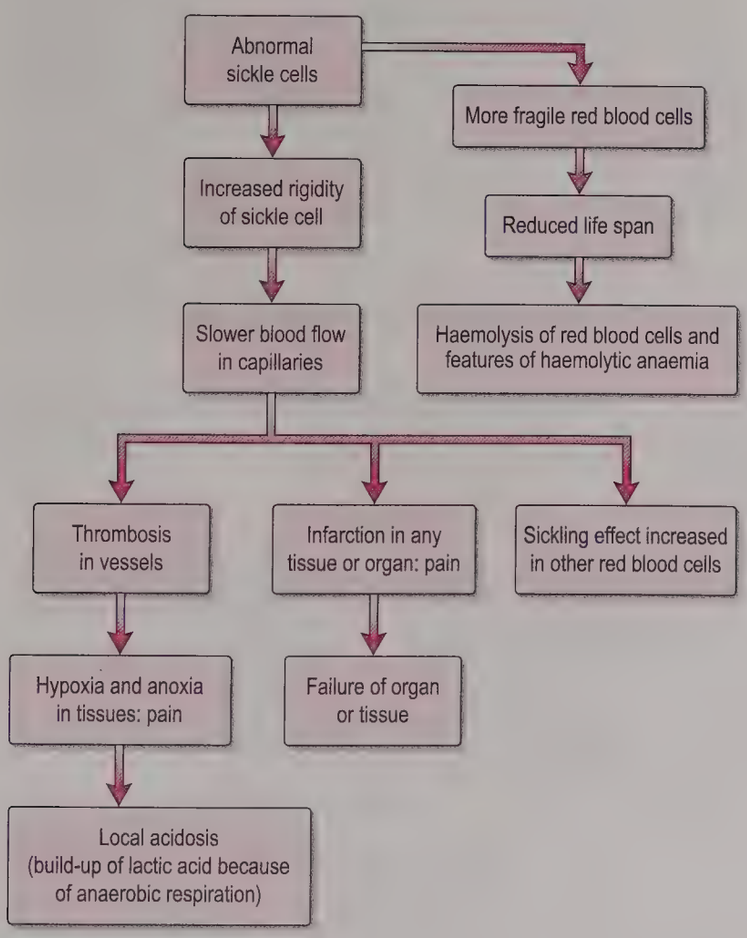

occurs more commonly among people of African, Caribbean, East Mediterranean, Middle Eastern, Indian and Pakistani origin. It is thought that this geographical distribution might be explained by the fact that sickle cell trait (not sickle cell anaemia) offers some protection against malaria (Hoffbrand et al 2001).

PATHOPHYSIOLOGY

The normal pattern of the amino acids in the beta chains of the globin part of haemoglobin (see p. 481) is altered in sickle cell haemoglobin by the substitution of a different amino acid for the normal one (HbS). HbS has certain properties which distinguish it from normal HbA haemoglobin. It is less soluble, especially when in a deoxygenated state and when the blood pH is below normal. Under these conditions crystals are formed within the red blood cell, making it more rigid and distorting it into a sickle shape (Hoffbrand et al 2001). The effects of this abnormal cell are shown in Figure 11.9.

Common presenting symptoms Sickle cell anaemia normally presents in childhood but might not become apparent until adulthood. Often the presenting symptoms are those of haemolytic anaemia (see Fig. 11.8) or of a painful 'sickle cell crisis' in response to a triggering factor (see Box 11.5). The clinical features of a crisis are:

- Pain caused by the obstruction of small blood vessels in the tissues. Characteristics of the pain are the acuteness of onset and its unresponsiveness to mild analgesics. The location of the pain depends on the location of the obstruction.
- Anaemia — although these patients are usually anaemic, the body often compensates so that the symptoms of anaemia occur only as the result of a very severe crisis.
- Infection — there is an increased incidence of minor infections, septicaemia, pneumococcal meningitis and osteomyelitis.

498 Fig. 11.9 Pathophysiology of sickle cell anaemia.

Box 11.5

Trigger factors in sickle cell anaemia

- Reduced oxygen, e.g. during strenuous exercise
- Anaesthesia
- Dehydration
- Infection
- Fever
- Pregnancy
- Sudden change in temperature
- Alcohol — possibly because of dehydration
- Emotional stress
- Extreme fatigue

MEDICAL MANAGEMENT

Investigations A blood film will demonstrate the presence of the sickle-shaped red blood cells. The presence of HbS can be demonstrated when the red blood cells are mixed with a special solution of sodium metabisulphite. The screening test for sickle cell anaemia and sickle cell trait uses electrophoretic analysis to measure the rates of movement of the different haemoglobins in an electrical field.

Treatment There is no cure for sickle cell disease. Management is based on alleviation of symptoms and promotion of a lifestyle that minimises crisis events and includes the following elements:

- avoiding situations that may trigger a crisis (see Box 11.5)
- early treatment of any infections, even minor ones
- prophylactic penicillin and pneumococcal vaccination
- education on general health and nutrition and prophylactic use of folic acid 5 mg daily
- managing crisis situations with prescribed analgesics, opiates are often required during crises
- learning to recognise complications of sickle cell disease, including bone and joint pains, leg ulcers, priapism in males, i.e. prolonged penile erection, gallstones, blurred vision, kidney disease in patients over 50 years of age, and peptic ulcers
- frequent follow-up in special clinics to monitor disease
- genetic counselling
- good antenatal care
- alerting other practitioners, e.g. surgeons and anaesthetists, to the condition
- obtaining support from sickle cell centres and social work departments in improving home conditions
- possible treatment with allogeneic stem cell transplant
- possible trial of hydroxyurea, a cytotoxic medication.

NURSING PRIORITIES AND MANAGEMENT: Sickle cell anaemia

Life-threatening concerns

Patients in sickle cell crisis admitted as emergencies to hospital may be very frightened. The nurse needs to appreciate the severity of the pain and the possible need for the administration of opiates. These should not be withheld and addiction problems rarely occur. The severe pain of a crisis does not respond to mild analgesics. Some hospitals within areas with a population in which sickle cell anaemia is relatively common have set up protocols for the management of patients admitted with sickle cell anaemia crisis in order to minimise the trauma of admission and to ensure the appropriate management of care.

Of equal importance to the alleviation of pain in sickle cell crisis is the management of the underlying cause of the crisis. An i.v. infusion may be commenced to maintain good hydration and to administer medications, e.g. antibiotics.

Patients admitted in a crisis require vigilant observation and monitoring. The underlying cause may not be apparent at first and therefore monitoring of the patient may alert nurses to signs and symptoms of the cause as well as to changes in the patient's condition.

Oxygen therapy (see Ch. 3) and blood transfusion (see p. 484) may be necessary.

Nursing considerations

Because these patients are often frightened, the nurse should listen carefully to their concerns. Since they may have had several previous episodes, such patients often know the best way that they should be treated when in a crisis.

Men may be admitted with a particularly embarrassing condition — priapism due to thrombosis in the corpus cavernosa. This requires not only the administration of analgesics, but also i.v. hydration and possibly exchange blood transfusion to reduce the percentage of sickle cells. Chronic priapism can occur and the patient's sexual function may be impaired (Midence & Elander 1996).

Before discharge from hospital, the patient should be made aware of the importance of recognising and avoiding situations that may cause a sickle cell crisis and of the need to seek medical advice at the onset of a painful episode, especially if it is accompanied by symptoms of another illness, including minor ailments.

A newly diagnosed patient will require a comprehensive education programme about the disorder, the ways to minimise complications, and any adaptations to be made to lifestyle. Arrangements should be made for the screening of all members of the family if this has not been done previously. Genetic counselling should be offered. Some areas with a high incidence of sickle cell disease employ special nurse counsellors to carry out screening and to advise patients and their families about the disorder and its consequences (see Ch. 6).

The emphasis in caring for a person with sickle cell anaemia is on promoting health and minimising ill-health.

11.6 It may not always be appropriate to ask a family member to act as an interpreter. Why?

Anaemia resulting from blood loss

The blood loss responsible for these anaemias may be:

- acute — loss of a large volume of blood over a short period of time, as in haemorrhage (for pathophysiology, medical management, and nursing priorities and management, see Chs 18, 20 and 27)
- chronic — loss of a small, even microscopic, amount of blood over a long period of time.

Chronic blood loss is very common and is the form that will be considered here.

There are a number of disorders in which there is a constant or intermittent loss of small amounts of blood. Thus, this type of anaemia is secondary to another disorder, although it may be the presenting illness. Frequently, it is only when a diagnosis of anaemia has been established that the causative illness is suspected. The most common causes of chronic blood loss are listed in Box 11.6. Some patients realise that they have been bleeding but are too afraid to seek advice and discover its cause.

PATHOPHYSIOLOGY

No ill-effects will be felt until the blood loss has caused depletion of the body's iron stores. Thus the pathophysiology is similar to that of iron deficiency anaemia.

Common presenting symptoms are as for iron deficiency anaemia (p. 489). There may be additional symptoms according to the underlying disorder, e.g. stomach pains, heavy menstruation, weight loss, or blood in stools — either fresh or digested — resulting in black tarry stools known as melaena. The patient may be known to have an underlying illness, e.g. peptic ulceration.

MEDICAL MANAGEMENT

History and examination are as for the diagnosis of iron deficiency anaemia. Detailed and careful questioning may uncover symptoms that the patient considers insignificant or is afraid to report.

Investigations are as for the diagnosis of iron deficiency anaemia. Other tests may be required according to clinical features presented. Common investigations include barium meal and barium enema, rectal examination and endoscopy.

Box 11.6

Common causes of chronic blood loss

- Peptic ulceration, including side-effects of steroid therapy
- Gastric irritation — side-effect of alcohol and some medications, e.g. aspirin
- Menorrhagia — excessive regular menstrual flow
- Genitourinary bleeding, e.g. with bladder carcinoma
- Liver disease
- Chronic inflammatory disease
- Oesophageal varices (blood loss may be acute)
- Malignancy

Treatment will depend on the specific cause of the blood loss. Possibilities for treatment include oral iron therapy and blood transfusion.

NURSING PRIORITIES AND MANAGEMENT: Anaemias resulting from blood loss

Life-threatening concerns

If anaemia is very severe, nursing care will be implemented according to the complications that arise (see Chs 2, 3 and 18). If immediate transfusion is required, nursing care will be as described on page 491. The nurse must monitor the patient very closely for possible cardiac failure and pulmonary oedema.

Nursing considerations

In the initial interactions with a patient who presents with unexplained bleeding, the nurse should bear in mind that the patient may be feeling apprehensive about receiving a diagnosis, and possibly guilty about not seeking medical advice earlier. Giving the patient clear information about necessary tests and investigations will help to allay anxiety. If the patient is to undergo tests at an outpatient department, a clear explanation should be given about any pre-investigative preparation, how long the tests will take and what they will involve, and about whether the patient will be fit to return home unaccompanied afterwards.

Thorough nursing assessment can be invaluable in establishing the cause of bleeding and will include questioning, observation, monitoring of vital signs and discussion with the patient's family and friends.

The patient should be informed about the implications of the diagnosis and the proposed treatment. In planning care, the nurse must attempt to prioritise the patient's needs and problems and be sensitive to individual values and perceptions. Counselling may help the patient, especially if the diagnosis is cancer or any other chronic disorder that will affect the patient's lifestyle. Counselling may also be appropriate if the patient has a self-inflicted disorder, e.g. alcohol-induced gastritis.

The patient with anaemia caused by blood loss may be treated in hospital, in an outpatient clinic or health centre, or at home. Good liaison among all staff involved in the various stages of treatment is vital in ensuring continuity of care. Whether the patient's care is long or short term, follow-up must be emphasised to ensure that the disorder has been cured or is being adequately monitored.

DISORDERS CAUSED BY OVERPRODUCTION OF RED BLOOD CELLS: ERYTHROCYTOSIS

A raised haemoglobin level usually indicates an absolute increase in the number of circulating red blood cells. This may be a false finding if the plasma volume is reduced, as in dehydration.

There are three situations in which the number of red blood cells is increased:

- Pathological proliferation of red blood cells with no erythropoietin stimulus — this is called primary proliferative polycythaemia or polycythaemia rubra vera
- Physiological response due to hypoxia, e.g. at high altitudes or with pulmonary disease — a secondary polycythaemia
- Inappropriate production of erythropoietin, or similar substance, in certain pathological conditions, e.g. malignant tumours — causing a secondary polycythaemia.

Polycythaemia vera

This disease, often characterised by high facial colour and suffused conjunctiva, occurs most commonly in men over the age of 40 years. If the disorder is well controlled, survival for 20 years is possible. There is usually an increased white cell and platelet count as well as a high red cell count.

PATHOPHYSIOLOGY

The raised red blood cell, leucocyte and platelet count and haemoglobin level have a number of consequences, including hyperviscosity of the blood, thrombosis and hypertension, all of which could precipitate cardiac failure. Thrombosis and sluggish circulation may precipitate peripheral vascular disease. Splenomegaly develops in 75% of all patients due to the increase in the number of red blood cells to be broken down.

Common presenting symptoms Hyperviscosity of the blood can give rise to symptoms associated with a sluggish circulation and arterial and venous thrombosis. The patient may therefore present with symptoms of:

- cerebral vascular disease, e.g. headaches, dizziness, blackouts, stroke and lack of concentration
- peripheral vascular disease, e.g. intermittent claudication
- hypertension, e.g. headaches, epistaxis, dyspnoea
- angina and cardiac failure.

Gout may also be a feature due to the increased cell turnover and raised uric acid levels. Excess histamine production released from basophils can cause gastric ulceration and pruritus, especially on exposure to extremes of temperature.

MEDICAL MANAGEMENT

History and examination The patient may not present to the doctor with any symptoms but may attend for a health check-up and be found to have hypertension. He may have a ruddy complexion and the palms of the hands and the oral mucosal membrane may be a deep red colour. An enlarged spleen is found in 75% of patients.

Investigations Blood analysis will include full blood count, haemoglobin level, PCV and blood viscosity. Estimation of the red blood cell mass will be made using radioactive chromium-51. Bone marrow aspiration will be performed and usually demonstrates a hypercellular state and an increased number of megakaryocytes, large nucleated cells of the marrow that produce platelets.

Treatment Venesection (the removal of whole blood) is the simplest form of treatment. It is repeated until the PCV is reduced to below 50% and leads to a dramatic alleviation of symptoms.

Once the diagnosis is established, radioactive phosphorus (^{32}P) may be given by i.v. injection. This treatment is given in an outpatient department, as the radioactive level within the body will not be high enough to present a risk to other people within the community provided the patient follows certain guidelines. This treatment takes up to 3 months to be effective.

Myelosuppressive medications, e.g. busulfan and melphalan, may be given orally until the disorder is controlled (see Ch. 31).

All patients will require frequent monitoring to minimise the effects of the disorder. Possible complications are thrombosis, haemorrhage, myelofibrosis (fibrosis of bone marrow tissue which interferes with all blood cell production) and acute leukaemia.

NURSING PRIORITIES AND MANAGEMENT: Polycythaemia vera

The main aims of nursing care are:

- to support the patient during diagnostic tests
- to help the patient understand the diagnosis, treatment and possible long-term effects
- to advise the patient how to detect the onset of complications.

Nursing considerations

Both the patient and the family will need to come to terms with a chronic disorder that may alter lifestyle and shorten life. The patient will probably undergo tests as an outpatient or day patient and the nurse should provide information about all investigations. The nurse will be required to assist the doctor in performing a bone marrow aspiration (see p. 487).

The patient undergoing venesection, commenced by the doctor, must be monitored for signs and symptoms of shock (see Ch. 18). One complication of venesection in patients with polycythaemia vera is difficulty in maintaining flow because of the hyperviscosity of the blood.

Patient education

Before receiving radioactive phosphorus the patient must be given, preferably in writing, clear instructions regarding limitations of activities or contact with people, e.g. children or pregnant women, in view of the fact they are radioactive. If this care is impossible at home, arrangements will have to be made to admit the patient to a single room in a ward. If admission is required, the need for isolation to protect other patients, visitors and staff must be tactfully explained to the patient (see Ch. 31).

Once treatment has begun, it is important to teach the patient how to monitor for any signs of thrombosis, e.g. pain. If medication has been prescribed, detailed instructions about taking oral cytotoxins will be given (see Ch. 31). The importance of continued monitoring via blood tests and outpatient appointments should be emphasised.

DISORDERS OF WHITE BLOOD CELLS AND LYMPHOID TISSUE

The following sections will consider the nurse's role in the treatment of:

- leukaemia
- lymphoma
- multiple myeloma
- myelodysplastic syndromes.

LEUKAEMIA

The leukaemias are a group of malignant disorders in which there is an abnormal and excessive proliferation of immature, and therefore ineffective, blood cells. When these cells are examined microscopically it is usually possible to identify the specific subtype of blood cell that is affected, e.g. granulocyte, lymphocyte or monocyte.

Leukaemia is divided into two types: acute and chronic. Acute leukaemia is characterised by the malignant proliferation occurring at the 'blast' level of cell maturity (see p. 482); in the chronic form, the predominant malignant cell appears to mature but function is usually abnormal.

Leukaemia is uncommon but occurs in all ages, in both sexes and in all races. The total number of new cases of leukaemia per year in the UK is approximately 180 per million population (Mehta & Hoffbrand 2000).

Within the UK, the incidence of leukaemia varies from region to region. This variance may, in part, be explained by the aetiological factors listed below.

Aetiology

The aetiology of leukaemia is not fully understood but exposure to certain factors which may affect the genetic makeup of the cell are associated with increased incidence. These factors include exposure to:

- radiation
- viruses
- chemicals, especially petroleum derivatives such as benzene
- some cytotoxic medications.

Congenital factors or genetic disorders such as Down's syndrome are also associated with chromosomal abnormalities and implicated in the development of leukaemic disease.

Acute leukaemia

PATHOPHYSIOLOGY

Acute leukaemia is thought to arise from a genetic alteration in a single bone marrow cell which then proliferates to produce a clone of identical cells. As these abnormal cells proliferate, they gradually crowd out the bone marrow. This affects the production of normal blood cells — red cells, platelets and white cells — so that fewer and fewer normal cells are produced, which leads to anaemia, thrombocytopenia and leucopenia, especially neutropenia.

Acute leukaemia is subdivided into acute myeloid leukaemia (AML), beginning in the myeloid stem cell,

and acute lymphoblastic leukaemia (ALL), beginning in the lymphoid stem cell. In adults, AML is three times more common than ALL, while in children ALL accounts for most cases (Treleaven & Mellor 2000). Though distinct, AML and ALL can coexist. They are classified by morphological differences according to an internationally recognised system, devised by French, American and British haematologists, known as the FAB classification. The World Health Organization has devised a more recent classification which is undergoing consideration (Viele 2003).

For further information on the FAB classification of acute leukaemia, see Bratt-Wyton (2000).

Common presenting symptoms Common symptoms, which derive from the effects of the disease on bone marrow function are:

- acute infection, associated with fever — with more than one infection coexisting, or recurrent episodes of infection occurring over a period of weeks, e.g. upper respiratory tract, oral *Candida albicans* or skin infections
- bleeding of the gums, epistaxis, purpura
- anaemia (see p. 486).

11.7 How can these symptoms be explained in terms of the function of the different blood cells?

Other symptoms may occur because leukaemic cells infiltrate tissues and organs:

- bones causing bone pain
- liver and spleen leading to hepatosplenomegaly causing abdominal pain
- gums causing gum swelling.

Less commonly affected are:

- meninges causing headaches
- testes causing swelling and pain.

In cases where there are high circulating counts of blast cells, symptoms of hyperviscosity will be manifested, e.g. headaches, blurred vision.

MEDICAL MANAGEMENT

History and examination The patient may describe either:

- an acute onset of symptoms occurring over the last 72 h and appear pale, pyrexial, tachycardic and exhibiting other signs and symptoms of acute infection, *or*
- a 2–3 month history of relatively minor recurrent infections.

On examination, evidence may be found of lymphadenopathy, petechiae, purpura and bruising (see Case History 11.2).

Investigations Diagnosis can be established by blood counts and microscopic examination of a blood film which together usually show a picture of:

- high white blood cell count (mainly blast cells)
- low red cell count
- low haemoglobin
- low platelet count.

CASE HISTORY 11.2
Mrs D

Mrs D, aged 40 years, is a housewife. She and her husband have two sons, aged 12 and 14. Mrs D's husband often works overtime so she is kept busy looking after the household. She enjoys gardening, keep-fit classes and reading.

Over the past 2 or 3 months she has been excessively tired. Although she sleeps well at night, she does not feel rested in the morning. She has had mouth ulcers, cold sores and a persistent sore throat. At first, she attributed these symptoms to being run down. Finally, she sought her GP's opinion about the sore throat. He prescribed antibiotics but, because of her other symptoms, took a blood sample for a full blood count in case she was anaemic. He advised her to contact the surgery in a few days for the blood test results and to return to see him if the sore throat continued.

Mrs D was very shocked when later that day the GP telephoned to tell her she was very anaemic and that he had arranged an emergency appointment at the local hospital for her to see the haematology consultant that evening. Mrs D was advised by the haematologist that she needed urgent investigation into her abnormal blood count; arrangements were made for her immediate admission.

Further investigation confirmed a diagnosis of acute myeloid leukaemia. After further discussion with the consultant and her husband, Mrs D has consented to chemotherapy.

A central venous access device, e.g. Hickman catheter, has been inserted to provide long-term access for drug administration, blood sampling, blood product transfusion and possible parenteral nutrition. Mrs D has received a blood transfusion so that her haemoglobin level immediately prior to the first course of treatment is 11 g/dL. She is neutropenic and thrombocytopenic.

Her nursing care for day 2 of her first course of chemotherapy is given in Nursing Care Plan 11.2. The chemotherapy medications she is receiving are i.v. daunorubicin and cytarabine.

This diagnosis will be confirmed by examination of a bone marrow aspirate and biopsy (see p. 487). Under the microscope, at least 30% of the bone marrow will have been replaced by leukaemic cells. Further laboratory testing of the marrow using cytochemistry, immunophenotyping, cytogenetic analysis and molecular studies will lead to a precise diagnosis of a particular subtype of acute leukaemia, often indicating prognosis.

For further information on bone marrow examination in acute leukaemia, see Mehta & Hoffbrand (2000).

Further aspirations of bone marrow are taken and examined during and after the completion of treatment to assess the response of the disease and help to indicate the prognosis.

If the patient has ALL, two further diagnostic investigations will be carried out:

- a lumbar puncture, as there is a high risk of central nervous system involvement, especially in the cerebrospinal fluid
- examination of the testes, as this is a region to which leukaemia may spread.

Treatment

Treatment is aimed at controlling and eliminating the disease with a long-term view of giving the patient months or

many years of disease-free survival. This is often achieved through the administration of chemotherapeutic agents and in some cases bone marrow or stem cell transplantation. Ongoing research into the use of therapies that target malignant cells without significantly affecting normal cells is also being examined (Stull 2003).

Before treatment commences several issues need to be considered.

- Assessment of the patient's general state of health, e.g. cardiac, renal and pulmonary function
- Assessment of CMV status through blood sampling. Blood products will be required during treatment and CMV negative patients are at risk of developing complications if given CMV positive blood (see p. 484)
- The insertion of a long-term central venous access device preventing the need for repeated venepuncture, e.g. Hickman line for blood sampling and the administration of medication
- Referral for the fitting of a wig
- The discussion of fertility issues with patients of childbearing age whose fertility may well be compromised by treatment. Male patients should be offered sperm banking facilities and female patients the opportunity to review the strategies available to them to maintain the possibility of future fertility (Foster 2002).

11.8 Reflect on the benefits, complications and long-term care of central venous access devices. Refer to Hamilton (2000).

Chemotherapy (see Ch. 31)

Chemotherapy refers to the use of chemical agents in the treatment of malignant disease. It aims to cure disease by eradicating and suppressing abnormal cell production. As these medications are relatively non-selective, normal cells which are undergoing cell division are invariably damaged, giving rise to potentially life-threatening complications, such as infection and haemorrhage caused by bone marrow suppression and side-effects such as nausea and vomiting, mucositis, alopecia and infertility. Treatment is often a fine balance between maximal destruction of malignant cells with minimal damage to normal cells.

The chemotherapy regimens used to treat acute leukaemia are based on national protocols of treatment devised by the Medical Research Council (MRC) (1995, 2001) which change over time in the light of ongoing research. Several courses of treatment are usually administered, each course lasting several days, using a variety of different chemotherapy medication combinations that affect cell death by different means.

Initial treatment (the induction phase) is aimed at achieving remission, indicated by a reduction of blast cells to <5% of the total white cell count in the bone marrow. Remission is then consolidated by further chemotherapy (the consolidation phase) with the aim of eliminating any remaining leukaemic cells. Maintenance therapy is administered to patients with ALL for a further year after the completion of consolidation chemotherapy.

The classification of chemotherapy medications is discussed in detail in Chapter 31. Table 11.5 outlines some of the combinations of medications commonly used in the treatment of AML (MRC 2001). All are administered i.v. except for thioguanine which is taken orally.

As can be seen, regimens of treatment are complex and are reviewed for individual patients prior to the administration of each course. Other combination options may be offered according to guidelines indicated by the MRC (2001).

Treatment regimens for ALL are more complex (see Table 11.6) and include an intensification phase between induction, which is split into two phases, and consolidation therapy. Once induction therapy is completed, patients may go on to undergo bone marrow or stem cell transplantation. This may be allogeneic or autologous (see Table 11.7) or consolidation chemotherapy. Maintenance therapy follows consolidation chemotherapy for patients with ALL using some of the medications already given by a variety of routes of administration.

Table 11.5 A possible treatment option for acute myeloid leukaemia (AML)

Phase of treatment	Course number	Drugs	Action
Induction chemotherapy	Course 1	Daunorubicin Cytarabine Tioguanine	Cytotoxic antibiotic Antimetabolite Antimetabolite
	Course 2	Daunorubicin Cytarabine Tioguanine	Cytotoxic antibiotic Antimetabolite Antimetabolite
Consolidation chemotherapy	Course 3	Amsacrine Cytarabine Etoposide	Dye derivative that intercalates with DNA Antimetabolite Plant alkaloid
	Course 4	Mitoxantrone Cytarabine	Dye derivative that intercalates with DNA Antimetabolite
	Course 5 (administered in some cases only)	Cytarabine	Antimetabolite

Adapted from MRC (2001).

Table 11.6 A possible treatment option for acute lymphoblastic leukaemia (ALL)

Phase of treatment	Drugs	Method of administration	Action
Induction chemotherapy:			
Phase 1	Vincristine	IV	Vinca alkaloid
	Daunorubicin	IV	Cytotoxic antibiotic
	Prednisolone	Oral	Steroid
	L-Asparaginase	IM	Protein synthesis inhibitor
	Methotrexate	IT	Antimetabolite
Phase 2	Cyclophosphamide	IV	Alkylating agent
	Cytarabine	IV	Antimetabolite
	6-Mercaptopurine	Oral	Antimetabolite
	Methotrexate	IT	Antimetabolite
Intensification	Methotrexate	IV	Antimetabolite
	L-Asparaginase	IM	Protein synthesis inhibitor
Consolidation therapy with either transplantation or four cycles of chemotherapy using different combinations of drugs	Fractionated total body irradiation over 4 days followed by Etoposide	IV	Plant alkaloid
	Vincristine	IV	Vinca alkaloid
	Cytarabine	IV	Antimetabolite
	Etoposide	IV	Plant alkaloid
	Dexamethasone	Oral	Steroid
	Daunorubicin	IV	Cytotoxic antibiotic
	Cyclophosphamide	IV	Alkylating agent
	Tioguanine	Oral	Antimetabolite

Adapted from MRC (1995).
IV, intravenous; IM, intramuscular; IT, intrathecal.

Table 11.7 Transplantation for malignant haematological disease

Type of transplant	Explanation
Bone marrow transplantation	This involves the transfer of bone marrow, which contains 90% of haematopoietic progenitor cells, into someone whose bone marrow has been destroyed by high dose therapy, to re-establish haematopoiesis. Marrow is harvested by multiple aspirations from the pelvis under general anaesthetic and infused intravenously
Stem cell transplantation	This involves the transfer of immature blood cells, known as stem cells, to re-establish haematopoiesis for someone whose bone marrow has been destroyed by high dose therapy. Stem cells may be obtained from peripheral blood or the umbilical cord and are infused intravenously
Syngeneic transplant	This refers to the transplantation of bone marrow or stem cells between identical twins
Allogeneic sibling transplant	This involves the use of bone marrow or stem cells from a matched sibling donor obtained from a bone marrow harvest or peripheral blood stem cell collection
Matched unrelated donor transplant (MUD)	Where a matched sibling donor is not available, a volunteer donor of bone marrow or stem cells may be found from national or international donor registries
Autologous transplant	This involves the use of a patient's own bone marrow or stem cells following high dose therapy to reduce the period of pancytopenia. The cells are usually taken during a period of remission, preserved and returned at a later date

Blood growth factors (see p. 482)
To reduce the period of neutropenia for certain patients, granulocytic colony stimulating factor (GCSF) can be given by s.c. injection. GCSF may also be given to promote the production of granulocytes:

- for patients about to undergo stem cell collection prior to storage
- for related or unrelated donors of stem cells for transplantation

(see Table 11.7 and Ch. 31).

Bone marrow or stem cell transplantation (see Table 11.7)
Transplantation involves the transfer of healthy bone marrow or stem cells into someone whose own bone

marrow has been destroyed by high dose chemotherapy. This may involve the use of the patient's own bone marrow or stem cells, or donor products. The bone marrow or stem cells engraft into the patient's marrow and restore normal marrow function. When bone marrow is used, engraftment may take 4–6 weeks. This is reduced to 2 weeks if stem cells are used. Bone marrow or stem cells may be 'harvested' from:

- the patient, as blood counts are recovering immediately after a course of chemotherapy
- a related or unrelated donor with a matching tissue type.

As there are many potential life-threatening complications and side-effects associated with transplantation, guidelines indicate which patients are most likely to benefit from this procedure.

For further information on stem cell/bone marrow transplantation, see Outhwaite (2000) and Provan et al (2004).

Research has shown that allogeneic transplantation offers a survival benefit for selected patients with acute leukaemia who are under 60 years of age (MRC 1995, 2001). The following protocols of selection are currently used.

For AML After the first course of induction chemotherapy, microscopic and cytogenetic analysis of a bone marrow aspirate will reveal the percentage of blast (leukaemic) cells present and their cytogenetic makeup. These results enable the patient to be assigned to a 'good', 'standard' or 'poor' risk group as defined by the MRC (2001) which will determine treatment thereafter. For patients assigned to the 'good' risk group, transplantation has not been shown to offer a survival benefit as compared to the use of chemotherapy alone. If an adult patient is assigned to the 'standard' or 'poor' risk group, then depending on age and availability of a donor, allogeneic transplantation from a matched sibling is recommended several weeks after the completion of chemotherapy.

Autologous stem cells may be collected after course 2 for use at a later stage.

For ALL All suitable patients less than 50 years of age who have a matched sibling donor are recommended to proceed to allogeneic transplantation in first remission. Patients who have poor cytogenetic indicators are recommended for unrelated donor transplantation in the event of a sibling donor being unavailable. Autologous transplantation may be recommended if a donor cannot be identified for the patient.

Prognosis

Over the last 40 years, 5-year survival for younger patients with AML has risen from 0% to approximately 45% although this varies according to age and prognostic factors (MRC 2001). The prognosis for patients with ALL is similar but also varies considerably depending on adverse factors such as age, speed of achieving remission and the presence of genetic abnormalities (MRC 1995).

Other medical interventions

As has been shown, leukaemic disease and treatment leads to the suppression of normal blood cell production. This predisposes the patient to thrombocytopenia, anaemia and neutropenia, all of which require medical intervention as the patient becomes symptomatic.

Thrombocytopenia Platelet transfusion will be required if the platelet count falls below 10×10^9 cells/L. Platelets will also be required with higher counts in other specific instances, e.g. bleeding gums. In some circumstances patients may need these to be CMV negative and/or irradiated (see p. 484).

Anaemia Red cell transfusion to minimise the effects of anaemia may be needed if counts drop below 10×10^9 cells/L. As for platelet transfusions, some patients may require CMV negative and/or irradiated blood products (see p. 484).

Neutropenia To reduce the incidence of infection, prophylactic antibiotics such as ciprofloxacin are often administered from the start of chemotherapy and for some time after the completion of treatment.

Antifungal and antiviral agents, e.g. itraconazole and acyclovir, are also administered to minimise the incidence of infections such as *Candida albicans* and those caused by the herpes virus. These agents will also be used as part of an oral hygiene regimen.

Neutropenic patients are extremely susceptible to infection and a pyrexia of ≥38°C for more than 1 h can indicate possible septicaemia. Treatment protocols for the management of neutropenic sepsis are specific to individual haematology units. Such protocols may vary from time to time and from hospital to hospital and include the taking of blood cultures and swabs, e.g. axilla and mouth, medical examination, chest X-ray and the administration of broad spectrum i.v. antibiotics.

Prevention of tumour lysis syndrome

Tumour lysis syndrome occurs as a result of the rapid breakdown of tumour cells during the induction phase of treatment. This leads to metabolic disturbances which include the excessive production of uric acid which is excreted via the renal system. If abnormally high levels are produced, crystals of uric acid may be deposited in the kidneys and lead to renal failure. In order to prevent this, oral allopurinol is administered from the start of treatment which slows the production of uric acid.

NURSING PRIORITIES AND MANAGEMENT: Acute leukaemia (see Nursing Care Plan 11.2)

The aim of nursing care for the patient undergoing treatment for acute leukaemia is to support the patient physically and psychologically through diagnosis, treatment and possibly relapse. The nurse should be present at any consultation taking place between medical staff and patient to reinforce and explain information given and should take time to inform the patient about pretreatment investigations and procedures. The nurse will also administer prescribed treatment and supportive care, offering psychological support throughout to patients and their loved ones.

Nursing Care Plan 11.2 Care of Mrs D during chemotherapy for myeloid leukaemia (see Case History 11.2)

Nursing considerations	Action	Rationale	Evaluation
1. **Risk of infection (because of neutropenia and chemotherapy)**	• Use a single room with separate toilet and washing facilities	To reduce contact with staff and other patients	All symptoms and signs of infection are noted and reported immediately and thus treatment for any infection commences early
	• Wash hands using antiseptic solution before giving any nursing care, with scrupulous attention to wrists and between fingers and careful drying	To remove commensal bacterial skin flora that may cause infection in patient; single most important preventive action against cross-infection	
	• Instruct and assist with personal hygiene using antiseptic solution	To reduce skin bacterial flora and risk of endogenous septicaemia	
	• Inspect skin daily for infection, especially folds of buttocks, axilla, perineum, breasts, puncture sites, skin breakdown, skin lesions and rashes	To detect any skin infection early	
	• Explain mouth care regimen: – use of chlorhexidine 0.4% solution after meals and at bedtime – use of antifungal agent in mouth care as prescribed by doctor (after all meals and at bedtime) – gentle brushing of teeth using a soft toothbrush	To prevent bacterial and fungal infections of mouth and reduce risk of septicaemia. To reduce risk of bacterial infection	
	• Inspect mouth daily for signs of infection using Oral Assessment Guide (see p. 513). Take swabs from any new lesions	Early detection of mouth infection	
	• Record axillary temperature, pulse and BP 4-hourly (unless patient is receiving blood products)	Early detection of infection. Axillary route used because of sore mouth and risk of infection	
	• Report any elevation of temperature to doctor immediately	To ensure any infection is treated appropriately and immediately	
	• Take blood cultures from vascular access device and peripherally as a baseline and at onset of pyrexia		

Continued ▶

Nursing Care Plan 11.2 Care of Mrs D during chemotherapy for myeloid leukaemia (see Case History 11.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
1. Risk of infection (because of neutropenia and chemotherapy) *(Continued)*	• Take nasal, throat and skin swabs from axilla, groin	To detect any microorganisms that might cause skin infections and septicaemia	
	• Inform patient and visitors of the restrictions re. plants and flowers	Earth is a source of *Serratia marcescens*, stagnant water a medium for *Pseudomonas aeruginosa*	
	• Advise Mrs D about dietary restrictions: no raw unpeeled fruit or raw vegetables	Raw, unpeeled fruit and raw vegetables may be contaminated with *Pseudomonas aeruginosa*, *Klebsiella* species and *Escherichia coli* and cause septicaemia	
	• Administer no medications rectally or evacuant enemas or suppositories	Can cause rectal abscesses and septicaemia in immunosuppressed patient	
	• Report any symptoms, e.g. dysuria, to doctor immediately. Report any change in patient's condition, especially increased drowsiness, headache, irritability or restlessness	To commence appropriate antibacterial/antifungal or antiviral treatment immediately Changes in central nervous system may be first indication of septicaemia	
	• Access vascular access device according to local protocol and observe exit site daily for signs of infection	To detect complications and ensure care of device and exit site dressing is appropriate	
2. Inadequate oxygenation of tissues due to anaemia	• Assist with all activities of living as appropriate	To conserve energy and reduce oxygen requirements	Patient is not unduly tired
	• Observe pressure areas twice daily	To detect any skin breakdown due to hypoxia of skin	Any pressure ulcer is detected at first sign, if not prevented
	• Organise nursing care or assistance to allow periods of rest	To conserve energy	
	• Use Spenco mattress on bed	To reduce risk of pressure ulcers	
3. Easy bleeding due to thrombocytopenia	• Inspect skin daily for signs of new bruises, petechiae, purpura	To detect any bleeding immediately	Bleeding is detected early and prompt treatment is given

Continued ▶

Nursing Care Plan 11.2 Care of Mrs D during chemotherapy for myeloid leukaemia (see Case History 11.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
3. Easy bleeding due to thrombocytopenia *(Continued)*	• Inspect mouth daily for bleeding		
	• Test urine daily for protein and blood • Test and inspect all stools for blood		
	• Observe any vomit for blood		
	• Observe any headache and/or change in conscious level		
	• Observe any other overt episodes of bleeding, e.g. epistaxis		
	• Report to doctor immediately any signs or symptoms of bleeding	To ensure treatment is given as soon as possible	
	• Record pulse and BP 4-hourly	To detect any hidden bleeding suspected because of tachycardia and hypotension	
	• Administer platelets as prescribed, ensuring compatibility of donor blood, observing and monitoring for any allergic or other reaction by recording quarter-hourly pulse and BP and asking patient about any complaints	To ensure platelets are given safely	
4. Side-effects of chemotherapy (a) Bone marrow suppression (b) Extravasation of chemotherapeutic agents, especially daunorubicin	See 1, 2, 3		All side-effects of chemotherapy agents are observed and prompt relevant nursing care is implemented so that Mrs D experiences as few side-effects as possible
	• Administer chemotherapy according to protocol • Access vascular access device according to protocol	To ensure safe administration of chemotherapy To reduce the risk of damage to the vascular access device	
	• Observe exit site of vascular access device and surrounding area vigilantly for extravasation	To ensure that extravasation is detected as soon as possible	
	• Report promptly to medical staff any signs of swelling, tenderness or inability to access vascular access device	To ensure that extravasation is dealt with promptly and appropriately	

Continued ▶

Nursing Care Plan 11.2 Care of Mrs D during chemotherapy for myeloid leukaemia (see Case History 11.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
4. Side-effects of chemotherapy (*Continued*)			
(c) Nausea and vomiting	• Administer antiemetics according to prescription	To prevent or minimise nausea and vomiting	
	• Report to doctor nausea and vomiting not controlled by antiemetics	So that antiemetic regimen can be reviewed	
	• Encourage patient to try alternative measures of controlling nausea and vomiting, e.g. relaxation tapes	To prevent or minimise episodes of nausea and vomiting	
	• Record all episodes of and measure all vomit	To assess possibility of dehydration and possible electrolyte imbalance	
	• Reassure patient that nausea will stop when chemotherapy course has been completed	Patient already aware of possibility but symptoms can be very depressing	
(d) Stomatitis	• As for mouth regimen in 1		
(e) Flu-like symptoms due to cytarabine	• Observe and report any symptoms to doctor immediately of shivering, headache or pyrexia	Early detection	
	• Monitor temperature 4-hourly		
(f) Red urine after i.v. daunorubicin	• Reassure patient that red urine is temporary consequence of i.v. daunorubicin		
	• Test all urine for blood during and immediately after bolus injection of daunorubicin	Difficult to differentiate between red colouring and bleeding due to thrombocytopenia	
(h) Hyperuricaemia because of rapid breakdown of tumour cells following chemotherapy	• Test urinary pH and measure output. Encourage oral fluid intake especially between administration of chemotherapy medications		
	• Administer allopurinol as prescribed	To reduce uric acid crystal formation and possible renal failure; to prevent or minimise high uric acid levels	
5. Anxiety about diagnosis, treatment, side-effects, prognosis	• Be prepared to listen to any anxieties		Mrs D feels able to talk with staff and feels she fully understands as much as she wishes to know about her disorder, its treatment and the consequences

Continued ▶

Nursing Care Plan 11.2 Care of Mrs D during chemotherapy for myeloid leukaemia (see Case History 11.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
5. Anxiety about diagnosis, treatment, side-effects, prognosis (*Continued*)	• Answer questions honestly and ensure, by reporting in writing, that all members of the multidisciplinary team know what information was given and what anxieties Mrs D is voicing		
	• Request further discussion with doctor or registered nurse as required		
	• Arrange for support from other relevant personnel if appropriate, e.g. social worker, chaplain, special organisations, e.g. CancerBACUP, Cancerlink	May require reiteration of information previously given by doctors, nurses or other members of the team, because of mental adjustment to diagnosis	
6. Altered body image			
(a) Alopecia	• Reassure Mrs D that hair loss is temporary: reinforce information given about when hair loss will occur, likely duration and rate of regrowth	To try to reduce emotional trauma of alopecia. Accurate information will help her to adjust and explain to her husband and her children	Mrs D is able to feel she is still attractive to her husband and that her appearance is acceptable to her children
	• Advise Mrs D to reduce handling of hair but encourage her to keep hairstyle attractive	To reduce trauma to weak hair and minimise loss	
	• Discuss ways of enhancing her appearance once hair loss starts, e.g. wearing a wig, turban or scarf	To help her to feel as attractive as possible when alopecia is complete	
(b) Herpes	• Give written information to read	To help her understand information given and a basis to ask further questions	Mrs D will feel staff understand the disfigurement of the herpes and that she is helping herself
	• Advise and assist Mrs D to carry out mouth care regimen as in 1		
(c) Sexuality	• Be sensitive to possible worries about sexuality	To help her explore feelings about changes in sexual function and body image, and to help her discuss this with her husband when she feels able	Mrs D will feel she received relevant information and is able to discuss this topic
	• Listen to worries; give truthful answers to any questions about sexual functioning		

Continued ▶

Nursing Care Plan 11.2 Care of Mrs D during chemotherapy for myeloid leukaemia (see Case History 11.2) *(Continued)*

Nursing considerations	Action	Rationale	Evaluation
6. Altered body image (c) Sexuality *(Continued)*	• Offer written information for her to read		
	• Listen to feelings and concerns about having a vascular access device in situ for a considerable period of time		
7. Inadequate nutrition and hydration (a) Anorexia	• Ensure oral hygiene regimen continued as in 1	To maintain infection-free mouth and because absence of blood improves taste	Weigh weekly: Mrs D should maintain admission weight
(b) Nausea and vomiting	• Administer antiemetics as prescribed by doctor	To prevent or minimise nausea and vomiting	
(c) Hypermetabolic state	• Help her choose a high-protein/high-carbohydrate diet from menu	To reduce or minimise effects of malnutrition, minimise weight loss and maintain protein intake	
	• Arrange for dietitian to talk to her daily to help meet dietary needs		
	• Discuss with Mrs D and her husband the possibility of him bringing certain foods she particularly wishes within restrictions (see 1)		
	• Encourage high-protein/high-energy drinks between meals		
	• Ensure meals are attractively served and in small portions if appropriate	To improve or minimise effects of malnutrition and immunosuppression	
	• Ensure 2–3 L fluid intake (see 4)	To prevent hyperuricaemia	Fluid balance assessed daily: Mrs D does not develop negative fluid balance

Nursing considerations

Prevention of infection

The most important aspect of nursing care of patients undergoing chemotherapy for leukaemic disease is assessing the risk and minimising the incidence of infection. Therefore, the nurse must be aware of the potential sources of infection, routes of transmission, sites of entry and common organisms involved.

Sources of infection may be exogenous (environmental) or endogenous (internal) to the patient. Protective isolation is discussed in Chapter 16 and involves nursing the patient in a single room, with en-suite facilities if possible, to reduce contact with environmental microorganisms.

Prevention of exogenous infection

This will be achieved by:

- all staff undertaking strict hand hygiene using bactericidal solutions prior to patient contact and between tasks performed for the same patient
- wearing protective clothing such as disposable plastic aprons when undertaking invasive procedures, disposing of excretory products or assisting in the personal hygiene of patients
- wearing sterile gloves for invasive procedures
- restricting the number of visitors
- encouraging the patient to avoid raw and uncooked foods
- restricting items taken into the single room
- avoiding stagnant water in humidification equipment or flower vases as these potentially harbour *Pseudomonas*.

For research findings and discussion about handwashing techniques and aseptic i.v. management, see Dougherty & Lister (2004) and Chapter 16.

Protection from endogenous sources of infection

The patient's own microflora pose more of a threat to the immunosuppressed patient than exogenous sources. Organisms that normally live with the patient during health and offer protection, take advantage of the immunosuppressed patient and cause opportunistic infection (Hart 2000).

Infection caused in this way may be prevented by:

- regular and vigilant observation of the patient, e.g. 4-hourly recordings of temperature, pulse and blood pressure
- regular observation and care of the mouth using bactericidal solutions (see p. 506 and Ch. 15)
- teaching the patient to pay particular attention to personal hygiene and handwashing practices
- consistent care of any vascular access device according to local protocol.

Prevention of haemorrhage

The nurse should carefully observe and monitor the patient to detect any bleeding. This should include:

- reporting all signs and symptoms of bleeding immediately to medical staff
- administering platelet transfusions promptly once prescribed by medical staff
- taking pulse and blood pressure readings at least 4-hourly, being aware of the risk of bruising from the sphygmomanometer cuff in thrombocytopenic patients, possibly necessitating a reduction in the frequency of recordings
- undertaking daily urinalysis for visible or occult blood
- testing all stools for visible or occult blood
- observing for changes in levels of consciousness or development of headaches which may indicate cerebral haemorrhage
- observing sputum and vomit for blood
- inspecting skin daily for purpura
- assessing pain, especially in the abdomen, as this may be an indication of haemorrhage
- avoiding i.m. injections and the use of aspirin-based medications, wet razors or harsh tooth brushes.

Minimising the side-effects of chemotherapy

General side-effects of chemotherapy are discussed in Chapter 31. Common short-term side-effects experienced by patients receiving chemotherapy for leukaemic disease are discussed here.

Nausea and vomiting

Nausea and vomiting may result in reluctance to accept treatment and, if left untreated, may lead to dehydration and electrolyte imbalance. However, control is possible through the use of antiemetic medications given prior to, and at regular intervals after, the administration of treatment. A wide range of medications is currently available so that alternatives can be used if first line medications are ineffective. The use of relaxation techniques may also help.

Compromised nutritional intake

Loss of appetite is common during and post chemotherapy. Several factors may influence the patient's inability to eat, such as nausea and vomiting, stomatitis and neutropenia, necessitating a restricted diet, usually avoiding raw and uncooked foods which are likely to cause infection in the immunocompromised patient. Advice should be sought from the dietitian about the best foods and supplementary drinks to take. Occasionally it may be necessary to give the patient parenteral nutrition for a period of time. If this is the case the patient will require careful monitoring to ensure electrolyte balance is maintained. Daily or weekly weighing of the patient will assess any weight loss.

Mucositis

Chemotherapy inhibits cell replication in the oral cavity and leads to inflammation of the oral mucosa known as mucositis. The production of saliva is also reduced, leading to changes in the normal microflora of the mouth, thus increasing the possibility of infection. Ulcers which develop within the mouth allow infection to enter the circulation, compromise nutrition and cause considerable pain, sometimes severe enough to merit the administration of continuous s.c. opioids. Daily oral assessment using a specialist tool (see Table 11.8) will help to ensure that oral hygiene is undertaken and evaluated regularly. Patients may be encouraged to use a bactericidal mouthwash several times a day, often in conjunction with an antifungal agent.

Table 11.8 Oral assessment guide

Category	Tools for assessment	Methods of measurement	Numerical and descriptive ratings		
			1	2	3
Voice	Auditory	Converse with patient	Normal	Deeper or raspy	Difficulty talking or painful
Swallow	Observation	Ask patient to swallow	Normal swallowing	Some pain on swallowing	Unable to swallow
Lips	Visual/palpatory	Observe and feel tissue	Smooth, pink and moist	Dry or cracked	Ulcerated or bleeding
Tongue	Visual/palpatory	Feel and observe appearance of tissue	Pink and moist; papillae present	Coated or loss of papillae with a shiny appearance with or without redness	Blistered or cracked
Saliva	Tongue blade	Insert blade into mouth, touching the centre of the tongue and the floor of the mouth	Watery	Thick or ropey	Absent
Mucous membranes	Visual	Observe appearance of tissue	Pink and moist	Reddened or coated (increased whiteness) without ulcerations	Ulceration with or without bleeding
Gingiva	Tongue blade and visual	Gently press tissue with tip of blade	Pink, stippled and firm	Oedematous with or without redness	Spontaneous bleeding or bleeding with pressure
Teeth or dentures (or denture-bearing area)	Visual	Observe appearance of teeth or denture-bearing area	Clean and no debris	Plaque or debris in localised areas between teeth (if present)	Plaque or debris generalised along gumline or denture-bearing area

Reproduced with permission from Eilers et al (1988).
This assessment tool, based on clinical experience and research, requires the nurse to score, on a scale of 1–3, eight different indicators of mouth hygiene and health, thus obtaining a total score of between 8 and 24. If a score of 8–10 is obtained, assessment should be repeated morning and evening. For scores >10, assessment should be carried out 8-hourly.

Communication (see Ch. 31)

Communication may be difficult for the patient because of changes in mood, sore mouth and feelings of lethargy. It is important for staff to listen to anxieties, fears and wishes.

Psychological care (see Ch. 31)

Patients with haematological disease may experience several factors which can affect them psychologically. For example, treatment involves repeated admission to hospital for courses of chemotherapy; having successfully completed one course, followed by a break at home, patients may find it difficult to face further hospitalisation and therapy. Periods of isolation cut the patient off from the outside world and may lead to sensory deprivation. Once discharged, after a period in isolation, patients may be so overwhelmed by a fear of the possibility of life-threatening infection that this takes over their lives.

Patient education

Helping patients to understand their illness and its management may allow them to retain a sense of control, even when very ill. Clear information will also help them to cope during periods at home between courses of treatment.

The active involvement of the family should be encouraged as the patient is given guidance in the following areas:

- monitoring body temperature
- recognising and responding to the symptoms of infection and haemorrhage
- maintaining a high standard of personal hygiene and oral care
- recognising and responding to complications associated with a vascular access device
- adhering to the oral medication regimen
- emergency contact details.

Discharge planning

On discharge, whether between courses or on completion of treatment, patients should receive a date for an outpatient appointment. The patient's GP and community nurse will be informed of discharge and arrangements made regarding

continuing care. It is also important that patients receive information about who to contact in the event of an emergency.

Other professionals who may be involved in discharge planning include:

- the social worker — for help with housing and social security benefit claims
- the occupational therapist — to assess both the patient's ability to cope with everyday activities and the need for any adaptations to the home environment
- the physiotherapist — to assess the patient's mobility and assist in the achievement and maintenance of optimal fitness
- the dietitian — to advise on nutrition and supplementary foods.

Many patients achieve remission from their disease for varying lengths of time. However, many relapse and require re-admission for further treatment.

11.9 A 21-year-old woman who is engaged to be married in 6 months is diagnosed as having acute leukaemia. She has undergone chemotherapy and is in remission, i.e. there is no evidence of leukaemic cells in the peripheral blood film or in the bone marrow. She has been in hospital for 3 months and is now about to be discharged. She has experienced a degree of alopecia, has lost a great deal of weight and is sensitive about her appearance. Reflect on the following:

(a) What do you think her main fears and anxieties might be?
(b) How could you help her to enhance her appearance?
(c) What support services are available in the community for the patient, her fiancé and her family?
(d) What practical advice should she be given prior to discharge?

Chronic leukaemia

PATHOPHYSIOLOGY

Unlike that of acute leukaemia, the onset of chronic leukaemia is insidious and the disease may be present for some time before the patient seeks medical attention. A proportion of patients are diagnosed as the result of incidental blood testing for some other condition.

Chronic leukaemia is subdivided into chronic myeloid leukaemia (CML) and chronic lymphocytic leukaemia (CLL). CML seems to be a disease of the pluripotent stem cells leading to an increase in neutrophils and their precursor cells in the peripheral blood (Mehta & Hoffbrand 2000, Treleaven 2000). Ninety-five per cent of the leukaemic cells have an abnormal chromosome known as the Philadelphia chromosome (chromosome 22) which results from a reciprocal translocation of part of the long arms of chromosomes 9 and 22 (Mehta & Hoffbrand 2000).

After a chronic phase of 2–3 years the disease enters an accelerated stage and finally transforms into acute leukaemia which is the main cause of death in patients with CML.

CLL is a malignant disorder of the B lymphocytes which proliferate and accumulate in the blood, bone marrow, lymph nodes and spleen. Most cases occur in adults aged between 60 and 80 years of age with men more often affected than women (Matutes & Dearden 2000). It is the commonest type of leukaemia in Western countries (Mehta & Hoffbrand 2000).

Common presenting symptoms These may be similar to those of acute leukaemia and include:

- fatigue
- anaemia
- weight loss
- infection
- painless lymphadenopathy (CLL)
- problems secondary to splenomegaly, e.g. abdominal discomfort.

MEDICAL MANAGEMENT

History and examination The patient may describe any of the above symptoms. Of patients with suspected CML, 90% will have splenomegaly and 50% will have hepatomegaly. For patients with suspected CLL, more than 66% of them will present with painless lymphadenopathy, infection and symptoms derived from bone marrow failure, e.g. anaemia, thrombocytopenia.

Investigations Diagnosis of either of these diseases will be confirmed by further investigations including peripheral blood count results, examination of a bone marrow aspirate, biochemistry results, CT scans and chest radiography.

Results of these tests indicating the presence of chronic leukaemia include:

- low haemoglobin
- abnormal white cell count which may be extremely high, e.g. 100×10^9/L
- low platelet count
- hypercellular bone marrow (CML)
- marrow infiltrated by lymphocytes (CLL)
- hyperuricaemia.

Treatment

CML For some time, the first line treatment for CML has been interferon which has been shown to have an anti-cancer effect, reduce white cell counts and induce remission in some patients although its mode of action is poorly understood (Howard & Hamilton 1997). For patients who fail to respond to interferon, a new medication called imatinib, which works by causing disruption to specific aspects of malignant cellular growth, has been found to give a progression free survival with fewer side-effects (Provan et al 2004). However, revised guidelines from the National Institute for Clinical Excellence (NICE) have now recommended imatinib as first line treatment for all patients with Philadelphia chromosome CML in the chronic phase (Campbell 2003).

Allogeneic transplantation is a potentially curative option and is recommended for younger patients that have a sibling donor. If undertaken when the patient is in chronic phase during first year of diagnosis, there is a 70% chance of cure (Mehta & Hoffbrand 2000). For those who do not have a sibling donor, matched unrelated donor stem cells or bone marrow will also provide the possibility of a cure, though the results are less encouraging (Treleaven 2000).

For patients whose disease transforms into acute leukaemia, treatment is highly problematic and may not be successful.

CLL Although there is no curative treatment for CLL, the administration of chemotherapy will control the disease. However, research suggests that treatment is harmful if administered in the early stage of the disease. Due to the older age of patients on presentation, approximately 50% will die of causes unrelated to CLL. When the disease does progress, treatment should be started. This may include splenectomy, leucopheresis and supportive care alongside the administration of chemotherapy and possibly allogeneic transplantation for a very limited number of patients (Breed 2003).

Examples of first line chemotherapy (Matutes & Dearden 2000) include:

- chlorambucil, an alkylating agent, *or*
- fludarabine, a purine analogue and cyclophosphamide
- a combination of cyclophosphamide, vincristine, doxorubicin (cytotoxic antibiotic) and prednisolone for its antitumour effect

followed, for younger patients, by autologous stem cell transplantation once remission has been achieved.

If these fail, second line treatment includes:

- a combination of fludarabine, cyclophosphamide and mitoxantrone (see Ch. 31)
- methylprednisolone alone.

The above medications are known for their antitumour effect in CLL if previous combinations are unsuccessful.

Supportive care may include the administration of intravenous immunoglobulin and antibiotics for patients experiencing recurrent infections, allopurinol to control hyperuricaemia, and radiotherapy.

Prognosis

The average survival for CML is 3–4 years, with transplantation offering a curative option for some patients.

CLL has a variable clinical course. Some patients may require little or no treatment for many years whereas others experience rapid disease progression.

NURSING PRIORITIES AND MANAGEMENT: Chronic leukaemia

Unless requiring intensive treatment, many patients remain at home. Some need little nursing care at home while others require considerable support as they cope with the reality of a life-threatening disease.

Hospital-based nurses may be involved in assisting with diagnostic procedures and investigations and the administration of supportive therapies such as antibiotic administration. However, if more intensive treatment or transplantation is pursued as a potentially curative option, nursing care will be more intensive and long term.

The nursing care required will include:

- giving information about tests, diagnosis and treatment options
- assisting in the administration of treatment
- providing psychological support to help the patient come to terms with a chronic and potentially life-threatening illness
- educating the patient about medication, including the importance of continuing with intermittent courses of chemotherapy, perhaps over several years
- supporting the patient who experiences concurrent symptoms, e.g. tiredness and abdominal discomfort
- giving advice about the level of work and activity that can realistically be attempted
- stressing the importance of follow-up in outpatient clinics.

LYMPHOMA

The lymphomas are a group of malignant disorders characterised by a proliferation of lymphoid cells originating in the lymph nodes or lymphoid tissue. Most often the disease is of B cell origin, more rarely of T cell origin.

Lymphoma is divided into:

- Hodgkin's lymphoma (Hodgkin's disease, HD)
- non-Hodgkin's lymphoma (NHL).

The incidence of HD is approximately 4–5 new cases per 100 000 of the population per year. It is most common among people between 20 and 30 or over 50 years of age and more common among men than women in the ratio of 1.5:1 (Pettengall 2000).

NHL is the more common of the lymphomas with approximately 11 new cases per 100 000 of the population per year (Dearden & Matutes 2000). Incidence increases with age and, as with HD, it seems to be more common in men than in women. The incidence of the disease has increased over the last 50 years, probably due to the incidence of HIV-related lymphoma.

Aetiology

Though the risk factors for HD and NHL remain unclear, several predisposing conditions have been identified including those related to genetic factors and exposure to viral infections and certain chemicals.

For further information see Dearden & Matutes (2000), Grundy (2000) and Pettengall (2000).

PATHOPHYSIOLOGY

In both HD and NHL, cells in the affected lymph tissue (usually lymph nodes) reveal a disruption of normal structure.

HD is characterised by the presence of large, multinucleated cells known as Reed–Sternberg cells within the lymphoma tumour mass. However, these are usually outnumbered by non-malignant cells such as lymphocytes, granulocytes, fibroblasts and plasma cells which are involved in mounting an immune response against the malignant cells. HD is classified according to a system known as the Revised European American Lymphoma classification (or the REAL classification) which uses morphological, immunological and genetic techniques to distinguish differences in the disease.

For further information, see Mehta & Hoffbrand (2000).

NHL is much harder to classify, which may explain why at least six different classifications have been devised over the years. Currently, the most commonly used system is the REAL classification (see above). In spite of the complications of classification, some generalisations can be made to divide NHL into 'high grade', 'intermediate grade' or 'low grade'. 'Low grade' lymphomas have the best prognosis, running an indolent course, whereas 'high grade' lymphomas are aggressive with an acute clinical onset. Paradoxically, 'high grade' lymphoma may be cured by and respond better to treatment than indolent disease, where relapse is common.

Common presenting symptoms

Hodgkin's disease For 80–90% of patients with HD, the most common manifestation of the disease is a painless enlarged lymph gland, often described as 'rubbery'. Such glands are found in the neck and supraclavicular fossae, axillae or inguinal regions. These may grow slowly or rapidly and compromise other organs by compression or obstruction.

Other symptoms include infection, pruritus and pain in the diseased lymph nodes on consuming alcohol. The reasons for this are unclear.

Non-Hodgkin's disease Patients with NHL may present similarly as for HD with painless lymphadenopathy. However, as extra-nodal disease is more common, a wider range of presenting symptoms may be seen such as:

- breathlessness — due to enlarged mediastinal lymph nodes or obstruction of the superior vena cava, affecting respiratory function
- oedema — especially of the limbs, due to lymph node obstruction
- backache — due to retroperitoneal lymph node enlargement
- acute or subacute bowel obstruction — due to small bowel lymphoma
- nausea, anorexia and upper abdominal discomfort — due to lymphoma of the stomach
- bone pain — due to bone involvement
- symptoms of anaemia — due to bone marrow involvement
- weakness or paralysis of one or more limbs (often involving both legs) — due to compression of spinal nerve roots
- infection caused by defective humoral and/or cell-mediated immunity (see Ch. 16).

Some patients, more commonly those with HD, also present with systemic symptoms medically known as B symptoms which may include one or more of the following:

- persistent unexplained fever of 38°C
- drenching night sweats requiring the patient to change bed linen and night clothes
- weight loss >10% of body weight.

These symptoms are significant when staging the disease and give some indication of prognosis.

MEDICAL MANAGEMENT

History and examination It can be very difficult to palpate certain lymph nodes and so clinical examination, which may also detect other signs of the disease, must be thorough.

Investigations Diagnosis is by means of:

- lymph node biopsy — undertaken as day case treatment, performed under local anaesthetic
- blood tests including full blood count, ESR and urea and electrolytes
- bone marrow aspiration (see p. 487)
- CT scan of chest, abdomen and pelvis
- Chest X-ray.

Staging of the disease After clinical examination and the results of investigations are known, the disease can be staged. This is done for both HD and NHL but is of more importance in HD. Staging establishes the extent of the disease by looking at the number and location of involved lymph nodes or extralymphatic sites and takes into account the presence or absence of B symptoms. This is known as the Cotswold Classification (see Box 11.7). Staging the disease in this way influences treatment options and prognosis.

Treatment

Hodgkin's disease Treatment depends on the stage of the disease. For early stage disease the following options are available.

- Radiotherapy alone may be used, localised on one side of the diaphragm (see Ch. 31). A mantle-shaped field is used to treat disease localised above the diaphragm and an inverted-Y field is used to treat disease localised below the diaphragm; however, approximately 30% of patients thus treated relapse.
- More often, the best choice of treatment for 'non-bulky' (i.e. small diseased lymph nodes) stage IA and IIA Hodgkin's disease is a short course of chemotherapy, aiming to eliminate disease outside the area targeted by radiotherapy, followed by localised radiotherapy.

Advanced stage disease is treated with combination chemotherapy, the most common combination used being ABVD, i.e. adriamycin (now known as doxorubicin), bleomycin (a cytotoxic antibiotic), vincristine, and dacarbazine

Box 11.7

Staging of lymphomas — the Cotswold Classification

Stage I	One lymph node involved or one extralymphatic site, e.g. stomach, Peyer's patches, thyroid
Stage II	Two or more lymph nodes involved but on the same side of the diaphragm or an extralymphatic site plus lymph nodes on the same side
Stage III	Lymph node involvement on both sides of the diaphragm with or without extralymphatic sites
Stage IV	Diffuse involvement of extralymphatic sites, e.g. bone marrow, liver

Associated with each stage will be either A (no symptoms) or B (fever, night sweats, >10% weight loss in preceding 6 months).

(an alkylating agent). The medications are usually given in 2-week pulses every 28 days for a total of six courses of treatment. If there is no response or the patient relapses, the combination of medications is changed.

Patients with 'bulky' (i.e. large diseased lymph nodes) mediastinal disease may be given chemotherapy followed by deep X-ray therapy.

Most of these treatments can be given on a day patient basis with no need for hospital admission unless side-effects of treatment occur, or the patient lives too far away to attend hospital on a day patient basis.

Patients who relapse post radiotherapy will be offered chemotherapy. Patients who relapse post chemotherapy for advanced disease may be offered high dose chemotherapy with autologous stem cell transplantation.

Non-Hodgkin's lymphoma Specific chemotherapy regimens are prescribed according to the type of lymphoma and the stage of the disease. Regimens are continually being refined as clinical understanding improves. A few examples of treatment are given here.

For further information, see Dearden & Matutes (2000).

- *'Low grade' NHL.* Patients who are asymptomatic with 'low grade' NHL are generally followed closely without treatment until symptoms, such as those listed previously (see p. 516) indicate the need. When required, chemotherapy will be administered either as single agents, e.g. chlorambucil, cyclophosphamide, fludarabine, or in combination, e.g. cyclophosphamide, doxorubicin, vincristine and prednisolone. Relapsed patients may respond to the same treatment that induced remission.
- *'High grade' NHL.* In the early stages of the disease combination chemotherapy is used with CHOP — i.e. **C**yclophosphamide, doxorubicin **H**ydrochloride (adriamycin), vincristine (**O**ncovin), **P**rednisolone — being the gold standard of treatment to date. For patients who relapse, further chemotherapy followed by autologous or allogeneic stem cell transplantation may be offered. Current research involving the use of monoclonal antibodies, e.g. rituximab, which target specific cells is being evaluated (Provan et al 2004).

Prognosis

Prognosis for HD depends on the stage of the disease. There is a >90% cure rate for patients with stage I and II disease but this falls to 50% for patients with stage IV disease (Mehta & Hoffbrand 2000).

For patients with NHL prognosis depends on the type of disease. Average survival rates for advanced 'low grade' NHL are 8–10 years. For advanced 'high grade' NHL, though remission rates are high at 80%, relapse occurs in 50% of patients within the first 5 years post treatment (Grundy 2000).

NURSING PRIORITIES AND MANAGEMENT: Lymphoma

Many patients with lymphoma are cared for in day bed units where they undergo diagnostic investigations and staging and receive subsequent treatment and follow-up. However, some patients will require admission to hospital, especially if they:

- live too far away from hospital to attend as a day patient
- are experiencing side-effects of radiotherapy treatment such as nausea, diarrhoea and fatigue which require medical intervention
- develop a significant infection after chemotherapy and require i.v. antibiotic therapy
- require high-dose chemotherapy and stem cell transplantation.

Nursing considerations

As lymphoma comprises such a diverse group of blood disorders and treatment is so varied, nursing care cannot be prescriptive. Some patients will remain independent of any nursing assistance, whereas others will be hospitalised throughout the course of treatment for their disease. Whether the patient is hospitalised or not, some generalisations can be made about nursing care offered. These include:

- explanation of diagnostic and staging investigations
- providing information about the disease itself
- administering specific treatment and managing side-effects with care and skill
- offering psychological support to patients who may be shocked by the possibility of serious illness
- enabling family and friends to care appropriately for their loved one.

After the course of treatment, nursing care may be required continually or intermittently. Patients should be given detailed information about post-radiotherapy/chemotherapy care. This should include the following information:

- a contact number when in need of advice
- the signs of infection or bleeding and who to contact should either of these occur
- medication and details about how and when to take it
- dietary advice
- level of activity and when to return to employment
- the importance of attendance at follow-up clinics
- appropriate self-help groups
- sexual counselling as appropriate
- referral to community nurse, social worker and GP.

Whatever the outcome of treatment, patients with HD or NHL require high-quality physical and psychological care from nursing staff who are able to recognise and meet their individual needs, values and concerns.

MYELOMA

Myeloma is an uncommon malignant disorder characterised by an abnormal and unregulated proliferation of plasma cells which develop from mature B lymphocytes. There are approximately 50 new cases per million population per year in the UK (Mehta & Hoffbrand 2000), the incidence increasing over the age of 40. It is a disease that is twice as common in people of Afro-Caribbean descent, less common in Asians (Provan et al 2004) and more prevalent in men than in women.

Aetiology

Though the cause of myeloma is unknown there appears to be some connection with occupational exposure to certain products, e.g. rubber, wood, textiles, petroleum and radiation (Dowling 2000).

PATHOPHYSIOLOGY

Normal plasma cells are present in bone marrow and develop from B lymphocytes following antigen stimulation. Each plasma cell produces a specific immunoglobulin with a specific immune function. In myeloma there is a malignant proliferation of one clone of plasma cells, which produce an immunoglobulin known as a paraprotein, which is incapable of normal function. Depending on the type secreted, the abnormal paraprotein may be detected in the serum and/or urine where it is referred to as Bence–Jones protein.

The plasma cells may form multiple tumours, plasmacytomas, in the bone — hence multiple myeloma — which have osteolytic properties and eventually erode the bone, resulting in lytic lesions.

Proliferation of the plasma cells and the production of an abnormal paraprotein lead to:

- infiltration of the bone marrow
- skeletal destruction
- high levels of the abnormal proteins in the blood, kidneys and other tissues
- depression in the production of immunoglobulins.

Each of these has pathological consequences as follows:

- Bone marrow infiltration will lead to pancytopenia
- Skeletal destruction will cause pain, hypercalcaemia (see Ch. 31) and pathological fractures
- Deposition of the abnormal proteins within the renal tubules may cause renal failure
- Abnormal proteins may lead to hyperviscosity of the blood, bleeding disorders and the presence of cryoglobulins, abnormal proteins which are insoluble at low temperatures and cause obstruction of the small blood vessels, and amyloidosis. Amyloidosis occurs when the abnormal protein accumulates, forming amyloid tissue which, if deposited in an organ, may lead to failure of function
- A reduction in immunoglobulin levels will immunocompromise the patient and increase the risk of infection.

Common presenting symptoms The most common presenting symptoms are:

- bone pain, especially in the lower back region, and pathological fractures
- spinal cord compression due to vertebral collapse
- anaemia, mediated by cytokines rather than by marrow replacement
- renal failure
- hypercalcaemia
- infection
- amyloidosis affecting the kidney and leading to proteinuria and nephrotic syndrome (see Ch. 8).

MEDICAL MANAGEMENT

History and examination The patient may have experienced symptoms for a number of months but may not have considered them significant enough to seek medical advice, e.g. back pain is often not reported until it becomes incapacitating. Alternatively, the patient may have been receiving treatment by a GP and/or physiotherapist for a condition which did not improve or even became worse.

Some patients have a history of 'sudden onset' bone pain caused by pathological fracture or experience extreme bone tenderness throughout the body. Others present with pneumonia due to neutropenia and lowered immunoglobulin levels, and yet others may present with clinical features of renal failure and/or hypercalcaemia.

Investigations To confirm a diagnosis of myeloma and determine its stage, evidence of two of the following three features is required:

- the presence of paraprotein
- lytic bone lesions
- infiltration of the bone marrow by excess plasma cells.

Evidence of the above will be determined by the following investigations:

- electrophoresis of the blood and urine
- skeletal survey and isotope bone scan (see Appendix 1)
- bone marrow aspiration and trephine biopsy.

To establish the systemic effect of myeloma on the body, the following tests are performed:

- full blood count
- serum urea and electrolytes
- serum calcium and alkaline phosphatase levels
- uric acid levels
- plasma viscosity.

Treatment Initial treatment for myeloma is aimed at controlling symptoms of the disease, particularly the presence of pain. Thereafter, although chemotherapy, radiotherapy and occasionally surgery are used, myeloma remains, with the rare exception of transplantation (see Box 11.7), an incurable disease (Dowling 2000).

Chemotherapy The most common chemotherapeutic agent used is the alkylating medication melphalan, usually given orally for a few days every month together with prednisolone, a steroid which potentiates the action of melphalan and appears to depress myeloma activity. Cyclophosphamide is also useful. However, none of these provides a long-term response and most patients experience a progression of their disease.

Younger patients able to tolerate more intensive treatment are offered vincristine and doxorubicin as a 4-day infusion together with a high dose of the steroid dexamethasone. This treatment has been shown to produce a rapid response for more than 75% of patients and is widely used prior to autologous transplantation.

Radiotherapy Radiotherapy is useful in the treatment of myeloma because it is a particularly radio-responsive disease. Specific bony lesions can be targeted, thus reducing bone deposits which will prevent fractures and reduce pain.

Surgery Internal fixation of fractured bones or areas of lytic lesions that are liable to fracture may be necessary to stabilise bones which are diseased.

Transplantation Allogeneic transplantation (see Box 11.7) offers a curative option for a small number of patients.

Younger patients under 55 years of age may be given intensive chemotherapy followed by a stem cell transplantation from an allogeneic sibling donor. Though relapses occur and transplant mortality is high, affecting approximately 30% of patients, more than 50% achieve complete remission (Samson 2000).

Autologous transplantation (see Box 11.7) can be given to patients under 65 years of age. Although this offers a survival benefit over conventional chemotherapy, it is not curative and all patients eventually relapse.

Plasmapheresis Plasmapheresis may be used to reduce a high blood viscosity, as the removal of the patient's plasma will also reduce the paraprotein level. This is done only as a temporary measure whilst other treatment is given.

Prognosis

Currently myeloma is an incurable disease, except perhaps for patients who have undergone transplantation when the median survival may be 3–4 years.

NURSING PRIORITIES AND MANAGEMENT: Myeloma

Myeloma is a serious disorder with multisystem effects, some of which are potentially life threatening. In order to plan and implement care, it is important that the nurse has a thorough knowledge of the disease and its effects on the patient.

Nursing considerations

Pain management

The most distressing symptom for the patient is often pain, which may have been present for some time. Assessment of pain must take this into account as the patient may well be exhausted and depressed by chronic pain (see Ch. 19). Pain management strategies will depend on the cause and level of distress associated with the pain. Strategies include the use of:

- radiotherapy to local bone lesions
- analgesics — opioids and non-steroidal anti-inflammatory drugs, the latter used with care as they have been associated with renal failure in older myeloma patients
- chemotherapy, which often alleviates pain soon after commencement
- lightweight braces which provide support for the spine for patients with multiple myeloma lesions.

Maintaining mobility whilst preventing fractures

Whilst prolonged periods of bed rest should be avoided, to prevent the increased risk of hypercalcaemia and pulmonary embolism, so too should too much activity which increases the risk of fracturing weak bones. Management should include:

- ensuring pain is controlled prior to attempting exercise and movement and being aware that increased activity may increase the level of pain and the need for analgesics
- working alongside the physiotherapist and occupational therapist in helping the patient attain an optimal level of activity
- maintaining a safe environment
- ensuring that a home assessment has been carried out prior to discharge for any adaptations that may be needed to facilitate access within the patient's home
- referring, if assessed as beneficial, to home care nursing staff when the patient is discharged.

The prevention of renal failure (see Ch. 8)

As renal failure is a common complication of myeloma caused by uric acid, calcium and Bence–Jones proteins, it is important that the patient is adequately hydrated. Since an intake of 3–4 litres of fluid a day is recommended, patients need to understand the need for this and be advised about strategies to maintain the high fluid intake, especially when they are at home.

When patients are in hospital receiving symptom control or chemotherapy, i.v. fluids may be necessary to ensure an adequate fluid intake.

Prevention of infection

Infection may be debilitating and occur frequently, most commonly affecting the respiratory and urinary tracts. Management strategies include:

- monitoring the patient for signs and symptoms of infection
- treating any infection promptly by i.v. antibiotics
- ensuring adequate hydration is maintained
- avoiding urinary catheterisation to prevent the possibility of infection
- maintaining a diet high in calories and protein to enable skeletal repair and to support the immune system.

Anaemia

Anaemia, causing fatigue, will be corrected by regular blood transfusion. Patients may need reassurance about the frequency of transfusion and to be assisted in establishing strategies to maximise their energy by ensuring adequate rest and minimising feelings of fatigue.

Prevention of hypercalcaemia (see Ch. 31)

Destruction of bone, leading to the liberation of excessive amounts of calcium, predisposes the patient to hypercalcaemia. This may be prevented by:

- encouraging an oral/i.v. intake of at least 3 litres of fluid daily
- encouraging physical activity which reduces the liberation of calcium
- observing the patient for signs and symptoms of hypercalcaemia, e.g. dehydration, confusion
- administering i.v. pamidronate promptly, if prescribed, to control the hypercalcaemia.

Prevention of spinal cord compression

This is regarded as an oncological emergency and occurs in 10–15% of patients with myeloma (Dowling 1997). Nurses need to know the signs and symptoms of this, commonly pain and sensorimotor impairment, and alert medical staff quickly as treatment *must* be prompt.

Communication

Good communication skills are vital to effective nursing intervention. On admission, in addition to coping with distressing and debilitating symptoms, the patient faces a diagnosis of a malignant disease which is probably incurable. Whether patients are young or old, the stress of ill-health and coming to terms with life-threatening illness will be keenly felt. Nursing management strategies include listening to the patient's anxieties — which may range from anxieties about their illness to financial worries or family issues — and answering questions honestly, in a way that is appropriate for the patient, bearing in mind that this may need to be repeated, further explained and/or written down.

Patient education

Acquiring knowledge about the disease and its management potentially helps the patient to feel more in control. In preparation for discharge, the patient should receive information about:

- the side-effects of treatment and how to self-monitor for these
- how to prevent or minimise complications, e.g. maintaining oral fluid and dietary intake
- safe techniques for moving and handling
- methods of reducing muscle weakness
- the importance of follow-up with the GP and attendance at outpatient clinics
- the availability of self-help groups (see Useful websites, p. 523).

Discharge planning

The nature of arrangements for discharge will depend on the patient's physical and psychological state, the type of treatment received and the availability of carers at home or in the community. Important aspects to consider in planning are:

- the level of dependency of the patient
- the availability of home carers and the type and degree of support needed by them, e.g. from Macmillan Nurses
- the skills to be learned by carers, e.g. safe moving and handling of the patient.

MYELODYSPLASTIC SYNDROMES (MDS)

These are a group of clonal disorders derived from an abnormal stem cell which retains the capacity to differentiate into end-stage cells. However, this differentiation is disordered and ineffective and leads to hypercellular bone marrow but cytopenic peripheral blood. Morphological abnormalities of red blood cells, white blood cells and platelets are common and these form the basis for diagnosis. During the course of MDS, the abnormal clone is prone to lose its ability to differentiate, with the disease transforming into acute leukaemia as occurs in approximately 10–40% of cases.

MDS is more common in men than women, and tends to be a disease affecting adults over 60 years of age. The annual incidence has been reported as four new cases per 100 000 population (Hamblin 2000), but as many cases remain undiagnosed, actual incidence is probably higher.

Aetiology

MDS occurs most often as a primary condition with an idiopathic cause, but it may also develop secondary to exposure to:

- cytotoxic medications, e.g. alkylating agents
- certain chemicals, e.g. benzene
- radiation.

PATHOPHYSIOLOGY

MDS occurs as a result of chromosomal damage, e.g. deletions on chromosomes 5 and 7, and genetic abnormalities which lead to more rapid cell division in the abnormal clone of cells as compared to normal cells. The disease is divided into five subgroups according to the FAB classification (Provan et al 2004).

For further information, see Mehta & Hoffbrand (2000).

Common presenting symptoms While some patients may present with symptoms of one or more of the cytopenic disorders, e.g. fatigue caused by anaemia or infection caused by neutropenia, others may be detected accidentally through routine blood tests carried out for other reasons.

MEDICAL MANAGEMENT

History and examination On presentation most patients are asymptomatic; the remainder may show signs and symptoms of bone marrow failure, infection, bruising or fatigue. In some cases hepatosplenomegaly may be present with occasional cases of gum hypertrophy, pleural and pericardial effusion, and painful, swollen joints.

Investigations Diagnosis is made on the basis of results from the following investigations:

- bone marrow aspiration and trephine biopsy, where morphological abnormalities and the degree of cellularity, e.g. hypercellular, will be detected
- full blood count revealing anaemia, neutropenia or thrombocytopenia
- MCV which is often raised
- vitamin B_{12} and folate levels to eliminate any deficiency that would affect the blood picture
- cytogenetic analysis, looking for chromosomal abnormalities.

Treatment Treatment is most often aimed at symptom relief. Interventions include:

- regular blood transfusion
- platelet transfusion administered prophylactically and when spontaneous bleeding occurs
- infection prevention strategies and prompt treatment in the event of infection
- the administration of colony stimulating factors such as GCSF and erythropoietin
- the administration of low dose or intensive chemotherapy, although neither of these proffers long-term survival
- allogeneic bone marrow transplantation, considered only for patients under 65 years due to the mortality and morbidity risks associated with this treatment

- autologous stem cell transplantation may be a future possibility for some patients with high risk MDS though further research is needed to determine the benefits of this (Burgoyne & Knight 2000).

Prognosis

The course and prognosis of MDS is variable, with some patients remaining stable for many years, whilst others experience rapid progression to AML. The majority of patients die within 2 years of diagnosis, the cause of death being more or less equally divided between:

- leukaemia occurring as a result of disease transformation
- complications of cytopenia
- unrelated causes such as cardiovascular disorders.

For younger patients who have undergone transplantation, cure rates of 40–45% have been quoted (Hamblin 2000) though treatment mortality increases with age.

Nursing management

The nursing priorities when caring for patients with MDS include:

- an understanding of the manifestation of the disease and its progression
- knowledge of treatment and supportive therapies
- the ability to educate the patient regarding treatment, nursing care and self-care
- the ability to support the patient through life-threatening illness.

As the care of patients with MDS is often shared between outpatient and inpatient services, it is essential that nursing staff in both areas share information about individual patients in order that they receive consistent care.

DISORDERS OF PLATELETS AND COAGULATION

Disorders of coagulation can be subdivided into three types:

- disorders due to lack of clotting factors
- platelet disorders
- disorders due to another cause, e.g. liver disorders.

These disorders may be inherited or acquired. All age groups are affected, but some coagulation disorders are sex-linked; for example, haemophilia occurs only in males but is genetically carried by females.

CLOTTING FACTOR DISORDERS

These disorders involve a deficiency in one or more of the blood factors required for haemostasis: inherited clotting disorders result from the lack of specific clotting factors; the acquired disorders involve the failure of certain clotting factors to be activated usually as a result of vitamin K deficiency or liver disease.

Haemophilia

The haemophilias are a group of inherited disorders in which there is a lifelong deficiency of one of the substances necessary to blood clotting. These deficiencies include (see Ch. 6):

- haemophilia A — lack of factor VIII
- haemophilia B or Christmas disease — lack of factor IX
- von Willebrand's disease — lack of von Willebrand factor, which is necessary for normal platelet adhesion and factor VII production; it is not sex-linked.

PLATELET DISORDERS

Thrombocytopenic purpura (TCP)

Any disturbance in the number or function of circulating platelets will affect the normal coagulation process (see p. 483). The condition thrombocytopenia implies a reduction in the number of platelets and may be either inherited or acquired.

PATHOPHYSIOLOGY

Inherited TCP is fortunately rare. Acquired TCP may occur as a result of factors which either decrease normal platelet production or increase platelet destruction (see Box 11.8). Decreased production is usually caused by drugs or some other agent whereby the bone marrow is suppressed. The most common form of TCP due to increased platelet destruction is idiopathic thrombocytopenic purpura (ITCP). This commonly affects individuals in their teens or early 20s and is thought to be autoimmune in origin. Whatever the cause, TCP will result in a prolonged bleeding time, which may give rise to bruising, purpura or petechiae. Less obviously, visceral bleeding can also occur.

Common presenting symptoms include a history of bleeding episodes, e.g. bleeding gums, epistaxis, melaena

Box 11.8

Causes of acquired thrombocytopenia

- Decrease in platelet production
- Aplastic anaemia
- Vitamin B_{12}, folic acid deficiency
- Bone marrow infiltration
  - — leukaemia and lymphoma
  - — carcinoma
  - — myelofibrosis: formation of fibrous tissue within the bone marrow cavity
- Other disorders
  - — viral infection
  - — bacterial infection
- Platelet destruction
- Idiopathic autoimmune disorder
- Idiopathic thrombocytopenic purpura (ITCP)
- Large-volume blood transfusion — due to the short life span of platelets, there may be no viable platelets in the blood transfusion units and the patient will, if requiring a large volume of blood, have insufficient platelets
- Disseminated intravascular coagulation (DIC) (see Ch. 29)

and haematuria. In contrast to haemophilia, if pressure is applied to the bleeding point, bleeding will stop and not recur unless further trauma occurs. As with leukaemia, symptoms of anaemia may be presenting features in chronic thrombocytopenia.

MEDICAL MANAGEMENT

History and examination A careful clinical history is required, especially to pinpoint any recent minor illness or drug therapy, including over-the-counter medicines. Thorough clinical examination is carried out to detect any signs of bruising, petechiae, purpura or any underlying disorder.

Investigations include:

- full blood count to identify low platelet count or anaemia and to exclude any other blood disorder
- coagulation screen to exclude other coagulation disorders.

Treatment Some cases of TCP resolve spontaneously, possibly because the formation of antibodies against the person's own platelet membrane antigens is transient. However, TCP usually becomes a chronic condition. In cases where an exacerbating factor such as a medication or chemical is withdrawn, spontaneous remission may also occur.

Steroid therapy may be given until resolution occurs, as steroids improve platelet survival. Response to steroid therapy is usually seen within days or weeks; however, thrombocytopenia may recur when the steroids are withdrawn.

Immunoglobulin G i.v. may be given for 3–5 days (see Ch. 16). Splenectomy may be required, as the spleen is a major site of platelet destruction. Platelet transfusions are given if bleeding is severe.

NURSING PRIORITIES AND MANAGEMENT: Thrombocytopenic purpura (TCP)

Nursing considerations

In hospital

Nursing priorities during the patient's stay in hospital include the following:

- Controlling superficial bleeding by application of external pressure. The bleeding tendency is not generally life threatening.
- Observing the patient for evidence of bleeding, and determining severity of bleeding by means of:
  - — regular monitoring of patient's pulse during diagnostic stage and initial treatment. Blood pressure is not usually measured as this may cause bruising and petechiae
  - — daily inspection of the skin for petechiae, purpura and bruises, and of the mouth for bleeding and infection. Precautions must be taken to minimise the occurrence of infection in soft tissue which has been damaged
  - — regular testing of urine, stools and vomit for less obvious sources of blood loss.
- Being alert to complaints of headaches and drowsiness, as these may indicate cerebral bleeding.
- Ensuring that the patient is protected from injury by advising on environmental hazards and that feelings of faintness may indicate anaemia or low blood pressure.
- Giving explanations and support during tests and treatment, and looking and listening for indications of anxiety.

Discharge planning

The aim of discharge planning is to enable the patient to make the transition from dependence upon the nurse to monitor the condition to becoming competent and confident in self-monitoring. The importance of monitoring all bleeding episodes must be stressed, along with the need for regular follow-up to assess platelet levels.

Precautions which the patient should be advised to take include:

- taking medicines as prescribed
- avoiding aspirin preparations
- avoiding i.m. injections
- carrying identification, e.g. Medic-Alert bracelet
- minimising potential for soft tissue injury
- avoiding contact sports.

The family should be included in the patient's education programme to ensure that all members of the household understand the necessity of certain restrictions upon lifestyle. However, it should also be stressed that it is important for the patient to maintain a balance between being overcautious on the one hand and taking unnecessary risks on the other.

The aim of rehabilitation is to allow the patient to achieve an optimal level of function until spontaneous recovery or throughout the remainder of life.

INTRODUCTION

Intact skin is vital to health and well-being. As the largest organ in the body, weighing approximately 4 kg, containing over a million nerve endings and having a surface area of 2 m^2, the skin has many vital functions (Hughes & Van Onselen 2001):

- sensation
- temperature regulation
- synthesis of vitamin D
- insulation and protection of internal organs
- barrier to harmful external factors.

Skin disorders range from minor conditions, resolved with over-the-counter (OTC) preparations, to potentially life-threatening skin conditions requiring intensive treatment in specialist units. Many conditions are of a cyclical long-term nature with patients requiring care in different settings: ward, outpatient treatment centre and community. This chapter aims to introduce dermatology nursing by discussing the most common conditions encountered. Dermatology as a visual specialty may require the reader to consult a colour atlas (Graham-Brown & Bourke 1998, White 2003).

Nurses in every specialty encounter individuals with skin disorders, creating opportunities to detect early disease, give knowledgeable treatment advice and provide emotional support to patients and family members coping with chronic conditions. A good knowledge base helps the nurse to dispel myths about the contagious nature of skin disorders, as the social and psychological implications of skin disease should not be dismissed lightly. Success, power and achievement are often dependent on appearance and 'image'. The media support images of the soft-skinned baby, blemish-free teenager, the smooth sophisticated adult and such images are reflected in money spent by both genders to achieve cosmetic perfection. Dermatology research has investigated the quality of life of patients with skin disorders and has recorded the impact of skin disease on an individual's life. The experience of skin disease may restrict social, professional and personal activities and impact on careers and relationships. Problems with sexuality and relationships can be linked to low self-esteem and the self-concept of an altered body image associated with having a skin condition (Marks 2003). The psychological morbidity of skin disease is often unrecognised by professionals (Lewis-Jones 1999) despite patients actively reporting their experiences of ostracism, stigmatisation and isolation — the 'unclean' leper status of having a skin disorder. The person with a skin disorder has to cope with the physical problem and its associated complex therapies while being confronted with psychological, social and cultural rejection.

12.1 Before reading further, try this exercise. You are in a communal changing room in a busy clothes shop when you realise the person trying on clothes next to you has a generalised rash. It appears to be very itchy, and as the person scratches, numerous flakes of skin are shed. Stop now and write down your immediate reaction to this scenario. Ask your colleagues to join you in this exercise.

Repeat this exercise when you have read through this chapter. Evaluate any changes in your answer.

Epidemiology

Skin disease is common and its prevalence is such that approximately 20% of the UK population have a skin disorder meriting medical management. The type, incidence and prevalence of skin disorders depend on social, economic, geographical, racial and cultural factors (Gawkrodger 2003). Internal and external factors contributing to skin disorders are summarised in Figure 12.1. The economic implications of skin disease can be considerable for individuals, families and employers. Skin diseases are the most common group of occupational health problems leading to absence from work. Industrial-acquired dermatoses lead to lost working time and often to compensation claims as work-induced disorders.

Age is an important factor in diagnosing disorders, with some conditions being exclusive to a particular age group, and others persisting throughout life. Atopic eczema, for example, is most common in infancy, while acne develops in adolescence and normally wanes by the late 20s. Middle age brings pemphigus and malignant melanoma. Older people show expected degenerative skin changes, with 27% having malignant skin lesions. Psoriasis and eczema occur in all age groups and can be cyclical in nature throughout life.

Research confirms malignant melanoma as a significant health problem in white adults, affecting 3% of that population and accounting for two-thirds of deaths from skin cancer (p. 549). In 1992, in response to the rise in skin cancer, the government defined a target and key actions to be taken to 'halt the year on year increase in the incidence of skin cancer by the year 2005' (DH 1992). Current UK campaigns aim to change social behaviour in relation to sunlight by educating the public that a suntan is a sign of damaged skin rather than a desirable fashion statement. The SunSmart Campaign (Cancer Research UK 2003) encourages people to protect themselves and their children from the sun's harmful rays and so reduce their risk of skin cancer. They stress the importance of the individual being aware of the appearance of their own moles, emphasising the fact that all moles change slowly over the years. People should be alert for specific changes, a vital factor in early detection of melanoma (see p. 550). Travel leaflets now promote sunscreens and avoidance of sunburn.

Genetic or hereditary factors can be relevant to the diagnosis, and a family history should be part of the assessment. Patients with skin disorders report stress as a contributory factor in creating or exacerbating their condition, e.g. divorce, trauma, bereavement, exams. Psychological stress is common, but while psychological problems can make conditions worse, most skin disorders are stressful conditions in their own right. Certain skin disorders are recognised as being entirely of psychogenic origin, e.g. dermatitis artefacta, trichotillomania and dysmorphobia.

Social factors are relevant to skin disorders, and improvements in standards of living, personal hygiene and nutrition have reduced the rate of certain skin disorders (Gawkrodger 2003). The current rise in the number of patients with asthma and eczema appears to be associated with increasing affluence and these might now be considered as diseases of the advantaged. Unemployment and low wages restrict job mobility and the patient with acquired industrial skin disease may have difficulty in making appropriate job changes to alleviate the condition. Continuing rises in prescription charges may force patients into decisions about which of the prescribed medications they can afford. Skin care prescriptions often involve combinations of preparations, and anecdotal evidence suggests that patients choose those parts of the prescription they can best afford, thus preventing full management of a skin disorder. Homelessness and poor housing create problems in maintaining skin care, the former often resulting in limited access to medical care. Nurses working with vulnerable client groups need to be aware of such issues.

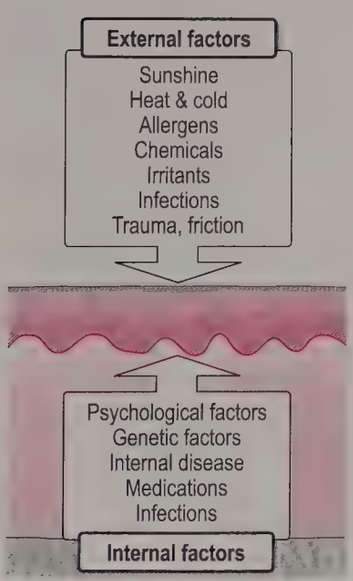

Fig. 12.1 Internal and external factors causing skin disease. (Adapted from Hunter et al 2002, with permission from Blackwell Science Ltd.)

The nurse's role

Since publication of the Patients' Charter (DH 1991), patients with skin disorders and associated support groups have asserted their right to access specialist staff and be nursed in specialist areas (DH 2004). Inpatient hospital management is an effective method of targeting, educating and training the patient in skin management techniques. Cure is not a word widely used in dermatology due to the cyclical nature of many conditions, so nurses involved in care often forge long-term relationships with patients. Nurses with dermatology experience of chronic skin disease can, through holistic practice, help patients who require sympathy, empathy and guidance from specialist practitioners who have the time, knowledge and willingness to share clinical skills with this motivated client group. Kurwa and Finlay (1995) reported inpatient management as improving quality of life for dermatology patients, while peer group interaction between patients in dermatology wards is recognised as a beneficial adjunct to therapy.

The role of the dermatology liaison nurse is now well established (Lawton 2004). The liaison role focuses on the sharing of specialist knowledge and skills, resulting in a seamless transition of care and the removal of arbitrary barriers that used to coexist between care settings (Ruane-Morris et al 1995). The supportive role of nurses in primary care is vital. Patients referred to dermatologists reflect a

small minority of people with skin disorders. Self-medication, OTC therapies (Nathan 1996) and nurse prescribing mean that, for many, community pharmacists and community teams are the first point of contact for most patients. The liaison nurse uses educational input to support the primary care team in providing information and therapies that are valid, accurate and up to date and, in an advisory and consultative capacity, helps sustain continuity of care (Stone 1997a). This independent role means availability to visit patients' homes, nursing homes, schools and places of work and provides expertise to reduce the fragmented care that sometimes exists in primary care settings. The NMC *Code of Professional Conduct* (2004) supports dermatology nurse practitioners in extending nurse-led initiatives in many areas of clinical practice (Legge 1997) including:

- nurse-led clinics for chronic disease management (eczema, psoriasis, acne), leg ulcers, cryosurgery (local freezing with liquid nitrogen), skin biopsy, iontophoresis (treatment for excessive sweating)
- laser therapy
- nurse counselling
- nurse-led phototherapy
- patient education programmes
- nurse prescribing.

Nurses are therefore an important group within the dermatology team, playing a vital role in the provision of direct specialised care.

ANATOMY AND PHYSIOLOGY

Structure of the skin

Originally formed from the embryonic ectoderm and mesoderm, skin is composed of two layers: epidermis and dermis. Beneath these layers, a bed of subcutaneous fat protects and insulates the underlying organs.

The epidermis

The epidermis is composed of stratified epithelium and varies in thickness between different parts of the body, e.g. the skin on the palms and soles is thicker than that on the face or back. There are no blood vessels in the epidermis, the cells being nourished by means of diffusion of materials. Structures tracking through the epidermis include hair follicles and sweat and sebaceous glands (see Fig. 12.2A). The epidermis is composed of several layers, its health depending on three factors involving these layers (Waugh & Grant 2001):

- regular division and migration of epidermal cells to the skin surface
- gradual keratinisation of these cells
- desquamation or rubbing away of these cells.

The layers of the epidermis are as follows (see Fig. 12.2B):

Basal layer (stratum basale) The cells lying nearest the dermis form the germinative layer where cell division occurs. Cells migrate upwards from this layer, becoming keratinised over a period of 21–28 days before being shed.

Prickle cell layer (stratum spinosum) Cells in this layer appear to be connected by fine processes or prickles. These intercellular connections act as protection against shearing forces or trauma to the skin.

Granular layer (stratum granulosum) Within this layer, fine granules form in the cells. This granular substance, keratohyalin, is a precursor of keratin, which gradually replaces the cytoplasm of the cells.

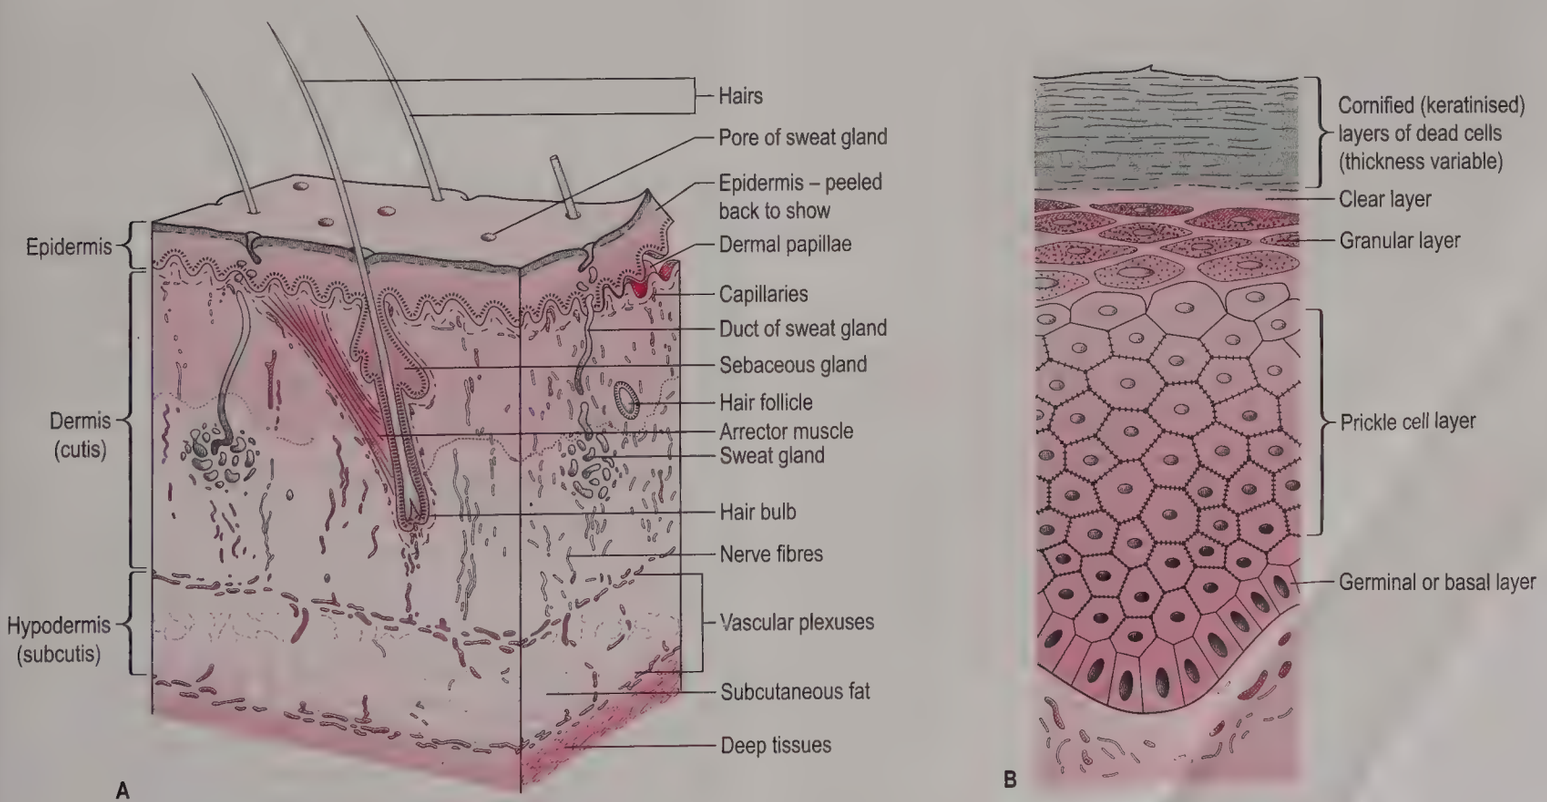

Fig. 12.2 A: The structure of the skin. B: The layers of the epidermis.

Clear cell layer (stratum lucidum) This layer is present only where the skin is thickened, e.g. the soles of feet. The cells exhibit nuclear degeneration and contain large amounts of keratin. Injury or friction to the skin increases the production of these cells, resulting in a callus or corn.

Horny layer (stratum corneum) This layer is composed of thin, flat, non-nucleated cells, the cytoplasm of which has been totally replaced by keratin.

The epidermal/dermal junction is convoluted into dips and ridges called rete pegs, which help to prevent damage to the skin from shearing forces. The configuration of these ridges is visible at the epidermal surface as corresponding characteristic, individualised patterns, e.g. at the fingertips.

The dermis

The dermis is composed of fibrous connective tissue providing a supportive meshwork for the structures and organs within. The papillary layer has many capillaries and lies next to the basal layer of the epidermis. The reticular layer, lying above the subcutaneous fat layer, has fewer blood vessels and is less reactive.

The ground substance of the dermis is a jelly-like material acting as a support and a transport medium. It functions as a water reservoir which may be utilised by the body in an emergency, e.g. during haemorrhage (see Ch. 18).

Tissue mast cells are often found near hair follicles and blood vessels, producing heparin and histamine when damaged.

Tissue macrophages have the protective function of engulfing foreign particles within the dermis.

Collagen fibres Ascorbic acid (vitamin C) is required by fibroblasts to generate these strong fibres, which bind with water molecules to give skin its tight, 'plump' appearance; 40–80% of the total body water is thought to be accommodated within the dermis. Wrinkling is thought to occur when collagen fibres lose their water-binding properties. They may also rupture during growth spurts, pregnancy or obesity, leaving fine white scar-like striae, recognised as abdominal stretch marks in pregnant women.

Elastin fibres These yellow fibres, also formed by fibroblasts, are bound loosely around bundles of collagen and, in combination with the ground substance and collagen, help the dermis to maintain its characteristic properties.

Lymph vessels play a major role in draining excess tissue fluid and plasma proteins from the dermis, thereby maintaining correct volume and composition of tissue fluids.

Nerve endings Specialised sensory receptors present in the dermis and basal layer of the epidermis detect mechanical and thermal changes (see Ch. 22).

Glands

Sweat glands are coiled tubes of epithelial tissue opening as pores onto the skin surface. They have individual nerve and blood supplies and secrete a slightly acid fluid containing excess excretory products (water and salts). Sweat also helps to keep keratin supple. Sweat glands are of two types: eccrine and apocrine. Eccrine glands are controlled by the sympathetic nervous system, producing secretions in response to temperature elevation or fear. Release of latent heat by the evaporation of sweat helps to lower body temperature. Apocrine glands in the pubic and axillary areas are not functional until puberty. They are thought to secrete pheromones, chemical signals released into the external environment.

The sebaceous glands are lined with epidermal tissue, secreting sebum, a greasy, slightly acid substance which helps to form a waterproof covering over the skin and, like sweat, to keep the keratin supple. The acid sebum has antibacterial and antifungal properties. Most sebaceous glands open into hair follicles. Sebum production is influenced by sex hormone levels.

Functions of the skin

Protection

The skin has several protective properties. The greasy horny layer forms a waterproof seal against undue entry or loss of water. The skin surface protects against microorganisms (through its acidity) and acts as a barrier to chemicals, gases and gamma and beta rays. Internal organs are shielded by the skin from minor mechanical blows, and repeated pressure or friction stimulates an increase in cell division, producing thickened areas of skin, e.g. corns and calluses. Melanin produced in the basal layer of the epidermis screens the dermis from ultraviolet rays.

Sensation

Nerve endings present throughout the dermis and basal epidermis continually monitor the environment and are most highly concentrated in areas such as the fingertips and lips. Innervated hair follicles help the individual to avoid injury by stimulating reflex action in response to touch.

Formation of vitamin D

Epidermal cells synthesise 7-dehydrocholesterol, which is slowly converted to vitamin D when skin is exposed to ultraviolet rays. Circulatory vitamin D, in combination with phosphorus and calcium, is essential to the formation of healthy bone. Deficiencies can lead to the development of disorders such as rickets and osteomalacia. Excess vitamin D, a fat soluble vitamin, is stored in the liver.

Temperature regulation (see Ch. 22)

Core body temperature is usually static at around 37°C. Heat is produced in the body by the metabolic processes of the liver, muscles and digestive system. Temperature is controlled by the heat-regulating centre in the hypothalamus, which responds to changes in the temperature of circulating blood and influences cardiovascular centres in the medulla oblongata. These centres control the size of the lumen of the arteries and arterioles and thereby control the rate of blood flow through the capillary beds in the dermis.

In cold conditions heat is retained by vasoconstriction and generated by the involuntary muscular action of

shivering. During overheating, sweating is induced and vasodilatation occurs. As sweat evaporates from the skin, latent heat is lost from the skin surface, causing it to cool. Vasodilatation allows large quantities of blood to circulate in the uppermost layers of the dermis. Heat is then lost through convection, radiation and conduction. Blood flow is controlled by precapillary sphincters via constriction or relaxation, directing blood either to the capillary bed closer to the skin surface (resulting in maximum heat loss) or to the deeper tissues of the skin (minimising heat loss).

Other functions

During starvation, subcutaneous fat is utilised both as an energy source and as a water reserve. Water can also be mobilised from the dermis during haemorrhage or shock. The skin also has an excretory function, with urea and salts being excreted in small amounts through sweat.

SKIN ASSESSMENT

In completing a comprehensive skin assessment, it is important to obtain a full history, which should include:

- onset, initial site and duration of the condition
- associated symptoms, e.g. itch, redness
- actions that worsen the condition, e.g. sunlight exposure
- family history, e.g. genetic predisposition, allergies
- associated systemic disorders, e.g. asthma, hay fever
- current medication — oral and topical therapies, prescribed and OTC
- social history — occupation, hobbies, housing, alcohol/drug intake
- impact of the disorder on daily life — personal coping strategies, self-esteem and self-image.

The history should reveal the person's description and understanding of the disorder as well as their perception of living with it. An effective assessment should determine the impact of the skin disorder on those around the patient. Skin disease, with all its social implications, has a major cultural impact that varies tremendously within our multicultural society. For example, in Asian society, skin disease may impact negatively on arranged marriages or payment of dowries for brides (Barker 1995). Cultural beliefs need to be identified if treatment programmes are to be adapted to acknowledge such issues. It is important to ask patients what they have already used to treat their skin disorder. Many OTC preparations or treatments, borrowed from well-meaning friends, can exacerbate an existing skin condition. When examining skin, the nurse must have a knowledge of 'normal' skin to be able to identify the abnormal. The entire skin surface is examined to determine the extent of the disorder. Palpation of skin lesions will determine changes in skin texture with associated crusting or scaling.

Refer to Gawkrodger (2003), pp. 14–15, for a diagrammatic representation of, and terminology associated with, dermatological lesions.

In skin disorders, the term 'lesion' describes a small area of disease, while an 'eruption' or 'rash' describes widespread skin involvement. Skin assessment includes routine examination of the hair and nails as changes can aid diagnosis, e.g. nail changes in psoriasis or fungal infection. The distribution of lesions can vary. Psoriasis tends to localise on the outer aspects of elbows and knees, while eczema is most common in the skin flexures.

During assessment, the nurse should recognise that skin changes can be a manifestation of systemic disorders, e.g. T-cell lymphoma (see Ch. 11). Peters (2001) reminds the nurse to recognise the wide diversity of skin colour and differences in pigmentation in our multiracial society. The physiology of the disorder will be the same, but differences in pigmentation can influence skin changes during illness. Skin assessment methods must be pertinent to racial groups. Communication with patients is important for accurate assessment, as a patient's description of symptoms is relevant to diagnosis and management. Initial nursing management involves alleviation of distressing symptoms while awaiting diagnosis.

The nurse should also recognise that the effect of the physical appearance of a skin disorder on quality of life is often viewed by the patient as being of greater importance than the discomfort of having abnormal skin (Lewis-Jones 1999).

PRINCIPLES OF THERAPY IN SKIN DISORDERS

This section looks briefly at the available therapies and the basic principles of application.

Topical therapy

The skin as the target organ of treatment is readily accessible and the pathology of many skin disorders requires topical therapy as the first line of management. Topical therapy describes all treatments applied directly to skin. The classification of topical preparations is outlined in Box 12.1, and the advantages and disadvantages in using topical therapies are outlined in Box 12.2.

Emollients — agents which moisturise and lubricate the skin — are the mainstay of dermatology treatment. They can be used in skin maintenance programmes and are vital in preparing the skin for the specific therapies available for different disorders, e.g. tar, steroids. The choice of emollient depends on the disorder:

- dry, hyperkeratotic skin — use oily occlusive ointments
- flaky rough excoriated skin — use grease-based preparations

Box 12.1

Classification of topical preparations

- Creams — have a light effect due to high water content. They rub in easily and cool the skin
- Lotions — used if skin is 'weeping'. Good for scalp treatment as they are not greasy to apply
- Ointments — greasy preparations used as a base for the drug being applied. They last for 6–8 h on the skin, encouraging absorption by a barrier effect
- Pastes — ointments applied to medicated bandages for occlusive use or used in combination as a stiffer paste to apply treatment directly to lesions. This permits a slower, more effective absorption on the target sites

Box 12.2

Advantages and disadvantages of topical therapy

Advantages
- Drug delivered directly to target area
- Reduces systemic absorption
- Patient can view improvement
- Side-effects easily identified

Disadvantages
- Time-consuming
- Messy
- Preparations smell or stain the skin
- Patient can see deterioration or lack of improvement

- erythematous, inflamed skin — benefits from the cooling effect of water-soluble creams.

Patients may use a combination of emollients for different areas, e.g. cream for the face and ointment for the body.

For further reading on the application of emollients, see Dawkes (1997).

The commitment needed to maintain treatment cannot be underestimated as topical therapies can be messy, time-consuming and smelly. Treatment programmes often have to be customised because of the unique therapeutic response of each patient.

Regular nursing assessment will identify any improvement or deterioration and allow treatment to be amended appropriately. In order to achieve the desired outcome, the skilled practitioner needs a sound knowledge of dermatology therapies balanced with clinical nursing abilities to educate, support and motivate the patient to complete lengthy treatment programmes.

Phototherapy (ultraviolet light B)

Patients with certain skin disorders, most commonly psoriasis and eczema, can be treated with ultraviolet light B (UVB) in measured doses. UVB is the wavelength in natural sunlight responsible for sunburn. Treatment requires outpatient attendance two to three times weekly over a period of weeks. A test dose administered to the patient's back determines a safe starting dose. This dose is gradually increased over the treatment period. Phototherapy is given in a cabinet with fluorescent lamps emitting UVB.

Photochemotherapy (psoralen and ultraviolet light A)

The treatment combination of psoralen and ultraviolet light A (PUVA) requires the patient to take oral psoralen (a natural plant extract) in tablet form 2 h before exposure to UVA. Photochemotherapy is given in a cabinet with fluorescent lamps emitting UVA. Bath PUVA (methoxypsoralen lotion) is a treatment in which a measured amount of psoralen is added to 150 L of bath water. Patients soak for a specific time, pat the skin dry and then treatment is given in a UVA light cabinet. Again, psoriasis and eczema can both be treated with PUVA. A test dose is administered to determine a safe starting dose and treatment is given in twice weekly sessions.

Patients having light therapy wear protective goggles during UVB/PUVA exposure. After PUVA they must also wear dark glasses for 24 h to protect the lens of the eye. UVB/PUVA is administered in specialist units to ensure accurate recording of the amount of light therapy given, as guidelines exist that restrict the amount a patient may receive. Patient education prior to initiating treatment, combined with effective nursing support during therapy, empowers the patient with the skills and knowledge needed to undergo therapy and to participate actively in it (Rathmell 2003).

Complementary therapies

The increasing interest in complementary therapies to treat skin disorders reflects a rise in public awareness of non-traditional approaches to treatment, perhaps stimulated by the failure of orthodox medicine to provide 'cures'. The nurse is ideally placed to discuss both the orthodox and complementary options available. Discussion should focus on the safe use of complementary therapies initiated by referral to a licensed practitioner who has undergone accredited training. A House of Lords Report (2000) stressed that complementary therapy should be viewed as a useful adjunct and not as a full alternative to routine therapies. Patients may wish to use such therapies as positive adjuncts to conventional management.

DISORDERS OF THE SKIN

PSORIASIS

Psoriasis is a chronic, non-infectious inflammatory skin disorder characterised by well-demarcated erythematous plaques with adherent silver scales. The epidermal cell proliferation rate increases greatly, while epidermal turnover time is reduced. During normal skin production, epidermal cells mature in transit through the skin layers and are eventually shed as keratin. In psoriasis, increased cell production and transit time mean that cells do not keratinise completely and so cannot be shed. This causes the build-up of a white, waxy silver scale as immature skin cells remain adherent to the skin. Psoriasis is prevalent in 2% of the UK population, yet the cause remains unknown. It can occur in any age group and is an unpredictable skin disorder with exacerbations and remissions. Genetic influences predispose to the condition, with 35% of patients showing a family history.

Precipitating/aggravating factors include:

- infection — streptococcal throat infection
- medications — can exacerbate or trigger psoriasis
- sunlight — in some patients, psoriasis improves during the summer and relapses during the winter; however, others report that sunlight aggravates the condition
- hormonal — psoriasis can get better or worse during pregnancy or menopause
- psychological stress — can exacerbate psoriasis, but the condition itself is recognised as stressful

- trauma — creates the 'Koebner effect' where psoriasis is triggered in damaged skin, e.g. the site of an injury or surgical scar.

Psoriasis varies from mild forms, with plaques localised to the knees and elbows, to severe forms which are potentially life threatening. Classification of psoriasis is made on clinical presentation (Hunter et al 2002).

Guttate psoriasis (see Fig. 12.3) presents as drop-like symmetrical lesions on the trunk and limbs. It is most common in adolescents and young adults and is often triggered by a streptococcal throat infection. It responds well to therapy.

Plaque psoriasis (see Fig. 12.4) presents as well-demarcated, erythematous plaques covered in dry, white waxy scale often localised to the knees and elbows. Removal of this build-up of keratin leaves small bleeding points. Plaques vary considerably in size and can extend to cover the trunk and scalp. Plaque psoriasis tends to be chronic, with exacerbations and periods of remission.

Flexural psoriasis affects the axillae, submammary and anogenital areas and looks different from typical psoriasis. Plaques are sharply defined but the skin has a thin glistening redness, often with painful fissures in the skin folds.

Pustular psoriasis (palmoplantar pustulosis) is a localised form of psoriasis affecting the hands and feet. It is characterised by yellow/brown pustules which dry into brown scaly macules. It is a painful condition, difficult to treat.

Fig. 12.3 Guttate psoriasis. (Reproduced with kind permission from Dr Graham Lowe, Ninewells Hospital, Dundee.)

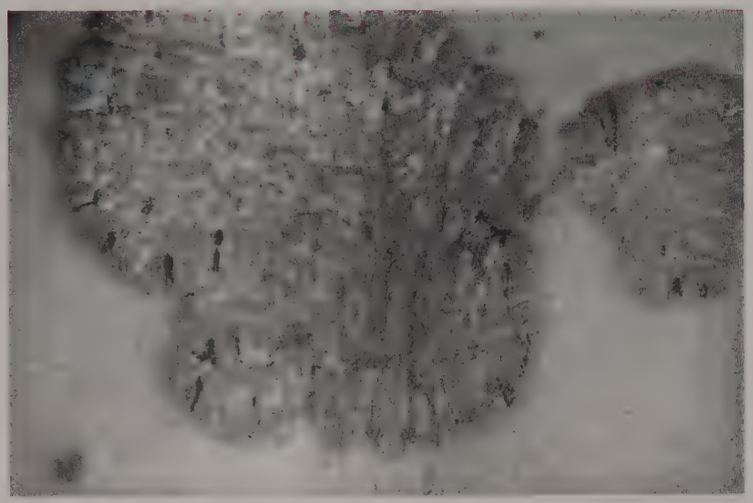

Fig. 12.4 Plaque psoriasis. (Reproduced with kind permission from Dr Graham Lowe, Ninewells Hospital, Dundee.)

Generalised pustular psoriasis is a rare yet serious form of the disease. Sheets of sterile pustules develop, merging on an erythematous background. These areas of skin shear and the patient will present with pyrexia, malaise and require hospital admission. It is often triggered when attempts are made to withdraw oral or topical steroids, or may just reflect the instability of the condition.

Scalp psoriasis can often be the sole manifestation of the disorder. Thick scale adheres to the scalp and can extend to the edges of the scalp margin and behind the ears.

Nail changes in psoriasis can involve pitting of nails and onycholysis, where the distal edge of the nail separates from the nail bed. There is no effective topical treatment for psoriatic nail changes.

Erythrodermic psoriasis is a rare but severe form. The skin becomes uniformly red with high blood volume flushing it. The patient feels unwell and maintaining body temperature is difficult. It can be triggered by the irritant effects of therapies, e.g. dithranol, tars, by withdrawal of oral/systemic steroids or by a medication reaction. Erythrodermic psoriasis is an unstable state that is potentially life threatening and warrants urgent hospital admission. The condition can progress to a generalised pustular psoriasis.

Psoriatic arthropathy Psoriasis can be complicated by psoriatic arthropathy, a 'rheumatoid-like arthritis' affecting about 5% of psoriatic patients. Joint changes occur in hands, feet, spine and sacroiliac joints. This 'rheumatoid-like arthritis' mimics rheumatoid disease but notably the rheumatoid factor test is negative. Psoriatic arthropathy is a difficult combination to treat, meriting the combined expertise of a rheumatologist and a dermatologist.

PATHOPHYSIOLOGY

The pathophysiology of psoriasis is characterised by certain general processes (see Fig. 12.5). The epidermis thickens, with an associated increased blood flow to the skin, and becomes raised to accommodate skin changes (parakeratosis).

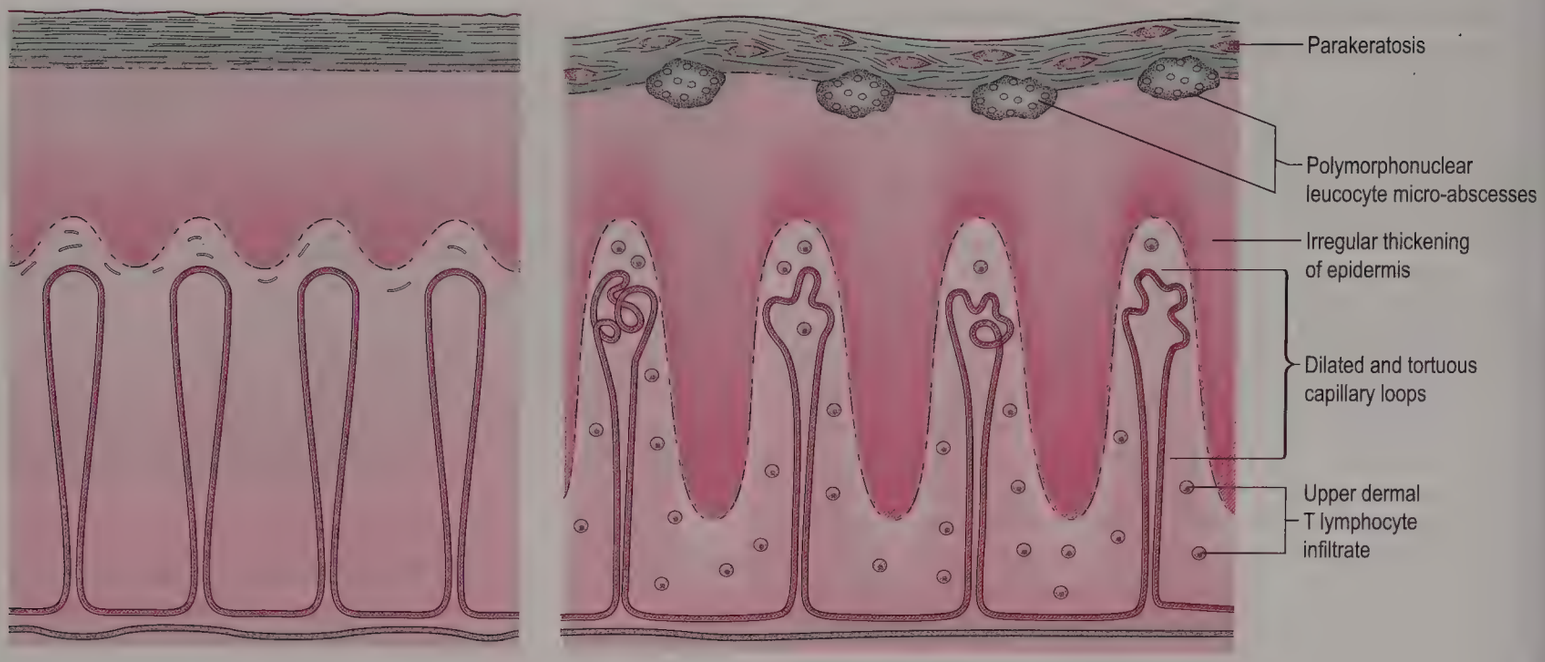

Fig. 12.5 Histology of psoriasis (right) compared with normal skin (left). (Reproduced from Hunter et al 2002, with permission from Blackwell Science Ltd.)

The epidermal cell proliferation rate increases. The transit time of epidermal cells maturing through normal skin is approximately 27 days, whereas in psoriasis it is 4 days. This suggests that psoriasis results from an increase in activity of dividing cells associated with an increase in their rate of reproduction, with trigger factors as yet unidentified.

Common presenting symptoms are as follows:

- *Pain.* Fissures form, particularly on hands and feet, because of loss of flexibility in the thickened epidermis.
- *Erythema.* Within the dermis, blood vessels dilate and increase blood flow to skin, causing generalised redness and heat loss.
- *Scaling.* The horny layer of the epidermis sheds easily in normal skin, but in psoriasis the cells become 'sticky' and build up, creating the silver-scale appearance diagnostic of psoriasis.
- *Pustules.* In inflammatory conditions, an infiltration of white blood cells is normal. Increased infiltration in pustular psoriasis accumulates as microabscesses in the outer layer of the skin.
- *Pruritus (itch).* Many textbooks describe psoriasis as non-itchy, but patients often report itch to be troublesome.
- *Sore throat.* Streptococcal throat infection is a common precipitating factor in guttate psoriasis.

MEDICAL MANAGEMENT

Where possible, psoriasis is managed on an outpatient basis, but the severity of activity in erythrodermic/pustular psoriasis will result in hospital admission to prevent potential life-threatening complications of an unstable psoriatic state (see p. 534).

Investigations Diagnosis can be made from the clinical picture and relevant history. Diagnosis and subsequent management may require all or a combination of the following examinations and tests:

- skin biopsy
- skin swab for flexural psoriasis
- throat swab
- Auspitz sign — gentle removal of the silvery scale from a plaque reveals pinpoint bleeding from the dilated superficial capillaries
- routine blood tests — viral check and full blood count.

Treatment may involve topical and systemic medication and phototherapy. PUVA/UVB are effective therapies for psoriasis (see p. 530). The combination of therapies chosen depends on diagnosis and severity of the disorder, topical prescribed therapies being the mainstay of psoriasis treatment (see p. 529).

Medication Combined systemic and topical medication is useful in the management of psoriasis. Systematic medications used include:

- antihistamines — to alleviate itch and promote sleep and rest
- analgesics — to reduce the pain and discomfort of inflamed skin
- antibiotics — to treat streptococcal throat infections.

The majority of psoriatic patients respond to topical therapies, but the more extensive forms of psoriasis may require a systemic approach (Hunter et al 2002). Medications that are particularly important in this regard are methotrexate, ciclosporin and retinoids (see p. 534).

NURSING PRIORITIES AND MANAGEMENT: Psoriasis

General nursing considerations

The goals of nursing management will vary depending on the type and severity of the psoriasis. For example,

erythrodermic or pustular psoriasis will merit skilful clinical inpatient management. However, many psoriatic patients will be treated as outpatients in a combination of settings, e.g. a specialist centre, the GP practice or at home. Education, support and empathy are vital to underpin the practical management of psoriasis. The nurse involved in outpatient management should have specialist dermatology knowledge and skills to support the patient through treatment regimens which can be messy and long-term. Decision-making regarding appropriate therapies should involve the patient and establish a partnership addressing the physical, social and emotional rehabilitation inherent in a successful outcome. Treatment sessions provide ideal opportunities for the nurse to explain the rationale for using topical therapies, to listen to concerns and to answer questions.

Psychological support

During skin assessment and nursing review, it often becomes apparent that the patient's psoriasis is affecting quality of life. The patient with a skin disorder is vulnerable and treatment sessions provide a private time between nurse and patient during which routine conversation can often reveal the true effect of the impact of the skin disorder on daily life (see Box 12.3). Psoriasis is a condition requiring long-term management, and it is through the collaboration of patient, carer and professional that the right blend of therapies for effective treatment can be found. Clinical psychologists in dermatology units work closely with the patient, as body image, sexuality, quality of life and personal coping strategies are all management considerations, and effective counselling can enhance the therapeutic effect. The Psoriasis Association (see 'Useful websites', p. 552) is a nationwide patient support group with local groups highly active in raising public awareness, supporting the patient and family, and raising funds for research.

Box 12.3

Problems reported by patients with skin disorders

Emotional problems
- Low self-esteem
- Feel body is 'unclean'
- Relationships can be problematic
- Feel people stare — real and imagined
- Regarded as infectious or contagious

Clothing restrictions
- Avoid short sleeves
- Avoid dark clothes due to skin shedding
- Avoid summer clothes where skin is exposed
- Clothes get stained or ruined due to messy creams

Social restrictions
- Skin gets itchy in hot pubs/clubs
- Avoid swimming or sports as people stare
- Avoid communal changing rooms when shopping

Financial implications
- Routine prescriptions are expensive but essential
- No allowances available to replace clothing or bedding
- No allowances available for fuel bills due to extra laundering and bathing

Nursing considerations in outpatient treatment

Management of topical therapy

A range of topical therapies is used in the outpatient management of psoriasis (see Box 12.4). The nurse should encourage patients to attend regularly for treatment, stressing the importance of meticulous adherence to prescribed treatment regimens. The nurse should also explain the different preparations used, giving advice on correct application and potential side-effects. Many prescribed topical therapies are not appropriate for use on the face. By providing clear information and ongoing psychological support, the nurse can help to ensure the patient perseveres with treatment. Specific considerations in using topical preparations are as follows:

Emollients The application of emollients is fundamental in the management of psoriasis. Bland emollients moisturise and lubricate the skin, helping to ease scaling and promote patient comfort. Regular applications seal the stratum corneum, thus reducing transdermal heat and fluid loss, which is particularly relevant in erythrodermic psoriasis (see p. 531). Patients with erythrodermic or generalised pustular psoriasis are often treated with emollients initially to allow fiery skin to 'settle' before the next line of treatment is introduced.

Coal tar ointments are distilled from coal in the production of gas. They are usually blended with white soft paraffin and have an antipruritic, anti-inflammatory and keratolytic effect. Treatment starts with low concentrations, which are gradually increased according to the tolerance of the skin. Tar applications are messy and smelly and they stain, so tend to be used for inpatient treatment. Proprietary blends of cleaner tar creams are available for outpatient therapy.

Tar is never applied to the face or to flexures. Patients must be advised that if ointment irritates or burns the skin,

Box 12.4

Examples of topical therapies used in psoriasis management

- Emollients — emulsifying ointment, 50/50 (white soft paraffin/liquid paraffin)
- Bath additives — Aveeno, Dermol 600, Hydromol, Oilatum
- Soap substitute — aqueous cream, emulsifying ointment, Epaderm
- Coal tar ointments — Alphosyl HC, coal tar solution, crude coal tar solution, Carbo-Dome
- Dithranol — Micanol, Dithrocream, Dithranol in Lassar's paste
- Vitamin D analogues – calcipotriol, tacalcitol, calcitriol
- Scalp therapy — olive oil, Cocois scalp application, Capasal shampoo, Polytar liquid, Alphosyl shampoo
- Phototherapy — ultraviolet light B (UVB)
- Photochemotherapy
  - — oral: psoralen tablets + ultraviolet light A (UVA)
  - — bath: trimethylpsoralen + UVA

it should be removed immediately in an emollient bath and advice sought.

Dithranol, originally obtained from the Goa tree in India and now made synthetically, suppresses cell proliferation (Buxton 2003). It is available in many forms, but patients must be informed that it can stain skin and clothes; staining can last for 10–14 days after treatment has finished. Dithranol is applied by spatula to affected skin and then covered with stockinette gauze to prevent the ointment spreading to surrounding skin. This procedure is time consuming and messy but effective. For outpatient therapy, short-contact treatment is available. Cream is applied to the plaque after protecting the surrounding skin with petroleum jelly and removed 30 min later.

Vitamin D analogues such as calcipotriol, tacalcitol and calcitriol are applied as a cream or ointment directly to plaques. They are non-messy, non-staining and well tolerated. Calcipotriol inhibits cell proliferation and stimulates epidermal cell differentiation, correcting the increased cell turnover time associated with psoriasis. Due to potential systemic absorption, there is a restriction on the quantities prescribed. The restriction will relate to the extent and severity of the psoriasis and it is important that patients are aware of the prescriptive guidelines.

PUVA/UVB (see p. 530) Both therapies are available to patients on an inpatient and outpatient basis. The treatment programme varies for each individual depending on identification of skin type and tolerance of sunlight. In PUVA therapy, 8-methoxypsoralen is taken orally 2 h before ultraviolet exposure is photoactivated, causing cross-linkage between DNA and inhibiting cell division. Retinoids (see p. 535) can be given with PUVA to stimulate more rapid skin clearance at lower total doses of ultraviolet light. Phototherapy is a pleasant treatment, the patient acquiring a gentle tan.

Goeckerman regimen This is a long-established and effective combination treatment in which the patient takes tar baths prior to exposure to ultraviolet light (Hughes & Van Onselen 2001).

Ingram regimen This is a combination therapy involving tar baths, ultraviolet exposure and dithranol applications.

Cocois ointment is a blend of tar, emulsifying ointment and salicylic acid used to treat scalp psoriasis. It is gently massaged into the scalp, left overnight and removed with shampoo of the patient's choice.

Olive oil can be used in maintenance therapy to reduce the build-up of scale on the scalp. For maximum benefit, patients are advised to warm the oil before applying it to the scalp.

Nursing considerations in inpatient care

Generalised pustular psoriasis and erythrodermic psoriasis can be life-threatening conditions requiring skilled nursing management.

Monitoring vital signs

Body temperature The patient will have difficulty in adapting to changes in environmental temperature. Body temperature must be monitored regularly, as skin temperature will fluctuate and may mask subnormal core temperature (see Ch. 22).

Blood pressure should be checked regularly. Hypotension may develop due to the shunt of blood to the peripheral circulation, leading to reduced cardiac output and potential cardiac and renal failure.

Maintaining fluid balance

Rehydration is important to correct the insensible fluid loss from the skin. The majority of patients will maintain a balance if encouraged to supplement their oral intake. The liberal use of topical emollients will help to reduce fluid loss.

For further reading on the management of erythroderma, see Gawkrodger (2003).

Other fundamentals of care

Basic hygiene Soothing emollient baths are ideal in psoriatic conditions to lubricate the skin and prevent further heat and fluid loss. In severe cases, however, bathing may be prohibited due to the disruption in the patient's thermoregulatory control caused by a high blood volume flushing the skin. Regular and liberal use of emollients will suffice until the patient's condition is stable enough to permit bathing (Hughes & Van Onselen 2001).

Rest This is of paramount importance to the patient's recovery.

Diet Because of the possibility of protein loss through the skin, dietitians should advise the patient on appropriate food choices, ensuring that foods are high in protein and have sufficient calories to counteract loss and promote healing. Supplementary protein drinks may also be indicated.

Physiotherapy This will help to minimise the side-effects of bed rest. Patients with psoriatic arthropathy will benefit from gentle exercise to maintain mobility and flexibility.

Systemic medication therapy

The severe nature of pustular and erythrodermic psoriasis usually merits systemic medication therapy, e.g. methotrexate and acitretin.

Methotrexate This cytotoxic medication, often used in the treatment of cancer (see Ch. 31), is a folic acid antagonist with an anti-inflammatory effect inhibiting mitosis. It is given once weekly via the oral, intramuscular or intravenous route. Careful monitoring of liver and bone marrow function is carried out and the patient on long-term methotrexate may require a liver biopsy to monitor the potential side-effect of liver fibrosis or cirrhosis. Improvement can usually be seen in 2–4 weeks. The patient should be advised to avoid alcohol and certain drugs that can interact with methotrexate, e.g. aspirin. As nausea is a

side-effect of methotrexate, patients are advised to take medication with food and an antiemetic should be prescribed.

Acitretin This retinoid is a vitamin A derivative which is very effective in pustular and plaque psoriasis. The medication is given on a daily basis in a dosage related to body weight. Acitretin influences the activity of the epidermis, normalising the plaques by thinning down hyperkeratotic lesions. A fasting blood lipid level is checked before starting acitretin and the patient is monitored for hyperlipidaemia during therapy, with referral to a dietitian for advice on a low-cholesterol diet if necessary. Patients may report side-effects persisting until the dose is reduced (as the psoriasis improves). Dryness of the mouth, lips and nose are common and unpleasant side-effects. Patients should be advised to use basic emollients and lip salves to ease discomfort. Reassurance that side-effects will abate once treatment is reduced or discontinued may help the patient to persevere with treatment.

Female patients taking acitretin require advice regarding adequate contraceptive measures during treatment and for 2 years after discontinuing, as this drug can be harmful to a developing fetus.

Complementary therapies

Many 'cures' are offered in psoriasis. For example, treatment programmes involving holidays in Israel are advertised, where therapy takes the form of skin exfoliation with Dead Sea salt during natural exposure to sunlight. Acupuncture, hypnotherapy and aromatherapy are also treatment options which have varying degrees of success. The best advice the nurse can offer is that the patient considering complementary therapy consults a recognised licensed practitioner. Combined complementary and conventional therapies can provide an active and beneficial treatment programme. Complementary therapies are becoming more widely available within GP surgeries (Ernst & White 2000).

The contribution of the nurse

The nurse's role in assisting the patient to manage their psoriasis will be varied and invaluable. Education, empathy and skilful clinical nursing must underpin practical management and psychological support (Penzer 1996). Psoriasis can have a major impact on quality of life. In a survey by Gupta et al (1993), of 127 patients with psoriasis, 10% reported a wish to die and 6% reported active suicidal intent. This study reinforces the importance of assessing the psychological impact of the skin disorder. The range of topical therapies can be bewildering, so the nurse must utilise clinical skills, supported by information leaflets, to ensure that the patient fully understands the treatment and methods of application. This practical support can enhance adherence with treatment and have a major impact on its success.

ECZEMA

The word 'eczema' comes from the ancient Greek 'to boil out of' and is the term applied to a range of inflammatory skin disorders. The aetiology of eczema is unknown. Most classifications of eczematous skin disorders use the term 'eczema' synonymously with 'dermatitis', as both terms apply to the inflammatory skin changes provoked by either internal (endogenous) or external (exogenous) factors. Eczema may occur as a result of one or both types of factor (Gawkrodger 2003).

Priorities of medical and nursing management are similar for all classifications of eczema.

Endogenous eczema

Atopic eczema (see Fig. 12.6)

Atopic eczema is a common inflammatory cutaneous skin disorder affecting 20% of infants in the UK; there are associated genetic and environmental factors. The word 'atopy' covers the classification of related disorders, e.g. asthma, eczema and hay fever. Atopic eczema can be a chronic itchy distressing disorder, having a major impact on a child's behaviour and quality of life and causing severe disruption to family life. Infantile eczema can resolve spontaneously but sometimes progresses to a chronic pattern of episodic exacerbations. Commonly affected sites are the flexural aspects of knees and elbows with involvement of the face and wrists. The prevalence of atopic eczema continues to rise and although this has been linked with increasing affluence in the UK population, it remains unclear how the two factors are related (Hay & Rustin 2004).

For further information on the impact of atopic eczema on the family, see Lawson et al (1998).

Pompholyx eczema

This blistering eczema is localised to palms and soles. It develops rapidly, causes acute discomfort on the hands and feet and can become secondarily infected. The cause is unknown and outbreaks do not appear to be related to any external factors.

Discoid eczema

This is an eczema of unknown aetiology, characterised by symmetrical coin-shaped lesions that affect the limbs and can be intensely itchy. It is more common in middle-aged and older people and may only last for a few weeks.

Asteatotic eczema

This condition mainly affects older people, commonly on the lower legs. It appears to be associated with a deficiency

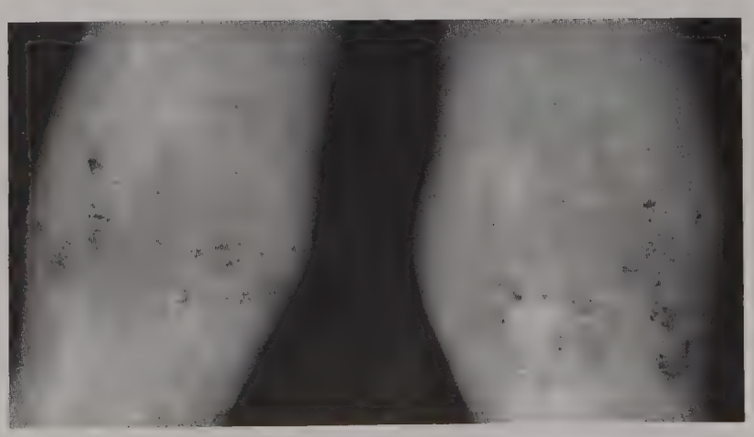

Fig. 12.6 Atopic eczema. (Reproduced with kind permission from Dr Graham Lowe, Ninewells Hospital, Dundee.)

of sebaceous secreting glands, resulting in excessive dryness and scaling of the skin. Central heating, diuretic therapy and over-frequent washing are also implicated as possible causes. The stratum corneum develops a 'crazy paving' appearance due to a network of fine red superficial fissures. Asteatotic eczema is readily treatable in the early stages with liberal use of emollients and bath oils. Scratching of a persistent itch creates a more resistant eczema which may merit topical steroid therapy.

Varicose eczema

This usually presents as chronic patchy eczema of the legs, with or without the presence of a varicose ulcer (see Ch. 23). The eczema arises due to associated chronic venous stasis and the area involved may become itchy. The eczema is often accompanied by the presence of varicose veins, oedema and pigmentation of the skin, the last occurring due to haemosiderin from the blood leaking through capillary vessels under elevated venous pressure (Gawkrodger 2003). Patients often develop a secondary response to this initial area of eczema and may produce associated eczematous areas on other parts of the body.

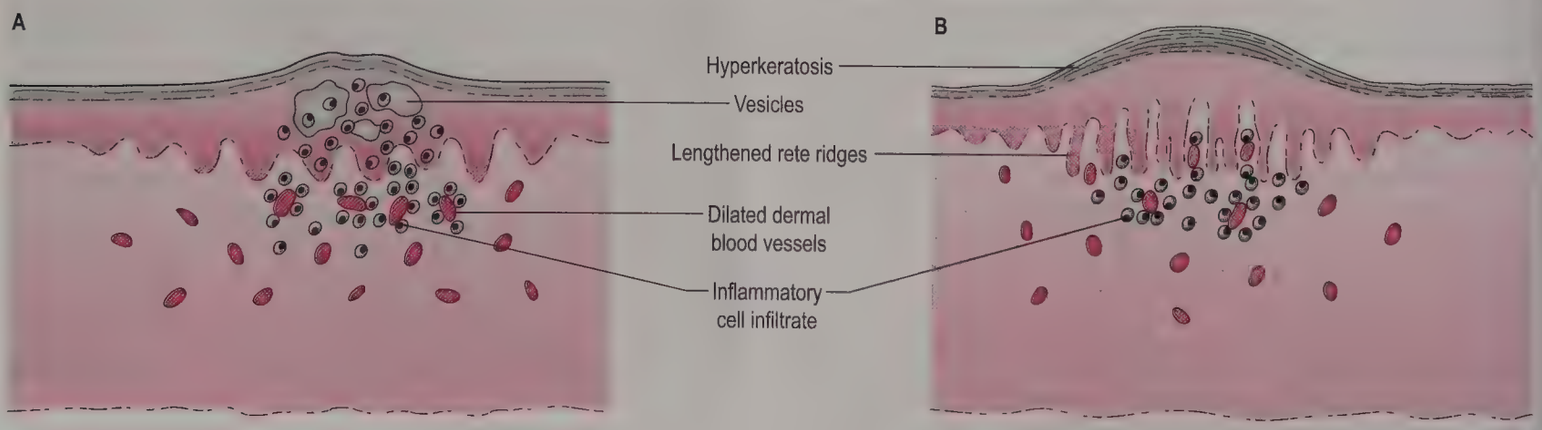
Exogenous eczema

Irritant contact eczema is very common, especially in industrial settings. The eczema usually erupts at the maximum point of contact. Presentation varies according to the nature of the irritant contact. The epidermis may be damaged by abrasion, and the effect of the irritant, e.g. coal dust, cement, is exacerbated by rubbing against clothing. Epidermal necrosis may occur within hours of contact with strong chemicals, while eczema triggered by milder substances, e.g. detergents, may take longer to evolve. Many patients with atopic eczema appear prone to irritant contact eczema and should be advised to avoid work where exposure to irritants could be problematic.

Allergic contact dermatitis

Allergic contact dermatitis is a condition in which the skin develops a specific immunological hypersensitivity. The most common allergic response of this type, particularly amongst women, is to nickel as found in inexpensive jewellery. Continued exposure to the allergen will result in an eczematous response, ranging from mild to severe. Allergic contact dermatitis may be triggered by, for example, rubber, certain plants and cosmetics; in many cases a change of job or avoidance of the allergen may be necessary (Hunter et al 2002). The most difficult cases to treat are those in which allergic contact dermatitis is suspected but no definitive triggering factor can be proven.

PATHOPHYSIOLOGY (see Fig. 12.7)



Acute eczema presents with redness and swelling caused by increased vasodilatation and generalised oedema of the skin. The erythema may be generalised over the body. Acute eczema exacerbated by scratching will extend to an exudative, scaling and crusting phase.

In chronic eczema involving recurrent exacerbations, the skin is scaly, excoriated, thickened and pigmented. The eczematous areas will be localised to more defined parts of the body and lichenification will be apparent. Lichenification is a skin response to repeated scratching in which the affected areas become thickened and toughened and show a marked exaggeration of normal skin markings. Chronic scratching and thickened skin in combination allow deep, painful fissures to develop as the skin loses its normal elasticity.

Common presenting symptoms are as follows:

Itch (pruritus), which accompanies most eczematous conditions, can be acute and distressing. The itch–scratch–itch cycle quickly becomes established. The skin is well supplied with sensory nerves that respond quickly to the mechanical stimulation of scratching or any external stimulation. Because of the manner in which sensory impulses are transported, itch has two components: a quick, localised prickly sensation, followed by a slow and diffuse burning itch.

Redness Blood supply to the skin is prolific and is normally only required to function at low volume. Inflammatory skin diseases alter this balance by causing dilatation of blood vessels feeding the skin, leading to a generalised total body redness (erythroderma). In atopic eczema, white dermographism can be evoked due to the abnormal response of the skin's vascular change. Firm strokes of the skin normally produce a 'weal and flare' response, a pink raised weal lasting about 30 min, but in atopic patients a simple white line arises, leaving the pressure site with no erythema.

536 Fig. 12.7 The histology of acute (A) and chronic (B) dermatitis.

Fissures/lichenification Chronic stages of eczema create a thickening of skin over flexures or any area traumatised by scratching. Open fissures are painful and slow to heal. In the chronic stages, there is also a generalised thickening of the prickle cell and horny layers of the skin.

Summary Eczematous conditions present with varying degrees of severity. An acute phase of eczema may present as a weeping, inflamed response, while a chronic condition gives rise to fissures and clearly defined excoriated areas. Patients will describe itch, pain and tenderness. Loss of the normal barrier of intact skin has associated fluid and heat loss. Excoriations may lead to secondary infections, which contribute to keeping the eczema active, and patients with atopic eczema tend to be more susceptible to viral infections, e.g. herpes simplex virus and eczema herpeticum (see p. 543).

MEDICAL MANAGEMENT

Diagnosis is made from the clinical picture of the disease process and the patient's history. Many of the exogenous conditions are managed in an outpatient setting; however, severe exacerbations warrant hospital admission.

Investigations Precise diagnosis may require all or a combination of the following.

Laboratory investigations will include:

- skin swabs — excoriated lesions may result in secondary infection
- skin scrapings — to exclude fungal infection
- skin biopsy — for immunohistological examination when the diagnosis is in doubt.

Patch testing may be carried out to confirm allergic contact dermatitis. A range of patch tests is available in which suspected allergens, e.g. nickel, fragrance, hairdressing products, plant material and rubber, are made up in a concentration which would normally produce no reaction unless the patient is sensitive to them. Allergens are applied to the back, left in situ for 48 h and then removed. The site of the test is 'read' at 96 h. Positive results vary from mild erythema to small blisters. Patch tests should not be carried out while the patient is in the acute phase of eczema or using a topical steroid to avoid exacerbating the condition or obtaining misleading results.

For further reading on patch testing, see Ratcliffe (1998).

Blood tests may indicate the presence of specific antibodies to external factors, e.g. dust mite, cat/dog hair or pollens, supportive of a diagnosis of atopic (exogenous) eczema.

Treatment is either systemic or topical.

Systemic medication therapy includes the use of:

- antihistamines — to reduce itch by blocking histamine receptors; although drowsiness is a side-effect, it may aid sleep and rest
- antibiotics — to treat bacterial infection, specifically *Staphylococcus aureus*, caused by excoriation
- analgesics, e.g. paracetamol — to ease heat, tenderness and localised pain.

Box 12.5

Examples of topical therapies used in the management of eczematous conditions

- Emollients — 50/50 (white soft paraffin/liquid paraffin), Dermol 500, Doublebase, Diprobase cream, Epaderm, Oilatum cream
- Bath additives — Aveeno, Cetraben, Dermol 600, Hydromol, Oilatum, Oilatum Plus
- Soap substitute — aqueous cream, emulsifying ointment, Epaderm
- Corticosteroids — very potent, potent, moderate, mild
- Corticosteroids/antibiotics — Dermovate-NN, Betnovate-C, FuciBET, Locoid C, Fucidin H
- Bandages — Ichthopaste, Quinaband, wet wrap dressings

Topical therapies are a priority in the management of eczema (see Box 12.5). Eczema also improves in some patients on exposure to natural sunlight.

NURSING PRIORITIES AND MANAGEMENT: Eczema

General nursing considerations

Nursing management is of central importance in the treatment of eczema, and patients and their families must be involved in setting goals for care. The short-term priority of management is to alleviate discomfort. A tired, hot, itchy patient is not in an ideal state to absorb information and learn self-care techniques, and therefore an immediate and sympathetic approach to care is important (Hughes & Van Onselen 2001). Ongoing support and reassurance are fundamental to achieving long-term goals. Informing the patient about eczema creates greater understanding of the condition and its outlook. Treatment sessions present the ideal opportunity to familiarise the patient with topical therapies, their effects and the rationale for their use.

Giving psychological support

Collaboration of patient, carer and health professional is vital to a successful treatment outcome. Substantial time and effort can be required to motivate, educate and empower the patient to share the process of managing the condition. The National Eczema Society is an active patient support group offering a wide range of information, skin education road shows and peer group support essential to raising self-awareness and self-esteem (Jeyasingham 1997).

Nursing considerations in topical therapy

Emollients

These moisturisers, used to make dry and scaly skin smoother, take the form of bath oils, creams and ointments and are the mainstay of treatment. Itch, heat and dryness all respond promptly to lubrication. Many emollients create a barrier for inflamed skin, preventing further fluid and heat loss. Eczema is a condition in which the skin is chronically dry, so long-term use of emollients maintains good skin

moisture. Patients should be advised to avoid perfumed products and use prescribed bath oils and soap substitutes. Continued use of emollients throughout the day is a major adjunct to therapy. In hospital, the patient will use very greasy moisturisers and emollients, but these products may be unsuitable for use at home or in the workplace. For community use, there are bland emollients such as Aveeno, Cetraben, Diprobase, Doublebase, Oilatum or Hydromol which are effective, non-messy and non-staining. Many of these are available in pump dispensers and are attractively packaged to encourage use.

Steroids

The application of steroid creams and ointments constitutes the next line of management in inflammatory skin disorders. These preparations are absorbed into the skin to dampen down the inflammatory response mechanism. Because steroid therapy will have a major impact on the eczematous skin, it is important that the patient understands the correct methods of application. Absorption of topical steroid and the volume of cream used will be greater if the skin is dry and excoriated (Morris 1998). Thus the skin must be regularly moisturised with emollient as an adjunct to steroid therapy, and steroids should be applied to freshly bathed skin or at least 20 min after the application of an emollient. Using the 'fingertip method', measured amounts of cream (see Fig. 12.8) are gently massaged into the affected areas for maximum effect (Hunter et al 2002).

Although the best treatment advice is to start with the lowest strength of steroid possible to treat the skin, many eczematous conditions require a potent steroid to switch off the inflammatory process. Treatment programmes involve starting with a medium to strong steroid applied twice daily, gradually reducing the strength of the creams used as the condition improves. Many patients are aware of the side-effects of topical steroids, e.g. systemic absorption, striae, loss of subcutaneous fat and fragile skin. The nurse must emphasise that it is prolonged use of strong topical steroids with inadequate use of emollients that produces chronic side-effects. In eczema, secondary bacterial infection may be present and treatment may include a combined steroid and antibiotic cream.

Bandaging

A variety of occlusive, medicated bandages is available for dermatological therapy (see Box 12.5). Applied overnight, they provide a cooling effect and their occlusive action creates a moist environment which aids the absorption of topical therapy. They also provide a mechanical barrier, preventing damage to the skin from scratching. The use of wet wrap dressings is a well-established therapy in managing the child or adult with eczema. The technique involves the initial application of emollient, or steroid and emollient, followed by covering with, first, a wet layer of Tubifast, a tubular conforming bandage, and then a dry layer of Tubifast. Water in the moist bandages evaporates, creating a cooling effect that markedly reduces pruritus (Page 2003). This is a simple procedure that is quick to apply, well tolerated and effective. The skilled community nurse who can teach bandaging techniques to parents can help to restore harmony to a family when a child with eczema is distressed by itch, particularly during the night. Tubifast garments for children have recently been introduced in the form of vest top, tights and leggings.

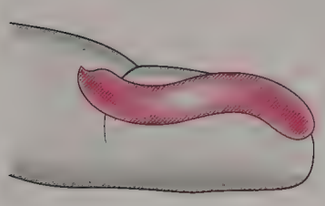


Fig. 12.8 Fingertip unit measures about 0.5 g of ointment. (Reproduced from Hunter et al 2002, with permission from Blackwell Science Ltd.)

Other considerations

Rest

Rest is imperative for recovery in more severe eczematous conditions. In hospital, the patient is afforded the opportunity to suspend activities of socialisation, taking time out to allow the skin to heal. In the home or school, disruptive, manipulative behaviour is often described in the child with atopic eczema, who may merely be distraught by itch and inadequate sleep (Titman 2003). The nurse must give clear information and reassurance on the safe use of antihistamine medications in children. Many parents are not keen to give their child medicines, but the judicious use of antihistamines will provide rest and relief for the eczema sufferer and the family (Bysshe 1996).

Diet

Diet is implicated in some forms of infantile eczema where the child is allergic or intolerant to milk or milk products. The best advice to give to patients is to maintain a well-balanced diet while avoiding foods known to cause irritation (Hughes & Van Onselen 2001). Exclusion diets to identify food allergy are difficult and should be attempted only under the supervision of a dietitian.

Complementary therapies

The stress of having a skin disorder applies particularly to eczema, where patients can be distraught with physical symptoms and altered body image. When conventional medicine, with its potential side-effects, cannot offer a cure, the nurse working with patients with skin disorders should also be aware of the diverse range of complementary therapies available.

These include:

- evening primrose oil
- homeopathy
- herbal therapy
- aromatherapy
- reflexology.

Complementary therapy should not be viewed as a total alternative to conventional medicine and referral to a qualified practitioner is essential for safe management. Traditional Chinese medicine using self-help tools from energy-based therapies, e.g. Dru Yoga, Shiatsu and Chi

Kung, can blend with Western techniques to reduce stress and boost the body's natural healing capacity. Habit reversal methods are available that focus on breaking the itch–scratch–itch cycle of eczema (Bridgett 1996). The main aim of habit reversal is to create awareness in patients of when and how often they scratch their skin. Treatment methods vary for each age group so specialist help must be sought before undertaking such techniques.

The contribution of the nurse

The specific role of the nurse depends on the severity of the condition and the treatment setting. Current policy to maximise outpatient management places the primary care team at the forefront of skin care, and therefore their clinical skills and educational abilities must address the identified need. Much of dermatology nursing focuses on the child with atopic eczema and their family, due to the acknowledged impact this condition has on quality of life. Co-ordinated care and holistic practice can be achieved through a multidisciplinary team approach (Lynn et al 1997).

School nurses can support and motivate the child to maintain skin care at school while educating teachers about the physical and psychosocial impact of eczema (National Eczema Society 2003). Health visitors should be involved in regular monitoring to ensure therapies are not inhibiting the child's development.

In the workplace, the occupational health nurse advises on changes in work practice to reduce risk factors and the incidence of industrial-acquired skin disorders (Payling 1996). In every setting, the nurse practitioner should utilise all available resources and refer patients appropriately to the relevant agencies and support groups.

12.2 Ms H is the single parent of three children aged 1, 3 and 5 years. She is unemployed and lives in rented one-bedroom accommodation while on a council house waiting list. Her 3-year-old son has severe eczema. He is kept awake at night by severe itch and disrupts the household.

Discuss with a health visitor how this mother might be helped to cope with this situation.

SKIN INFECTIONS AND INFESTATIONS

This section describes infections and infestations commonly encountered in the community; awareness of them is particularly relevant to the community practitioner. Many of these conditions cause consternation among sufferers because of their real or perceived social implications. Sound common sense, the ability to dispel myths, and practical skill in identifying, assessing and treating the conditions described are fundamental to care (Docherty 2001).

Fungal infections

The most common fungal infections are caused by the dermatophytes *Trichophyton* and the yeast-like fungus *Candida albicans*, which are responsible for superficial infections confined to the skin and mucous membranes. Deep fungal infections can remain localised or cause systemic disease.

Dermatophyte infections

Dermatophytes are botanically related fungi responsible for superficial fungal infection. Some dermatophyte infections are confined to humans, while others principally affect animals, although transfer of fungal infections from animal to human does occur, causing severe inflammatory skin reactions. Dermatophytes grow in keratin, i.e. stratum corneum, hair and nails, and these superficial infections are usually indirectly acquired by contact with keratin debris carrying fungal hyphae (Gawkrodger 2003). The term 'tinea' is the generic description given to these fungal infections.

Tinea pedis or athlete's foot is the most common of the dermatophyte infections. The patient complains of itchy, scaling skin between the toe webs, commonly acquired through contact with infected keratin on the floors of swimming pools or showers.

Tinea cruris affects young males, presenting as scaly erythematous lesions on the inner thighs and spreading to the perineum and buttocks. The source of infection is usually athlete's foot and the fungus is transferred to the groins on fingers or towels.

Tinea unguium is the term for fungal dystrophy of the toenails in which the nail thickens, discolours and becomes very friable.

Cattle ringworm (tinea corporis) is common amongst farm workers or visitors to farms. The fungus is picked up from gates or fences where cattle have left keratin debris containing the organism. The face and forearm tend to be affected and the fungus provokes a severe inflammatory reaction.

MEDICAL MANAGEMENT

Skin scrapings taken for examination under the microscope and fungal culture are used to confirm the diagnosis. Topical treatments are broad-spectrum antifungal creams, e.g. miconazole (Daktarin) and clotrimazole (Canestan), which are available over the counter. Topical therapy for dystrophic nails is ineffective. Oral therapy is available for scalp, nails and skin ringworm.

NURSING PRIORITIES AND MANAGEMENT: Dermatophyte infections

Nursing management focuses on containment of infection and promotion of basic hygiene (Hughes & Van Onselen 2001). Avoidance of shared face cloths/towels prevents further spread. The nurse can advise on prescribed and OTC therapies and their correct method of application. Treatment programmes may involve combined oral and topical therapies, and patients should be advised to persevere where therapies take time to resolve the condition. Conditions can recur, so educating the patient in management of the condition is beneficial in preventing this.

Candida infection

Candidiasis (thrush) is the term applied to infections of the skin and mucous membranes by *Candida albicans*. This

fungus is a normal commensal of the human digestive system, only becoming pathogenic if the opportunity presents itself. Immunosuppressed patients, people with diabetes, patients on broad-spectrum antibiotics or on topical and systemic steroid therapies are all at risk from this opportunistic infection.

Buccal mucosal candidiasis refers to oral thrush presenting as milky curd-like spots on the tongue and inner cheeks. It often affects babies, older people and patients on broad-spectrum antibiotics (see Ch. 15).

Candida vulvovaginitis describes vaginal thrush, which presents with a creamy vaginal discharge and itchy erythema of the vulva. This condition tends to be associated with pregnancy, use of oral contraceptives, antibiotics and diabetes.

Candida balanitis is a thrush infection of the foreskin and glans. It tends to be more common in uncircumcised males and may be associated with poor hygiene or diabetes. It can recur if a sexual partner also has vaginal thrush.

Chronic paronychia is a candidal infection of the nail plate which is common in people whose occupation involves repeated immersion of the hands in water, e.g. hairdressers, nurses, bartenders. The nails become distorted and the nail base is painful, red and swollen.

Intertrigo is the term given to candidal infection of the skin folds. Where two skin folds are in opposition, such as the groins, axillae and submammary regions, there is increased heat and humidity and thrush infections are common, e.g. nappy rash. Obesity and poor hygiene exacerbate the problem. The skin displays erythematous, well-demarcated erosive lesions and is tender, moist and painful in these areas.

Angular cheilitis is a common condition of older people where the deep grooves at the side of the mouth tend to be moist with saliva; a *Candida* infection exacerbates the problem. It is common in denture wearers but can also be a feature of iron or vitamin B_{12} deficiency.

MEDICAL MANAGEMENT

Skin swabs, scrapings or nail clippings are taken to confirm diagnosis. Urinalysis should be performed to exclude diabetes. A full blood count must be carried out in older people with angular cheilitis.

Treatment is specific to the area affected. Antifungals in the form of creams, ointments and pessaries are very effective. Oral antifungal drugs are indicated in the treatment of nail infections. A combined mild steroid/antifungal, e.g. clobetasone butyrate (Trimovate), is appropriate to treat intertrigo, reducing both inflammation and infection. Combination packs of vaginal pessary and cream are available for vaginal thrush, e.g. clotrimazole, and these are usually single applications, depending on the dose/strength of the preparation. Newer OTC preparations include a single dose of the antifungal drug fluconazole (Diflucan).

NURSING PRIORITIES AND MANAGEMENT: Candida infection

Providing advice on basic skin hygiene and information about therapies available, whether prescribed or OTC, is an important nursing role. The nurse must be able to identify those at risk of opportunistic infection, e.g. older people, babies and patients having chemotherapy. The nurse's role as counsellor is vital in the treatment of genital thrush and confidential information should be respected when sexual partners are treated concurrently to prevent reinfection.

Infestations

Scabies

Scabies is a skin infestation caused by the mite *Sarcoptes scabei* and acquired by prolonged close physical contact with the mite. The female scabies mite burrows approximately 1 cm into the stratum corneum, is fertilised by the male mite and begins to lay eggs along the burrow. For the first 4–6 weeks after infestation there may be no itching, but thereafter, pruritus dominates the picture, especially at night. This is thought to be due to a hypersensitive response to the mite (Hunter et al 2002). Skin examination usually reveals burrows, principally on the hands and feet, the sides of fingers/toes, between finger and toe webs, the wrists and the insteps. Facial burrows are only seen in babies. Burrows can also present on the genitalia of males. A scabies 'rash' may be present in the axillae, umbilicus and thighs. Excoriation can cause burrows to become eczematised and infected, which can often confuse diagnosis.

Norwegian scabies is the term given to the form of scabies presenting in patients who have sensory deficits where the sensation of itch is absent, e.g. in spinal injuries, or in patients who are immunosuppressed either because of disease or treatment of disease, e.g. AIDS, lymphoma, systemic steroids or transplantation. Absence of scratching leads to large numbers of mites remaining on the skin in crusted lesions. During skin shedding, mites are shed into the environment, and therefore any person in contact is at considerable risk of developing scabies from the patient with Norwegian scabies.

MEDICAL MANAGEMENT

Diagnosis can be confirmed by using a needle to remove a mite from a burrow and examining it microscopically. Current topical therapies are permethrin and malathion (see Box 12.6 for treatment advice and guidelines for application). Once the infestation is treated, further therapy with a combined steroid/antibiotic cream may be necessary to reduce itch and treat excoriated lesions until the skin is fully healed. Antihistamine tablets are appropriate if itch disturbs sleep. Soothing topical preparations, e.g. Eurax cream, can be useful until residual itch disappears.

NURSING PRIORITIES AND MANAGEMENT: Scabies

The priority is to treat the patient and identify close contacts requiring treatment. The nurse combines practical advice with psychological support, recognising the social

Box 12.6

Patient advice sheet for the self-treatment of scabies

How to apply a scabicide

1. Read the advice leaflet thoroughly before starting treatment
2. The skin should be cool and dry. Avoid bathing immediately before applying cream
3. Apply the cream as prescribed from the neck down — avoid the face
4. Pay particular attention to finger/toe webs, the soles, skin folds (axillae/groin), under finger- and toenails
5. Put on clean nightwear and change bed linen — normal laundering is adequate
6. Leave the cream for 8–12 h as the prescription states (overnight is ideal)
7. Bathe or shower at the end of the 8–12 h period

Points to note

- It is important that all family members/contacts are treated at exactly the same time. If there is any delay in treatment, avoid further contact with the person until they are treated
- If hands are washed during the treatment period of 8–12 h ensure cream is reapplied to the hands
- Weaker strengths of cream are available for pregnant women or infants
- Treatment can be repeated but your doctor will decide if this is needed
- Scalp treatment may be required in infants and older people

embarrassment that infestation can create. Outpatient management is ideal and the nurse must identify current treatments and their correct method of application. As recurrent scabies is often due to poorly applied treatments, both patient and nurse should read carefully the advice leaflets provided with topical scabicides. The patient may require repeated applications of scabicide until the condition resolves. Transient contact with the patient is unlikely to cause transmission and the nurse can be reassured and can reassure colleagues about this. However, the patient with Norwegian scabies is highly contagious and should be isolated while treatment is ongoing. Local infection control policies must be followed. Normal washing of linen and clothes is adequate.

12.3 A family of five (two adults and three children, aged 15, 6 and 3 years) have to treat themselves for a scabies infestation. Their GP suggests that a leaflet could be given to them to ensure they follow the correct advice. Review existing printed leaflets. How would you guide the family in obtaining information from the world wide web?

Head lice (pediculosis capitis)

Head lice are transmitted by close contact. The adult female louse lays eggs which are cemented to the hair approximately 0.5 cm from the root. Scalp irritation and itch are due to the saliva produced as the louse bites the scalp. The 'nit' is the empty case left once the larvae have hatched — the case becomes white and is more easily detected. Head lice is an emotive topic, as it continues to be endemic amongst schoolchildren and causes great consternation to parents.

NURSING PRIORITIES AND MANAGEMENT: Head lice

The initial priority is to treat the patient and appropriate contacts. Treatment usually consists of a lotion applied to the scalp, e.g. malathion (Prioderm), which is left on for a number of hours and then shampooed out. Treatment may need to be repeated. Gently combing with a fine-tooth comb assists in the final removal of nits. Department of Health (2001) guidelines rotate scalp therapies to prevent the development of treatment-resistant head lice.

Carbonyl, a product found in head lice treatments, was highlighted as carcinogenic in animals and many scalp preparations were restricted to prescription-only availability. Department of Health guidelines also identified a theoretical risk to humans and acted in response to public alarm. At present the nurse should continue to reassure parents that adherence to treatment is preferable to an uncontrollable rise in head lice infestation. Current scalp therapies are constantly reviewed and their safe use is encouraged, following the treatment guidelines issued with each product. These preparations cannot be used as prophylactic treatment to prevent infestation. The school nurse is ideally placed to target and educate students, teachers and parents in the treatment, preventive strategies and environmental measures that will assist in the reduction and control of head lice.

Bacterial infections

Staphylococcal and streptococcal infection: cellulitis

Cellulitis is an acute, spreading and potentially serious infection of dermal and subcutaneous tissue, characterised by red, tender skin at the site of bacterial entry. Organisms isolated in cellulitis include *Staphylococcus aureus* and *Streptococcus pyogenes*. Cellulitis is a common condition in older people, who tend to suffer from lower limb oedema (see Ch. 2). Infection enters the skin in a variety of ways, including surgical wounds, stasis eczema or leg ulcers, minor abrasions and i.v. drug injection sites. Erysipelas is the name given to a superficial streptococcal infection of the skin.

In adults, the most common presentation is cellulitis of the lower limbs, with the point of entry of infection usually being a fissure between the toes which may be secondary to tinea pedis (athlete's foot). The site affected will be oedematous, red, hot and painful. An associated general malaise with rigors and fever develops. Enlarged local lymph nodes may be present.

MEDICAL MANAGEMENT

Management involves isolation of the organism by blood cultures and treatment with appropriate oral or i.v. antibiotic therapy. Analgesics reduce the pain of inflammation.

NURSING PRIORITIES AND MANAGEMENT: Cellulitis

Bed rest, monitoring of temperature and appropriate action if rigors occur are the first line of nursing management. Pain assessment and administration of regular analgesics will ease discomfort.

Cellulitis of the lower limbs requires bed rest and elevation of the affected limb to reduce oedema. Exercising reduces the complications of prolonged bed rest and should be encouraged. Once the condition resolves, general advice on basic skin care and avoidance of predisposing factors is helpful. Patients can have recurrent cellulitis and may be prescribed prophylactic antibiotic therapy to prevent future episodes.

Staphylococcal infections

Impetigo

Impetigo is a superficial bacterial infection of the skin caused by *Staphylococcus aureus*, sometimes combined with haemolytic streptococci. The head and neck are the most common sites. The condition starts as a small but gradually enlarging pustule that ruptures to leave a raw exuding surface. The exudate dries and forms the yellow golden crust typical of impetigo. It can occur as a secondary infection, e.g. associated with eczema and scabies.

Folliculitis

Folliculitis, an infection of superficial hair follicles by *Staphylococcus aureus*, presents as a small pustule on an erythematous base centred around the follicle. In dermatological conditions, folliculitis may be exacerbated by the use of greasy ointments, occlusive bandages and tar therapies.

MEDICAL MANAGEMENT

In all bacterial infections, treatment is by the use of topical and oral antibiotic therapies (Gawkrodger 2003).

NURSING PRIORITIES AND MANAGEMENT: Bacterial infections

The nurse should give guidance about each infection and its transmission. Guidelines on personal hygiene and the avoidance of communal use of towels/cloths can reduce the spread of infection. Practical management includes the gentle application of mild topical antiseptics to remove crusted lesions. Correctly applying creams and ointments in the direction of the hair growth can reduce the incidence of folliculitis and patients should be advised to complete their course of systemic or topical antibiotics to ensure treatment efficacy. The nurse must recognise and acknowledge the profound psychological impact of having a skin infection, as the social stigma of impetigo and the public perception that these conditions are associated with poor hygiene create major worries for both patient and family. Good clinical practice, enhanced with practical information and sympathetic support, will help to address the patient's physical and psychological needs.

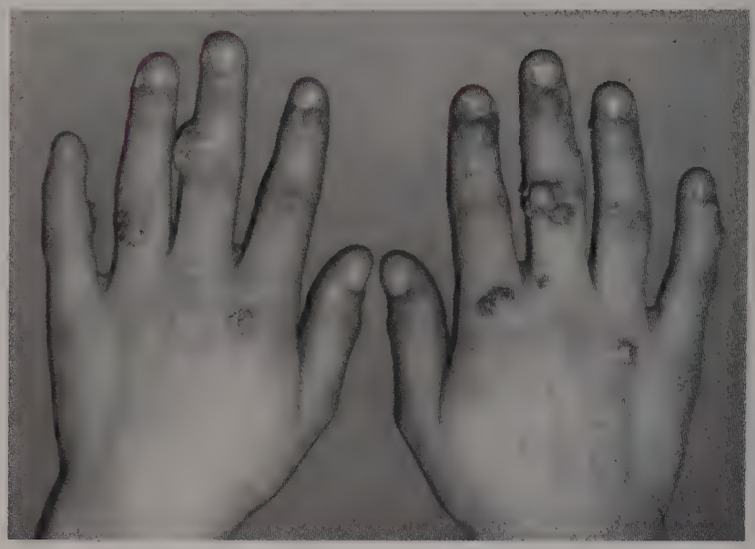

Fig. 12.9 Hand warts. (Reproduced with kind permission from Dr Graham Lowe, Ninewells Hospital, Dundee.)

Viral infections

Warts (see Fig. 12.9)

Infection by the human papilloma virus affects the DNA in epidermal cells, creating warts. Different clinical manifestations are specific to different viruses (Gawkrodger 2003).

Warts are benign, highly contagious and can be cosmetically unacceptable. Group transmission is the mode of contact, e.g. in gyms, swimming baths or schools. The classification of warts is outlined in Box 12.7.

MEDICAL MANAGEMENT

Diagnosis is based on history and clinical appearance. Treatment may involve topical application of ointments or premedicated plasters containing salicylic acid to soften and remove the wart, or cryosurgery.

The nurse should explain virus transmission and encourage the meticulous continuation of treatment. Many patients become disheartened by the slow resolution of the problem and discontinue treatment. Regular assessment by the practice nurse may encourage adherence to recommended treatment.

Box 12.7

Classification of warts

- Common warts — hyperkeratotic nodules occurring on the hands and feet of children. These often resolve spontaneously
- Plane warts — smooth flat-topped warts appearing on the face and hands
- Plantar warts — commonly known as verrucae where the papilloma virus is pressured into the dermis, creating a callus. The most common site is the feet
- Genital warts — a mass of warts with a cauliflower-like appearance present on the perianal and genital areas

Molluscum contagiosum

This is a pox virus producing solid, skin-coloured or pearly-white papules on the skin. It affects adults but is more common in children, arising over a period of 2–3 months. The lesions may be single or multiple, occurring on the neck and trunk.

MEDICAL MANAGEMENT

Initial diagnosis is based on history and clinical appearance but if the condition does not resolve spontaneously, freezing the papules with local applications of liquid nitrogen can be carried out. When the condition occurs in children, parents require explanation and reassurance that the condition tends to be self-limiting. Normal basic hygiene rules prevent further spread.

Herpes simplex virus (HSV)

There are two types of herpes simplex virus: type 1 causes cold sores on the lip and face; type 2 is associated with genital herpes. Initial contact with the herpes simplex virus is usually in childhood and often goes unnoticed. However, development of primary cutaneous herpes simplex can occur and, in a child with atopic eczema, can be a severe life-threatening condition. Following primary infection, the virus can establish itself in sensory ganglia and be reactivated by, for example, sunlight, stress and colds. Reactivation of the virus is preceded by a tingling sensation before a cluster of small vesicles develops. The vesicles burst and lesions then crust, usually resolving in 10–14 days. Genital herpes is a sexually transmitted disease affecting the penis, vulva, perianal area and rectum. Following the primary episode, the virus persists in the presacral ganglion and can recur. This can be a serious condition in pregnant women because of the risk of transmitting the virus to the baby during labour and delivery.

MEDICAL MANAGEMENT

Recurrent herpes simplex is treated with topical aciclovir (Zovirax) which is now available over the counter. It must be used immediately on awareness of the tingling sensation, and applied five times daily for 5 days to inhibit vesicle eruption. Patients with genital herpes should be referred to genitourinary medicine for further investigation, appropriate management and expert counselling.

NURSING PRIORITIES AND MANAGEMENT: Herpes simplex

The nurse can advise patients at risk of recurrent episodes of primary herpes simplex on the use of topical aciclovir and should recommend its continued use until course completion. The patient should be reminded of basic hygiene standards to avoid further transmission of the virus during the active phase. The patient with genital herpes may require support and counselling from specialist genitourinary services. The pregnant woman with genital herpes requires good liaison between the woman and her obstetrician and midwife, to acknowledge the condition and its potential complications and to initiate appropriate action to minimise virus transfer during delivery (Gawkrodger 2003).

Eczema herpeticum (complication of HSV)

Eczema herpeticum is a widespread cutaneous herpes simplex infection occurring in patients with atopic eczema. In children it can be life threatening and the patient will be systemically unwell and febrile. Vesicles erupt rapidly over the face and neck and can extend over the rest of the body. The skin is taut, red and painful. As vesicles erupt and rupture, the patient becomes susceptible to secondary bacterial infection, e.g. impetigo (see p. 542).

MEDICAL MANAGEMENT

Treatment depends on the severity of illness and is a combination of antiviral and antibiotic therapies. The patient who is pyrexial and systemically unwell should be hospitalised. A side room to ensure source isolation is ideal, but good infection control procedures using standard infection control will reduce the infection risk to other susceptible patients (see Ch. 16). Oral aciclovir is adequate in minor cases, but if the patient is unwell then aciclovir is given by the i.v. route. The patient with eczema using topical steroids must discontinue these immediately until the virus resolves. Any secondary bacterial infection should be treated with topical antibiotic cream and oral antibiotic therapy. Analgesics may also be required, e.g. paracetamol.

NURSING MANAGEMENT AND PRIORITIES: Eczema herpeticum

The nurse's role in hospital is to maintain infection control policies in order to reduce the transmission of infection. The patient who is systemically unwell requires regular observations of temperature, fluid intake and rest until infection resolves. The nurse should assist in topical applications of prescribed creams as the patient may feel too unwell or too distressed by pain to manage this independently. Once the viral infection resolves, the nurse can advise the patient on restarting topical steroids for the eczema. Patients who are at risk of cold sores should keep aciclovir in reserve to use promptly if a cold sore develops. As aciclovir is now an OTC preparation, effective treatment is easier to achieve. A few days' delay in getting an appointment with a GP can be detrimental as this condition erupts quickly.

Herpes zoster (shingles)

Herpes zoster is caused by the varicella zoster virus. After an attack of childhood chickenpox, the virus remains dormant in the dorsal root ganglia of the spinal cord but can be reactivated later in life as shingles. The trigger factor is unknown, but the condition is common in immunosuppressed or stressed patients (see Ch. 16) and tends more commonly to affect middle-aged and older people.

PATHOPHYSIOLOGY

Once reactivated, the virus multiplies by invading host cells and utilising the replicatory mechanisms of the host cell to produce new DNA. The cell is lysed and virus particles are released to invade another cell. The virus particles migrate along the nerve fibres towards the skin surface, causing nerve damage and consequent pain. Balloon degeneration of the prickle cell layer of the epidermis results in the formation of fluid-filled vesicles (Gawkrodger 2003),

which erupt across the thoracic and/or cranial dermatome with a characteristic unilateral band-like distribution. Fluid taken from vesicles will contain virus particles.

Pain and tenderness often precede the vesicular erosions, and patients may have fever and will feel generally unwell. As the vesicles crust over, the infective risk resolves over a period of 2–3 weeks. The lesions can be erosive and may take longer to heal in older people.

MEDICAL MANAGEMENT

Diagnosis is confirmed by clinical history and viral culture. Treatment is by topical antiviral agent if lesions are still erupting, e.g. aciclovir. Oral or i.v. aciclovir is essential management in immunosuppressed patients. The potential complications of herpes zoster are:

- herpes zoster ophthalmicus
- postherpetic neuralgia — this merits the attention of the specialist pain team.

NURSING PRIORITIES AND MANAGEMENT: Shingles

In an acute attack of shingles, the patient may require hospitalisation. Standard infection control policies provide guidelines for isolation of the patient until the infectious stage resolves. The patient should be nursed by staff who have had chickenpox to reduce the contact problem, as there is a risk that contact with a patient suffering from shingles may cause chickenpox to anyone without immunity to that disease. In the early stages of shingles, topical applications of antiviral cream, e.g. aciclovir, can shorten the duration of the illness. The more seriously ill patient will require oral or i.v. aciclovir. Prompt referral to an ophthalmologist is vital for the patient with any eye involvement (see Ch. 13).

Certain groups of people are particularly susceptible to the transmission of herpes zoster, e.g. patients having radiotherapy and/or chemotherapy, and immunocompromised patients on oral or topical steroids. Community nursing staff should be aware of the long-term problems associated with shingles. A small proportion of patients report persistent pain (postherpetic neuralgia) continuing for many years. Chronic pain has a major impact on daily living and requires full assessment. Treatment options available for postherpetic neuralgia include transcutaneous electrical nerve stimulation (TENS), ultrasound, antidepressants and/or anticonvulsant therapy. Referral to a pain control clinic is advisable for the patient with intractable pain (see Ch. 19).

For further reading on skin infections, see Gawkrodger (2003), pp. 44–59, 64–65.

BULLOUS DISORDERS

The term 'bullous disorders' covers those skin conditions in which large watery blisters (bullae) arising within or immediately under the epidermis are a presenting feature (Hunter et al 2002). There are many causes of bullae (see Fig. 12.10) and histological location influences the classification of the disorder.

Early detection and treatment are essential, as many of the bullous conditions are severe and potentially life threatening.

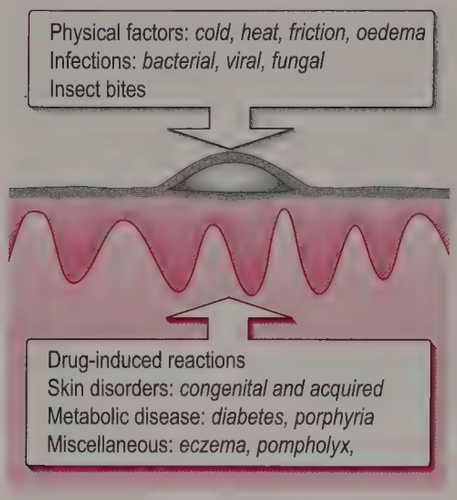

Fig. 12.10 Causes of blisters (bullae).

Pemphigus (intraepidermal bullae)

PATHOPHYSIOLOGY

This is an autoimmune disease occurring in adults. It is characterised by the development of autoantibodies against epidermal cell surface molecules creating superficial erosions and blisters on epidermal and mucosal surfaces.

Common presenting symptoms The main presenting feature is the presence of superficial fluid-filled blisters within the epidermis. These blisters are flaccid, thin-roofed and offer little resistance; consequently they shear, leaving raw, denuded skin. Pain from the exposed sites is a major factor in management. Oral lesions are common.

Clinical diagnosis is confirmed by a positive Nikolsky's sign, such that when lateral pressure is applied to the skin surface with a thumb, the epidermis shears and appears to slide over the dermis (Buxton 2003).

Pemphigoid (subepidermal bullae)

PATHOPHYSIOLOGY

This is more common in older people; 80% of patients are usually aged 60 and over (Marks 2003). Like pemphigus, pemphigoid is an autoimmune disease. Antibodies bind to the junction between dermis and epidermis, and blisters are formed in response to enzymes released from inflammatory cells.

Common presenting symptoms The patient reports generalised intense itch, followed by erythematous plaques on the skin (pre-pemphigoid stage), followed by the development of tense blisters affecting any area of the body. Nikolsky's sign is negative.

Toxic epidermal necrolysis (subepidermal)

PATHOPHYSIOLOGY

This condition presents as a dermatological emergency and is often precipitated by a drug hypersensitivity. The skin split is subepidermal and the entire epidermis shears off

in layers, leaving raw, denuded areas. A review of the patient's medication and removal of the causative factor(s) are essential to management.

Common presenting symptoms The skin is erythrodermic and painful, with the skin shearing off in sheets. Nikolsky's sign is positive. The patient will be distressed by pain and may have erosions in the mouth, oesophagus and bronchus.

MEDICAL MANAGEMENT

Early diagnosis is imperative due to the life-threatening potential of bullous disorders. Hospitalisation is a major aspect of treatment and management.

Investigations will include the following:

- Skin biopsy — to identify the type of skin split and exclude other bullous disorders
- Blood tests — to monitor urea and electrolytes in view of the associated fluid loss from eroded skin. In pemphigus the serum contains antibodies binding to the intracellular areas of the epidermis; titration of these antibodies is relevant to building a picture of the disease activity
- Skin swab — to define the bacteriological status of skin exposed to secondary infection.

Treatment will involve medication with the following:

- Antibiotics — to treat secondary infection
- Corticosteroids — in pemphigus and pemphigoid, high-dose oral steroids, e.g. prednisolone 60–100 mg/day, are the first line of management and are maintained until blistering stops. A gradual reduction in dosage is then commenced, aiming for low-dose maintenance therapy
- Analgesics — to alleviate pain from eroded skin lesions; choice is dependent on patient need and disease activity
- Antihistamines — to reduce itch and aid rest
- Immunosuppressants, e.g. cyclophosphamide, azathioprine — used in combination with oral steroids to control the disease process of pemphigus and pemphigoid.

Plasmapheresis is considered in severe cases and allows monitoring of circulating pemphigus antibodies. Topical therapy is non-specific, aiming for patient comfort.

NURSING PRIORITIES AND MANAGEMENT: Bullous disorders

This section focuses on general nursing care of the three disorders described. Although rare, they are more commonly seen in dermatology units. It may help the reader to understand the rationale behind nursing priorities to note that these patients have similar needs to patients with severe burn injuries (see Ch. 30).

Major nursing considerations

Analgesia

Analgesia must be effective and consistent. Pemphigus and toxic epidermal necrolysis are distressing, painful conditions when shearing of the skin is active. Pain assessment tools (see Ch. 19) permit the nurse and patient to determine pain control needs, ensure accurate delivery of analgesics, and evaluate their efficacy, which is particularly relevant prior to dressing changes. Pain clinics are a specialist service to assist in prescribing appropriate analgesics by the most effective route for this type of pain.

Bed rest

Patients must rest to avoid further trauma to the skin. Pressure-relieving beds are available which are helpful in nursing patients with these conditions.

Hygiene

The maintenance of good personal hygiene and the prevention of cross-infection are extremely important. Gentle washing or the application of soaks, i.e. potassium permanganate, for their mild antiseptic/antipruritic effect can be soothing and help to minimise further trauma.

Isolation may be necessary due to skin loss. The patient will be susceptible to infection and the use of immunosuppressants will increase this susceptibility. In severe cases, barrier nursing may be required (see Ch. 16).

Diet

Approximately 20% of an adult's dietary protein is used for skin repair and growth in normal health. Therefore, an increased intake of dietary protein is advisable in bullous conditions. Referral to a hospital dietitian will ensure the prescription of any necessary supplements. Constipation induced by fluid loss, or as a side-effect of analgesics, is an associated problem. Mild laxatives may be indicated to prevent added discomfort.

Monitoring vital signs

Temperature Regular observation of body temperature is required, as fluctuations may occur due to fluid and heat loss from the skin. Variations in environmental temperature can be reduced by nursing the patient in a side room.

Blood pressure is checked regularly if there is associated fluid loss, steroid-induced hypertension or rehydration by i.v. fluids.

Monitoring electrolyte and fluid balance

This is imperative in any condition associated with skin loss. Rehydration may initially be achievable by increasing the patient's oral intake and monitoring output. An i.v. infusion may be necessary in severe cases. If skin loss presents problems in siting a peripheral infusion, a central line may be required, with monitoring of central venous pressure providing an accurate assessment of fluid requirements.

Urinalysis should be monitored for a potential diabetic state induced by oral steroid therapy.

Dressings and topical therapy

A dressing procedure provides the best opportunity to complete a skin assessment and evaluate disease activity. In pemphigus and toxic epidermal necrolysis, raw areas are recorded and dressed. The tense bullae of pemphigoid are identified and left intact to permit reabsorption of blister fluid, thereby minimising further trauma. Blisters restricting movement are uncomfortable for the patient and can be

aspirated using a sterile alcohol swab, syringe and needle, leaving the blister roof intact (Hughes & Van Onselen 2001). Administration of analgesics prior to the application of topical therapy is important to reduce the patient's apprehension about dressing changes. Each patient's needs and disease severity determine dressing requirements, but the main aims of management are to:

- keep dressing changes to a minimum
- maximise patient comfort
- ensure dressings are easily removable.

By following these guidelines, the nurse minimises further trauma and promotes skin healing. Simple applications of soothing emollients or a non-adherent dressing secured by gauze stockinette will possibly be all that is tolerated. Heavier pads and bandaging create constriction and pain. The skilled practitioner will be guided by the patient's comments and will adjust dressings appropriately.

Special care beds/pressure-relieving equipment

Facilitating rest and comfort is a primary aim in care. The use of low-pressure, air-fluidised beds enhances comfort and reduces the need for positional changes which contribute to shearing forces on the skin. The temperature regulator in these beds maintains an appropriately warm environment, helping the patient to maintain body temperature. This warm environment also increases the amount of insensible fluid loss, so the patient's fluid intake must be increased to compensate. Most patients achieve this by increasing oral intake, but i.v. fluid supplements are a consideration. Dressings are kept to a minimum and remain moist with the use of these beds, and so tend to be easily removed.

Care in the community

Although these conditions are rare, as our older population increases, the incidence will rise. The community nurse has a dual role: firstly, in identifying disorders and coordinating referral for specialist help; and secondly, after discharge from hospital, in ensuring the patient understands the rationale behind long-term maintenance medication, encouraging adherence to and monitoring side-effects of systemic therapies.

ACNE

Acne is a disorder of the pilosebaceous glands. It is a common condition, usually developing during adolescence, between 11 and 14 years. It reaches a peak between 17 and 21 years, gradually improving and disappearing around 21 years in most cases. However, 6% of adults between 25 and 40 years still experience acne (Cunliffe & Gollnick 2001). The psychological impact of acne should not be underestimated, as its onset during the years when visual impact is important to developing new relationships can have a devastating effect on the young adult. Dermatologists are very aware of the impact that acne can have on quality of life.

PATHOPHYSIOLOGY (Fig. 12.11)

During puberty, circulating androgens stimulate sebum production. Hyperkeratosis occurs at the mouth of the hair follicle and the dilated chamber fills with sebum. The

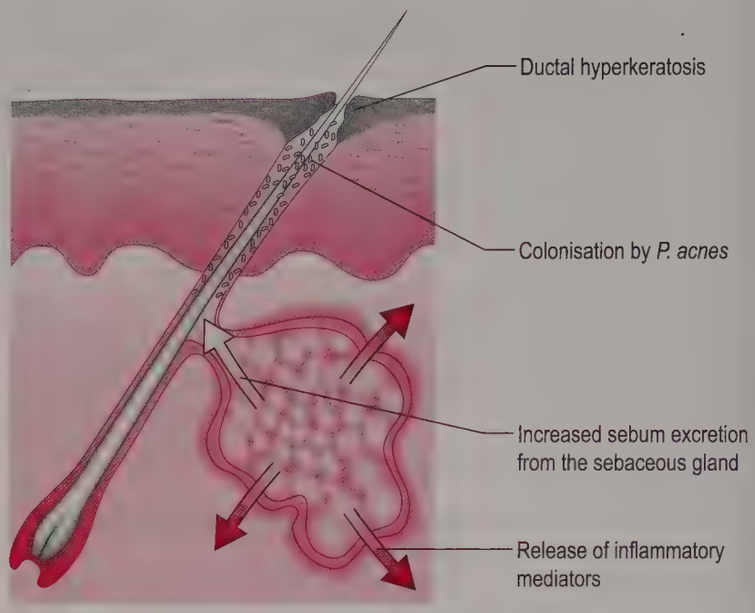

Fig. 12.11 Aetiopathogenesis of acne.

organism *Propionibacterium acnes*, commonly referred to as *P. acnes*, grows in large numbers, creating the comedone. *P. acnes* breaks down the sebum into inflammatory chemicals which leak into the surrounding dermis or pour out through a rupture in the follicle wall (Gawkrodger 2003).

Common presenting symptoms Acne affects the face, neck, upper back and front of the chest. In more severe cases, these lesions may spread further. Lesions can include comedones, papules, pustules, nodules, cysts and residual scars.

MEDICAL MANAGEMENT

Treatment relates to the severity of the condition. Mild acne should respond to topical therapies, antiseptic washes and antibiotic preparations, while moderate/severe acne will merit combined topical and systemic therapies (Layton 1995), as follows:

- Antibiotics — oral tetracyclines given over a 6-month period reduce the inflammatory process. Side-effects of and contraindications to tetracycline should be noted (British National Formulary 2006). If the patient is intolerant of tetracyclines, the drug of choice would be erythromycin.
- Isotretinoin — a medication derived from vitamin A that reduces sebum production. It does have side-effects and careful monitoring of liver function and blood fat levels is indicated. The medication is teratogenic and female patients must use effective contraception. Isotretinoin has been shown to clear acne in 90% of patients with no recurrence. At present it is only available by prescription from hospital dermatology departments (Cunliffe & Gollnick 2001).

NURSING PRIORITIES AND MANAGEMENT: Acne

The role of the nurse is to educate and dispel the many myths of acne (Boston & Preston 2001). The patient should be reassured that acne is not linked to poor diet, an excess

of sweets or chocolate, or poor hygiene. Indeed, most acne sufferers are overzealous in personal hygiene. The nurse should encourage continuation of topical and oral therapies for the full treatment course. The female patient starting isotretinoin needs referral to family planning services to ensure adequate contraceptive measures are established from 1 month before starting treatment until 3 months after completion.

The nurse must respond sympathetically to the acne sufferer. The degree of distress may not always equate with the severity of disease, and care must address the social and psychological impact of acne. Skin disease has been known to provoke suicide, and the nurse working with acne patients should recognise that individuals can become so disturbed by their perceived problem that they are pushed to this extreme (Cotteril & Cunliffe 1997). It is imperative that the impact of acne is not underestimated, and prompt referral to a dermatologist will initiate effective treatment.

12.4 You are asked to provide a series of health talks for a group of school students. Acne is one of the topics requested. Devise a plan for your talk with relevant aims for this age group. Consider answers to the questions you may be asked on diet, cosmetics, infection and social impact.

PHOTODERMATOSES

This term applies to skin disorders that are induced or aggravated by sunlight. These disorders are relatively common and can impose severe limitations on daily life. This section will highlight specific disorders and briefly describe diagnostic techniques and treatment options. The discussion on nursing management focuses on assisting the patient to maintain independent living within the limitations imposed by photosensitivity.

Sunlight

Sunlight is composed of different wavelengths of ultraviolet light, divided into ultraviolet A (UVA), ultraviolet B (UVB) and visible light. UVA in larger doses can produce erythema, passes through window glass and is less variable in intensity. UVB is well recognised as the cause of sunburn. Visible light consists of longer wavelengths and easily penetrates the epidermis with minimal significance. Some conditions, however, demonstrate an abnormal sensitivity to visible light. Certain factors affect the intensity of sunlight:

- time of day — strongest between 11.00 and 15.00 h
- geography — weaker in northern latitudes
- season — UVB less intensive in winter months
- reflective effect of snow, water and sand.

Note that clouds do not protect against sunburn as UVB penetrates cloud cover.

Types of photodermatosis

PATHOPHYSIOLOGY

Polymorphic light eruption (PLE) is the most common of the photodermatoses, with women being affected twice as frequently as men (Gawkrodger 2003). It affects patients in early spring, disappearing in autumn. Several hours after exposure to sunlight, the patient develops an itchy papular, pruritic rash, which persists for 7–10 days. The rash can be provoked by UVB or UVA wavelengths, and it should be remembered that UVA also penetrates window glass and thin clothing.

Solar urticaria is very rare and appears as itchy red patches which may be swollen and resemble nettle rash or weals. This reaction occurs almost immediately, within 10 min after sunlight exposure, and subsides within 1 h of sunlight avoidance, with no residual damage to skin.

Photo-aggravated dermatoses Some pre-existing skin conditions, e.g. atopic eczema, psoriasis, rosacea (a chronic inflammatory facial skin condition) and herpes simplex, can be exacerbated by sunlight exposure.

Photo-contact dermatitis refers to disorders in which direct contact of the skin with a substance, e.g. tars, sunscreens, followed by exposure to ultraviolet light provokes a dermatitis. Certain genetic disorders, e.g. xeroderma pigmentosum, also produce a photosensitive reaction.

Chronic actinic dermatitis This condition particularly affects men over the age of 50 years but can also occur in women (Gawkrodger 2003). Patients are sensitive to sunlight (UVB, UVA, visible light) and artificial light sources and have many allergies to substances in direct contact with their skin, e.g. plants, flowers, wood, perfumes, sunscreens and rubber. Sparing of the shaded skin can be present, e.g. behind ears, eyelids, under a watch strap, and there may be marked differences between skin covered by clothing and exposed skin, particularly the neck and arms. The condition presents with marked erythema, eczema and thickening of the skin of the face, neck and hands. Skin changes may be evident in areas covered by clothing, e.g. the arms.

MEDICAL MANAGEMENT

Management begins with a full history and assessment of related factors and presenting symptoms (see Box 12.8).

Investigations required are as follows:

Phototesting provides an objective assessment of photosensitivity disorders and is available in specialist photobiology/dermatology units. Phototesting is performed with the use of a monochromator (Ferguson 2004) to identify if abnormal light sensitivity is present and establish which wavelengths are responsible, i.e. UVA, UVB or visible light. The patient's back is the test site used. Varying doses at different wavelengths are irradiated to small areas and delayed erythema is noted at 7 and 24 h. These responses are compared with known responses of a control group, thus helping to determine the degree of photosensitivity and wavelengths responsible.

Patch testing is used to identify contact allergies causing an exacerbation of the disorder. Patients may have multiple allergies which are relevant to diagnosis and subsequent management.

Treatment involves systemic and topical therapy and sometimes UVB and PUVA therapy (see p. 530). Drug therapy

Box 12.8

Influencing factors and common presenting symptoms of photosensitive conditions

Influencing factors
- Drug history
- Family history
- Hobbies
- Allergies
- Occupation
- Sites involved
- Skin type

Common presenting symptoms
- Eczema
- Erythema
- Heat
- Itch
- Oedema
- Pain
- Urticaria

may include antihistamines, immunosuppressants and oral and topical steroids. Sunscreens offer a sun protection factor (SPF) either by chemically absorbing and filtering ultraviolet light or by physically reflecting and scattering ultraviolet rays to protect the skin. A combination sunscreen creates a more effective sun block. Some light-sensitive conditions, e.g. PLE (see p. 547), can be treated with a course of phototherapy (UVB/PUVA) desensitisation and patients should be encouraged to continue exposure to maintain their new tolerance level. Unfortunately, this is lost during winter and the phototherapy has to be repeated the following spring.

NURSING PRIORITIES AND MANAGEMENT: Photodermatoses

Patients with diagnosed photosensitive disorders require practical help and support from nursing staff trained in the management of photodermatology. Many patients are relieved that investigations have produced a diagnosis rather than a dismissal of symptoms as merely 'a bit of sunburn'. Factual information from nursing staff is vital if the patient is to cope with lifestyle changes imposed by the diagnosis. General advice includes:

- regular use of emollients
- meticulous, regular (every 2 h) application of prescribed sunscreens to exposed sites
- treatment with a steroid ointment/cream if the condition flares
- sun avoidance between 11.00 and 15.00 h
- protective, closely woven clothing, to provide a further effective barrier to sunlight; in severe cases, a wide brimmed hat, scarf and gloves may prove helpful
- use of clear museum film, which blocks out ultraviolet light, applied to house windows and car windows (Dawe et al 1996).

Giving psychological support

Social isolation is a major problem for individuals with severe photosensitive disorders. Many patients, distressed by their diagnosis and the restrictions it entails, reject management regimens which would lead to a life indoors or only leaving home after sundown. They often find maintenance of topical therapies to be time consuming, messy and cosmetically unacceptable. Others stoically accept the limitations and persevere with the use of sunscreens to permit them freedom to continue a restricted form of daily living.

The nurse must display a sympathetic understanding of the psychological trauma associated with the restrictions imposed by such a diagnosis. The overall aim of nursing support should be for the patient to control skin management in an informed and motivated manner, with instant access to professional help as needed.

URTICARIA, ALLERGY AND ANAPHYLAXIS

Urticaria is a common condition and lesions are described as 'hives' or nettle rash. The skin feels irritable and produces white raised weals that turn pink with a bordered edge. The weals can be extensive over the body. There are many causes, but the condition often resolves spontaneously. In some cases the condition can extend, creating swelling around the eyes, mouth and throat known as angioedema (see Ch. 16). In severe attacks, breathing can be compromised, so angioedema must be treated promptly (Mygind et al 1996).

PATHOPHYSIOLOGY

In response to the initial trigger factor, the dermis becomes oedematous with dilatation of blood vessels and degranulation of mast cells and the release of histamine. The weal of urticaria is oedema of the dermis, which can extend rapidly into the subcutaneous tissues causing angioedema.

Classification of urticaria (see Box 12.9) Acute contact urticaria can be related to contact factors, e.g. animal fur, plants, insect stings. Extensive urticaria associated with

Box 12.9

Classification of urticaria

- Chronic — idiopathic
- Acute — IgE-mediated, e.g. food allergy, drug reaction
- Physical — dermographism, cholinergic, cold, solar, heat, delayed pressure
- Contact — immune (e.g. animal saliva) or non-immune (e.g. nettle sting)
- Pharmacological — aspirin, opiates, non-steroidal medications, food additives
- Systemic cause — systemic lupus erythematosus, lymphoma, thyrotoxicosis, infection, infestation
- Inherited — hereditary angioedema
- Other — urticarial vasculitis, papular (insect bites), mastocytosis, pregnancy

Reproduced with permission from Gawkrodger (2003).

angioedema is usually idiopathic but can be related to the ingestion of food or drugs, such as strawberries, nuts, aspirin and penicillin. Urticaria is more common in individuals with atopic eczema. Cold, heat, sun, pressure and water can all induce physical urticaria. Sweating in response to physical exercise or eating spicy food may also induce urticaria with isolated facial swelling. Hereditary angioedema is a rare and potentially fatal autosomal dominant condition. It presents in childhood and requires skilful long-term management during acute attacks and in establishing prophylactic therapy (Gawkrodger 2003).

MEDICAL MANAGEMENT

Clinical history and skin examination will help to determine the provoking factors. Antihistamines are essential in the management of urticaria. These H_1 antagonists block histamine release and the newer preparations, e.g. cetirizine, desloratadine, are non-sedating. In acute attacks, the patient requires oral antihistamines until the condition resolves, usually in a few days. In chronic urticaria, the patient may require maintenance antihistamines for several months. In an acute attack of angioedema, the use of i.v. antihistamines may be necessary. Urticaria can be associated with anaphylaxis (see Ch. 16) and, in this situation, adrenaline and antihistamine drugs will be used in combination. Severe urticaria may also require short-term use of systemic steroids. Patients with identified severe reactions to foodstuffs are trained to administer i.m. or s.c. adrenaline at the onset of attacks (Lawlor 1998).

NURSING PRIORITIES AND MANAGEMENT: Urticaria, allergy and anaphylaxis

The nurse in every setting will encounter the patient with allergies. Angioedema and anaphylactic reaction can prove fatal, so professionals must recognise the urgency of the situation and be fully trained in initiating emergency action (McGeary 1997). The role of the nurse during an acute attack is to assist with medical management until the acute phase stabilises. Afterwards, the nurse's role as provider of factual information and management of the condition begins.

Dietitians provide dietary advice to assist in the avoidance of foods that trigger urticaria. Dietary exclusion is difficult, as food labelling is not always helpful. Public pressure has persuaded food companies and supermarkets to focus on the importance of accurate food labelling, as the incidence of food allergy, and in particular peanut allergy, seems to be increasing (Ministry of Agriculture, Fisheries and Food 1996). Peanut allergy and sensitisation can lead to severe anaphylactic shock and death, so accurate food labelling is vital. Expectant mothers are advised to avoid eating nuts to prevent sensitisation in children. However, as knowledge of the mechanisms of food allergy improves, diagnosis and management will also improve. The link between breast feeding, weaning and allergy continues to be researched (Stabell Benn et al 2004).

The patient who has severe allergic reactions should be trained in the use of adrenaline pens (EpiPen). The nurse can help the patient and family in relation to all aspects of the allergy, in particular to recognise warning symptoms and to use the EpiPen promptly whilst seeking medical assistance. It will be necessary for those involved in caring for the child with an allergy, e.g. school teachers, to be aware of potential problems and to be given instruction on using the EpiPen (Keen & Comer 1995).

The nurse has a positive role in raising awareness of allergies, giving informed advice to patients, carers and fellow professionals, and providing the empathy and support required to improve and maintain patients' quality of life.

SKIN TUMOURS

The skin, as a complex organ system, can produce many tumours, both benign and malignant, within the epidermis and dermis. The reader should refer to a colour atlas of dermatology to fully appreciate the wide diversity of skin tumours (White 2003). Skin biopsy for histology is necessary in the diagnosis, prognosis and management of skin tumours.

Malignant melanoma is the most serious of the skin tumours and its incidence is rising. Melanoma accounts for less than 10% of cutaneous tumours but is responsible for 80% of skin cancer deaths – over 1600 each year in the UK (Cancer Research UK 2003). Figures in the UK suggest that 65% of patients with melanoma have a survival rate of 5 years (Cancer Research UK 2003). Melanoma commonly arises in a naevus (mole), involves the pigment-producing melanocytes and can metastasise rapidly via the circulatory and lymphatic systems. This differentiates it from other skin tumours. Prognosis depends on tumour thickness (Breslow 1970). Early detection and excision of thin tumours (less than 1 mm thick) carries an excellent prognosis and potential cure. Late-stage untreated melanoma with secondary deposits has a poorer outcome and treatment is often palliative, e.g. radiotherapy, chemotherapy, laser therapy (see Ch. 31).

Research suggests that excessive childhood sun exposure is an important factor in the aetiology of melanoma. Current campaigns such as Cancer Research UK (2003) and Scotland's 'Keep Yer Shirt On' are targeting the early years. In Scotland, the incidence of skin cancer has doubled in the last 20 years; approximately 6000 people are diagnosed with non-melanoma skin cancer and approximately 600 with malignant melanoma (Scottish Executive 1999). The aim is to significantly reduce the incidence of skin cancer in those under 75 years by the year 2010. The 'Keep Yer Shirt On' campaign, funded for 3 years by a New Opportunities Grant, has a coordinated partnership approach involving health promotion, education services, childcare partnerships and dermatology.

Overall, the aims of the campaign are to increase public awareness of the dangers of excessive sun exposure and the importance of regular skin checks to ascertain changes in moles at an early stage (see Box 12.10), and to promote 'safe sun' and encourage behavioural and social changes that might prevent or reduce the incidence of melanoma. Advice includes:

- avoidance of direct sun between 11.00 and 15.00 h
- use of high sun protection factor (SPF) creams
- use of T-shirts/sun hats.

Nurses in contact with any group of people can encourage regular checking of 'moles' as a preventive strategy which

Box 12.10

Mole watching — warning signs of melanoma

- Are new or existing moles getting larger?
- Changes in the normal smooth edge of the mole to a more irregular shape
- Changes in colour of the mole
- Is the mole itchy or painful?
- Is there any surrounding or underlying inflammation?
- Is there any bleeding, oozing or crusting?

could have a profound impact on the early detection, incidence and mortality rates of malignant melanoma (see Research Abstract 12.1).

For further reading, see Van Der Weyden (1996), Buchanan (2001) and Chapter 31.

A DEVELOPING SPECIALISM

This chapter has focused on some of the more common skin disorders encountered in hospital and in the community, but there are many more that could have been included. Further reference to a specialist textbook will reveal the full scope of dermatology as a major specialty. It is recognised that the majority of patients with a skin disorder are managed in primary care and that sound knowledge and skills in dermatology are important for community nurses. This is particularly important for nurses who are nurse prescribers (Bowman 1998).

The British Dermatological Nursing Group (BDNG) was established in 1989 as an independent specialty group for nurses and health care professionals with an interest in dermatology. It continues to develop educational initiatives, guidelines and protocols, addressing the needs of nurses working with patients with skin disorders. The Royal College of Nursing document *Standards of Care for Dermatology Nursing* (RCN 1995) was developed to provide an established level of requirement on which to base specialist practice (Stone 1997b). In 2002, a group of specialist dermatology nurses, together with NHS Education for Scotland, prepared a competency framework for dermatology nursing to support continuing professional development, and a core curriculum for caring for people with dermatological conditions has now been published (NHS Education for Scotland 2003).

There is also value in practice initiatives such as:

- the development of care systems (Gradwell & Haynes 1999) to enhance communication with patients, thus empowering them to be involved in care delivery
- the incorporation of quality of life indices into nursing assessment, providing subjective measurement of the impact skin disorders have on life (Thoms 1997)
- the role of the named nurse in assessing and ensuring that care plans are patient focused and need centred
- the education, counselling and sharing of clinical skills to underpin a supportive partnership that will enhance treatment concordance
- the development of advice leaflets, reinforcing verbal instructions. Simple to prepare, these are beneficial to patients who may be overwhelmed by the bewildering array of ointments and lotions prescribed for their skin disorder.

The development of dermatological nursing in the UK over the last decade has been considerable in relation to service innovation, educational initiatives, growing involvement in research and the shaping of policy. Major changes have also taken place in the patterns of care delivery, the role of the patient and family in disease management and the collaboration between all health care professionals. Nurses must continue to develop their knowledge and skills as they are a key resource for dermatological clients in both hospital and home.

RESEARCH ABSTRACT 12.1

It is known that individuals can make a significant impact on identifying early melanoma, when still curable, by conducting periodic skin self-examination (SSE), thus detecting new lesions or significant changes in pre-existing lesions. Providing patients with photographs as a baseline measure may encourage them to carefully watch lesions, detect changes or perform SSE more regularly.

A study conducted in New York (Oliviera et al 2004) set out to assess the impact of a brief nurse-delivered intervention, using digital photographs, on patients' adherence to performing SSE. Patients (n = 100) at high risk for melanoma skin cancer (five or more dysplastic naevi) had whole-body digital photography as part of their clinical evaluation. Patients were randomized: Group A (n = 49) received a teaching intervention (physician and nurse education module) with a photo book (personal whole-body photographs compiled in the form of a booklet, with nurse instruction on how to use the photographs); Group B (n = 51) received the teaching intervention only. Self-administration questionnaires were provided at three intervals: baseline, post-teaching intervention and at the 4-month post-baseline visit. To assess adherence with SSE, patients were asked, 'How many times in the past 4 months did you or someone else thoroughly examine your skin?'. In Group A, 10.2% of patients at baseline reported skin examination three or more times during the past 4 months, while 61.2% reported skin examination three or more times at the 4-month follow-up. In Group B the respective figures at baseline and 4-month follow-up were 19.6% and 37.2%. The increase in reported skin examination was compared between the two groups (>51% v >17.6%, P = 0.001).

The results suggest that a brief nurse-delivered intervention is effective at increasing patient adherence with SSE. The effect of the intervention was further enhanced with the use of digital photographs as an adjunct to SSE.

INTRODUCTION

The principal aims of this chapter are to present the knowledge and specialised care required for the ophthalmic patient, to raise awareness pertaining to visual impairment (VI) and how VI impacts upon the social, physical and psychological aspects of daily living, and to consider the implications for practice of a range of disability-related legislation such as the Disability Discrimination Act (DDA 1996) (Casserley 2001). Changes in patient care management, including the trend towards a decrease in the length of hospital stay and the increasingly 'normal' practice of day case or short-stay regimens, has led to a greater need for partnerships between hospital and community teams. As life expectancy increases in the UK, there is a higher incidence of cataract, age-related maculopathy and diabetic eye disease and it is increasingly important, therefore, for health care professionals to recognise adverse ocular signs and symptoms and to ensure prompt referral for specialised care. Not all ocular conditions cause VI, and many clinical conditions are successfully treated with medical and surgical interventions. The ocular conditions and diseases presented in this chapter will provide the reader with a sound knowledge base related to causes, diagnoses, treatments and related nursing care. The nurse, in all environments, has a duty of care to be up-to-date in practice, and to facilitate health promotion and screening in primary and secondary care settings (McSherry & Pearce 2002, Tingle & Cribb 2002, NMC 2004).

Incidence of visual impairment and blindness

The World Health Organization (WHO) estimates that, globally, 180 million people are visually impaired and, of this number, 40–45 million are blind (www.who.int). It is thought that with appropriate resources, improved environmental conditions and timely intervention, 80% of the global incidence of blindness could be avoided either by treatment, e.g. cataract surgery, or by prevention programmes, e.g. for trachoma. The developing countries account for 9 out of 10 of the world's blind population. It is predicted that the global burden of blindness will double by 2020 (www.who.int) due to an increase in the population and longer life expectancy (Thylefors 1998).

The main causes of blindness globally are:

- cataract — opacity of the lens — the leading cause, responsible for 50% of all blindness, but readily treatable with surgery
- trachoma — ocular inflammation and corneal opacity caused by repeated infection of the cornea and conjunctiva by *Chlamydia trachomatis*. This is the most

common preventable condition and accounts for 12.5% of all blindness

- xerophthalmia — dryness and ulceration of the cornea associated with vitamin A deficiency. This preventable condition, which accounts for 6% of all blindness, can be eradicated with vitamin A supplementation
- glaucoma — raised intraocular pressure (IOP), causing optic nerve damage with associated visual field loss. Although the condition itself, which accounts for 15% of all blindness, is not preventable, the threat to sight can be reduced by screening, topical medication and surgery
- onchocerciasis — river blindness — caused by a microfilarial (parasitic worm) infestation transmitted by bites of the black fly. The parasitic worms invade the eye, destroying all structures. It is estimated that there are 18 million people infected worldwide and that Africa has the highest prevalence, with the disease being endemic in 30 African countries. This disease can be prevented by controlling the black fly population and can be treated by the drug ivermectin. WHO assists with funding and supports both trachoma and onchocerciasis programmes which have established health education and promotional work in progress.

WHO is also at the forefront of 'Vision 2020 – The Right to Sight: A Global Initiative for the Elimination of Avoidable Blindness'. The aim is to eliminate avoidable blindness as a public health problem by the year 2020.

For further information, see www.who.int and www.v2020.org.

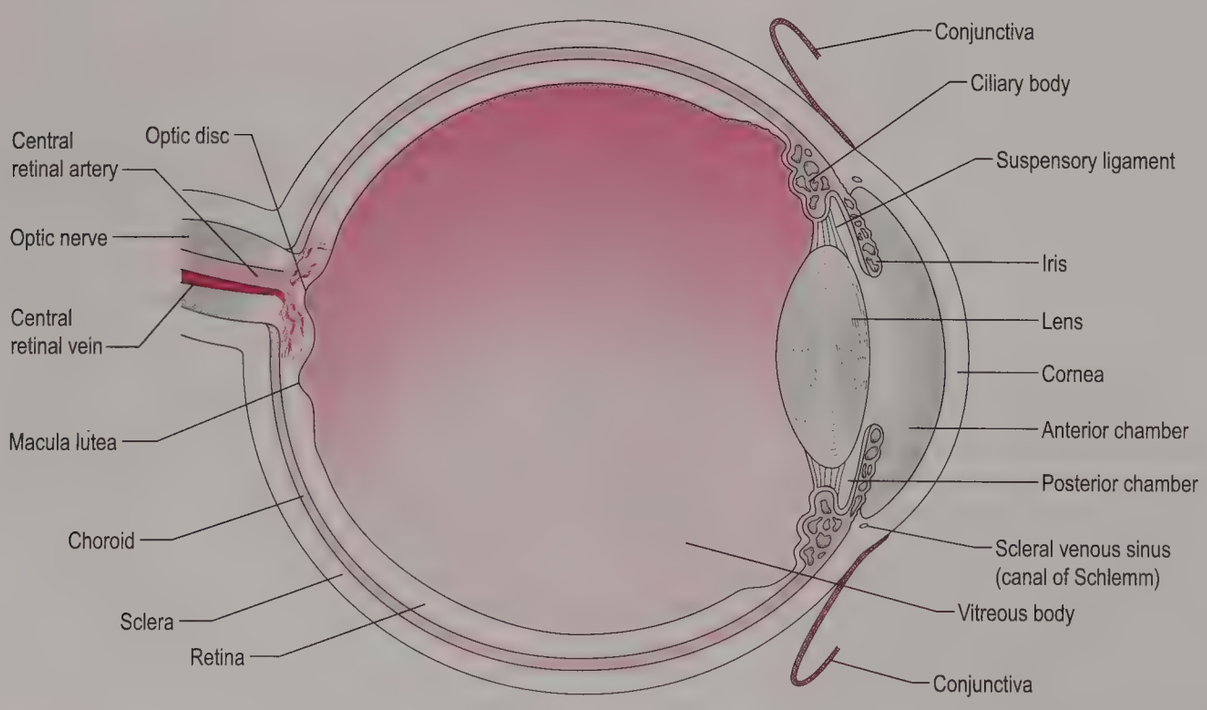
In developed countries such as the UK, resources are more readily available and government-led initiatives such as 'Action on Cataract' (NHS Executive 2000) have been targeted to streamline clinical services and reduce the number of people with cataract. The main causes of VI and blindness are cataract and glaucoma (see p. 553), with age-related maculopathy (see p. 584) and diabetic eye disease (see p. 585) accounting for most of the remaining VI and blindness. Although none of these conditions is preventable, modern drug, laser and surgical treatments mean that there is more opportunity for controlling the course of the disease and thus reducing the potential for VI and blindness. The Royal College of Ophthalmologists (RCO) estimate that 4.3 million people over 65 years of age in the UK have a VI in one or both eyes (see 'Useful websites'). The cost to the government is estimated at greater than £120 million per annum for cataract treatment alone.

13.1 Using associated websites (see 'Useful websites') and library resources such as CD-ROM, investigate epidemiological trends in relation to blindness and its causes.

ANATOMY AND PHYSIOLOGY

The components of the sensory mechanisms responsible for sight are the eyes, the optic nerves and tracts, and the visual cortex and association areas of the brain.

Accessory structures play a vital role in enabling the eyes to scan and focus on objects in the environment and in protecting and maintaining the optical properties of the eyes.



The eye

The eyeball (see Fig. 13.1)

With minor individual variations, the eyeball is spherical in shape, with the cornea on the anterior aspect being slightly more steeply curved. The length of an adult eye is approximately 24 mm.

The eyeball or globe has three main layers of tissue:

- *The outer layer* of the globe consists of the fibrous white sclera posteriorly and the transparent cornea anteriorly. The junction of the two is called the limbus. The cornea

554 Fig. 13.1 Section of the eye.

is transparent due to its avascularity and the regular arrangement of its fibres. It is well supplied with nerve endings from the trigeminal nerve.

- *The middle vascular layer*, known as the uveal tract, consists of the choroid, the ciliary body and the iris. The choroid lines the sclera in the posterior compartment of the eye and continues into the muscular ciliary body, into which are inserted the suspensory ligaments. These ligaments extend to the lens and hold it in position. This diaphragm-like ligamentous structure is known as the zonule. The contraction or relaxation of the ciliary body changes the shape of the lens and controls its refractive and focusing power. The iris is the pigmented anterior portion of the uveal tract. It contains both circular and radial muscle fibres which control the size of the pupil.
- *The inner layer* of the eyeball is the retina. It contains several million photoreceptive cells which are responsible for converting light into electrical impulses. The retina arises just behind the equator of the eyeball in an area known as the ora serrata. This leaves a small anterior section of the choroid — the pars plana — exposed. This is important because it allows surgical access without retinal damage.

The retina consists of two layers: the pigmented outer layer, which lines the choroid, and the innermost neural layer, which is in contact with the vitreous humor. Rod cells predominate in the periphery and function best in dim light. Cone cells predominate near the centre of the retina and are adapted for bright light and colour vision. The greatest concentration of cone cells is at the macula, a small area in the centre of the retina which has as its midpoint the fovea centralis, the most vital part of the retina for high-definition vision. These photoreceptor cells are linked through a series of synapses to ganglion cells whose axons run together to form the optic nerve.

The two compartments and three chambers of the eye

Inside the globe, the lens, suspended by the zonule, divides the eye into two main compartments. The anterior compartment is itself divided into two chambers, the anterior chamber in front of the iris and the posterior chamber behind the iris. The compartment behind the lens is sometimes referred to as the vitreous chamber, as it contains the clear jelly-like substance called the vitreous humor.

Internal environment and intraocular pressure (IOP)

The anterior compartment is bathed in a clear fluid called aqueous or aqueous humor, which is produced by the ciliary body and which provides nutrients to the lens and cornea. Aqueous flows from the posterior chamber through the pupil to the anterior chamber and drains away through the sieve-like fibrous trabecular meshwork located in the angle between the iris and cornea around the circumference of the eye (see Fig. 13.2). This in turn drains into the vascular canal of Schlemm and thereby into the systemic venous circulation. The production and drainage of aqueous must be constant in order to maintain a normal IOP, which is variable over a 24-h period, within the range of 10–20 mmHg (Waugh & Grant 2001).

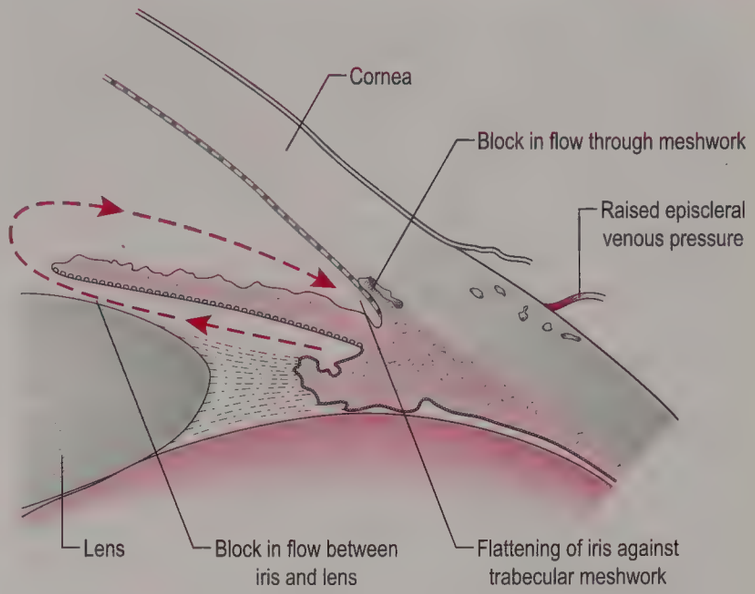


Fig. 13.2 Normal aqueous drainage and possible sites of obstruction. (Adapted from Khaw et al 2004, with permission from the BMJ Publishing Group.)

Box 13.1

Terms associated with visual acuity and refractive errors

- Emmetropia — normal sight; light rays focus on the retina
- Ametropia — defective sight due to refractive error
- Myopia — short-sightedness; light rays focus in front of the retina
- Hypermetropia — long-sightedness; light rays focus behind the retina
- Presbyopia — loss of focused reading/near-vision capacity, resulting from loss of lens elasticity due to ageing
- Astigmatism — irregular curvature of the cornea which prevents light rays from focusing at a single point

The shape of the eye can, by determining the depth of the anterior chamber and the angle between the cornea and iris, affect the functioning of the drainage system. The larger, elongated eye of the myope (short-sighted person) has a naturally occurring deep anterior chamber with an open angle, whereas the small eye of the hypermetrope (long-sighted person) has a shallow anterior chamber with a narrow angle (see Box 13.1). Any interference with normal drainage of the aqueous humor raises the IOP, leading to the decreased blood supply, pain and impaired vision associated with conditions such as glaucoma and postoperative or traumatic complications.

The visual pathways and interpretative centres

The optic nerve runs from the posterior aspect of the globe and enters the cranial cavity via the optic foramen. The

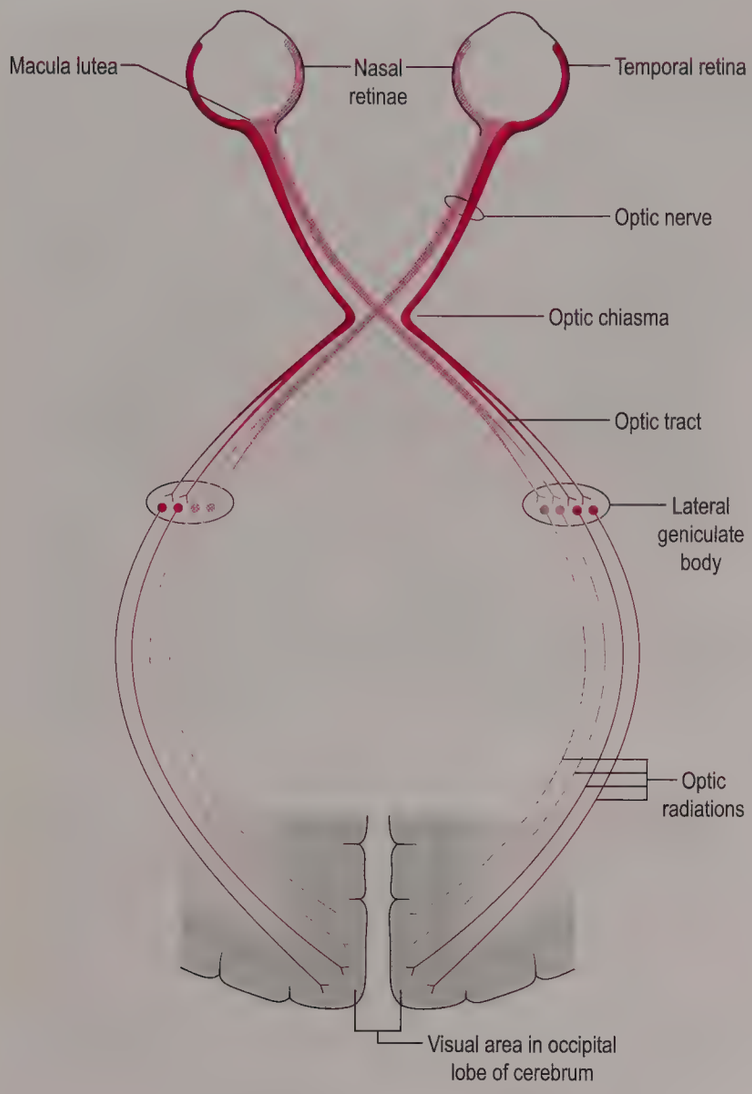

Fig. 13.3 The optic nerves and their pathways.

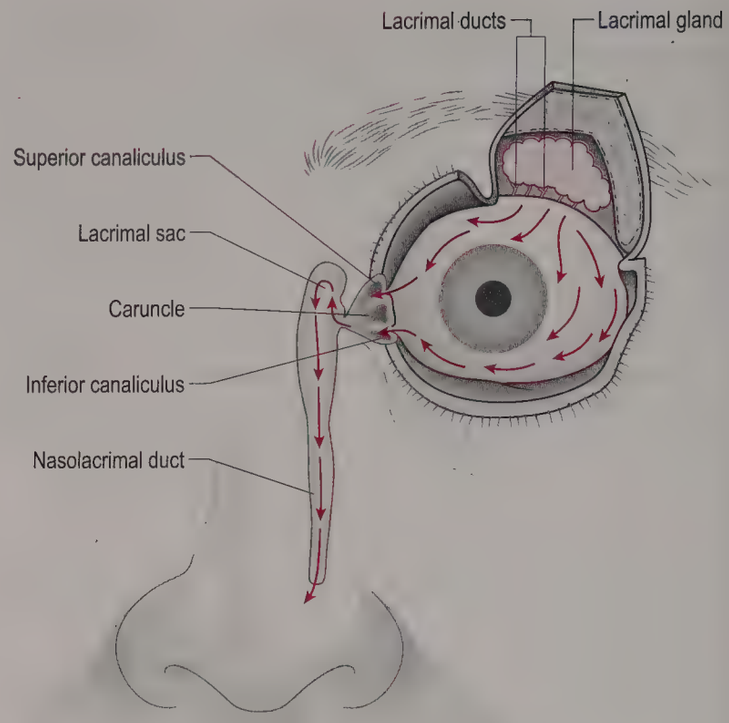

Fig. 13.4 The lacrimal apparatus. Arrows show the direction of the flow of tears.

medial nerve fibres cross over to the opposite side at the optic chiasma (see Fig. 13.3) to join with the lateral fibres and form the optic tract before synapsing in the lateral geniculate body of the thalamus. From the lateral geniculate body, the fibres run in the optic radiations to the occipital lobe of the cerebrum.

The main blood supply to the eye is via the ophthalmic artery, a branch of the internal carotid artery, which runs alongside the optic nerve.

Accessory structures

The exposed anterior aspect of the eyeball is protected by the eyebrow, eyelids and eyelashes. The conjunctiva, a mucous membrane, lines the eyelids (palpebral conjunctiva) and reflects back on itself to cover the exposed sclera. This fold forms the conjunctival sac or fornix and is an ideal site for the instillation of topical drugs. At the limbus, the conjunctiva is modified to form the epithelial layer of the cornea. The conjunctiva facilitates free movement of the globe.

The exposed surface of the eye is also covered by a three-layered film of tear fluid. Mucous secretion from conjunctival goblet cells forms the first layer of the tear film and ensures an even spread of tears over the cornea. The second (middle) layer of the tear film is the watery fluid secreted by the lacrimal glands, situated under the outer aspect of the upper orbital rim, and by the accessory glands in the conjunctiva. The third (outer) lipid layer of tear film is secreted by the Meibomian glands of the lids. This is thought to reduce the evaporation rate of tears and to prevent the lids sticking together during sleep. The main functions of tear fluid are to lubricate the eye, to facilitate O_2 and CO_2 exchange, to provide an optically smooth corneal surface and to cleanse the eye with the bacteriostatic enzyme, lysozyme.

Excess tears are drained from the eye via the lacrimal apparatus at the inner canthus at the nasal end of the lid margins, into the lacrimal sac and thence into the nose through the nasolacrimal duct (see Fig. 13.4).

Posteriorly and laterally the globe is protected by the bony orbit, the extraocular recti and oblique muscles, responsible for tracking movements, and by orbital fat.

The physiology of vision

Light rays are bent (refracted) as they pass through the varying densities of the clear media of the cornea, aqueous, lens and vitreous to focus on the retina. The cornea is responsible for approximately two-thirds of the refractive power of the eye and is relatively constant. However, by virtue of its elasticity, the lens has the ability to change shape and thereby vary the amount of refraction for clarity of focus. This is known as accommodation and is necessary in order for objects at different distances to be visualised with equal clarity.

The normal eye in its relaxed state brings rays of light from distant objects into sharp focus. However, for clear

focusing on near objects, an autonomic reflex known as the synkinetic near reflex comes into play. This reflex involves accommodation, miosis and convergence, as follows:

- *Accommodation* — the ciliary body contracts and changes shape, thus releasing tension on the zonular fibres and allowing the lens to thicken and increase its refractive power
- *Miosis* — constriction of the pupil — accompanies accommodation and ensures that light rays are concentrated to pass through the centre of the lens and focus on the macula
- *Convergence* — in-turning of the eyes — seeks out the object to be focused on.

Failure to focus may be described as ametropia, or refractive error (see Box 13.1).

Once the rays of light are focused on the retina, their energy is converted into neuroelectrical energy by the photoreceptor cells. These nerve impulses are transmitted via other neural cells in the retina to the optic nerve and so by the visual pathway to the visual cortex. Here, they are interpreted as sensations of light, form and colour and are processed into images of objects which are given meaning by other cerebral areas through correlation with information stored as memory in the association areas of the brain (see also Ch. 9).

ASSESSING THE EYE AND VISUAL FUNCTION

Examination of structure

It is vital for nurses working with ophthalmic patients to learn to examine the eye in a systematic way and to recognise abnormalities and their significance. In order to do so, it is necessary to know what a normal eye looks like and what normal expectations are for an eye recovering from surgery or disease. It is essential to work in good light using a pen torch and to proceed systematically, examining all ocular structures from outermost to innermost as follows:

- lids — observe position, closure, bruising, discharge
- conjunctiva — observe degree of injection (visible blood vessels), chemosis (bulging effect due to oedema), discharge, wounds
- cornea — observe clarity, type and extent of any opacity, shape, suture lines, wounds
- anterior chamber (AC) — observe depth, clarity, presence of hyphaema (blood in AC), hypopyon (pus in AC)
- iris — observe colour, position, appearance
- pupil — observe size, shape, position, colour of reflection from lens
- intraocular lens (IOL) — if appropriate, observe position and reflection
- retina — examine through dilated pupil using ophthalmoscope.

The possible implications of clinical features that may be found in the course of an eye examination are listed in Table 13.1.

Testing visual function

Visual acuity

Visual acuity (VA) assessment is generally carried out by nurses and is the mathematical estimation of visual function for different distances.

Table 13.1 Significance of clinical features found on eye examination

Structure	Clinical features	Possible significance
Lids	Bruising (ecchymosis) Swelling Drooping Increased lacrimation Discharge	Surgical handling Trauma Infection
Conjunctiva	Redness (injection) Swelling (chemosis)	Surgical handling Trauma Allergy Infection
Cornea	Cloudy Crinkled Fluorescein staining Suture line not intact Penetrating injury	Increased IOP Infection Loss of AC Ulceration
Anterior chamber (AC)	Hyphaema (blood in AC) Hypopyon (pus in AC) Shallow AC	Hyphaema due to surgery should gradually resolve Increasing IOP = bleeding/inflammation Hypopyon = infection Shallow = ? aqueous loss
Iris	Muddy	Inflammation
Pupil	Irregular shape	Iris prolapse Adhesions Trauma

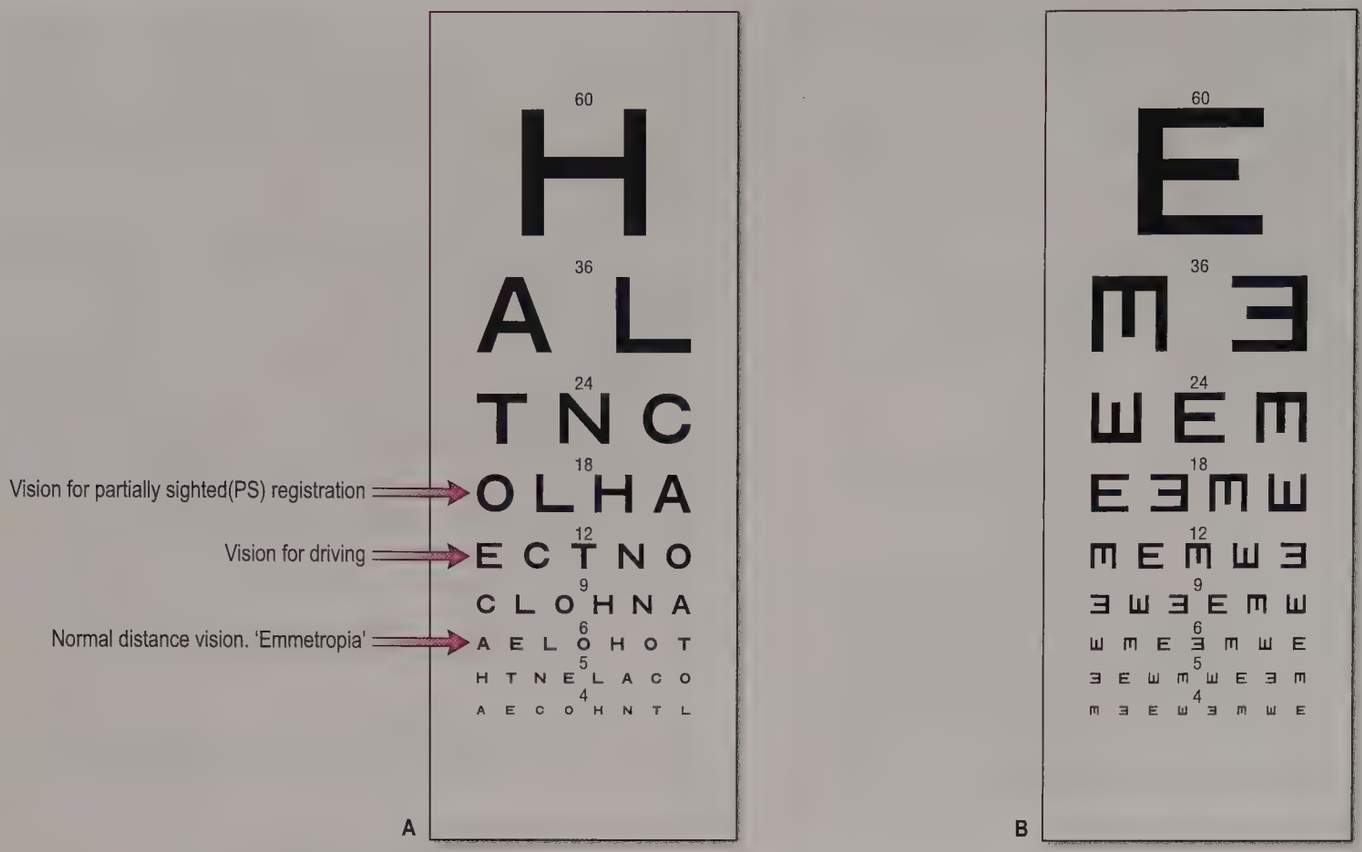

Fig. 13.5 Eye testing charts. A: Snellen test-type chart; the standard method for testing visual acuity in the UK. B: 'E' chart for non-English speakers. The patient is given a wooden or plastic E and is asked to make it indicate the positions in which it appears on the chart.

Distance vision This is tested using Snellen test-type charts. These charts display letters or pictures arranged in rows of precise and diminishing size (see Fig. 13.5). Each eye should be tested separately, with the benefit of any spectacles or contact lenses, if the patient normally wears these, to ensure that what is being checked is 'best corrected vision'. The eye not being tested must be completely occluded. In normal testing, the patient is positioned 6 m away from the chart and asked to read each line aloud until they can no longer make out the letters. The result is recorded as a fraction of the distance from the chart in metres over the normal reading distance of the last complete line read, plus the number of extra letters read from the line below or minus the number of letters read incorrectly, e.g. 6/9 – 2 with correction (i/c) (see Fig 13.5). If glasses or contact lenses are worn, this is recorded as i/c gls. or i/c CL, respectively.

Normal distance acuity is accepted as 6/6, although the expectation of what the patient is likely to achieve will vary with age. If the result is 6/9 or less (see Fig. 13.5), the patient may be asked to read the chart again, looking through a pinhole (PH). A pure refractive error should improve with this simple method of sharpening focus. The improved acuity would be recorded as 6/9 i/c PH.

If the patient cannot read the top letter, recorded as 6/60, then ability to count fingers (CF) at 1 m, detect hand movements (HM) or perceive light (PL) is tested. Awareness of direction of a light source may also be noted (projection). Testing in more complicated situations, such as when the patient cannot read or understand English, can be facilitated by using a Snellen 'E' chart (see Fig. 13.5B). If the patient has learning difficulties, poor concentration or expressive dysphasia (see p. 417), then testing of visual acuity can be carried out using a Sheridan Gardiner singles booklet in which single letters or pictures of varying size are presented one at a time for the patient to identify or match.

Near vision is tested in a similar fashion by asking the patient to read text in various sizes of standard print, which are prefixed with the letter N. N5 is accepted as normal reading acuity. Near vision should be checked in conditions of good illumination.

Binocular vision involves simultaneous perception of an image by both eyes and fusion of the two images in the visual cortex to form a single image. Binocular vision is thought to play a role in depth perception. Having two eyes also widens the field of vision and counters gaps in the visual field caused by natural blind spots.

13.2 Look carefully straight ahead and note what you see. Now close one eye. What do you not see? Now repeat with the other eye. What do you no longer see?

The visual field The range of what the eye can see with respect to angle of view, rather than distance, is called the visual field. Normally this is about 60° nasally, 90° temporally, 50° superiorly and 70° inferiorly. Assessment of the integrity of the visual field is an important aid to diagnosis of retinal detachment and neurological disease

and is essential in the management of open-angle glaucoma. Visual field testing can be carried out in the following ways:

- *Simple confrontation test* — the examiner compares the patient's field of vision with their own. Facing the patient, who is asked to maintain a fixed gaze on the examiner's face, the examiner moves a finger from various points on their own periphery of vision and asks the patient to indicate when it appears in their field of vision.
- *Perimetry*, using basic to increasingly more sophisticated field analyser systems, e.g. the Henson, Friedmann, Goldmann or Humphrey systems, gives accurate measurements of visual field defects known as scotoma.

For examples of perimetry printouts, see Kanski (2003).

Colour blindness

Colour vision depends on the normal functioning of the retinal cones. A colour-blind person is unable to distinguish between some colours — usually red and green. While approximately 10% of the male population are born with defective colour vision, this problem is estimated at only 1% in females (Chong 1996). Colour blindness can also be acquired; it is characteristic of certain disease processes such as optic neuritis and some macular disorders, and may develop in people with a drug dependency.

The most common method of testing for colour blindness is by means of Ishihara colour plates. These are a series of cards on which numbers, composed of red and green dots, have been printed against a background of different coloured dots. A person with defective colour vision would be unable to distinguish the numbers from the surrounding background.

Some occupations require normal colour vision, usually for reasons of safety. For example, an electrician needs to be able to distinguish between coloured wires, and an airline pilot between the coloured lights on the aircraft's instrument panel. Applicants for positions such as these will be tested for colour vision. There are no restrictions on driving cars, lorries or buses, as traffic lights have a fixed sequence and can be recognised by position rather than colour.

13.3 What other occupations can you think of that require normal colour vision?

Eye changes with ageing

By age 70, most people will need some form of visual aid, since, with advancing years, the ability of the lens to accommodate decreases as it becomes less elastic. Focusing is affected as the cornea flattens, causing astigmatism (see Box 13.1). A decrease in pupil size reduces the amount of light entering the eye, and retinal cells become less efficient due to deposits laid down by ageing pigment epithelial cells. Tear film is reduced in volume and altered in structure, with the result that tears evaporate more quickly, leading to dryness and irritation of the eye. However, some older patients complain of watering eyes, e.g. due to malposition of eyelids (see 'Entropion'/'Ectropion', p. 584). The corneal periphery often develops a marked grey ring at its junction with the sclera — known as arcus senilis.

For further information on caring for older people with visual impairment, see Chivers (2003).

PRESERVATION OF VISION

Nurses can do a great deal through health education and active intervention to help people preserve their vision (Milligan 2002). The following list highlights methods which all nurses should use to contribute to health education and promotion:

- Promote the maintenance of good health through regular exercise, not smoking and a balanced diet. It is believed, although not proven, that these actions will reduce the risk of ocular degeneration, especially in people with diabetes mellitus.

For further information, see www.diabeticretinopathy.org.uk/prevention

- Observe individual behaviour and general appearance; missed appointments, unkempt clothes and a reluctance to go out may suggest ocular problems. Should any changes be noted, prompt action and referral to ensure early screening and accurate diagnosis are vital. The community nurse's observation of changes in appearance or behaviour in patients can often bring ophthalmic problems to light and result in early diagnosis and treatment. Prompt referral to the appropriate health professional is essential.

13.4 Take 5 minutes to consider changes in behaviour or appearance that may be indicative of deteriorating vision.

- Encourage regular eye examination — especially in children, people over 40 years of age and individuals in high-risk groups, e.g. those with diabetes mellitus or hypertension. Free sight testing is available for people over 60 years of age, those in high-risk groups, lower income groups and people over 40 years of age who have a family history of glaucoma.

For further information on free sight testing and benefits available, see www.rnib.org.uk

- Provide advice and ensure the correct use, storage and cleaning of glasses and contact lenses. It is vital that contact lenses are properly maintained and used according to optometrists' and manufacturers' guidelines. If guidelines are not followed, there is a risk of long-term, possibly permanent damage to the cornea, due to infection, ulceration or abrasion.
- Monitor carefully oxygen therapy in babies to prevent retinal damage.
- Treat promptly any eye infections, in order to prevent ocular damage.
- Encourage the use of eye protection where required. Both work- and leisure-related eye injuries can be prevented by wearing eye protection (see Box 13.2). Milligan (2002) reviewed the causes and measures for the prevention of ocular injuries: 85% occur in males aged 20–40 and approximately 70% result from industrial accidents. While statutory and health and safety regulations and better supervision by occupational health nurses have helped to reduce the number of industrial eye injuries, lack of eye protection remains a problem. The occupational health nurse and the prison nurse (in those custodial settings with work

Box 13.2

Preventing eye injury

Protective eyewear should always be worn during any prolonged exposure to strong sunlight or snow, as well as for the following activities:

- Chipping masonry
- Chopping wood
- Drilling
- Laying insulation
- Playing squash
- Pruning trees or shrubbery
- Stripping paint
- Sunbed bathing
- Welding
- Working under the chassis of a car.

programmes) are in a prime position not only to instruct on first aid irrigation for chemical eye injuries, but, just as importantly, to encourage the use of eye protection, through promoting attitude change and participating proactively in risk assessment of work which requires eye protection. Although the wearing of eye protection is mandatory in certain work environments, e.g. chemical laboratories and any area where grinding of metal occurs — Health and Safety at Work Act (1974) and Personal Protective Equipment at Work Regulations (1992) — nurses should be aware that some people are reluctant to wear eye protection as it may be uncomfortable and can obscure vision.

- Advocate the correct and safe labelling of chemical products, and ensure first aid, e.g. eye irrigation, is available for emergency use. Individuals should be urged in the workplace and at home to heed the labels on chemical products indicating whether they are harmful to the eyes: careful note should also be taken of first aid instructions in case of accidental splashing.
- Ensure that visual display units (VDUs) are used in accordance with the Health and Safety Executive (2003) recommendations for short, frequent rest periods to prevent eye fatigue. Employers must provide an annual sight test for all VDU users.
- Promote the wearing of sunglasses. Exactly what type of ocular damage exposure to sunlight can cause is not known, but it is believed to contribute to long-term ocular changes, i.e. cataract, macular degeneration.

For further information, see www.afbp.org.

THE VISUALLY IMPAIRED PERSON

It is difficult for sighted individuals to appreciate fully the value and importance of vision in everyday life.

13.5 Using a structured model of activities of daily living (AL) such as Orem (2001) or Holland et al (2003), discuss and list how being VI would impact upon these. Working through this may help you to gain some understanding of the daily experience of the visually impaired person (VIP). To experience a 'temporary VI' ask a colleague to blindfold you, using a sleep shade, and then to guide (see Fig. 13.6) and assist you through as many of the ALs as possible. Include eating a meal, going into a busy room, buying an item with the correct money and travelling on public transport. Reflect on this experience by asking yourself how it affected the essential 'you'. Did you feel any less intelligent? Did you feel anxious or vulnerable? Did it change the way others reacted to you? Share your experiences and insights with your colleagues.

Registration of blindness, i.e. severely sight impaired, and partial sight, i.e. sight impaired

There are few totally blind people, as most visually impaired people have some residual sight. An ophthalmologist will certify the degree of impairment, using a certificate of vision impairment form (CVI in England) or blind person form (BP1 in Scotland). Rehabilitation support can be obtained without registration.

For further information on Wales and Northern Ireland, see www.rnib.org.uk.

Registration, which is completely voluntary, entitles the individual to many local and national benefits. These will be explained by the social worker, who visits individuals in their homes and helps to arrange for appropriate support. Some areas also have the benefit of a mobility or rehabilitation officer, who is specially trained to help newly registered individuals to relearn certain daily living skills, and to move about safely in their own environment. This may involve the use of special canes or guide dogs (see 'Useful websites'). Rehabilitation officers also teach communication and information technology (IT) skills and advise on retraining for employment. Their overall aim is to enable the VIP to function as independently as possible.

People with impaired vision may be referred to a low-vision clinic and assessed by an optometrist or specialist nurse, to determine whether a variety of low visual aids (LVAs), for distance or near vision, can help individuals to make best use of their residual sight. These professionals may also provide information and advice on adaptation or retraining for employment. Employers can also be advised by various agencies, including Action for Blind People (afbp) and the Royal National Institute of the Blind (RNIB) (see 'Useful websites') about the sophisticated electronic equipment now available for VI employees. The introduction of the Disability Discrimination Act (DDA) (1996) made it unlawful to treat disabled individuals in a discriminatory way (Brading & Curtis 2000). Employers and service providers, including the NHS, must make reasonable adjustments to their services, ensuring, for example, equal access for disabled persons (Thomas & Ryan 1997).

Considering the needs of the visually impaired person

All nursing care should be planned using a structured approach to assessment and implemented using an agreed care pathway. This approach facilitates accountability and audit mechanisms.

Orem's model for nursing (Orem 2001) takes account of universal needs but focuses on specific areas of self-care deficit, builds on the individual's strengths and promotes personal responsibility for health maintenance. Education and counselling are also essential components of this model.

Some general principles of care for the VIP are outlined below:

- *Orientation to place* — if the person is at home, the environment is familiar and it is therefore important to keep things in their usual place. Every assistance should be given to help the person to move around the community and workplace until confident to do so independently. Appropriate visual aids should be used. If the person is admitted to hospital, it is the nurse's responsibility to provide adequate orientation, based on individual needs. Older people can become confused in this situation and need constant reassurance and support.
- *Maintaining a safe environment* — it is essential to remove any hazardous objects in the person's environment. Doors should be either fully open or properly closed. Fires should have guards. Loose flooring must be secured.

13.6 Examine the hospital or home environment to identify problems that the VIP may encounter. How could you reduce or eliminate these problems?

- *Communication* — a VIP will need to utilise other senses, especially hearing and touch, as approximately 80% of sensory information is obtained visually. Perception, through focused use of these other senses, will therefore be heightened (www.rnib.org.uk). Ensure the VIP has access to radio, talking books/newspapers, information in large print, Braille or on audiotape, and other more sophisticated means of communication as required. When approaching, address the person by name and identify yourself. Describe what you are doing so that the VIP feels involved. Remember also to say when you are leaving the room, as otherwise the VIP may not be aware of this.
- *Eating and drinking* — in hospital and community care settings it is best practice that food should be placed close to the VIP, bearing in mind their functioning visual field. The content and position of food on the plate should be described using a clock-face analogy. Plate guards, non-slip mats, and using crockery which contrasts with the food colour can be helpful for those with severe visual impairment. Many safety devices are available for use in the home to help with cooking.

For further information, see www.rnib.org.uk

- *Personal hygiene and grooming* — after initial orientation and help, the VIP should be encouraged to be as independent as possible, within the realms of safety.
- *Mobility* — early mobilisation should be encouraged in the home and hospital and all appropriate assistance given. The preferred method of guiding a person with visual impairment is illustrated in Figure 13.6.

The *Getting On – Services for People with VI* booklet offers valuable advice and in-depth information; see www.afbp.org.

Fig. 13.6 Guiding a VIP. Before you set off, offer your arm to the VIP. Ask which side is preferred. The VIP should hold your arm just above the elbow. Check that the VIP is ready to go. Always walk one pace in front and at the same pace as the person. Describe the environment and warn the VIP of any obstacles or changes in the journey, e.g. stairs (up or down), doors, kerbs. In this way, the VIP can sense any manoeuvre or turning of the guide's body and can walk more confidently. The 'collapsible' cane or the guide dog is in the VIP's 'free' hand. (Reproduced with permission from Medical Photography Department, St. John's Hospital, West Lothian.)

With good rehabilitation training and family support, the VIP should be able to get around in their environment safely and effectively. It will take confidence, time and patience to achieve this level of ability, and the VIP will require understanding and ongoing support. Scullion (2001) believes that if impairment is badly managed or met with hostility, then disability will occur.

DISORDERS OF THE EYE

The more common eye disorders and their management are described in the sections which follow. The coverage is

not exhaustive and the reader is urged to consult specialist ophthalmic texts, such as those given in the Further Reading list.

The present survey of common eye disorders and their management will begin by setting out the basic principles that must be followed when carrying out ophthalmic nursing procedures.

NURSING PRIORITIES AND MANAGEMENT: General ophthalmic procedures

The eye is a delicate organ which can be easily damaged — even in the course of treatment. In providing care, the nurse must therefore at all times observe the following principles.

Asepsis

Asepsis should be observed by the nurse and the underlying principles taught to patients and relatives. The nurse must, however, be realistic in the assessment of how and what the patient and relatives will manage in the home setting. Each eye should be treated separately. Drops and ointments should only be used in the eye for which they are prescribed. In hospital, topical medication should be dated upon opening and discarded after 1 week (after 4 weeks in the community). These precautions will reduce the risk of eye infection, which can pose a threat to vision.

Handling

Gentle handling is essential. Pressure on the eyeball must be avoided. This applies particularly to the cleansing of the upper eyelids. A sterile, moist, non-woven swab, dental roll or cotton wool ball is used to wipe from inner to outer canthus along the eyelash line and is discarded after a single use. Cotton wool balls can be used with the proviso that they have been thoroughly soaked and then squeezed out to ensure that no dry fibres are protruding. Patients should be cautioned against rubbing their eyes. The cornea is particularly vulnerable to abrasion injuries.

Irrigation

When irrigating the eye, the warmed solution should be directed across the skin of the lateral cheek so as to prepare the patient for the solution coming into contact with the eye. After this the irrigating motion should be directed away from the nasal side of the sclera. This will wash harmful foreign material away from the lacrimal duct to the side of the cheek, where it can be received in a kidney dish (see Box 13.5, p. 580).

Examination

Both eyes should be examined systematically (see p. 557) before and after any treatment, using a pen torch. Any abnormality or significant change in visual acuity must be reported. The patient should be asked to describe how each eye feels. Any pain must be reported immediately. As eye complications can develop rapidly, it is vital to refer patients immediately to avoid permanent damage. Both eyes should be examined, because the unaffected eye may react in sympathy with the affected one (sympathetic ophthalmitis). Photophobia is to be expected postoperatively and following trauma.

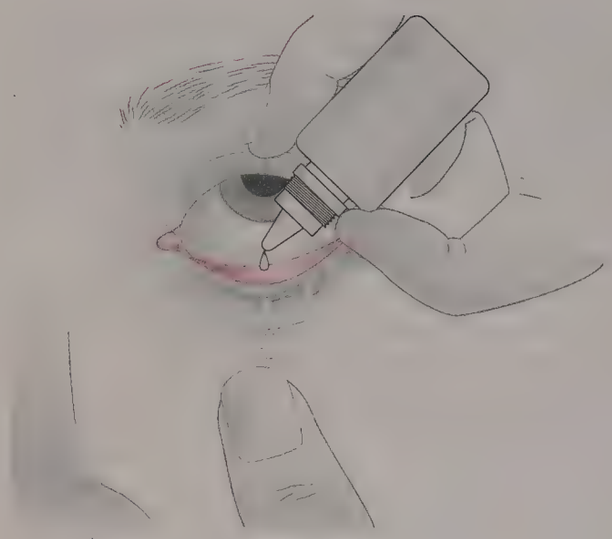

Fig. 13.7 Instilling eye drops into the lower central fornix.

Instilling eye drops and ointments

Eye drops are inserted into the middle of the lower conjunctival sac. To facilitate this, the patient is asked to tilt their head back and look up, while the lower lid is gently pulled down (see Fig. 13.7). Dropping the solution onto the sensitive cornea will cause discomfort and trigger a reflexive squeezing shut of the eye. After drop instillation the patient is asked to close the eyes gently for 30 s to maximise absorption.

Eye ointment is instilled into the lower conjunctival sac with the patient's head tilted back as described above. Contact of the tube with the eye should be avoided.

Topical drugs used in ophthalmology are listed in Table 13.2.

Padding the eye

Eye pads are applied to promote healing or to apply pressure to the eye and occasionally for comfort, when photophobia or lacrimation is excessive. It is important to appreciate that the term 'double padding' does not mean that both eyes are covered but that two pads are applied to the treated eye.

Eye pads are applied after eyes have been cleansed (if required), examined and treatment instilled. Ensure that the eye is closed underneath the pad at all times to prevent corneal damage.

The eye pad is held in position and non-allergenic tape is applied by first attaching one end lightly to the forehead, then diagonally across the eye pad towards the lateral aspect of the cheek, before the end is secured with light pressure. The downward movement maintains lid closure. The diagonal position of the tape facilitates comfort, permitting facial muscle movement. To facilitate removal a tab should be made at the top of the tape. This is grasped and with a gentle, even pressure the tape is removed. The skin on the forehead and cheek are supported as this is being done in order to reduce any dragging movement on the eyeball. The eye is examined when a pad is removed and the pad must be inspected for signs of infection or haemorrhage before discarding.

When the eye cannot be closed voluntarily, e.g. in the unconscious patient, care should be taken to avoid corneal

Table 13.2 Classification by usage of topical drugs utilised in ophthalmology

Drug	Strength	Specific action and usage
Dilatation of the pupil		
Drugs in this group act on the autonomic nervous system to induce mydriasis (dilatation of the pupil by acting on the iris muscles) or cycloplegia (contraction of the ciliary muscles). Some drugs (*) have a combined mydriatic cycloplegic action. All examples given have rapid onset (within 20 min) and short duration of action (4–24 h). They are frequently used in combination to facilitate refraction (cycloplegia required), ophthalmoscopy, fundal photography, cataract and retinal surgery, and the laser treatment of diabetic retinopathy.		
Cyclopentolate (G)*	0.5% and 1%	Treatment of anterior uveitis
Tropicamide (G)*	0.5% and 1%	
Phenylephrine (G)	2.5%	
Glaucoma medication		
There are now topical drugs which combine a beta-blocker with a prostaglandin analogue or a carbonic anhydrase inhibitor.		
Pilocarpine (G)	0.5–4%	Constricts the ciliary muscle and increases the aqueous outflow via the trabecular meshwork (action is accompanied by pupil constriction — miosis) More commonly used in the management of acute glaucoma or as an adjunct treatment for chronic glaucoma
Timolol (G)	0.25% and 0.5%	A non-selective beta-blocker which reduces aqueous production Used for the treatment of chronic and secondary glaucoma
Brimonidine (G)	0.2%	An α_2-blocker which reduces aqueous production and increases aqueous outflow via the uveoscleral outflow system Used for the treatment of chronic and secondary glaucoma
Latanoprost (G)	0.005%	A prostaglandin analogue which increases aqueous outflow via the uveoscleral outflow system Used as an adjunct treatment for chronic glaucoma
Dorzolamide (G)	2%	A carbonic anhydrase inhibitor which reduces the production of aqueous Used for the treatment of chronic and secondary glaucoma
Anti-inflammatory		
Betamethazone (G) or (Oc)	1%	Steroid Used to treat anterior segment inflammations May be combined with the antibiotic neomycin
Flurbiprofen (G)	0.03%	Non-steroidal Used to inhibit intraoperative pupil miosis
Antibacterial		
Chloramphenicol (G) or (Oc)	0.5%	Broad-spectrum bacteriostat
Fusidic acid (G)	1% viscous eye drop	Broad-spectrum bactericidal
Antiviral		
Aciclovir (Oc)	3%	Disrupts the synthesis of viral DNA in the treatment of herpes simplex keratitis
Anaesthetic agents		
Surface active anaesthetics which have rapid onset (30 s) and short duration of action (20 min). Used to facilitate the removal of conjunctival and corneal foreign bodies, investigative procedures which require surface anaesthesia, and selectively as pain relief.		
Oxybuprocaine (G)	0.4%	Used in combination with G fluorescein for tonometry
Tetracaine (amethocaine) (G)	1%	Commonly used for minor surgical procedures
Proxymetacaine (G)	0.5%	Causes less initial stinging which makes it useful for children
Staining agents		
Fluorescein (G)	1% and 2%	Stains damaged living tissue Facilitates the detection of corneal surface damage, i.e. abrasions and leaking corneal wounds

Continued

Table 13.2 Classification by usage of topical drugs utilised in ophthalmology *(Continued)*

Drug	Strength	Specific action and usage
Staining agents *(Continued)*		
Rose Bengal (G)	1%	Stains dead devitalised tissue Facilitates the diagnosis of keratoconjunctivitis sicca (xerophthalmia)
Lubricating agents		
Tear replacement solutions — surface contact time is improved by the choice of generic viscous bases		
Liquifilm (G)	1.4%	Viscosity from polyvinyl alcohol
Viscotears (G)	0.2%	Viscosity from polyacrylic acid
Lacri-Lube (Oc)		Viscosity from white soft paraffin Useful overnight

G, guttae — drops; Oc, occulentum — ointment.
Based on data from Kaiser et al (2004) and Riordan-Eva & Whitcher (2004).

abrasion from bedclothes or other articles when turning or otherwise attending to the patient. The cornea can be kept moist by the instillation of lubricants and lid closure can sometimes be improved with the application of a paraffin gauze dressing, as in the case of a sedated and ventilated patient.

NURSING PRIORITIES AND MANAGEMENT: Conditions requiring surgical intervention

The term 'intraocular surgery' describes procedures that are carried out inside the globe of the eye and which may involve structures in the anterior, posterior or vitreous chambers. Although there are many ophthalmic conditions which require operative intervention, the present discussion will focus on cataract, retinal detachment, glaucoma and perforating injuries. These conditions will have in common certain general priorities for ophthalmic and perioperative nursing management along with specific priorities relating to each condition. The general principles of perioperative ophthalmic nursing care are outlined below, followed by a discussion of nursing care specific to particular conditions. To facilitate shorter patient admission periods, patient assessment and education are increasingly undertaken in pre-assessment clinics which are frequently nurse-run. The reader is also referred to Chapter 26 for the principles of pre- and postoperative nursing management.

General nursing considerations

Assessing visual status

The patient's visual acuity and functional status are determined at the pre-assessment clinic through formal testing and interview. It is important to establish normal visual status so that the patient is not demeaned by inappropriate restrictions. It is equally important to determine any risks to ensure that a safe environment is maintained. The patient should be orientated to the ward or day bed area with a view to maintaining as normal a degree of independence as possible. Dependency level will fluctuate during the perioperative period, e.g. owing to anaesthesia, treatment and/or padding. The potential difficulties should be discussed fully with the patient.

Alleviating stress

Anxiety levels are normally high for patients admitted to hospital and this may be exacerbated in ophthalmic patients by fear of blindness and loss of independence. The patient should be given the opportunity to discuss particular fears and should be provided with clear and realistic information. Care should be taken not to raise false expectations about operative results. The patient may have practical concerns about managing everyday activities following the operation. These should be addressed and the patient should be reassured that continuing guidance and support will be available from the health care team and community organisations.

Giving information

Most patients are anxious to know the time of their surgery and how long it will take. If a local anaesthetic is to be used, they may be concerned about their level of awareness during the procedure and about whether they will be able to cooperate (see Research Abstract 13.1). Depending on the patient's visual acuity, it is often helpful to discuss the operation using a model of the eye. It is important to anticipate and dispel any misconceptions that the patient may have about eye surgery. However, not everyone will want to know the details of the surgery and the appropriate amount of information for each individual should be provided and their wishes respected.

Procedures for preoperative eye preparation should be explained. If the patient is able to carry out self-medication, instruction in the instillation of drops can provide a good opportunity to begin a teaching programme for postoperative self-care.

For further information on the nurse's role in promoting the correct administration of topical eye treatment, see Marsden & Shaw (2003).

RESEARCH ABSTRACT 13.1

The effects of handholding on anxiety in cataract surgery patients under local anaesthesia

This Korean study by Moon and Cho (2001) aimed to assess the effectiveness of handholding on the anxiety levels of patients undergoing elective local anaesthetic cataract surgery in a country where over 100 000 cataract patients undergo this type of surgery annually.

An experimental and control group design was used pre- and post-test involving visual analogue scales, interviews and physiological measures of pulse and blood pressure. Blood was also taken pre-handholding and before the end of handholding to assess a variety of body chemicals associated in the immune system's response to stress.

The results showed a significant decrease in anxiety levels during operation in the handholding group (n = 30) compared to the control group (n = 32). Epinephrine levels in the handholding group were also significantly lower. This suggests that handholding has the potential to reduce anxiety in patients having cataract extraction under local anaesthesia.

Moon J S, Cho K S 2001 The effects of handholding on anxiety in cataract surgery patients under local anaesthetic. Journal of Advanced Nursing 35(3): 407–415

Managing positioning and activity

As a general rule, any position or activity that markedly increases venous pressure in the head should be avoided in ophthalmic patients. It is usually recommended, though sometimes not feasible, that they are nursed with the head slightly raised, with the patient either semi-recumbent or lying on the unoperated side. Exceptions to this are:

- in cases of retinal detachment — the surgeon will prescribe both pre- and postoperative positions, depending on the site of the detachment
- following vitrectomy — the surgeon may prescribe the position.

It is vital that such instructions for positioning are followed precisely.

Postoperative vomiting should be prevented by ensuring that an antiemetic is prescribed and given promptly if the patient complains of nausea. Increased blood flow caused by a head-down position or straining will raise IOP and can result in damage to optical structures or suture lines. The majority of patients go home shortly after surgery and some restrictions on activity and positioning may be applicable. The reason for these activity and positioning regimens, and for their duration, should be explained to the patient and encouragement to follow these recommendations should be given.

Examining the eye

The eye should be examined systematically, both pre- and postoperatively, using a pen torch, to check for signs of infection, and to ensure that normal healing occurs. Early recognition of abnormalities reduces the risk of potential damage which might result in loss of sight. It is helpful to use the non-affected eye as a baseline against which to compare the operated or injured eye.

Subconjunctival haemorrhage is not abnormal, particularly in patients who have had cataract surgery under local anaesthetic. Often a localised subconjunctival bleed may be noted in the area of the anaesthetic infiltration or in the postoperative antibiotic injection site, if the needle or cannula has disrupted a small blood vessel. If bleeding into the anterior chamber (hyphaema) is present, it should be recorded and a diagram indicating size relative to the anterior chamber entered in the medical and nursing notes. Postoperative expectations may include some degree of lid bruising and swelling, especially following local anaesthesia. Conjunctival redness (injection) and oedema (chemosis) are sometimes noted to spread out from the postoperative antibiotic injection site. The cornea and anterior chamber (AC) should be clear. A fine suture line may be evident, although cataract wound size is often so small and the wound tunnelled in such a way that it is self-sealing and therefore does not require sutures. The wound is concealed under the top lid and examined by asking the patient to look downwards and then gently retracting the top lid. The depth and shape of the AC should be noted, as a shallow AC, i.e. one in which there appears to be a decreased space between the cornea and the iris, may indicate that aqueous from the AC is leaking from the site of the wound.

Managing dressings

The eye is protected by a plastic Cartella shield at night for up to 1 week postoperatively. Dark glasses may be worn during the day to reduce the discomfort of glare. The patient should be taught to put the glasses on over the forehead to avoid accidentally poking the earpieces into the eye.

PAINLESS LOSS OF VISION

Cataract

Any opacity of the lens can be defined as a cataract. Cataracts can develop as part of the ageing process. They can also be congenital or develop following trauma, as sequelae to inflammatory and degenerative disease, or as a result of the prolonged use of some medications, e.g. corticosteroids.

For further information, see Yanoff (1998).

PATHOPHYSIOLOGY

The lens of the eye is normally transparent due to the regular arrangement of its crystalline fibres and the nature of the proteins inside them. These fibres, which originate in the epithelium of the lens capsule, continue to be laid down throughout life. This results in thickening and a loss of elasticity. Opacity will eventually develop with ageing.

Clinical features The main feature of a mature cataract is that it reflects as a grey or milky white lens behind the pupil, which normally appears black.

Common presenting symptoms of age-related cataract are as follows:

- gradually decreasing acuity affecting distance vision more than near vision

- general dimming of vision because of the reduced amount of light reaching the retina
- more frequent refractive errors because of reduced elasticity of the lens
- increased dazzle and glare in bright light and appearance of haloes around lights at night
- monocular diplopia — double vision or a 'ghosting' effect in one eye
- alteration in colour and depth perception.

13.7 Wrap several layers of clear adhesive tape around both lenses of a pair of glasses. Alternatively, smear both lenses with petroleum jelly. Wear them for a while to experience something of what it feels like to have bilateral cataracts. Then try this with vision totally occluded in one lens and the other lens wrapped in just a few layers of tape or smeared with a thin film of jelly. How would this affect your daily activities? Discuss the experience with your colleagues.

MEDICAL MANAGEMENT

During the developmental stages of cataract, spectacles may provide a degree of improvement in visual acuity. It is impossible, however, to reverse the opacification process. Surgical removal of the cataract will ultimately be the only effective treatment. The National Cataract Survey (Desai et al 1999) indicated that 70% of all cataract procedures in the NHS were performed as day cases and this is recognised as the preferred form of care (Royal College of Ophthalmologists 2001). The NHS Executive (2000) reported that, in the late 1990s, 86% of cataract surgery was being done under local anaesthetic. This trend towards local anaesthetic day care is likely to remain popular, as it offers the least disruption to the patient's daily routine and makes effective economic use of health resources.

The retinal function is examined and, although there may be age-related maculopathy or other coexisting ocular pathology, cataract removal will still be considered, albeit with a guarded prognosis.

Surgical procedures Cataract removal is performed when the cataract interferes with activities of living (ALs).

Before the operation, the pupil is dilated to facilitate lens delivery and to reduce the risk of damage to the iris. An incision is then made into the globe at the limbus in the 12 o'clock section of the eye. The principal methods of lens removal are:

- phacoemulsification — ultrasonic fragmentation to break up the nucleus and aspirate soft lens material, leaving the posterior capsule intact
- extracapsular extraction — removal of the entire nucleus and cortex through a large incision, leaving the posterior capsule intact. This procedure is carried out more often in developing countries as it is not dependent on the availability of sophisticated phacoemulsification equipment and of the necessary technical maintenance.

Intraocular lens implantation The best visual correction is achieved by the insertion of an intraocular lens (IOL) positioned in front of the posterior capsule at the time of cataract removal. This is possible in the majority of cases. Unforeseen surgical complication, e.g. severe posterior capsular rupture with the release of a large amount of vitreous into the anterior chamber, is the main contraindication to insertion of an IOL. In the UK, the strength of lens is calculated for each patient based on a combination of:

- biometry — measurement of the axial length of the eye along the visual axis
- keratometry — measurement of the corneal curvature
- the patient's previous optical history.

The nurse must not only be able to carry out the tests, but also to interpret them proactively with a view to obtaining the best postoperative vision.

IOLs may be inserted as a secondary procedure. It is important to know which kind of lens is in situ in order to ensure appropriate postoperative care. In the rare situation when no IOL is inserted, a contact lens or corrective spectacle may be issued.

Postoperative medication The inflammatory response, which accompanies all healing, is controlled postoperatively by a combination of topical steroids and antibiotics. It is vital that the patient understands the reasons for the prescribed postoperative instillation of drops and why treatment must not be stopped before completing the course.

NURSING PRIORITIES AND MANAGEMENT: Cataract extraction and implantation of an intraocular lens

As day case cataract surgery has become the norm, most ophthalmic units will have developed care pathways using local or national clinical guidelines such as those of the Scottish Intercollegiate Guidelines Network (SIGN 2001). The evolution of cataract documentation relates to the rapid and safe throughput of patients and to the associated need to incorporate multidisciplinary notes that reduce duplication while promoting individualised care. The principles of perioperative management are covered in Chapter 26 and those relating to intraocular surgery in Nursing Care Plan 13.1. The following points specific to cataract extraction and IOL implantation should be noted.

Major nursing considerations

IOL management

It is important for the nurse to find out which method has been used for extraction and whether or not an IOL has been implanted. If an IOL is in situ, its position must be checked at each eye examination.

Problems which may arise following IOL implantation include:

- a secondary rise in intraocular pressure, usually accompanied by severe one-sided headache above the brow of the operated eye
- cystoid macular oedema which results in the patient noting reduction and distortion of vision
- infection, with the rare, but sight-threatening possibility of endophthalmitis.

Should any of these signs and symptoms be present, the patient and relatives should know who to contact promptly so that action can be taken to prevent permanent eye damage.

Nursing Care Plan 13.1 A patient undergoing intraocular surgery

Nursing considerations	Action	Rationale	Expected outcome
Preoperative preparation			
1. Anxiety relating to local anaesthetic; being awake during the procedure; draping procedure in theatre; communication with staff during procedure	• Explain that local anaesthetic ensures painless procedure, reduces postoperative discomfort of general anaesthetic, and enables earlier discharge	Information given about procedures reduces patient anxiety and discomfort	Patient is able to recall details of preparation and appears more relaxed
	• Explain that draping and skin cleansing are carried out to reduce the risk of infection		
	• Explain that the unoperated eye needs to be closed to protect the cornea from accidental damage and reduce eye movement		
	• Explain that whilst the eye is anaesthetised it is possible to overcome muscle activity and position the eye in the orbit so as to permit easy access to most surgical sites	Patients commonly express a fear that the eye will be placed on the cheek to facilitate surgery. Placing the eye on the cheek is impossible without total destruction of the optic nerve, which, together with the extraocular muscles and cheek ligaments, tethers the eye securely within the orbital cavity	
	• Explain that some patients may experience periods of 'seeing lights' during the procedure		
	• Explain that throughout the time in theatre one nurse will hold the patient's hand and they will agree on a signalling system so that if the patient has any discomfort or pain this can be communicated; remedial measures will be taken immediately	An agreed communication system reduces anxiety and increases well-being the operation well	Patient communicates appropriately during the procedure and tolerates
Discharge considerations			
1. Anxiety about visual function following surgery	• Explain that visual recovery is not complete until the eye is fully healed	Improved knowledge reduces anxiety	Patient is able to recall information given
	• Visual function is to be assessed at first dressing within 48 h		Patient can demonstrate procedure used
	• Explain that 'floaters', which occur following discharge, and the experiencing of flashing lights may precede the development of complications and urgent review in the OPD should be sought		Patient outlines procedure to obtain urgent OPD review

Continued ▶

Nursing Care Plan 13.1 A patient undergoing intraocular surgery *(Continued)*

Nursing considerations	Action	Rationale	Expected outcome
Discharge considerations (Continued)			
2. The patient has a parkinsonian tremor and is unable to instil the eye drops	• Teach carer(s) to instil eye drops prior to surgery. If there is no carer (or neighbour), the community nurse should visit and instil eye ointment twice daily	Rehabilitation and discharge planning should begin at pre-admission clinic or first hospital attendance. Early liaison with the community nurse will help to ensure that treatment continues and that the nurse is fully informed of individual aspects of the case. It will also reassure the patient that a supportive health care team exists	

OPD, outpatient department.

It should be explained to the patient and the family that during the healing process there will be a period of adaptation, as the brain adjusts to changes in visual perception. The patient should be told to take care with moving about during this period, especially if there are pre-existing conditions that affect balance.

Premature cessation of treatment by patients, or failure to ensure regular instillation of the eye drops, is a recognised risk following eye surgery, and particularly so in day case cataract surgery, which accounts for the majority of ophthalmic day care. This is thought to be linked to the professionals' concerted drive to shorten and normalise this surgical event to a 2–3 h visit, with no fasting requirements (for patients having a local anaesthetic) or need for the patient to remove clothing and change into a hospital gown, thus possibly leading patients to misinterpret this situation and equate what appears to them to be 'low level care' with 'no care'. As a result, they may view the postoperative eye drop administration as an optional extra, rather than an essential part of their total care package. Education must therefore be clear and consistent and the nurse should check that the patient and the family or carers understand the instructions and the importance of following these precisely.

Refractive laser treatments

Individuals with myopia, hypermetropia or astigmatism have become dissatisfied with the inability to obtain their best vision with either spectacles or contact lens. This consumer demand has led to the current practice of laser surgery to correct their refractive errors.

Current excimer laser techniques include photorefractive keratectomy (PRK), which alters corneal curvature by ablating surface corneal tissue and results in a reduction of refractive power. Laser in situ keratomileusis (LASIK) consists of cutting a hinged flap of cornea under very precise conditions, performing the laser ablation in the corneal bed and then replacing the flap. This is thought to reduce discomfort and promote faster visual recovery (Riordan-Eva & Whitcher 2004).

Prior to undertaking any treatments, it is essential to seek advice from an ophthalmologist, as complications can occur, including over- or undercorrection, and loss of best corrected VA.

For further details, see www.moorfields.org.uk.

13.8 One of your patients has undergone a cataract extraction and IOL implantation. As you systematically examine the eye, you note the following clinical signs:

- eyelids — slightly bruised and swollen
- conjunctiva — pink
- cornea — cloudy, suture line intact
- anterior chamber — formed, hyphaema noted and more extensive than at previous dressing
- iris — muddy
- pupil — dilated and round
- posterior chamber IOL — in situ and reflecting.

Which clinical signs are within normal expectations and which would alert you to a problem that demands immediate attention? What could this problem be? What action will you take?

Glaucoma

Glaucoma can be defined as a disease process with a characteristic pattern of cupping of the optic disc and reproducible field loss. The IOP may be raised or normal. The condition may be acquired or genetic in origin. Acquired glaucoma can be further classified as primary open-angle glaucoma (POAG), primary closed-angle glaucoma (PCAG — both acute and chronic), and glaucoma secondary to pathological processes (secondary glaucoma).

13.9 Revise your knowledge of aqueous dynamics within the eye.

Primary open-angle glaucoma

This type of glaucoma, also known as chronic simple glaucoma, causes progressive and irreversible loss of the peripheral visual field, with the central 10% being spared until a later stage. It is initially symptomless.

PATHOPHYSIOLOGY

The normal range of IOP is 12–20 mmHg and this varies throughout the 24-h period. In POAG, the pressure is generally elevated and the diurnal variation may show considerable fluctuation, i.e. IOP is lower in the morning, peaks during the day and lowers again in the evening (Kanski 2003).

Raised IOP decreases the blood flow in the optic disc capillaries with resultant excavation and atrophy of the optic nerve head and subsequent loss of nerve fibres passing through it (cupping). A progressive loss of the visual field results from damage to nerve fibre bundles as they enter the optic disc.

Clinical features The outward appearance of the eye is normal. On examination, if there is cupping of the optic disc, peripheral visual field loss and possible raised IOP, a diagnosis of glaucoma may be made.

Common presenting symptoms There is usually a gradual and painless loss of peripheral vision. The patient rarely notices this deterioration until considerable damage has been done. This loss of vision is irreversible. The glaucoma is often detected by an optometrist during a routine eye examination.

MEDICAL MANAGEMENT

The main aim of treatment is to reduce IOP to allow better capillary perfusion at the optic nerve head. This involves improving the aqueous drainage system or decreasing the production of aqueous, or a combination of both. Medical treatment is the mainstay in the majority of cases (European Glaucoma Society 2003), although there is a growing trend towards early surgical or laser intervention.

Tests and investigations Diagnosis and medical assessment of the nature and severity of the condition will rely on the following:

- tonometry — measurement of IOP with instruments that allow for corneal contact
- visual field analysis
- ophthalmoscopy to examine the optic nerve head and estimate the degree of cupping
- gonioscopy — examination of the state and depth of the angle of the eye
- phasing — measurement of IOP by tonometry at different times of the day.

Treatment Whether the medical regimen is implemented alone or in combination with a surgical procedure, it is important to maintain monitoring of the efficiency of treatment indefinitely. The regimen may include the administration of some combination of the following medications:

- Topical beta-blockers, and topical carbonic anhydrase inhibitors to reduce aqueous production (see Table 13.2). Topical regimens may be prescribed for long-term continuous use; systemic drugs are generally prescribed for short-term or intermittent use
- Topical prostaglandin analogues to increase uveoscleral outflow are increasingly being used in the initial treatment of POAG
- Topical miotic drops to constrict the pupil and stretch open the trabecular meshwork, thus facilitating aqueous drainage.

Surgical treatment for POAG is usually performed when conservative management has failed, indicated by progression of visual field loss and persistent elevation of IOP, or when the patient's social situation or health prevents adherence to the recommended eye drop regimen.

The principle of surgery is to create a fistula between the anterior chamber and the subconjunctival space in order to bypass the existing drainage system and increase the outflow of aqueous. The most commonly used procedure is trabeculectomy.

Postoperatively, a small bleb under the conjunctival flap will be visible. A small V-shaped hole in the iris may be noted if a peripheral iridectomy has been performed.

The success of surgery is measured by whether the IOP remains within normal limits, but there can be no actual improvement in visual acuity. If a trabeculectomy drains well, topical treatment may be discontinued.

Laser treatment involves applying short bursts of a laser beam through a lens resembling a gonioscopy lens, targeting selected areas of the trabecular meshwork. Application of argon laser burns to the trabecular meshwork (argon laser trabeculoplasty) has been found to be effective in selected cases in reducing IOP. The scarring caused by the laser burns appears to stretch the tissues between the burns, thus opening up spaces in the trabecular meshwork and facilitating drainage of aqueous.

NURSING PRIORITIES AND MANAGEMENT: Primary open-angle glaucoma (POAG)

Major nursing considerations

Screening

Measurement of IOP and visual field testing may be carried out in the community by the optometry service as part of a 'shared care' scheme or in hospital-based screening clinics. More hospitals are providing nurse-led screening clinics. These present ophthalmic nurses with the challenge of expanding and extending their roles, enabling them to combine patient education with new skills such as optic disc photography and disc assessment using a slit lamp and lenses.

Patient adherence to treatment recommendations

This is a major concern, especially in the outpatient department and the community setting where most patients with glaucoma will be seen. It is a nursing responsibility to assess the patient's understanding of the condition as well as the rationale for treatment, together with the patient's ability to instil the drops and continue with other aspects of treatment, such as punctal occlusion after topical beta-blockers.

Self-administration of drops may be difficult and requires arm and neck flexibility and hand dexterity to manage the drop dispenser bottle successfully. Various appliances are available to help with the procedure but it still requires skilful demonstration to patients and carers to ensure success. In some cases, the community nurse may be best placed to know how to encourage particular patients who have good hand dexterity, but low confidence, to be more active in their own eye drop instillation.

13.10 How could you encourage a patient who is prescribed topical antiglaucoma treatment to adhere to the regimen?

Postoperative observation and monitoring

Depth of AC Postoperatively, the depth of the AC in the operated eye should be compared to that of the unoperated eye and variations must be reported. It is possible for overdrainage to result in a shallow AC or for underdrainage to result in a deeper AC.

Signs of raised IOP Severe postoperative pain, accompanied by a cloudy cornea and flat AC, is abnormal and must be investigated.

Administering laser treatment

Fully explaining what is involved and reassuring the patient of support throughout the procedure, and monitoring afterwards, will be helpful in allowing the treatment to be administered precisely and safely. Protective goggles are mandatory for all staff in attendance.

During application of laser treatment, it is necessary for the nurse to understand the potential hazards to the patient and to staff (see Nursing Care Plan 13.2).

For further information, see Batterbury & Bowling (1999) and Al-Husainy et al (2001).

Retinal detachment

Retinal detachment describes a separation between the neural and pigmented layers of the retina.

PATHOPHYSIOLOGY

The light-sensitive cells in the neural layer are detached from the essential pigments in the pigment layer as fluid effusion between the layers gradually causes more separation. Retinal detachments are most frequently associated with holes or tears in the retina. These occur as a consequence of vitreous traction, degenerative disease or vitreous loss, which may be traumatic or postoperative. Predisposing factors include myopia, aphakia, trauma or retinal/choroidal tumour. If one eye is affected, the other is also at risk.

Common presenting symptoms The patient may present at various stages with painless visual disturbances or loss of vision. The external appearance of the eye is unchanged, unless recent traumatic injury or surgical intervention has taken place. During the early stages, the rods and cones are falsely activated, causing sensations of flashing light. As flakes of pigment are shed into the vitreous, the patient may see showers of floating shapes and strands in the vitreous field. Later, the patient may describe an impression of a curtain coming down or across the line of vision.

MEDICAL MANAGEMENT

Treatment The exact nature and extent of the retinal detachment and the presence of retinal fluid will dictate the specific procedure for repair that is used. An internal approach, i.e. a vitrectomy, in which some of the vitreous humor is removed and the volume replaced with expansile gas or silicone oil, will almost inevitably induce a cataract within a 1–2 year period. Depending on the precise location of the detachment, an alternative external approach, with use of a scleral band, may be possible. This procedure does not carry the same sequelae, but may not be appropriate, due to the position of the detachment.

Surgical procedures The aim of surgery is to produce a controlled inflammatory response to seal the detachment, release the subretinal fluid and bring the retinal layers into normal apposition. Surgery should be undertaken at the earliest opportunity to give the best possible visual outcome, especially in those situations where the macula is still attached or has been detached for less than 1 week.

External cryotherapy in the form of a carbon dioxide (CO_2) freezing probe can be applied to the sclera behind the detached retina or an internal laser can be targeted at the appropriate area of the retina: both of these treatments will cause an inflammation of the choroid and retina and lead to adhesion of the detached neurosensory and pigment epithelium layers. Draining of subretinal fluid aids repositioning of the layers, which may be supported by internal tamponade, created by intravitreal air, silicone oil or volume-expanding gases. A silicone explant may be sutured onto the outer surface of the sclera. Once it is seen to be in the correct position and of the correct size and provides the surgeon with the appropriate retinal indentation, it is permanently tied with non-absorbable sutures, in order that the compressive effect is not lost over time. The explant is not normally visible.

Outpatient treatment with argon laser and volume-expanding gases may be satisfactory in cases of dry retinal detachments. Here, the inflammatory response is controlled by mydriatic and steroid eye drops.

For further information, see Chignell & Wong (1999).

NURSING PRIORITIES AND MANAGEMENT: Retinal detachment

Major nursing considerations

Patient positioning

Correct positioning is a vital component of the management of retinal detachment. Individualised regimens determined by the surgeon must be strictly observed. The positioning prescribed will depend on the site and the nature of the surgical repair. The patient must be fully informed of the reasons for positioning, as adherence to the regimen is very important to the success of the treatment. If the outcome of the surgery is simply re-attachment with no predicted improvement in vision, the patient may decide against surgery and the associated positioning, which can prove

Nursing Care Plan 13.2 Ensuring patient cooperation in laser treatment associated with glaucoma

Nursing considerations	Action	Rationale	Expected outcome
Anxiety due to: • **Lack of understanding of laser treatment** • **Fear of pain and discomfort during procedure**	• Explain to the patient about sitting during the procedure as for gonioscopy and that a similar lens will be applied to the eye	The patient will have experienced gonioscopy as part of the earlier examination and will therefore be familiar with the procedure	The patient can demonstrate awareness of what the procedure entails and has confidence in the medical and nursing team
	• Describe the anatomy of the eye, how the laser beam is targeted on the problem areas and what the expected outcome will be	Expectations of a positive outcome will reduce anxiety	
	• Explain the importance of maintaining a steady position and gaze	The patient's cooperation is necessary to ensure that only targeted areas are exposed to the laser	The patient is cooperative during the treatment, keeps a steady direction of gaze and does not appear unduly anxious. Accidental burns are avoided
	• Reassure the patient that the treatment may be uncomfortable but should not be painful. Patient will experience bright flashes of light and there may be a slight headache afterwards • Reassure the patient that the procedure is well controlled and that there will be careful follow-up	Information given about procedures reduces patient anxiety and discomfort	

arduous for those with musculoskeletal and respiratory conditions. Normal functional positions are usually allowed at mealtimes and for toilet purposes. Complete bed rest is seldom necessary for longer than 24 h postoperatively, after which mobilisation is permitted with the patient following an individualised regimen of head positioning if intravitreal air or gas is used (see Nursing Care Plan 13.3).

The overall aim is to enable the detached area to fall back into position preoperatively and to maintain normal apposition postoperatively. Generally, if the detachment is superior, the patient will be nursed lying flat with one pillow; if the detachment is inferior, nursing will be with the patient sitting upright in bed or in a chair. In the case of a temporal or nasal detachment, the patient will be nursed lying on the opposite side to the affected area. These positions are reversed postoperatively if surgery has included internal tamponade, i.e. intravitreal air. This surgery is more likely to be performed under general anaesthetic.

Patient education and counselling

The patient should be made aware that vision may be temporarily poorer than before surgery due to the manipulation of the eye, administration of mydriatic eye drops and the alterations to the focusing power of the eye resulting from any explant, e.g. scleral band, which might be present. Visual improvement, unless there is an already existing eye condition such as macular degeneration, will be a gradual process.

Postoperative pain

Postoperative pain can be expected to be fairly severe, depending on the complexity and the duration of the surgery. If severe pain persists despite the use of narcotic analgesics, an acute rise in IOP, possibly precipitated by retinal surgery, should be suspected and reported. If severe pain persists and the IOP is within normal limits, some problem with the explant must be suspected.

Postoperative appearance of the eye

In retinal surgery, the conjunctival incision is encircling, there is extensive handling of the globe and, if vitrectomy instruments have been used, there may be considerable trauma to the conjunctiva. The nurse can therefore expect to observe marked chemosis with bruising and swelling of the eyelids. Pressure dressings or regular cold compresses

Nursing Care Plan 13.3 Positioning of a patient with retinal detachment

Nursing considerations	Action	Rationale	Expected outcome
The patient has knowledge deficit about enforced positional bed rest to prevent further detachment of retina and help postoperative recovery	• Establish knowledge base by preparing and presenting a teaching session using a model of an eye. Include a family member if patient has significant visual loss. Include: – description of normal retina and its function – possible cause of detachment – description of surgical procedure – positioning before and after surgery to help retina fall back into place. Explain that this will be prescribed by the specialist and that every attempt must be made to observe it	Misconceptions about eye surgery are often lurid and frightening. Understanding what really happens will reduce fear and make cooperation with instructions more likely. The informed patient experiences a significant reduction in anxiety levels and is more likely to cooperate	The patient is able to describe what happens in retinal detachment, how it can be repaired, and asks questions which indicate an acceptable level of knowledge Patient appears more relaxed about the need for positioning and is very cooperative
	• Encourage questions	Given time and encouragement, patients may express a variety of questions and individual concerns	
	• Reinforce explanations frequently	Due to the blocking effect of anxiety, patients do not always absorb information and it may be necessary to repeat or rephrase it	

may be applied postoperatively. The eye must be monitored closely to ensure that the conjunctival incision heals cleanly and that there is no evidence of rejection or extrusion of the silicone explant.

Corneal transplant (keratoplasty)

Indications for corneal transplant include destruction of the cornea by injury or disease, some cases of advanced keratoconus (conical cornea) and corneal opacity. Transplants may be full or partial thickness. Keratoplasty is primarily an elective procedure with donor material supplied principally by the Corneal Transplant Service Eye Banks in Bristol and Manchester. The donor eyes and donor blood are screened thoroughly (Armitage & Easty 1998) to minimise the risk of using donor material where underlying infection or corneal disorder is present. The donor material should be harvested within 24 h of death.

NURSING PRIORITIES AND MANAGEMENT: Corneal transplant

The perioperative period is managed as for other intraocular surgery.

Special considerations

The use of donated tissue

Recipients rarely ask questions regarding the source of a donated cornea, but nurses must be ready to give reassurance and support, as the use of donor corneas can be an emotive issue. Sometimes the donor's relatives ask if the tissue has been used. If the nurse is involved in giving confirmation, care should be taken not to violate confidentiality whilst still providing adequate information. The entire team caring for the patient must invest time in preparing and delivering consistent, individualised information.

Postoperative examination

Following surgery, any conjunctival redness (injection) should gradually lessen. If the conjunctiva does not soon return to the 'white eye' state, the cause may be raised IOP or transplant rejection. These possibilities must also be considered when inspection of the cornea reveals a loss of clarity, a finding which must be reported immediately. The wound should be examined to ensure the suture line remains intact and the corneal disc (transplant) has stayed

in position, as disruption of either may affect the optical power of the transplant.

Patient involvement and cooperation

Both the patient and the family should be made aware that corneal transplant requires a lengthy follow-up period. The cornea is an avascular structure, and therefore healing will be slow. The corneal sutures will remain in situ for several months. If a good optical result has been obtained, it may be decided to leave the sutures in indefinitely, rather than risk disturbing the transplant.

It must also be emphasised that any topical medication prescribed must be continued, to avoid rejection of the transplant and prevent infection. The patient should be warned that optimal visual recovery cannot be expected for some months, or even up to 2 years after surgery. Some may be disappointed by the initial outcome, when vision may seem to be poorer than before transplant.

Prior to discharge, patient and carer teaching should ensure that the need for attending review appointments is understood, as early rejection may be asymptomatic, and that they are aware of the importance of early recognition of symptoms of transplant rejection. Such symptoms may include:

- increased redness of the conjunctiva
- cloudiness of the cornea
- reduction of visual function, and/or
- discomfort in the operated eye.

Temporal arteritis (giant cell arteritis, cranial arteritis)

This is a progressive disease process affecting the over-60 age group, in which the middle layer of medium-sized arteries becomes inflamed. When the external carotid system is involved, ocular damage results with sudden loss of vision, which may be preceded by, or accompany, polymyalgia rheumatica (stiff aching muscles, especially around the shoulders).

PATHOPHYSIOLOGY

There is degeneration of the retina, which results from thrombosis or occlusion of the ophthalmic artery, secondary to necrotic inflammatory changes in the middle layer of the temporal and cranial arteries. The cells in the destroyed middle layer are replaced by collagen. During the active phase of this process, there is a raised erythrocyte sedimentation rate (ESR) (see Ch. 11).

Clinical features Patients often complain of general malaise, loss of weight and lethargy, or a 'flu-like' illness which may last for a few days or weeks and which precedes a sustained visual disturbance. This is in contrast to the prodromal phase, in which fleeting episodes of blurred vision may occur, accompanied by unilateral temporal or occipital headache. On presentation, the patient may complain of scalp tenderness and jaw claudication. The loss of vision is sudden in onset, usually affecting one eye before the other. The length of time between both eyes being affected is extremely variable, ranging from several hours to several days.

MEDICAL MANAGEMENT

Diagnosis is made following ophthalmoscopy and the identification of a raised ESR. The ESR may not be high in the early stages of the disease and repeat tests may be necessary. The diagnosis may be confirmed by carrying out a temporal artery biopsy.

Treatment may be instigated in the community or in hospital and consists of systemic corticosteroid therapy which lowers the ESR to within normal limits. The initial dose may be given i.m. to achieve the effective therapeutic level. The starting high-dosage rate, i.e. 80–120 mg/day, is reduced to a maintenance oral dose, which may be administered for up to 2 years. Topical treatment is not usually prescribed unless a secondary condition, e.g. iritis, develops.

NURSING PRIORITIES AND MANAGEMENT: Temporal arteritis

Nursing intervention is directed towards the care of a patient undergoing corticosteroid therapy. In particular, monitoring and recording regimens, e.g. of blood pressure, urinalysis and body weight, will be required to give warning of any complication arising from the therapy. If vision deficit is severe, help and support will be necessary and registration as a blind or partially sighted person may be required.

RED EYE

Primary acute closed-angle glaucoma (PCAG/ACAG)

Closed-angle glaucoma presents as an acute episode of severe raised IOP, usually unilateral. It is an ophthalmic emergency and requires immediate intervention from a specialist department, as permanent ocular damage occurs if untreated or treated incorrectly. Prophylactic treatment is required for the unaffected eye.

PATHOPHYSIOLOGY

Raised IOP develops as a result of disruption of the circulation of aqueous humor in the anterior chamber, which can be associated with hypermetropia. Pupil dilatation is accompanied by forward displacement of the iris, which blocks the trabecular meshwork, reducing or stopping the flow of aqueous to the canal of Schlemm. The pupillary margin of the iris also comes into contact with the lens, causing the pupil to become semi-dilated and fixed, further impeding the flow of aqueous and increasing forward displacement of the iris. Aqueous build-up results in corneal oedema and disturbance of sensory nerve fibres.

Common presenting symptoms are as follows:

- Sudden onset, with severe pain in one eye accompanied by frontotemporal headache on the affected side
- Nausea and possible vomiting; these symptoms can sometimes lead to a misdiagnosis of gastric or abdominal problems
- Blurred and reduced vision
- Photophobia and increased lacrimation

- Red eye, especially around the limbal area (due to marked ciliary injection)
- Corneal haze due to oedema
- Semi-dilated pupil, unreactive to light
- Poorly defined iris details (muddy in appearance)
- On palpation over a closed lid, the eye feels hard because of raised IOP.

MEDICAL MANAGEMENT

Tests and investigations include the following:

- A full history (see Table 13.3)
- Systematic ocular examination using slit lamp
- Gonioscopy — examination of the angle of the eye (see Fig 13.2)
- Measurement of IOP.

Acute signs and symptoms should be managed as follows:

- Pain relief by analgesics, including i.m. opiates
- Control of nausea and vomiting with i.m. antiemetics
- Increase in outflow of aqueous humor by freeing the iris angle. To achieve this, a regimen of intensive topical miotic therapy is commenced to constrict the pupil rapidly and draw the iris away from the angle. Prophylactic therapy is also prescribed for the other eye to prevent an acute attack
- Reduction in production of aqueous humor by administration of carbonic anhydrase inhibitors such as acetazolamide (Diamox), either orally or intravenously. If the response to this is unsatisfactory, osmotic diuretics such as oral glycerol or i.v. mannitol can be used.

Surgical intervention Once the acute signs and symptoms have been managed, surgical intervention may be contemplated. The method depends on the appearance of the angle and may be any of the following:

- Argon laser trabeculoplasty (ALT) — small holes are created in the peripheral iris of the affected eye
- Surgical procedures, including iridectomy or trabeculectomy (see 'Glaucoma', p. 568)
- Post ALT, topical steroid treatment and possible long-term antiglaucoma therapy (see Table 13.2) to reduce inflammation and stabilise IOP.

For surgical procedures, the preparation and perioperative care are as for Nursing Care Plan 13.1 (see p. 567).

NURSING PRIORITIES AND MANAGEMENT: Primary acute closed-angle glaucoma (PCAG)

Screening

It is essential to acknowledge that the patient may experience severe pain and fear at the potential loss of vision. Reassurance and support are vital at this time.

The experienced ophthalmic nurse requires the skills to assess the ocular condition through a knowledge of clinical signs and symptoms (see p. 557). This will aid possible diagnosis and prompt referral for specialist intervention. Nursing priorities and management are as for POAG (see p. 569) and a patient undergoing laser treatment (see Nursing Care Plan 13.2). Further tests, for example of visual fields and of IOP, should be delayed until acute signs and symptoms have resolved.

Table 13.3 Systematic approach to history-taking

Assessment	Question	Rationale
History of injury	How did the accident occur? When did the accident occur? Where did the accident occur? Which eye is affected? Is the injury unilateral/bilateral? Were safety goggles worn?	To aid diagnosis For medicolegal reasons
Ophthalmic history	Are glasses or contact lenses worn? Has a similar accident occurred before? Has patient had a previous eye injury or operation?	To ascertain if preventive lessons are learnt To aid clinical examination and diagnosis
Medical history	Does patient have any general health problems?	Some systemic disorders may affect the eye, e.g. diabetes mellitus, hypertension, altered thyroid activity
	Has patient had previous surgery?	Patient may require surgery and may have had a reaction to an anaesthetic previously
Medications	Is patient taking medication at present?	Some medications may affect the eye, e.g. aspirin and the contraceptive pill Patient may have an allergy to a medication To ensure safe prescribing and avoidance of any contraindications to use
Allergies	Is patient allergic to any substance, e.g. medications, Sellotape, Elastoplast?	A substance may inadvertently be given to which the patient is allergic, complicating the condition

Uveitis

PATHOPHYSIOLOGY

Uveitis is inflammation of the uveal tract. Anterior uveitis (or iritis) can involve the iris or the ciliary body, or both. Posterior uveitis involves the choroid (choroiditis). It is an acute condition, the exact cause of which may be unknown, although it is often associated with rheumatoid conditions, irritable bowel syndrome (IBS), ankylosing spondylitis and sarcoidosis (Kunimoto et al 2004). Recurrent episodes are expected; they usually respond to prompt treatment and carry a fairly good prognosis. Secondary iritis may accompany other eye infections or trauma.

Clinical features are as follows:

- Mild to severe pain, due to ciliary body spasm
- Red eye, due to vascular congestion in the conjunctival vessels at the limbus
- Photophobia
- Cloudy aqueous, due to the increase in aqueous protein content and presence of white blood cells (the debris floating in the aqueous is known as 'flare and cells')
- Reduced vision, dependent on the severity of the attack and degree of inflammation
- Cellular exudates, i.e. keratic precipitates (KPs), may be present on the posterior surface of the cornea
- Loss of iris details (muddy iris)
- Inflammation of the iris may cause it to adhere to the anterior surface of the lens (synechiae formation); this will interfere with aqueous flow
- Possible raised IOP, which, if untreated, may progress to secondary glaucoma.

MEDICAL MANAGEMENT

- Patients should be investigated to determine the cause of recurrent uveitis via blood tests, the most commonly used being HLA-B27 and ESR. The aetiology is most commonly idiopathic or autoimmune (Kunimoto et al 2004).
- Outpatient review is usual, but in severe cases hospital admission may be required.
- Usual treatment is with topical steroids and cycloplegics, eye drops which dilate the pupil and paralyse the ciliary muscle; however, in severe cases, these may be given via subconjunctival injection.
- Raised IOP must be treated, as described in the PCAG section (see p. 573).
- Ocular pain must be managed, and the wearing of dark glasses can alleviate photophobia.
- Treatment will be long term if attacks are frequent with acute flare-ups.

NURSING PRIORITIES AND MANAGEMENT: Uveitis

Major nursing considerations

Setting priorities (triage)

Screening for potential health problems and prioritising patients' needs are two interrelated aspects of the nurse's role in the community. It is vital that community nurses are able to recognise ophthalmic conditions which need urgent medical attention. Uveitis is one such condition, as raised IOP and/or severe inflammation will quickly cause irreparable damage if treatment is delayed.

13.11 List the ophthalmic conditions that require emergency treatment.

Education

Once the diagnosis is confirmed and treatment has been commenced, the nurse's role will include providing guidance and support for both the patient and the family to ensure adherence to the treatment regimen, recognition of signs and symptoms, and prompt self-referral if the condition recurs. These actions will serve to reduce the severity of the attack and the risk of complications.

Ensuring a safe environment

Dilated pupils allow an increased amount of light to enter the eye, causing photophobia. Patients experience dazzle when in bright sunlight or when facing car headlights from oncoming traffic at night. Appropriate adjustments to lifestyle, such as not driving or working heavy machinery whilst on cycloplegics, is a medicolegal requirement for the duration of the treatment (Ayres & Shaw 2001).

Keratitis

Keratitis refers to inflammatory conditions of the cornea. These may be caused by certain bacteria, viruses or fungi resulting in corneal ulceration. They may also be associated with trauma, external eye disease, dry eye and extensive contact lens wear (Kunimoto et al 2004). If the superficial layer, the epithelium, alone is affected, there is minimal damage with little visual loss. If the middle portion (stroma) is involved, loss of transparency and altered corneal curvature may lead to significant loss of vision. Severe inflammation may result in inflammatory debris being shed into the anterior chamber and settling as a collection of cells (hypopyon).

PATHOPHYSIOLOGY

Clinical features are as follows; the severity of signs and symptoms will vary dependent upon the actual cause:

- Red, inflamed eye
- Photophobia with spasm of the eyelid (blepharospasm)
- Lacrimation/profuse tears, although there are some instances of dry eye presentation
- Reduced vision
- Possible discharge and 'sticky' eye.

Bacterial keratitis

The most common causative agents are *Pneumococcus*, *Streptococcus* and *Pseudomonas*. These invade the cornea, resulting in an inflammatory reaction. The condition tends to recur, may range from superficial to severe and may result in corneal thinning and, in rare cases, perforation.

Viral keratitis

The most common form is dendritic (herpetic) ulcer, which is caused by the herpes simplex virus. Its distinguishing

feature is the branching, tree-like pattern it forms on the cornea, which is visible only on corneal staining with fluorescein.

Fungal keratitis

Fungal infections of the eye are an increasing problem. The damage they cause is severe, and specific antifungal treatment agents are limited, making clinical management complex. Complications can develop rapidly. The distinguishing feature of this kind of ulceration is that it appears as feathery extensions over the cornea. It can be associated with minor trauma from vegetation, e.g. plants, or with contact lenses.

Acanthamoeba

This form of keratitis is associated with acanthamoeba, an organism which inhabits polluted water and swimming pools. Although rare, it is serious and is linked with certain features of contact lens wear, e.g. use of soft, disposable lenses, poor hygiene levels and excessive contact lens wear which breaches the manufacturer's guidance (Kunimoto et al 2004). Clinical features include ring abscess formation and corneal melt, as well as typical keratitis signs and symptoms previously mentioned (see p. 575). Treatment is medical and intensive, but poor response to treatment can result in severe visual impairment.

For further information, see www.revoptom.com/handbook/default.htm and select 'keratitis'.

MEDICAL MANAGEMENT

Conjunctival and corneal swabs, and fluorescein staining can confirm the diagnosis. The fluorescein fixes to damaged corneal tissue and turns the affected area a bright fluorescent green, indicating the extent of the damage. Topical antibiotic, antiviral or antifungal therapy is usually commenced immediately to avoid rapid development of complications. Differential diagnosis must be sought, by:

- obtaining a thorough patient history
- taking corneal scrapings
- slit lamp examination
- sending contact lens/lenses for culture and sensitivity.

Possible secondary ocular complications of raised IOP or iritis must be treated as necessary. Steroids are generally contraindicated for keratitis. Patients should be managed, wherever possible, by an ophthalmic corneal consultant.

NURSING PRIORITIES AND MANAGEMENT: Keratitis

Patients are generally cared for on an outpatient basis, unless they present in an acute state and require intensive topical treatment day and night. The principles for uveitis (see p. 575) should be followed with these additions:

- The patient should be taught not to touch or rub the eye as this may extend the ulceration.
- Careful hygiene is essential to prevent cross-infection. Tears should be wiped from the cheek only, using a clean disposable tissue on each occasion. Principles of isolation and infection control will be observed in the hospital situation (see Ch. 16).
- With regard to dendritic ulcer, anyone who has an outbreak of herpes simplex, commonly known as 'cold sores', should be advised to guard against touching the sores and then rubbing their eyes. Nursing staff with active sores should not have contact with ophthalmic patients.
- Re-education regarding contact lens wear. Long-term use may be contraindicated. The principles of contact lens care are as follows:
  - Maintain strict hygienic practice
  - Do not exceed the recommended wearing time
  - Do not clean with saliva or tap water
  - Remove lenses if the eyes become inflamed or sore
  - Remove soft lenses whilst administering drops containing preservatives (Batterbury & Bowling 1999).

Conjunctivitis

Conjunctivitis, i.e. inflammation of the conjunctiva, is a common condition, which may be acute, subacute or chronic. It can be unilateral or bilateral in presentation, the latter form often being due to cross-infection. Causative agents are bacteria, viruses, fungi, parasites, toxins, chemicals, foreign bodies and allergies.

PATHOPHYSIOLOGY

The activating agent causes vascular dilatation of both the palpebral conjunctiva (lining the eyelid), and the bulbar conjunctiva (covering the eyeball), cellular infiltration leading to formation of papillae and follicles, and serous exudation. In severe cases, oedema of the conjunctiva (chemosis) may occur.

Clinical features include:

- Brick-red appearance of the conjunctiva
- Gritty feeling as of a foreign body in the eye
- Mucopurulent discharge, common in bacterial conjunctivitis, the eyelids sticking together at night
- Varying degrees of pain.

The patient may be photophobic, but visual acuity is not necessarily affected. Eversion of the lids may reveal follicle formation, i.e. cellular structures within the conjunctiva are inflamed and raised, which is the cause of the gritty sensation.

MEDICAL AND NURSING MANAGEMENT

Accurate diagnosis is made through slit lamp examination, conjunctival swabs or taking corneal scrapings to obtain cells, in order to detect accurately the cause of the infection, so that appropriate treatment can commence. As well as educating the patient in eye hygiene and self-medication, the nurse must monitor for complications such as secondary corneal inflammation (keratoconjunctivitis), which would cause visual reduction. Conjunctivitis is highly infectious and family members, peers and other patients should be advised about the prevention of cross-infection. Scrupulous hand washing and the use of individual towels should be emphasised.

For further information, see Khaw et al (2004).

Herpes zoster ophthalmicus (ophthalmic shingles)

This is an acute unilateral infection of the trigeminal ganglion, which extends from the scalp to the nose and includes the eye. It is caused by the chickenpox virus and is fairly common in people over 50 years of age (see Ch. 16).

PATHOPHYSIOLOGY

Common presenting signs and symptoms, all on the affected side, are as follows:

- Pain and tingling sensation
- Swollen eyelids
- Skin rash of the forehead and around the eye
- Characteristic vesicular eruptions over the course of the nerve
- Potential serious ocular complications, including uveitis, keratitis and conjunctivitis
- Regional adenopathy and general malaise of the patient.

MEDICAL MANAGEMENT

- Prevention of cross-infection
- Immediate administration of systemic antiviral agents, usually commenced by the GP
- Topical antiviral agents, usually commenced by the ophthalmologist
- Analgesics for associated pain
- Ocular lubricants if required to relieve ocular discomfort
- Regular eye-bathing if ocular discharge.

Allergy to topical medication

Allergic reaction to topical eye medication manifests as inflammation of the eyelids extending to the cheeks. The lids become red and oedematous and may be moist in the acute stage, drying to form light crusts later. There is intense itching, which may result in excoriation. Common causative agents are atropine, neomycin and preservatives in eye drops.

Management consists of reviewing medication, suspending all medication for 24 h if possible and substituting an alternative agent. Cortisone lotion and cool bathing may be prescribed for the affected skin area to relieve itching and oedema.

EXTERNAL EYE DISEASES

These are common and easily treated, once accurately diagnosed. Nurse specialists in many ophthalmic units manage patients with such diseases and it is advisable for community and nursing home staff to contact the local ophthalmic unit to confirm best practice and to obtain advice.

Blepharitis

This is a chronic inflammatory condition of the eyelids and eyelashes, resulting in redness, crusting and itchiness. Blepharitis may predispose the patient to stye or chalazion and may recur, requiring long-term management using:

- lid hygiene (see Box 13.3) and application of warm flannel compresses
- topical antibiotics
- ocular lubricants, if associated with dry eye (see 'Age-related conditions', p. 584)
- systemic antibiotics.

If there is acne rosacea, psoriasis or eczema and if treatment is ineffective, referral to a dermatologist should be considered (Khaw et al 2004) (see Ch. 12).

Stye

This is an infection of an eyelash follicle, which should be treated with warm compresses and topical antibiotics.

Chalazion or meibomian cyst

This is a blocked duct from the meibomian 'lipid secreting' glands. Treatment is as for blepharitis in the first instance, progressing to 'incision and curettage' if the condition persists. This procedure is performed under a local anaesthetic by an ophthalmic nurse practitioner in the ophthalmic outpatient department. Biopsy of the cyst contents is necessary should the cyst recur.

Cysts and lesions of the eyelids can have a similar clinical appearance; careful history of the duration and pathology are therefore essential. Referral to an ophthalmic consultant is advised to exclude any possible malignancies.

For further information, see www.revoptom.com/handbook/default.htm.

Box 13.3

Lid hygiene

This is a method of cleaning the eyelids to remove excess oily secretions from the meibomian glands. It is an effective therapeutic treatment in the prevention and management of external eye disease. Requirements are:

- any type of mild baby shampoo. Do not use other types of shampoo as these are too harsh and will irritate the eyelids
- some cotton buds
- a quarter of a teacup of cooled, boiled water.

Method

The procedure is explained to the patient. Add a few drops of baby shampoo to the water and mix well. Wet the end of the cotton bud and gently rub the bud along the root of the eyelashes on the external lid. Ask the patient to look down when bathing the top lid and up when bathing the bottom lid. Use separate cotton buds for each eyelid. The process is continued for 5–10 min and is usually carried out four times daily. It should be continued long term, and at least once or twice daily as part of general hygiene. Frail and handicapped people may require assistance in order to prevent them from sustaining a conjunctival or corneal abrasion in the course of self-care. Lid hygiene with cotton buds is unsuitable for children, as they are more inclined to move during the procedure and acquire an abrasion.

DIPLOPIA (DOUBLE VISION)

Diplopia refers to a person's experience of seeing the same object in two different areas of their visual field. Diplopia can be either monocular — 'with one eye only' — associated with cataract, refractive error, macular disease and retinal detachment, or binocular — 'present with both eyes' — usually associated with nerve palsies, squint, trauma or myasthenia gravis. Different factors are involved in childhood squints and for further information reference should be made to paediatric texts.

NURSING PRIORITIES AND MANAGEMENT: Diplopia

The cause of diplopia should be established prior to any intervention or long-term treatment to alleviate symptoms. Nurses should reassure their patients and attention should be given to maintaining a safe environment in case of dizziness or nausea. Advice must be sought from the local ophthalmic unit. One eye may be occluded to make the patient more comfortable during the investigation period which may last days or weeks and may on occasion involve neurological tests and a brain scan. Binocular diplopia of sudden onset must be referred promptly to rule out any underlying life-threatening cause such as a cerebral space-occupying lesion.

MEDICAL MANAGEMENT

Following diagnosis, treatment includes:

- occlusion of one eye after assessment by an orthoptist and ophthalmologist
- use of prisms on the patient's glasses
- injection of botulinum toxin to overactive muscle — this results in temporary paralysis, for approximately 3 months, and encourages increased function of the underactive muscle. The botulinum blocks the transmission of the nerve impulses at the neuromuscular junction by interfering with release of the neurotransmitter acetylcholine (see Ch. 9)
- surgical intervention to correct squint, either by 'recession' or 'resection'. This is not considered until other treatments have been implemented.

EYE INJURIES

It is vital to record an accurate history (see Table 13.3) to rule out any non-visible injury, such as an intraocular foreign body (IOFB). The visual acuity (VA) must be measured and a systematic eye examination (see Table 13.1) conducted to establish a diagnosis and for medicolegal reasons. The only exception to this practice is in the case of chemical injury, when the main priority is irrigation. A triage system (see Box 13.4) must be utilised in clinical practice which, together with the nurse's professional judgement, aims to facilitate the preservation of vision. Some of the more common types of eye injury are described below.

Hyphaema

This refers to a haemorrhage in the anterior chamber of the eye.

Box 13.4

Ophthalmic triage

Patients attending an ophthalmic emergency department are placed in one of three categories depending on the severity of their clinical condition.

Emergency
True emergencies requiring immediate specialist attention:

- Chemical burns (initiate first aid immediately)
- Penetrating injuries
- Intraocular foreign body
- Acute glaucoma
- Retinal detachment
- Sudden loss of vision in one eye
- Blunt trauma

Urgent
Specialist attention required as soon as possible:

- Hyphaema
- Corneal foreign body, abrasion or ulcer
- Radiation and welding burns
- All acute infections or allergies
- Suspected postoperative complications

Non-urgent
Minor ocular irritations, such as chalazion and long-standing visual disturbances

PATHOPHYSIOLOGY

A direct blow to the eye, e.g. a clenched fist, golf ball or champagne cork, causing rupture of the small iris blood vessels, usually results in a primary hyphaema. It may be microscopic, with diffuse red cells visible only with the aid of a slit lamp, or severe, with a level of blood seen in the anterior chamber (AC) of the eye. Occasionally, the blood can completely fill the AC. The degree of pain and the reduction in vision depend upon the severity of the bleeding. A secondary hyphaema may occur after intraocular surgery.

MEDICAL MANAGEMENT

A patient with a microscopic or moderate hyphaema will not require admission, but will be advised to rest at home for several days. These hyphaemas rarely re-bleed.

A patient with a severe hyphaema may be admitted for observation, as there could be an associated rise in IOP or further bleeding. Quiet activity will be allowed. Investigations will include B-scan, fundal examination, blood tests to estimate clotting time and possible CT scan to determine cause. Topical drops will be prescribed, including antibiotics, cycloplegics and steroids (see Table 13.2).

NURSING PRIORITIES AND MANAGEMENT: Hyphaema

Observation of the level of hyphaema is made according to the ophthalmologist's instruction. Any increase in pain or discomfort may be caused by raised IOP or a re-bleed.

In order to reduce the risk of increased bleeding, or dislodging the hyphaema into the posterior chamber of the eye, the patient is advised to bend at the knees to reach

things from below waist height and not to bend over, lift or strain.

On discharge, the patient will be advised to avoid active or contact sports until the first follow-up appointment and to assess visual function in the injured eye daily to detect possible complications, e.g. retinal detachment (see p. 570 and Nursing Care Plan 13.1). Protective eyewear will be necessary in the future, e.g. whilst playing squash, to prevent recurrence of a similar injury (see Box 13.2).

Penetrating injuries

Whatever the apparent extent of a penetrating injury, these must always be treated as an emergency and thoroughly investigated. Depending on the results of history taking and examination, X-rays and ultrasound scanning may be necessary to confirm the presence, location and type of any foreign body.

MEDICAL MANAGEMENT

Treatment is dependent on the cause of the injury and on the extent of involvement of ocular structures. It may include the administration of mydriatic, steroid and antibiotic eye drops, and possibly of systemic antibiotics to reduce the risk of complications from inflammation and infection. In addition, the measures described below will be taken.

Perforating injuries The patient will be admitted to hospital for surgical repair of the wound and possible excision of iris prolapse. If the lens is damaged it may be removed at the same time. If facial or other injuries are present, these will be reviewed and treated by the appropriate specialists (see Ch. 15).

Small puncture wounds These may seal themselves, but the patient is admitted to ensure that the wound stays closed and that intraocular infection does not develop. If the wound is not completely sealed, a cyanoacrylate glue or 'bioadhesive' may be instilled onto the affected cornea and a 'bandage' contact lens placed over this site to seal the wound and hold the lens in place, until such time as the wound has healed. The glue gradually dissolves to allow for removal of the surface lens.

Intraocular foreign bodies Admission is essential for surgical removal of the foreign body, which could be embedded in the iris, vitreous humor or lens. If the foreign body is metallic, it may be removed with the aid of a magnet. If it is found in the lens, a lens extraction is carried out (see p. 566). Vitrectomy may be necessary if there has been vitreous haemorrhage.

Complications following penetrating injury The most common complications are corneal scarring, raised IOP, haemorrhage, hypopyon, iris prolapse and retinal tears/detachments.

Severe infections can occur following any injury, making intensive treatment with antibiotic eye drops and systemic antibiotics necessary.

It is always important to examine the uninjured eye for signs of 'sympathetic ophthalmitis', a rare complication which presents as a low-grade iritis. The cause of the sympathetic inflammatory process is thought to involve an immune response to damaged uveal tissue. The use of topical steroids has reduced the occurrence of this potentially sight-threatening condition, which was formerly managed by enucleating the injured eye.

A severely damaged eye with no prospect of useful vision may become very painful and unresponsive to analgesics. It may be necessary to enucleate the eye to give relief to the patient.

Following repair of large penetrating injuries, or severe infections, the eye may collapse entirely and become a shrunken mass in the orbit. This wasting of the globe (phthisis bulbi) can be unsightly and the patient may wish the eye to be enucleated.

NURSING PRIORITIES AND MANAGEMENT: Penetrating injuries

Anxiety

The patient and relatives will be highly distressed at the possibility or reality of severe injury and permanent sight loss, therefore the nurse's key responsibility is to comfort and offer support. The patient's main concerns are the degree of visual impairment, the altered body image and changes in working life and everyday lifestyle. Effective communication is vital to prevent any misunderstandings. Any questions and concerns must be answered honestly. A process of grieving is normal when any degree of vision is lost.

Return to the community

If the eye is damaged to the extent that no useful vision is retained, the patient will need continuing support in the community. Patients in this situation are particularly susceptible to depression when they return home and begin to grapple with the full implications of their disability (Karlson 1998). They will need practical and psychological support through the grieving and adaptation period. Assessment of the level of support required should be carried out prior to discharge and with regard to the patient's home and work environment. The community nurse should be advised of immediate practical measures regarding dressings and wound care but also how further support and information can be accessed on behalf of the patient, e.g. from a psychologist or orbital prosthetist. Liaison with support groups and counselling options should be discussed. Where possible patients should be encouraged to meet their own eye care needs.

For further information, see Nursing Times (2003).

Chemical burns

These must be treated as emergencies and irrigation (see Box 13.5) must be started immediately (Khaw et al 2004), prior to prompt referral to an ophthalmic emergency department. Many chemical substances have antidotes, so the chemical label or details on the container should be taken to the emergency department along with the patient.

PATHOPHYSIOLOGY

The burn may be caused by an acid or an alkali, e.g. substances such as antifreeze, car battery acid, household

Box 13.5

Irrigation of an eye

Copious irrigation of the affected eye(s) should be carried out with 1 litre of sodium chloride 0.9% via an i.v. giving set; alternatively, non-sterile water can be used in an emergency. Ensure the patient is comfortable, reclining on their back with the head and neck supported. Clothing should be protected by a waterproof cape and towels. Ask the patient to hold the receiver dish and to turn their head slightly to the affected side. Instil topical anaesthetic drops (e.g. tetracaine 1.0% or proxymetacaine, 1 or 2 drops). Gently pull down the lower eyelid and irrigate with a steady flow of fluid, while asking the patient to move the eye around and to evert the upper lid to ensure thorough irrigation. Continue irrigation for at least 15 min, re-instilling local anaesthetic drops as required. Remove particles or foreign bodies with a moistened cotton bud or forceps. Wait 5 min prior to checking pH levels of the tear film, which should be 7.4 or below. Continue irrigation until this neutral pH is indicated when reading the colour reaction of a strip of universal pH paper when it touches the tear film in the lower fornix of the eye.

Box 13.6

Rodding of fornices

Local anaesthetic eye drops are instilled and a glass rod lubricated with antibiotic ointment is inserted under the upper eyelid. The patient is asked to look down and the rod is passed gently but firmly from side to side several times whilst outward pressure is exerted. This breaks down any adhesions already formed and leaves a film of ointment in the fornix to prevent any recurrence.

This process is repeated under the lower eyelid with the patient looking up.

cleaning agents, cement and superglue. In general, acids cause only superficial burns because coagulation of the tissues prevents further penetration. The structures involved are usually the palpebral and bulbar conjunctivae and the cornea. Alkalis penetrate the eye structures more deeply and, as well as severely damaging the eyelids, conjunctivae, cornea and sclera, readily penetrate the internal eye.

The patient will complain of severe, burning pain due to the exposure of the pain receptors of the trigeminal nerve. Absence of pain or a white eye, 'blanching', does not mean the burn is mild: it may be so severe that it has destroyed the nerve endings. There will be extreme watering of the eyes due to reflex action and the lids will be very swollen and red. Burns to the surrounding skin may also be evident.

MEDICAL MANAGEMENT

On arrival in the emergency department the patient is taken for immediate irrigation of the eye (see Box 13.5). This is one time when visual acuity is not assessed before treatment. Anaesthetic eye drops are instilled to reduce the pain and ensure the patient's cooperation with irrigation. The irrigating fluid will be either sodium chloride 0.9% or a solution of trisodium edetate — a neutralising fluid used specifically for lime burns. Once the nurse is sure that all traces of the chemical have been removed, a full history can be taken and visual acuity assessed.

Following irrigation, ocular examination will be carried out using a slit lamp to assess the extent of the injury. Chemical injuries are usually successfully treated without causing any long-term damage. Occasionally, however, the burn can cause extensive damage to the cornea and conjunctiva.

Treatment for minor burns An antibiotic ointment is prescribed, and possibly cycloplegics to relieve iris spasm, prior to an eye pad being applied for 6 h. If both eyes require padding, the better eye is left exposed until the patient arrives home, when the other eye should be padded. The topical treatment is prescribed for several days but the patient may be asked to return for review the day after commencement of treatment.

Treatment for severe burns Admission to the ward for intensive treatment and observation is usual. Depending on the severity of the pain, i.m. analgesics are given for at least the first 24 h. An antibiotic ointment is applied at least four times daily to lubricate the fornices, and mydriatic eye drops are instilled to relieve accompanying iris spasm and iritis. Usually topical steroids are administered. To prevent the development of conjunctival adhesions (symblepharon), rodding of the fornices may be required (see Box 13.6). Monitoring of IOP is required in the event that uveitis occurs and leads to a secondary glaucoma.

NURSING PRIORITIES AND MANAGEMENT: Chemical burns

Anxiety

Suffering chemical burns causes high levels of anxiety, and the nurse's role is to provide reassurance and emotional support by explaining the procedures, answering questions, ensuring adequate pain relief and contacting the patient's family. Eye pads or dark glasses are used to reduce the photophobia caused by iris spasm and pupil dilatation.

Return to the community

It is essential to maintain prescribed treatment and to attend follow-up outpatient appointments. It is also important for the nurse to educate the patient about the severe risk to sight (and to livelihood) posed by such burns, and to stress the necessity for wearing eye protection in DIY, manual work and when using strong cleaning agents, in order to reduce or prevent further sight-threatening accidents (see Box 13.2). If there is permanent damage to one or both corneas, a keratoplasty may be carried out (see p. 572).

It may be necessary, in cases of significant sight loss, to ensure that the patient and carers are fully supported and are offered appropriate advice by special community services for the visually impaired person (see 'Penetrating eye injury', p. 579).

Radiation injuries

Irradiation from ultraviolet, infrared or laser light can cause eye damage.

PATHOPHYSIOLOGY

Ultraviolet radiation causes corneal epithelial damage (arc eye, welders' flash) and most commonly occurs when approved eye goggles with protective sides are not worn during welding or when the individual is using a sun bed or sunlamp (see Box 13.2). Usually the signs and symptoms do not appear until several hours after exposure, when the patient presents with photophobia, pain and excessive lacrimation. The reason that there is this latent period is not fully understood. Fluorescein drops show dot-like staining of the cornea. Treatment is symptomatic and includes pain relief and the use of eye pads or dark glasses. The corneal healing is variable but there should be no long-term effects.

Infrared radiation penetrates the eye through the cornea and can cause cataract.

Laser radiation can cause irreversible damage to the retina.

NURSING PRIORITIES AND MANAGEMENT: Radiation injuries

Prevention

Health education and accident prevention are major parts of the nurse's role. The need for those at risk to use protective eyewear must be stressed. Nurses working in occupational health, general practice, in the community and in emergency and outpatient departments with laser equipment should implement a programme of health education which focuses on this topic. It is also important to stress that other people working in the immediate environment of the radiation source may sustain injuries. Nurses must be aware of relevant legislation (Al-Husainy et al 2001).

13.12 Can you think of reasons why people might fail to use appropriate eye protection? Is there any legislation governing the provision of protective eyewear? Discuss this issue with your lecturer, mentor and colleagues and reflect on how it applies to your own workplace.

Central retinal artery occlusion (CRAO)

This condition is an ophthalmic emergency. The patient will experience sudden, complete and painless loss of vision in one eye, due to an obstruction of the central retinal artery. It is associated with emboli, thrombosis, diabetes mellitus, hypertension, giant cell arteritis and trauma (Kaiser et al 2004). The retinal artery and some of its branches may be obliterated. The damage to retinal cells is irreparable.

MEDICAL MANAGEMENT

Emergency intervention Treatment must begin within minutes if any degree of visual recovery is to be achieved. Vital time is often lost as the patient may think that the visual loss is transitory and therefore may not seek help immediately. The aim of treatment is to reduce the normal IOP rapidly by massage of the globe, administration of osmotic medication, e.g. i.v. mannitol, to draw fluid from the eye by osmosis and/or paracentesis to release aqueous from the anterior chamber. This should allow the retinal artery to dilate and the clot may be flushed along to a peripheral arterial branch.

Continuing management Once the emergency stage has passed the patient is given a full examination. Any underlying medical condition, e.g. hypertension, is diagnosed and treated appropriately, often by the GP. Residual visual impairment is assessed and the patient given all necessary support in terms of health education and maintaining independent living when back in the community.

Minor eye injuries

Corneal foreign body

There is usually a history of something entering the eye. The eye will be extremely painful, especially on blinking. On examination, a foreign body will be visible on the anterior surface of the cornea. Anaesthetic eye drops are instilled and the foreign body is removed with a moistened cotton bud or a 10G needle. This can be carried out by the doctor or an experienced ophthalmic nurse (see Box 13.7 for additional information).

Subtarsal foreign body

The nurse should suspect the presence of a foreign body when, despite the patient's complaint of something entering the eye, nothing can be seen on normal inspection. There will be discomfort, especially on blinking. The upper lid should be everted and the foreign body, if present, removed with a moistened cotton bud (see Box 13.8). The nurse should check for a possible corneal abrasion.

Box 13.7

Rust ring

If a metallic foreign body is left in contact with the cornea for more than 4 h, a rust ring may develop around its perimeter.

It can be easily removed after 1 day of the application of antibiotic ointment. This is done with a 10G needle or a small battery-powered instrument called a burr.

Box 13.8

Eversion of an eyelid

This procedure is carried out if the presence of a foreign body is suspected under the upper eyelid. With the patient's eyes open and looking down, the upper lid lashes are grasped. At the same time, the upper edge of the tarsal plate (at the crease of the eyelid) is depressed, using a glass rod or cotton bud. This allows the lid to be turned over to expose the subtarsal conjunctiva and facilitates inspection, irrigation and foreign body removal.

Corneal abrasion

Usually caused by a fingernail, a twig or other sharp object, this is an extremely painful condition, with profuse lacrimation. Fluorescein eye drops should be instilled in order to determine the extent of the abrasion.

An eye pad is not always required after treatment for abrasion or removal of a foreign body. Need depends upon the severity and location, i.e. if the abrasion is central and large. If the patient feels more comfortable with the eye closed, a pad may be worn for about 6 h. Antibiotic ointment may be prescribed to prevent infection, as well as mydriatics if pain is severe.

A follow-up appointment may be given depending on the severity of the abrasion or the depth at which the foreign body was embedded.

SURGICAL REMOVAL OF AN EYE

There are three methods of removing an eye:

- *Enucleation* — surgical removal of the globe. The extraocular muscles are cut at their insertion and the optic nerve severed.
- *Evisceration* — removal of the contents of the globe, leaving the scleral shell.
- *Exenteration* — a more extensive operation involving removal of the eye and surrounding tissues.

Special considerations

The choice of operation is dependent upon the diagnosis which has necessitated the removal of an eye. A badly injured eye may be enucleated (see Nursing Care Plan 13.4) whilst an infected eye would require to be eviscerated. Exenteration would be required when a malignant tumour extended beyond the globe.

Maintenance of a good cosmetic appearance post-surgery has led to the development of a range of socket and orbital implants, which may reduce the psychological trauma experienced.

Management is as for extensive penetrating injuries. The nurse may find that if a patient has suffered severe pain and blindness in an eye, the relief from pain after it has been removed is often so great that this helps in coping with the loss. Contact with others who have had an eye removed may help to reassure the patient that it is possible to adapt and to live a full life following this traumatic experience. Many areas throughout the country have support groups which allow the patient the opportunity to share and discuss feelings and coping mechanisms with others who have gone through the same experience.

Artificial eye fitting

The National Artificial Eye Service (NAES) (1998) in Blackpool provides training to enable personnel to make and fit artificial eyes. Patient education, support and follow-up services are also provided by technicians in local ocular prosthetic departments.

An artificial eye is individually designed to fit the socket and implant exactly and is painted by an ocular artist to match the patient's other eye. The prosthesis is shell-like in shape and form and not, as anticipated, ball-shaped. If an orbital implant has been inserted, the artificial eye will move in unison with the natural eye because the extraocular muscles have been preserved and attached to the implant.

Unfortunately, lack of information about artificial eyes can cause a great deal of anxiety and often a degree of revulsion. This is usually dispelled by explaining that the appearance of the socket is similar to the inside of the mouth. Anxiety is further reduced by contact with people who have adapted successfully to living with an artificial eye and by an opportunity to see and handle an artificial eye before surgery and thereby gain reassurance that they look quite natural (see Nursing Care Plan 13.4).

Principles of artificial eye care

Nurses should be prepared to assist or advise on the care of an artificial eye. Principles of daily management are as follows.

Removal of an artificial eye

A special extractor is provided by the ocular prosthetic department. The eyelids are opened with the thumb and forefinger, and the lower edge of the eye is gently levered out with the aid of the extractor. If an extractor is not available, then a finger will suffice (see Fig. 13.8A).

Insertion of an artificial eye

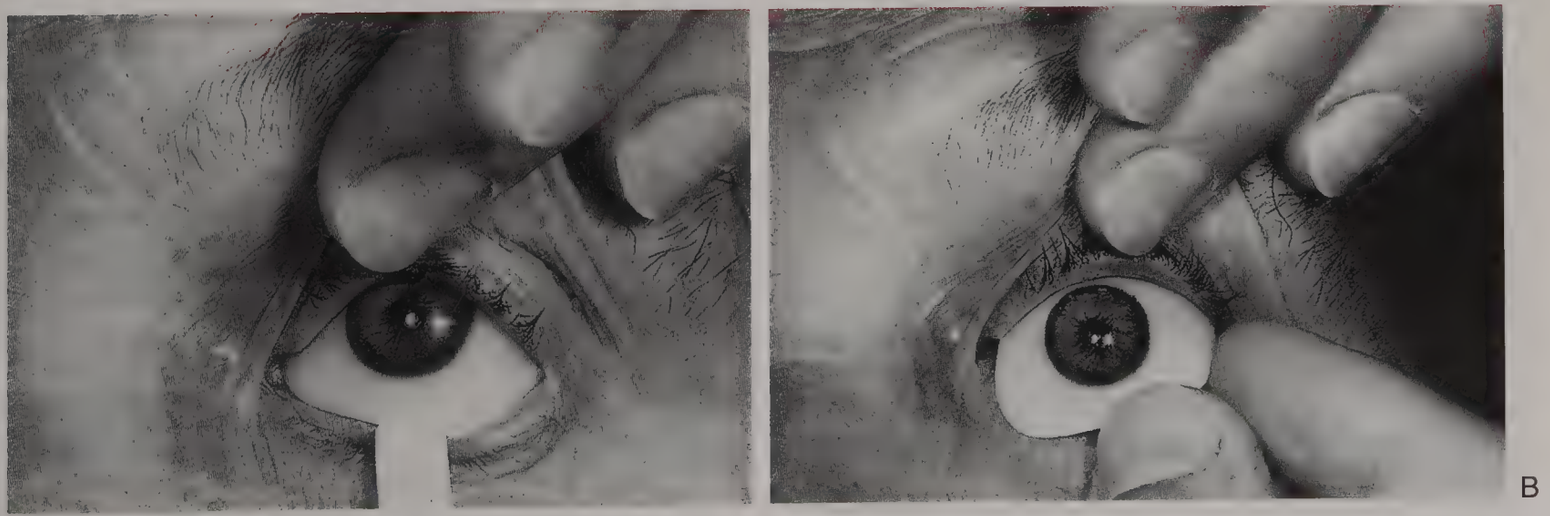
The eyelids are opened with the thumb and forefinger. The eye is inserted under the upper lid with the curve of the eye towards the nose. The lower lid is depressed slightly. The eye can then be slipped into position (see Fig. 13.8B).

Care of the artificial eye

An artificial eye should be cleaned at least once a day with ordinary soap in cold or lukewarm water. It should be thoroughly rinsed afterwards under running water. Chemical cleansers or disinfectants must not be used.

The patient is encouraged to wear the eye both day and night. If they prefer not to, the eye should be placed in cold water or a saline solution in a clean, labelled receptacle.

When not in regular use, the eye should be stored in cotton wool or tissue to prevent scratching. Through normal wear the eye may lose its high polish. In this case it can be sent to the nearest ocular prosthetic department for repolishing, free of charge. Replacements can be obtained cost-free (NHS patients) from the same department. The community nurse may need to prompt older patients in particular to take advantage of this service, and they may need to approach their GP for initial referral to a consultant.



Care of the socket

The socket should remain healthy if the artificial eye is kept clean in the recommended way. Occasionally, infection or irritation may result from scratches on the eye and lead to ulceration.

The socket can be irrigated with normal saline and treated with an antibiotic ointment for a short period. The artificial eye should not be inserted until the infection or irritation has cleared up.

Nursing Care Plan 13.4 A patient undergoing enucleation: postoperative

Nursing considerations	Action	Rationale	Expected outcome
Anxiety/distress			
• **Due to having eye removed**	• Reassure and spend time with the patient. Encourage the patient to express feelings and talk about fears. Reassure the patient that it is normal to grieve over the loss of an eye	Giving information reduces anxiety and aids recovery	The patient will come to terms with the necessity of having the eye removed
• **Due to altered body image**	• Discuss what the wound and socket will look like after surgery, likening it to the inside of the mouth. Discuss aftercare of socket and show an artificial eye, allowing the patient and family to handle it, if they wish		
	• Arrange for someone who has had similar surgery to come and talk with the patient. Suggest dark glasses can be worn until the patient is fitted with an artificial eye	Reduces fear about the after-effects of the operation	The patient will be adjusted to altered body image and will accept the situation of wearing an artificial eye
• **Due to fear of having wrong eye removed**	• Eye to be removed is identified and checked with patient, doctor and case notes (some units mark the forehead with an arrow to identify correct eye)		
	• Reassure patient that many checks are made prior to the operation to ensure correct eye is removed	Relieves anxiety and reassures the patient	Correct eye will be removed. Patient will be reassured of this

A B

Fig. 13.8 A: Removing an artificial eye. B: Inserting an artificial eye. (Reproduced with permission from The National Artificial Eye Service 1998.)

It is not advisable to leave the eye out for long periods as shrinkage of the socket can occur, causing difficulty and discomfort on re-insertion of the eye.

AGE-RELATED CONDITIONS

Age-related maculopathy (AMD)

Macular degeneration is the major cause of blindness in older people in developed countries. It accounts for 50% of individuals on the blind (severely sight impaired) or partially sighted (sight impaired) register and the incidence is increasing. Central 'fine detail and focus' vision is affected, with peripheral vision maintained.

PATHOPHYSIOLOGY

Retinal pigment epithelial cells (RPEs) wear out with age and are never replaced. As they degenerate they deposit material on the underlying membrane, which accumulates to form yellowish white spots on the retina. Initially this process does not affect vision, but eventually the cell loss will result in atrophy of the RPE layer, which may then disperse pigment into the macula. It affects form and colour vision primarily and the patient notices difficulty with activities such as reading and sewing, and problems in identifying faces and coins.

In some cases, a new blood vessel membrane may develop and cause lifting of the central retina. This results in distorted and blurred central vision.

AMD can occur in the presence of other eye conditions such as cataract and glaucoma, complicating the diagnosis and treatment of the other disorder.

MEDICAL MANAGEMENT

There is limited treatment available, with research ongoing. Any underlying disease should be accurately diagnosed through assessment of visual acuity (reading and distance), Amsler grid, colour vision, clinical examination and possible fundal fluorescein angiogram (FFA) (see 'Diabetic retinopathy', p. 585) and treated. New developments include the following:

- *Argon laser treatment* — this could be beneficial if there are early symptoms of new blood vessel membrane formation. In some cases a degree of vision can be regained following this, although if there is foveal damage there will be a persistent central scotoma (blind spot).
- *Photodynamic therapy (PDT)* — this treatment is the process of i.v. injection of verteporfin, 'a light sensitive drug', circulated into the retinal vessels to allow photodynamic treatment (laser) of the degenerated tissue (Murphy & Nesbitt 2001).
- *Vitamin and mineral supplements in high dosage* (www.icapsinfo.co.uk) — prior to the patient starting treatment, discussion with the GP is essential, as the supplements, including lutein, selenium, copper and zinc, have been linked with certain systemic side-effects, e.g. high dose beta carotene has been linked to an increased risk of lung cancer. High dose vitamins and minerals are believed to reduce the progression in advanced AMD, but not in early AMD (Bartlett & Eperjesi 2003, Kaiser et al 2004). Many ophthalmologists believe a well-balanced diet with a daily intake of fruit and vegetables (see Ch. 21) is as effective and that these supplements are not required.
- *Low visual aids (LVA) and referral to welfare advisor* — to discuss registration (see p. 560), available support, local and national organisations such as the Macular Disease Society (see 'Useful websites').

Nursing intervention is that of a supportive and educational role, especially at the point of diagnosis and possible registration, as grief, fear and depression are common (McBride 2001). Liaison with the multidisciplinary team and social services is needed to ensure the VIP is fully supported and empowered to live as full and independent a life as possible.

13.13 You are a community nurse who visits Mr S (see Case History 13.1) daily to give him his insulin injection. Mrs S breaks down whilst you are there. What advice would you offer her and where would you advise her to go for assistance?

For further details, see www.maculardisease.org and Kanski (2003).

Entropion

Defined as a malposition of the eyelid with the lid margin turned towards the globe, this condition most commonly affects the lower lid and is caused by reduced elasticity of the connective tissue, which may be a result of the ageing process, of trauma or of a badly applied eye pad. The inturned eyelashes irritate the cornea and can cause discomfort and ulceration.

Nursing and medical management Discomfort can be relieved in the following ways:

- Short-term intervention by the application of tape to the affected lid margin, usually the lower one, to retract it in such a way that downward traction of the tape, when applied to the cheek, restores the normal position
- Botulinum toxin injection, as a short-term measure and alternative to taping
- Ocular lubricants, either ointment or drops, to lubricate the eye

CASE HISTORY 13.1

Mrs S

Mr and Mrs S are both 70 years old and live in a bungalow on the outskirts of a large town. Over the past 2 months, Mrs S has noticed a marked reduction in her near vision. Increasingly, she has noticed that she requires help to identify shopping items and to clean the house. Her enjoyment of completing the crosswords and reading has been lost. After a visit to her optician and GP she is referred to the eye hospital. At her appointment, the consultant tells her she has age-related macular degeneration and that, although she will not go blind, her sight will not improve. He recommends that she should consider becoming registered as partially sighted. Mrs S is distressed by this and goes home to think about it.

- Topical antibiotics if the cornea is damaged by infection or abrasion
- Repositioning of the lid by a simple surgical procedure or eversion sutures.

For further details, see www.revoptom.com/default.htm and select 'entropion' and www.eyelidsurgery.co.uk/treatments/blb-coralimplant.htm.

Ectropion

Defined as a malposition of the eyelid when the lid margin is turned away from the globe, mainly affecting the lower lid, this condition is associated with atonic tissue around the eyes. Due to malposition of the lid and punctum, tears overflow and run down the cheeks. The individual constantly wipes the eye, drawing the lid even further down and exacerbating the condition.

Nursing and medical management The use of ocular lubricants may be required if the eye is infected or sore. Topical cream to the skin is soothing if excessive tearing (epiphora) is causing excoriation. Cautery to the inner eyelid contracts the tarsal conjunctiva and inverts the lid. Minor oculoplastic surgery may be required to reposition the eyelid.

Dry eye syndrome (keratitis sicca)

This is a common, chronic and bilateral condition, requiring prompt assessment, diagnosis and management.

PATHOPHYSIOLOGY

Either a reduced quantity of tear production, poor quality of tear film, or both, result in symptoms of dry, burning and gritty eyes, occasionally with excessive epiphora which is exacerbated by humidity, wind and cigarette smoke. The diagnosis can be complex as the condition is associated with systemic disease such as rheumatoid arthritis and Sjögren's syndrome.

Nursing and medical management and nursing priorities
These are dependent upon the severity and actual cause of the condition, but consist of one or more of the following:

- Instillation of ocular lubricants four times a day or when required and at night — the ophthalmologist may recommend a preservative-free preparation
- Punctal occlusion — inserting collagen or silicone plugs into the upper and lower punctum, preventing drainage of tears
- Punctal cautery to seal puncta
- Corrective surgery, e.g. tarsorrhaphy, which involves partial closure of the lids, thereby decreasing the surface area of the cornea from which the tear film evaporates (Kanski 2003).

Entropion, ectropion and dry eyes are common conditions in older people, who may not always realise that a simple treatment such as the instillation of ocular lubricants or minor lid surgery is often effective in treating the great discomfort associated with the conditions. It is often the community nurse who is best placed to detect, assess and refer for further advice, as well as to provide encouragement to those patients to attend the ophthalmic unit.

SYSTEMIC DISEASE AND DISORDERS OF THE EYE

The eye is a sensitive indicator of systemic disease. Visual disturbance or abnormal appearance of the retina or optic disc may be the first manifestation of health breakdown. In this section, ophthalmic conditions associated with some of the more common systemic diseases will be described. Other conditions are described in Table 13.4.

Nursing priorities and management should be based on the general principles of ophthalmic management as well as the specific principles that pertain to the disease process in question. The reader should refer to relevant chapters in the present text as well as to more specialised ophthalmic texts.

For further information, see Blaustein (1994).

Diabetes mellitus

Diabetes mellitus is a common disorder in developed countries and its incidence is increasing markedly in both developed and developing countries worldwide as diets include more processed foods and refined sugars (see Ch. 5). Poorly controlled diabetes can lead to retinopathy, early cataract development, vascularisation of the iris (rubeosis) and a high incidence of minor eye conditions such as chalazion.

Diabetic retinopathy

PATHOPHYSIOLOGY

Elevated blood sugar levels, associated with prolonged poor diabetic control, damage the blood vessel basement membrane. In the retina, this leads to leakage and the formation of fatty and haemorrhagic lesions. These changes are given the term 'retinopathy'. The patient will usually complain of gradual and painless loss of vision — unless there is bleeding into the vitreous humor, in which case loss of vision may be sudden and very frightening (Hall & Waterman 1997). The diagnosis and progression of the disease can be confirmed by fluorescein angiography. Diabetic retinopathy is the leading cause of preventable blindness in the working population in developed countries (Vafidis 2000).

There are two forms of the condition: background and proliferative.

Background retinopathy The small retinal vessels become fragile, aneurysms form and leakage occurs, causing localised oedema and haemorrhage. Background retinopathy can cause loss of central vision if macular oedema occurs and the hard exudates encroach on the fovea. Peripheral vision will be retained.

Proliferative retinopathy In this condition there is further deterioration as new blood vessels and fibrous bands form in response to breakdown and occlusion of the normal circulation. The main complications that can arise from this are bleeding into the vitreous humor and tractional retinal detachment. Eventually, proliferative vascularisation

Table 13.4 Further eye problems secondary to systemic diseases

Disorder	Main ophthalmic clinical features	Cause	Treatment
Thyroid function imbalance (Graves' disease)	Upper lid retraction	Sympathetic nerve innervation	Lubricating drops during day and antibiotic ointment nightly
	Exposure keratitis	Exposure of eyeball	As above
	Swelling of lids and conjunctiva	Infiltration of lymphocytes in orbital tissue and associated oedema	Partial tarsorrhaphy
	Exophthalmos		Systemic steroids
	Compression of optic nerve		Surgical decompression
	Diplopia	Infiltration of lymphocytes in muscle tissue leading to fibrosis	Prism spectacles Botulinum A neurotoxin injection into the appropriate lid muscle Strabismus surgery
Migraine	Headache with visual disturbances Characteristic aura: multicoloured, jagged shape, firework-like	Idiopathic; possibly chemical changes in the brain caused by various triggers, e.g. stress, or dietary, e.g. eating oranges or chocolate	Feverfew herbal remedy Ergotamine Rest
Multiple sclerosis	Uniocular	Localised demyelinating lesion to the cranial nerves III IV	Symptoms may recover spontaneously but will always recur
	Small unequal pupils: do not react to light but do with accommodation, unable to dilate with atropine	VI	
	Optic neuritis Rapid reduction of central vision Sudden onset of pain especially when looking upwards		Systemic painkillers
	Central scotoma Diplopia		Prism spectacles Botulinum A neurotoxin injection Strabismus surgery
Intracranial aneurysm	Uniocular/binocular Diplopia Blurred vision Ptosis Visual field defects	Pressure on visual pathway Pressure on cranial nerves III IV VI	Detection and clipping of aneurysm Botulinum A neurotoxin injection Strabismus surgery
Nephritis	Blurred vision Papilloedema Retinal haemorrhage Retinal detachment	Hypertension	Reduce hypertension Laser treatment Vitrectomy Surgical repair of detachment

can affect the angle of the eye by blocking the trabecular meshwork and causing glaucoma.

MEDICAL MANAGEMENT

Early diagnosis is critical, as is good control of blood sugar levels and regular monitoring of ophthalmic status. Complications are treated as they arise. Laser treatment may be used to delay the progress of proliferative retinopathy. This involves treating the peripheral retina with multiple laser burns, panretinal ablation, so that the oxygen requirement of retinal tissue is reduced. This in turn reduces the stimulus for new vessel formation. Focal burns may also be used to seal off leaking blood vessels. Small 'grid pattern' burns may be used to aid the absorption of the fluid from vessel leakage.

Severe vitreous haemorrhage or tractional retinal detachment may be treated by removing the vitreous humor (vitrectomy) and replacing it with clear infusional fluid, gas or silicone oil.

NURSING PRIORITIES AND MANAGEMENT: Diabetic retinopathy

Patient education

Ongoing education and encouragement to adhere to diabetic regimens are important in the attempt to delay the onset or progression of complications and to encourage early awareness of visual changes. The community nurse or diabetic specialist nurse has a key role to play by reinforcing the connection between maintaining good blood sugar levels

and reducing the risk of ophthalmic complications. Explanation and support during laser treatment will be particularly important to encourage the patient's cooperation so as to prevent accidental burns (see p. 571).

Vitrectomy management

Perioperative care for patients undergoing vitrectomy procedures is as for other retinal detachment surgery (see p. 570), with a particular emphasis on ensuring that the prescribed postoperative position is maintained. Outpatient care and education are aimed at encouraging active patient participation and attendance for review so that this problematic sight-threatening scenario is carefully monitored.

Cerebrovascular accident (CVA)

A CVA involves an interruption of the blood supply to a part of the brain and may be caused by blockage or rupture of a blood vessel. CVA results in ischaemia of the affected part and development of neurological defects. If the visual pathways are involved, vision will be affected and the damage may be permanent. When a patient suffers a transient ischaemic attack (TIA), vision may be temporarily affected, but will usually be restored when the attack subsides (see Ch. 9).

NURSING PRIORITIES AND MANAGEMENT: Cerebrovascular accident (CVA)

The extent of the visual deficit must be assessed to facilitate rehabilitation and maintain patient safety. This may be difficult if the patient's ability to communicate has been affected by the CVA. The accuracy of the assessment is dependent upon the nurse's skilled observation and on the patient's health status at the time of assessment.

13.14 You have a patient who has recently suffered a right-sided CVA. He is aphasic (unable to speak) and has left hemiplegia (paralysis of the left side). Discuss how you might go about detecting visual field loss just by observing his activity. Having done this, describe how your findings would affect your care plan.

Hypertension

Fundal examination of the eye is part of the screening process for hypertension (see Ch. 2).

Hypertensive retinopathy in a young adult appears as widespread narrowing of the retinal arteries caused by spasm of the arterial walls. In an older person with arteriosclerosis, the arteries are narrow and rigid. As hypertension increases in severity, haemorrhages and exudates become visible. The haemorrhages are flame-like in appearance and are found close to the disc. The exudates are due to lipids and occur around the macula. Oedema of the retina occurs in malignant hypertension and may also be present in some cases of mild hypertension. The optic disc is swollen and hyperaemic. The patient will complain of varying degrees of visual disturbance. The condition is painless. The outward appearance of the eye remains normal.

The eye condition improves as hypertension is brought under control by appropriate treatment (see Ch. 2).

Acquired immune deficiency syndrome (AIDS)

Ophthalmic complications affecting both the anterior segment of the eye and the retina develop in about 30% of patients with AIDS. They are caused by HIV infection, opportunistic infections and AIDS-related neoplasms, and may affect any part of the eye (Riordan-Eva & Whitcher 2004). (For further information on HIV and AIDS, see Ch. 37.)

HIV retinopathy

Clinical signs are yellowish-grey, cotton wool-like spots, dot-like haemorrhages and microaneurysms over the retina. Vision remains normal unless the macula is involved. Some patients respond to antiviral agents.

HIV encephalopathy nystagmus

In central nervous system involvement, nystagmus, gaze palsies and visual field defects may occur. No treatment is available at present.

Opportunistic infections

HIV/AIDS patients are prone to all types of eye infection. The most common infections include severe herpes zoster ophthalmicus, herpes simplex, *Candida* retinitis, *Toxoplasma* choroidoretinitis and cytomegalovirus (CMV) retinitis. Some of these infections may respond to prolonged administration of systemic antiviral agents.

CMV retinitis, the most common retinal infection in AIDS, is seen in 15–46% of patients, in particular when the CD4 count is <50 cells/mm^3 (see Ch. 37) (Kaiser et al 2004). Fear of blindness is often more distressing for the patient than fear of dying. CMV retinitis, with intraretinal haemorrhages and retinal necrosis, leads to retinal detachments and progressive loss of vision, but the use of highly active antiretroviral therapy (HAART) has dramatically reduced the incidence of this infection in developed countries (Khaw et al 2004). Palliative treatment by antiviral agents, e.g. ganciclovir, may be offered in an attempt to prevent blindness in the last few months of life. This can be given intravenously or by intravitreal implant.

AIDS-related neoplasms

Kaposi's sarcoma may involve any of the ocular structures. Treatment may include cryotherapy, radiotherapy or the administration of cytotoxic drugs.

NURSING PRIORITIES AND MANAGEMENT: Aids-related eye diseases

The general principles of nursing a patient with AIDS (see Ch. 37), together with the principles of nursing a patient with eye infections, apply in all of the above conditions. Full care and support facilities should be made available to both the patient and the family/partner.

CONCLUSION

This chapter has demonstrated the specialised care required for ophthalmic patients and visually impaired people. It is a dynamic field of health care, therefore nursing roles and responsibilities are evolving in response to the influence of technological, statutory and organisational changes (Lee & Waterman 2003). Nursing roles within this specialty include nurse practitioners, nurse consultants and clinical nurse specialists (Conway 1996). These experienced nurses have been educated and empowered to develop and enhance clinical practice and to provide expert care, which includes, for example, performing incision and curettage, neodymium:yttrium-aluminium-garnet (Nd:YAG) laser treatment, emergency eye care, glaucoma monitoring and cataract pre-assessment care. These advances in nursing roles can in part be attributed to the effect of the European working time directives (McSherry & Pearce 2002) and reduction in junior doctors' hours (Harris & Redshaw 1998). However, eye disorders may be encountered in a wide range of contexts. It is therefore vital that general and community nurses should have a working knowledge of basic ophthalmic nursing care so that they are competent to prepare the individual and the family and/or carers for the necessary procedures, and to monitor progress and aftercare when the patient has returned home, thus working in partnership with the ophthalmic unit team. They must also be able to recognise when it is necessary to seek further advice and prompt referral, if appropriate, either to an ophthalmologist or to an experienced ophthalmic nurse. Staff education and effective dialogue should be established through ophthalmic in-service study days and visual impairment awareness programmes.

The impact of visual impairment on everyday life must never be underestimated. This chapter has stressed the importance of recognising the significance of adverse signs and symptoms and the fact that delay can result in irreparable damage and permanent loss of sight. It has emphasised the nurse's responsibility in helping to preserve sight and in supporting the patient and the family and/or carers as they meet the practical and emotional challenges of visual impairment. Ophthalmic nursing care should be 'seamless' and address not only the clinical aspects but also the psychosocial aspects of patient need, especially for those for whom sight loss cannot be remedied by medicine or surgery.

INTRODUCTION

Some problems of the ear, nose and throat (ENT) are very common. Most people at some time in their lives suffer from nosebleeds, sore throats or earache. Many of these problems will be dealt with successfully at home, often with the advice of a pharmacist or general practitioner (GP). Some ENT problems, however, can be life threatening, requiring an immediate visit to an emergency department (ED), surgery and, in some cases, a period of nursing care at home following discharge.

To nurse ENT patients effectively in a home or hospital setting, a basic knowledge of the anatomy and physiology of the relevant structures, along with a thorough understanding of the clinical features of common disorders, is essential. The health visitor, district nurse, practice nurse, school nurse or occupational health nurse is often in a position to detect problems before the medical practitioner or even the patient is aware of them.

This chapter will describe, in turn, the basic structure and functioning of the ear, nose and throat, describing the most commonly encountered disorders of each, and outlining appropriate medical and nursing interventions. As in every area of nursing care, one of the most important contributions that nurses can make is in the area of communication and education as they provide support and reassurance to the patient and family, and convey information about the causes of the patient's condition, its treatment and measures to prevent its recurrence.

THE EAR

ANATOMY AND PHYSIOLOGY OF THE EAR

The ear can be divided into three sections: the external ear, the middle ear and the inner ear. The external and middle ears are primarily involved with the transmission of sound. The inner ear contains the organ of hearing as well as structures concerned with body balance (see Fig. 14.1).

The external ear comprises the cartilaginous pinna and the external auditory canal (or external meatus), the inner two-thirds of which is composed of bone rather than cartilage. The purpose of the pinna and canal is to capture sound waves and funnel them to the tympanic membrane,

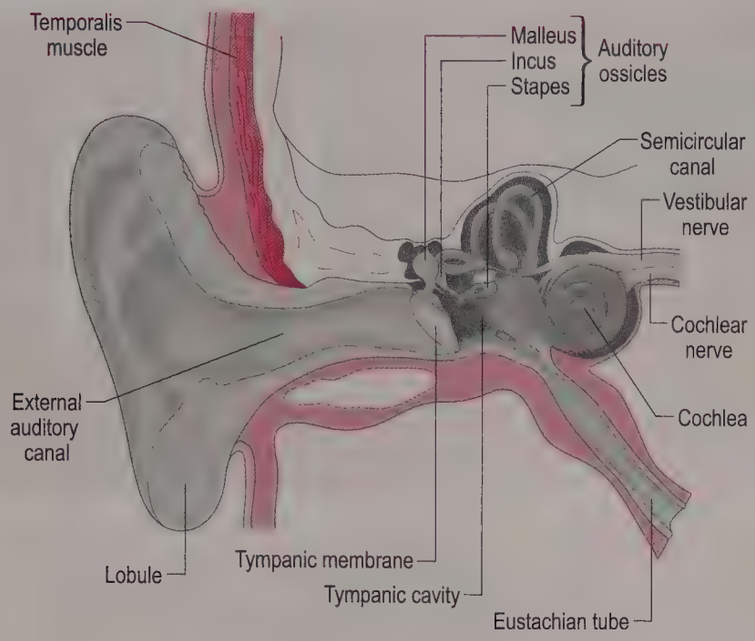

Fig. 14.1 Sagittal section of the ear.

which is located at the end of the external canal and divides the external from the middle ear. The healthy membrane has a pearly sheen and reflects light.

The middle ear is ventilated by the eustachian tube, which communicates with the nasopharynx. Three small bones, called the auditory ossicles or ossicular chain, pass on sound vibrations received by the tympanic membrane to the inner ear. The first of these, the malleus, i.e. 'hammer', is attached to the tympanic membrane and joins with the incus, i.e. 'anvil' or middle ossicle. The incus in turn is attached to the stapes, i.e. 'stirrup', the 'footplate' of which lies against the membranous oval window or fenestra of the inner ear.

The inner ear houses the cochlea, which is shaped like a snail shell and is the organ of hearing. The cochlea contains the organ of Corti, which consists of cells with hair-like projections on a membranous layer and connects with the terminal ends of the auditory nerve. The canals of the cochlea and the organ of Corti are bathed in endolymph. Perilymph is the fluid contained within the bony (osseous) cavities of the inner ear, whereas endolymph is the fluid within membranous cavities. As sound waves are transmitted by the ossicles they travel along this fluid and disturb the hair cells. This disturbance changes to impulses, which travel along the auditory nerve to the brain stem and cortex, where they are interpreted as meaningful sound.

The posterior part of the inner ear is formed by three semicircular canals and by the vestibular apparatus. These assist in the perception of body position against gravity and in the maintenance of balance. The vestibular apparatus consists of the utricle and saccule and is sensitive to linear acceleration. The semicircular canals are sensitive to rotatory acceleration. Balance is maintained by the adjustment of muscles, joints, tendons and ligaments in response to information gathered by the vestibular apparatus and the canals as well as that received by the eyes.

For further information, see Becker et al (1993).

DISORDERS OF THE EXTERNAL EAR

Otitis externa

PATHOPHYSIOLOGY

The most common causes of otitis externa, or inflammation of the external ear, are infection and allergy. Infection may be caused by scratching the ear with contaminated fingernails or other sharp objects. Instruments such as auriscopes or hearing aid earpieces placed in the meatus may cause minor injuries, giving rise to infection if they have been inadequately disinfected (see Ch. 16). Itching is an early symptom of allergy and may be caused by cosmetics or antibiotic preparations. In otitis externa, multiple bacteriological flora are usually present. The condition most commonly occurs in hot, humid climates, where it tends to be recurrent and may be severe.

Common presenting symptoms The patient usually presents with a history of pain and itching localised to the ear and a burning sensation followed by discharge, which initially may be watery and then becomes thicker. If there is gross oedema of the meatus and a large amount of debris is present, the patient may suffer from conductive deafness (see p. 593).

MEDICAL MANAGEMENT

If a discharge is present in otitis externa, a swab is obtained for culture and sensitivity. Cleansing of the external meatus is performed so that a full inspection can be carried out and to ensure good skin contact for any topical treatments.

NURSING PRIORITIES AND MANAGEMENT: Otitis externa

The first priority of the nursing staff is to clean the external meatus so that an examination can be carried out and any prescribed treatment administered effectively. This procedure is called aural toilet and should only be carried out by an appropriately qualified ENT nurse. Cotton wool dressed carriers can be used. Care must be taken not to damage the skin. Gentle pulling of the pinna will straighten the canal and allow easier access. The best light source is a Bulls' eye lamp and head mirror or an operating microscope. Large amounts of discharge and debris are best removed by an appropriately qualified nurse or doctor using microsuction via a fine-bore tube under an operating microscope in the outpatient department.

It may be necessary to administer an oral analgesic before the external auditory canal can be properly examined, as often any movement of the pinna is painful.

Since the vast majority of patients are seen in the community or outpatient department, the nurse's involvement will range from the total management of ear conditions in a nurse-led clinic to demonstrating how to administer topical preparations effectively. The nurse should also teach the patient safe techniques for cleansing the external ear and stress the importance of frequent, thorough cleansing of any appliances, including hearing aids, that are put in the ear.

For further information on nurse-led aural care clinics, see Zeitoun et al (1997).

Cerumen excess

PATHOPHYSIOLOGY

Cerumen is the normal waxy secretion of special glands in the external auditory canal. Along with shed skin scales and hair, the cerumen normally migrates to the external meatus but can be hindered by coarse hair, particularly in the older male, or if the individual impacts the material by attempting to clean the ears with cotton wool buds or other instruments. Nurses should provide patients with health education information regarding the normal cleansing mechanism and avoiding the use of cotton buds and other foreign bodies (Reynolds 2004).

Common presenting symptoms The patient usually presents with dulled hearing. Tinnitus may develop, causing the patient distress (see p. 600), and disturbance of balance may result from pressure of the hard material on the tympanic membrane.

MEDICAL MANAGEMENT

Sometimes small amounts of soft wax can be removed by instruments or suction under a microscope. If there is an excessive amount, the doctor, district nurse, practice nurse or outpatient nurse will need to remove the material by irrigating the external canal. Often, however, the wax is too hard and compacted for this to be carried out immediately and a course of drops, containing sodium bicarbonate in glycerol or warmed olive oil, has first to be prescribed for several days to soften the wax. At this stage, written information on the procedure can be taken home by the patient to aid understanding.

NURSING PRIORITIES AND MANAGEMENT: Cerumen excess

Individuals with cerumen excess are usually seen in the doctor's surgery or, more rarely, in the outpatient department, for removal of the impacted wax. Ear syringing with a metal syringe is now obsolete and impacted wax is removed by ear irrigation or microsuction (Price 1997).

The nurse will have to teach the patient how to insert the eardrops at home over the required period before the irrigation is carried out. The doctor or nurse who performs the irrigation should first take a full history to eliminate the presence of a weakened tympanic membrane and should examine the ear for any infection, inflammation or perforation in order to determine that the tympanic membrane is intact, thus eliminating the danger of the solution being introduced into the middle ear and causing infection and damage. During the procedure the patient sits upright with clothing protected by a waterproof covering. It is helpful if the patient can cooperate by holding a container under the ear to receive the returning fluid. Various types of ear irrigator are available. Unless a special solution has been prescribed, tap water or an isotonic solution such as normal saline may be used to irrigate the canal.

It is important that the solution is at 37°C, i.e. body temperature, as variations in temperature may cause the patient to experience vertigo (see p. 601).

Before starting, ask the patient to inform you if any discomfort is experienced. The pinna is pulled gently upwards and backwards to straighten the canal while the solution is introduced from the irrigator in an upwards direction so that the wax will be washed out with the return flow. It is important that the flow of water is not aimed directly at the tympanic membrane as this could cause damage. When the canal is clean or when 2 min have passed (Harkin 2002), the procedure is discontinued and the canal gently dried and re-examined. To avoid vertigo the patient should be encouraged to remain seated for a few minutes to recover.

Patients should also be advised that, following effective wax removal, they may be hypersensitive to even quite normal sounds for a short time.

For further information on ear irrigation, see Price (1997) and Harkin (2002).

Foreign bodies in the ear

Small objects may become lodged in the ear by some mishap or, as frequently occurs among children, by accident during play (Reynolds 2004). Such objects may lie undetected for years unless they have damaged the tympanic membrane. Sometimes gentle irrigation will wash out the foreign body, but if it has become impacted it may be necessary for the patient to be admitted to hospital as a day case and for the object to be removed under general anaesthetic.

Only objects that will not expand when in contact with water should be irrigated.

DEAFNESS AND HEARING LOSS

Although total deafness is comparatively rare, many people suffer hearing loss to varying degrees. Deafness can affect both adults and children. Many children who are deaf continue to be so for all of their lives, but some can be helped to maximise auditory function. This chapter will concentrate on hearing problems among adults. There are estimated to be 9 million deaf and hard of hearing adults in the UK. This figure is rising as the number of those over 60 increases, with 698 000 of this age group being severely or profoundly deaf (RNID 2003).

PATHOPHYSIOLOGY AND MEDICAL MANAGEMENT

Deafness is usually classified into conductive and sensorineural disorders, as follows.

Diagnosis of the type of hearing loss from which an individual is suffering will be by examination and audiometry (see Box 14.1). Conductive deafness can often be helped by removing any obstruction (cerumen or a foreign body) or by amplifying sounds by means of a hearing aid. Because the external and middle ear are fairly accessible, surgical intervention may also be an option. By contrast, in sensorineural deafness, where the damage is to the organ of Corti or the cochlear portion of the VIIIth cranial nerve, surgery does not usually have much effect.

Conductive deafness results from a reduced ability of the sound waves to reach the fluid in the cochlea. The sound is quieter but not distorted. This can be due to:

- congenital abnormality
- otitis externa
- foreign bodies

Box 14.1

Hearing tests

Tuning fork tests

These tests are a simple means of determining a patient's basic auditory status. They may be performed in a clinical or home environment.

Rinne test

Air conduction is tested by holding a vibrating tuning fork first to the front of the ear and then by placing the tuning fork footplate against the mastoid bone. Patients should hear sound clearer to the front of the ear. Result = Rinne positive. Normal hearing.

Weber test

Bone conduction is tested by placing the vibrating footplate of a tuning fork to the middle of the forehead. This sound should be heard centrally. If conductive hearing loss is present, sound will be lateralised. If sensorineural hearing loss is present then sound will localise to the good ear.

Audiometry

Audiometric tests measure hearing acuity. Relatively simple tests, which include delivering tones of variable frequency and intensity, the spoken word and measuring middle ear pressures, are amongst the methods used to determine the type and source of any hearing loss. Electric response audiometry measures the patient's response to an acoustic stimulus by way of an electroencephalogram and can provide reliable and exact information on the site of a disorder, e.g. the cochlea, auditory nerve tract or brain stem.

Detailed descriptions of these tests can be found in Becker et al (1993).

- excessive cerumen
- otitis media (secretory and suppurative)
- damage to the tympanic membrane, incus, malleus or stapes.

Sensorineural deafness is caused by a defect of the cochlea or its connecting nerves. The sound heard is quieter and is also distorted. This is a result of the loss of the high frequencies, which register consonant sounds. In severe cases, patients may not be able to hear the sound of their own voice. This can be due to:

- ageing
- medication
- trauma, including head injury and noise
- infection
- Ménière's disease
- congenital malformation.

Presbycusis, the most common type of sensorineural deafness, develops as a consequence of ageing and is becoming increasingly prevalent in Western society. In the UK, 55% of people over 60 are deaf or hard of hearing (RNID 2003). Audiometry initially shows loss of ability to hear high tones, but there is gradual deterioration of lower tone hearing as well. Degeneration of the nervous tissue leads to loss of intelligibility in the sounds that are heard. Hearing loss in this disorder is symmetrical, i.e. it affects both ears. A hearing aid may be of slight advantage, but distortion and poor discrimination may cancel out any benefit from amplification. When communicating with these patients, it is important to speak a little slower and distinctly and to try to eliminate any background noise. Because the high tones are affected first, the individual may have trouble hearing consonants, as these are usually of higher tone than vowels.

Medication It has been recognised for some time that salicylates and quinine can cause deafness, but this can be reversed by discontinuing these medications. Other drugs, such as antibiotics of the aminoglycoside group, some diuretics, such as i.v. furosemide, and cytotoxic agents of the nitrogen mustard group can cause irreparable damage.

Trauma Noise-induced hearing loss is well documented and has become recognised as an industrial disease. Socioacusis, the term used to describe the hearing loss caused by sources of noise outside work, can be as great a risk as loud noise in the workplace (RNID 1999). A single exposure to a loud noise such as an explosion or gunshot can cause permanent deafness, or the injury may be temporary. Tinnitus usually accompanies this injury and often takes longer to resolve than any deafness (see p. 600). Exposure to loud noise over a period of time leads to destruction of the hair cells in the organ of Corti. The Noise at Work Regulations (HMSO 1989) laid down strict standards of noise control and protection for employers, who are liable to be prosecuted if they do not comply (see 'Useful websites' for more information). Occupational health nurses have a role to play in monitoring noise levels and encouraging auditory health through education. Unfortunately many people, particularly the young, willingly subject themselves to high levels of noise, e.g. at rock concerts and clubs, where the music is usually amplified, and also when listening to their personal stereos or car radios. Although personal stereos present less of a risk than rock concerts, it is recommended that only those with a mechanism to limit the volume be used, and children should be prevented from playing with toys that make a loud sound close to their ears (RNID 1999). On audiometry, early changes in hearing caused by exposure to noise are seen as a dip that gradually deepens and involves adjacent frequencies.

Head injuries or trauma resulting in deafness usually involve fractures or penetrating injuries of the temporal bone. Occasionally, concussion (see Ch. 9) can cause deafness due to haemorrhage into the middle ear or cochlea. These injuries are often accompanied by severe vertigo, nausea and vomiting.

Infection leading to deafness is usually viral in origin. The causative viruses are those associated with mumps, measles, meningitis, chickenpox and rubella.

Ménière's disease See page 601.

NURSING PRIORITIES AND MANAGEMENT: Deafness and hearing loss

In the case of conductive deafness, the nurse's role may be to prepare the patient for surgery and facilitate postoperative recovery. Some of the surgical procedures that may benefit patients are myringoplasty, ossiculoplasty and stapedectomy. A patient for whom surgery is not feasible may be fitted

with a hearing aid and educated in its use by members of the audiology department, including the hearing therapist. In this case the nurse, as a member of the multiprofessional team, should also explain how to obtain the greatest benefit from the aid. Most patients in this situation also benefit from learning how to lip-read. Lip-reading sessions are available as a day or evening class at the audiology department or a local college. It can take many months to become proficient at lip-reading, so the earlier the patient starts the better. Slow progress, combined with deteriorating hearing, can be very demotivating.

Communicating effectively with a hearing-impaired patient is a very important nursing priority. In the assessment, the nurse should obtain and record information about the patient's preferred method of communicating, e.g. lip-reading, finger-spelling or sign language. For a less profoundly deaf patient, it may be that speaking face to face in a distinct voice and eliminating background noise are adequate (see Box 14.2). A study by the RNID (2004) suggested that deaf adults who used sign language were dissatisfied with and disadvantaged in their communication with health care staff, including nurses (see Research Abstract 14.1).

It is now recognised that deafness can have a profound psychological impact and that hearing-impaired individuals may require support to help resolve problems. Many deaf people would prefer to have counselling from a counsellor who is deaf, and attempts should be made to find such a professional if preferred (via BACP if necessary; see 'Useful websites'). According to Ratna (1994), the problems deaf clients bring to counselling include isolation, frustration, discrimination and physical and sexual abuse.

Box 14.2

Talking with someone who has a hearing deficit

- Do not speak until you have the person's attention and they can see your full face
- Never turn your back on the person when you are speaking or cover your mouth
- Ask the person if they can lip-read
- Do not exaggerate your lip movements
- Direct your voice to one ear if it has better hearing than the other
- Speak slowly, enunciate clearly and do not shout
- Remember that vowels are heard more easily than consonants
- Check that the person has understood what you have said
- If the person has difficulty in understanding, try rephrasing the sentence
- Do not laugh at misinterpretations
- Have patience. Give the person time to adjust their hearing aid if necessary
- Encourage the person to participate in group conversations when the occasion arises
- If verbal communication is impossible, explore alternative means, e.g. sign language

For information on the experience of deafness, see Taylor & Bishop (1991).

Chan (1997) confirmed this when describing a service he and his team of hearing and deaf health care professionals have developed for deaf people with mental health problems.

Nurses can make a valuable contribution by recognising the problems faced by patients with hearing loss and helping them to obtain the appropriate help.

14.1 How might a person with a severe hearing deficit know that the telephone or doorbell is ringing?

Community nurses can provide tremendous help and support for patients and their relatives when sensorineural deafness is a problem. They should be able to assist their patients to obtain many of the aids available, including a hearing dog for the deaf, which can help to overcome communication difficulties in everyday life. There are many associations, both voluntary and professional, which can provide support and help. The nurse working in the community should be a resource person for patients and guide them to the support that is available (see 'Useful websites').

14.2 Find out which professional or voluntary support groups there are for deaf people in your area. What services do they offer? Compile a resource list.

Hearing aids

It is estimated that there are 2 million hearing aid users in the UK. In addition, there are thought to be another 3 million people who would benefit from the use of a hearing aid (RNID 2003).

All electronic hearing aids have a microphone, which picks up the sound; the sound is processed electronically either by analogue or digital circuits to make it more audible. This is then delivered to the receiver, converted back to sound and reaches the ear via an ear mould. As there are many models on the market, it is important that the most appropriate one is chosen for each person's needs and lifestyle. While most hearing aids enclose all the components in a neat package on or near the ear, they differ in such aspects as frequency response, output and ability to reduce the effects of sudden, loud noise. Hearing aids conduct sound either through air or via the bone behind the ear.

After the most appropriate model of hearing aid has been identified, the patient will require some training in order to be able to receive maximum benefit from it. The fact that most aids make all sounds, including background noise, louder, means that the patient will have to develop the skill of picking out sounds essential to communication. Social interaction may be difficult until this skill is mastered, and if the individual is not given enough information and support, the aid may be abandoned as useless. Digital aids are designed to overcome this problem as they can customise how sound is processed.

14.3 Find out how many patients in your ward or on your community caseload have a hearing aid. How much training and support regarding their use did they receive? How many use them? How useful do they find their hearing aids to be? What would you do if you were visiting an older person in their own home, and they responded to your questions by showing you a drawer containing several hearing aids and saying, 'None of these are any use'?

RESEARCH ABSTRACT 14.1

Are we being heard?

The RNID decided to commission this report because of the frequency with which they received examples of poor communication experienced by deaf and hard of hearing people when attempting to use the NHS. The study took place within the context of the Disability Discrimination Act (1995), which came into force in 2004, and places a legal obligation on the NHS to meet the needs of disabled people. The NHS in England, Wales and Scotland have acknowledged defects in their services which affect disabled people, including difficulties in communication with staff and in finding their way around premises. There are thought to be approximately 9 million deaf and hard of hearing people in the UK. As one in every seven people in the UK has some level of hearing loss, and it is known that the average GP will have up to four patients with hearing loss in their surgery daily, it is important that health care professionals in all care settings are aware of the particular needs for effective communication of those who have reduced hearing.

The RNID and the UK Council on Deafness conducted this research in collaboration with 21 UK-based deaf and hard of hearing groups and charities; a total of 866 participants completed the survey.

The main findings reported by deaf and hard of hearing people when using GP services concluded that 35% had experienced difficulty communicating with their GP or practice nurse and 15% avoided going to see their GP because of communication problems. Making and keeping appointments was another problematic area, with 28% reporting that they found their hearing loss made it difficult for them to make an appointment and of 24% who stated they had missed an appointment, 19% had missed more than five. Of those who did see their GP or nurse, 35% reported being unclear about their condition because of communication problems. Of those who used British Sign Language (BSL), 33% were either unsure about medication instructions or had taken inaccurate doses.

The situation in NHS hospitals is equally disturbing, as 42% of the deaf and hard of hearing who had visited a hospital for non-emergency treatment found it difficult to communicate with staff. BSL users experienced even more difficulties, with 77% of this group reporting communication problems for emergency and non-emergency overnight stays and 70% of those admitted to emergency departments were not provided with a BSL/English interpreter to facilitate effective communication.

Overall, the picture is one of poor communication, resulting in people having inadequate access to health care and insufficient information about their health condition and treatment, thus limiting their ability to make informed choices, and being placed in higher risk situations than their hearing counterparts. It is also unacceptable that family, including young children, and friends have to act as interpreters and on occasion convey critical health information. The financial cost to the NHS of missed appointments is put at approximately £20 million a year. The financial and non-financial costs to the patient, family and friends will never be known.

The report notes that NHS staff do wish to deliver a better and more equitable service to the deaf and hard of hearing but that often the necessary resources and infrastructure are not available. Solutions recommended include increasing the number of BSL/English interpreters, using video phones, providing improved written information, installing loop systems to allow better use of hearing aids in noisy environments, providing visual displays in appointment areas and clear lighting, and providing deaf awareness education, including communication skills, for all health care staff, whether working in hospital or community settings. Deaf awareness seminars should be provided for appropriate hospital departments and GP surgery staff, so that these areas have at least one formally trained 'front line' staff member.

RNID 2004 A simple cure. A national report into deaf and hard of hearing people's experiences of the National Health Service. RNID, London (see also 'Useful websites')

All hearing aid models are battery powered and have an on/off switch which is sometimes combined with the volume control. Many models also have a switch marked 'T' which is for use with telephone and other systems fitted with an induction loop. This loop eliminates some background noise and clarifies incoming speech.

14.4 Where in your area are induction loops fitted? How can you tell?

The ear moulds are individually made to fit each user's ear. They can be disconnected from the aid for cleaning, which should be done frequently. The tube that connects the earpiece to the main aid can also be detached and washed and any blockage removed with a pipe cleaner. If a hearing aid is not working, make sure that:

- the switch is in the 'on' position
- the battery is still good and is of the right type
- the mould is clean and fits properly (check for excessive cerumen)
- the connecting tube is pliable and patent.

If all of the above are in order and the aid is still not working, it should be returned to the hearing aid clinic for maintenance. All hearing aids and batteries supplied by the NHS are maintained and replaced free of charge.

DISORDERS OF THE MIDDLE EAR

Secretory otitis media (glue ear)

Glue ear is the most common cause of hearing impairment and the most common reason for elective surgery in children. Approximately 80% of children will suffer from glue ear before they are 4 years old (Scottish Intercollegiate Guidelines Network 2003).

PATHOPHYSIOLOGY

This disorder is known as glue ear because it is characterised by a thick, tenacious fluid, which collects in the middle ear. Normally, the mucosal secretions of the middle ear drain down the eustachian tube into the nasopharynx. It is not certain whether the abnormal accumulation of this fluid is caused by the viscosity of the fluid, congestion of the eustachian tubes or obstruction caused by enlarged adenoids or a tumour.

Common presenting symptoms Pain is rarely associated with this condition. The adult patient usually comes to the medical practitioner complaining of hearing loss. A child might never complain, and their condition might be discovered only upon investigation into poor performance at school or during routine screening of hearing at school.

MEDICAL MANAGEMENT

Examination of the tympanic membrane by auriscope usually confirms the diagnosis, as in this disorder the membrane has a characteristic dull grey or orange appearance. It will also lose its normal translucence and become retracted.

Treatment

Conservative treatment is to prescribe a decongestant, or antihistamines, to reduce oedema of the nasal mucosa. Mucolytics, which liquefy the mucus, have been shown to have no effect on the condition (Scottish Intercollegiate Guidelines Network 2003).

Surgical intervention involves performing a myringotomy, incising the tympanic membrane and suctioning of the glue. If a grommet is not inserted, the delicate tympanic membrane heals within a few days. The fluid may, of course, accumulate again. The insertion of a grommet (see Fig. 14.2) is sometimes considered appropriate, although some specialists think this can lead to scar formation in later years which will impair hearing. If a grommet is inserted, it usually gradually slides out of the membrane over 9–12 months; patients sometimes find it on their pillow when they waken one morning. A grommet allows aeration of the middle ear, thus restoring middle ear air pressure. There is usually a marked improvement in hearing after this procedure, which is maintained in about 75% of patients.

NURSING PRIORITIES AND MANAGEMENT: Secretory otitis media (glue ear)

Only care specific to ENT patients is outlined in this chapter. The reader is referred to Chapter 26 for details of perioperative care.

Preoperative care

Most of this surgery is carried out on a day case basis, and the nurse must ensure that the patient and family are adequately informed about what the surgical procedure will entail. This may involve the use of diagrams and it may be helpful to show a grommet to them if one is to be inserted. As grommet insertion is usually performed on children and young people, it is vital that the appropriate emotional and psychological support is given by suitably qualified staff in a specialist area. When communicating with the patient preoperatively, the nurse should make allowances for hearing loss (see Box 14.2).

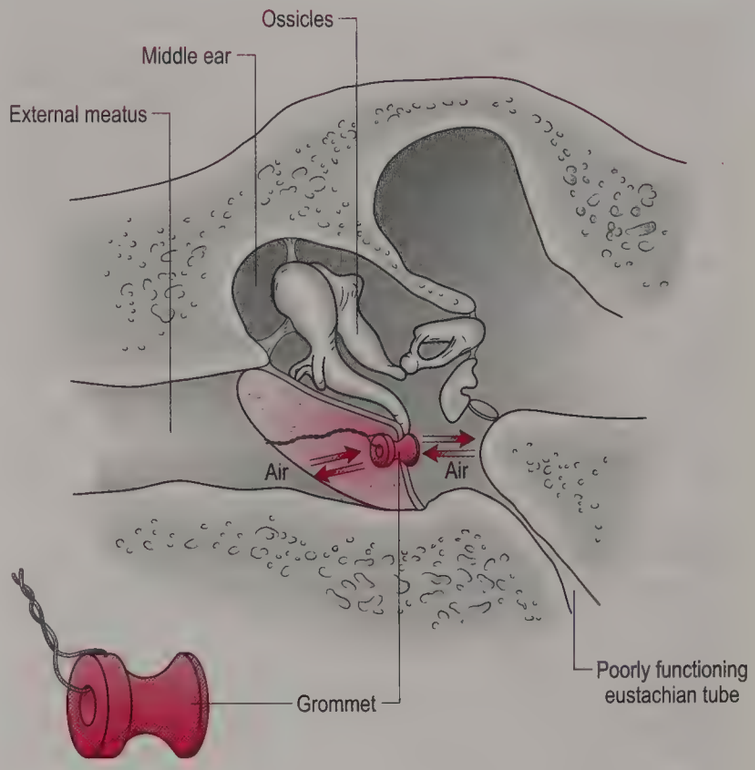

Fig. 14.2 Grommet and grommet in situ.

Postoperative care

The anaesthetic for this operation is very light. Measures to prevent the spread of infection, e.g. washing the hands before and after touching the affected ear, how to change and dispose of cotton wool plugs in the external auditory canal, and specific instructions about whether and when it is safe to allow water to enter the ear must be discussed with the patient. When a grommet is in place, some surgeons allow swimming, as long as the patient does not dive or swim underwater. Others prefer their patients not to swim until it has been expelled. Usually, a cotton wool plug moistened with petroleum jelly is inserted in the external canal when the hair is being washed or when taking a shower. The nurse must ensure that the patient and family understand this advice and that information booklets or advice sheets are given. The importance of attending the clinic for a follow-up visit, even if the hearing has improved dramatically, should be stressed. This visit is to ensure that the membrane is healing satisfactorily, to check the position of the grommet and to check for signs of infection. Patients should be told to go to their GP if they experience any pain or if there is a bloodstained discharge from the ear. Most of these precautions apply to all patients who have undergone aural surgery.

Sigler & Schuring (1993) give information which the nurse should explain to the patient in relation to postoperative self-care at home.

Otosclerosis

Otosclerosis is a condition in which the ossicles in the middle ear, along with the temporal bone, begin to soften. This spongy bone gradually becomes a dense sclerotic mass; the ossicles may become fixed and less effective in passing on auditory vibrations. The individual with this condition will complain of increasing hearing loss. While this loss is conductive in origin, if the damage extends to the cochlea, sensorineural loss of hearing will also occur. Mild tinnitus (see p. 600) may also be experienced, in which case some people find that they can actually hear better in a noisy environment where their tinnitus is masked.

This disorder commonly begins in adolescence and its cause is as yet unknown. Heredity, vitamin deficiency and otitis media have all been cited as significant factors.

Medical management and nursing priorities

Although no cure for otosclerosis is known, surgery can often dramatically improve hearing. The surgery of choice, stapedectomy, involves freeing the stapes and replacing it with a prosthesis. This restores the vibration necessary to permit the transmission of sound waves. The procedure is a very delicate one requiring the use of an operating microscope, as the stapes is one of the smallest bones in the body. Surgery may be performed under local anaesthetic and hospital admission may be no more than 24 h (Ayache et al 2003).

Great care must be taken in the early postoperative period, as the patient may take a little while to regain their sense of balance. This short-term vertigo, if discussed and explained in the preoperative period, should cause minimal distress to the patient. Prior to discharge, advice should be given on the prevention of aural infection, the importance of preventing the entry of water into the ear and the need to guard against blowing the nose until the operative site is completely healed. Violent nose blowing can force air up the eustachian tube, increasing middle ear pressure, which can affect the operated area and prosthesis. Follow-up appointments in the outpatient department and appropriate community support by the GP will ensure optimal progress and recovery.

For those for whom the symptoms of otosclerosis are not too severe, or for whom surgery is inappropriate, a hearing aid may restore and maintain satisfactory hearing. For others, neither surgery nor a hearing aid will have long-term effectiveness and varying degrees of deafness will result.

Acute suppurative otitis media (ASOM)

PATHOPHYSIOLOGY

This is an acute bacterial infection of the middle ear which is especially common in childhood. The most common causative organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes* and *Staphylococcus aureus*. Onset usually follows acute tonsillitis, the common cold or influenza, when infection travels up the eustachian tube to the middle ear. The whole middle ear may be affected, including the mastoid air cells, small air spaces in the posterior portion of the temporal bone, behind the middle ear (see Fig. 14.1).

Common presenting symptoms The patient usually presents with acute ear pain. There may be deafness, general malaise and pyrexia. On examination, the eardrum is red and bulging due to the collection of pus in the middle ear. The tympanic membrane may rupture, releasing the discharge and dramatically and instantaneously relieving the pain.

MEDICAL MANAGEMENT

Treatment The patient with ASOM is usually seen and treated by a GP. The exact treatment given will depend on the stage of the infection, as follows.

Early stage At this stage the tympanic membrane will still look normal. A broad-spectrum antibiotic effective against the most common organisms is usually prescribed. Antipyretic analgesics such as paracetamol will be necessary to relieve pain and reduce fever. Vasoconstricting nasal sprays may also be helpful in keeping the eustachian tubes patent, thereby allowing escape of fluid from the middle ear. In severe cases, admission for i.v. antibiotics and pain control may be necessary (Scottish Intercollegiate Guidelines Network 2003).

Bulging eardrum If the infection has reached this stage, a myringotomy may be performed. This involves applying a local anaesthetic before making an incision in the tympanic membrane to allow the pus to escape. If a myringotomy is performed in preference to allowing the eardrum to rupture, the membrane will heal with less scarring and hearing should not be impaired. During this procedure a swab of the discharge will be taken for culture and sensitivity so that the appropriate antibiotic can be prescribed.

Discharging ear By this stage the tympanic membrane will already have ruptured. A swab of the discharge will be taken and the ear carefully mopped out and then dressed with a small plug of cotton wool. Broad-spectrum antibiotics will be prescribed in the first instance while the results of bacteriology are awaited.

The patient will have to visit the GP regularly so that healing of the membrane can be monitored. If necessary, a myringoplasty (reconstruction of the eardrum) will be performed.

NURSING PRIORITIES AND MANAGEMENT: Acute suppurative otitis media (ASOM)

Early stage

If at this stage a nurse, possibly a practice nurse, is involved, their role will be to ensure that the prescribed course of antibiotics is completed in order to eradicate all the organisms. It may be necessary to teach the patient or a relative how to administer a nasal spray.

Discharging ear

If the disease has reached this stage, the nurse's role will include mopping out the external ear as often as required and carrying out microsuction clearance of the debris.

If appropriate treatment is given early enough, ASOM should resolve and hearing return to normal. Occasionally, complications do occur, including chronic suppurative otitis media and acute mastoiditis, which are described below.

Chronic suppurative otitis media (CSOM)

PATHOPHYSIOLOGY

Common presenting symptoms This condition follows unresolved ASOM. The patient will present with a perforated tympanic membrane, a discharging ear and some degree of conductive deafness. Pain is not usually a complaint. The discharge may be intermittent and is mucoid, becoming purulent in the presence of secondary infection.

MEDICAL MANAGEMENT

The recommended treatment is to keep the ear dry by the use of topical medication before correcting the hearing loss by performing a tympanoplasty.

For further information on middle ear reconstructive procedures and care, see Waddington et al (1997).

Tympanoplasty Following removal of diseased tissue, an attempt may be made to re-establish the sound transmission mechanism in the middle ear by reconstructing the tympanic membrane (myringoplasty) using a connective tissue graft taken from the fascia covering the temporal bone and reconstructing the ossicular chain (ossiculoplasty). This combined reconstruction is known as a tympanoplasty (Brackman et al 2001).

NURSING PRIORITIES AND MANAGEMENT: Tympanoplasty

Preoperative care

The patient is usually admitted on the day of surgery. In view of their obvious hearing deficit, the establishment of good communication is very important. To help avoid complications, the ear must be dry and free from infection. Hearing tests will be carried out to confirm the degree of hearing loss.

If some of the patient's hair has to be removed, this will be done in the operating theatre. To help alleviate anxiety, the nurse should give the patient information about the procedure and warn about sensations that may be experienced afterwards, such as dizziness and tinnitus (see p. 600). It is also helpful to describe the very bulky bandage that will be present around the head and affected ear so that this does not alarm the patient and family. Hearing aids should be worn to the operating theatre.

For patients who are having surgery on the ear in which they normally wear a hearing aid, a temporary aid may be fitted to their other ear if appropriate.

Postoperative care

General postoperative care is as described in Chapter 26. The majority of patients undergoing ear surgery are given a hypotensive anaesthetic in order to reduce bleeding and thereby allow the surgeon a clearer view of the tiny operative field. This involves the i.v. administration of a hypotensive agent such as pentolonium. Frequent blood pressure readings are therefore required until the preoperative baseline levels are regained.

Following the operation, the patient should be encouraged to lie with the affected area uppermost and should be observed for nausea, vomiting and vertigo, all of which might be present due to possible interference with the semicircular canals during surgery. The aim of the pressure dressing and bandage is to prevent bleeding and haematoma formation, but the nurse should always observe the patient's bandages and pillows for bloodstains.

Following this type of surgery, the patient should be asked to smile, wrinkle their nose and shut their eyes tightly. The ability to perform these movements indicates that there has been no damage to the facial nerve. A record of the time of checking and level of function of the nerve should always be kept for medical and legal reasons. Because of its location, the VIIth cranial (facial) nerve is at risk of damage during surgery to the middle or inner ear.

Most patients are able to be up on the evening of surgery and return home the next day. They should be advised that they may experience dizziness during the following 2 or 3 weeks and should avoid sudden movements such as quickly turning the head. Sutures should be removed in 5–7 days, either at the GP's surgery or on the ward. Packing is usually present in the external meatus for between 1 and 3 weeks following surgery. The patient will be shown how to change the piece of cotton wool at the entrance to the meatus as required, without disturbing the packing.

Patients will naturally be very anxious to know if the graft has taken and if the infection has been completely removed. Offering accurate information and giving specific answers to questions will help to alleviate these anxieties (Gerber et al 2000).

CSOM with cholesteatoma

PATHOPHYSIOLOGY

This potentially dangerous condition is sometimes called attico-antral disease, because it is found in the attic (upper) area of the middle ear. On examination it may be possible to see the cholesteatoma, an ingrowth of keratinising squamous epithelium from the external ear into the middle ear, usually from the site of a previous perforation. The squamous epithelium growing within the middle ear produces keratin, which has the ability to erode the bony ossicles and may even spread into the inner ear.

Common presenting symptoms The patient will complain of a foul-smelling discharge from the ear and of deafness.

MEDICAL MANAGEMENT

The treatment of choice is mastoidectomy (see below).

Acute mastoiditis

This condition arises from acute otitis media and is caused by the infection spreading to the bony walls of the cells of the mastoid process.

MEDICAL MANAGEMENT

Conservative medical management is by administration of antibiotics; surgical management is a cortical mastoidectomy.

Mastoidectomy A cortical mastoidectomy involves incision, drainage and removal of unhealthy mucosa and bone cells from the mastoid process of the temporal bone, leaving the middle ear structures intact. A modified mastoidectomy may be performed if the disease is confined to the attic or upper area and the patient has good hearing. This is currently the most common surgical procedure for middle ear infection. It involves removal of most of the air cell system within the mastoid cavity, especially in the attic area, and preservation of the remnants of the tympanic membrane and the ossicles, although these are not usually functioning. Every effort is made to preserve the ossicular chain and tympanic membrane in order to retain hearing. The procedure involves exenterating (clearing out) the mastoid cells and removing the outer attic and posterior wall, thus leaving a large cavity to allow air from the meatus to circulate and dry up secretions.

NURSING PRIORITIES AND MANAGEMENT: Mastoidectomy

Nursing care is as for patients undergoing tympanoplasty (see p. 599).

Other complications of middle ear infection

Less common complications of middle ear infection are facial nerve paralysis, meningitis, extradural or subdural abscess, labyrinthitis, lateral sinus thrombosis and brain abscess.

DISORDERS OF THE INNER EAR

Tinnitus

Tinnitus is a little understood but most distressing feature of some ear diseases and disorders. It may also occur spontaneously or as a postoperative complication. Possibly because it is so puzzling, has no known cause and is not a visible symptom, sufferers often feel that they receive very little sympathy and understanding.

PATHOPHYSIOLOGY

Tinnitus is usually a subjective sensation of sound in the ear. It is a relatively common complaint which may arise in association with a wide range of conditions, including inner and middle ear disease, overuse of medications such as aspirin and quinine, abnormalities of the auditory nerve, renal problems, cardiac problems and anaemia. It is often accompanied by vertigo and/or deafness.

The Tinnitus Association produces an excellent range of factsheets and a free newsletter for interested professionals, as well as helping sufferers (see 'Useful websites').

Common presenting symptoms Tinnitus can vary in severity from an intermittent mild ringing sensation in the ear to an incessant noise, loud enough to make life unbearable. The perceived sound varies in volume and character from one individual to another. Some patients are aware of the sound only during their waking hours, while others are aware of it mainly at night or when they are somewhere very quiet. Tinnitus may cause difficulty in sleeping, with irritability, tiredness and lack of concentration following restless nights. The persistent symptoms cause many tinnitus sufferers to feel anxious and depressed (see Box 14.3). The feelings are exacerbated in some by fears that the tinnitus is an indication of a more serious underlying disease or that it will cause an increase in hearing loss.

In the worst cases, individuals with tinnitus may suffer total deafness because the noise in their ear eliminates all other sounds.

Box 14.3

An experience of tinnitus

I shall never forget the first time I experienced tinnitus. It was in the dead of night when I heard a high-pitched whine in my left ear. I was so taken aback that I got up out of bed and went in search of the source of the noise. Before long, however, I realised that the noise was being carried with me.

The tinnitus had been preceded about a month beforehand by nausea and severe vertigo which I had accepted as transitory. To find that I was left with this noise made me feel very anxious indeed. I had difficulty in coming to terms with the fact that it might always be present. My reaction was 'It can't be! There must be something to combat it and make the noise go away!'.

When it became clear to me that I was now a 'tinnitus sufferer' I experienced a phase of reactive depression and felt that life was not worthwhile. Naturally, I searched for a cure and eventually joined the local branch of the Tinnitus Association. This was a move which I made by myself, but the Association proved to be an invaluable source of emotional and practical support and information.

A hearing therapist and a clinic psychologist have now joined the team at my audiology clinic and they are giving tinnitus sufferers like me a great deal of help in many ways.

MEDICAL MANAGEMENT

To aid diagnosis, a careful history must be taken, including information about all other symptoms and any medications. This should be done in a tinnitus clinic within an ENT department. A hearing test and careful examination of the ear (including radiography) may help determine the cause. Unfortunately, in many instances, no treatable cause will be found. In certain patients, a hearing aid can give some relief by reducing or masking the tinnitus. A noise generator that looks like a hearing aid can help to cancel out the undesirable sound and can be of help to some. Tinnitus retraining therapy (TRT) aims to reduce the brain's perception of tinnitus and so reduce the problem it is causing. TRT may include counselling, relaxation therapy, the appropriate use of hearing aids, noise alleviators and medication, as well as the treatment of any stress and anxiety.

For an overview of the issues surrounding the use of this therapy, see Sizer (1998).

NURSING PRIORITIES AND MANAGEMENT: Tinnitus

Very few tinnitus sufferers will be patients in hospital, unless their condition has arisen as an early postoperative complication. The majority will attend their GP's surgery or their nearest ENT outpatient department. Wherever nursing staff encounter these patients, high priority should be given to allowing them to express their fears and to recognising and relieving their anxiety and possible depression. Once an ENT specialist has carried out all the tests required to determine a diagnosis, any prescribed treatment and training can be commenced. Where there is no medical treatment, a planned programme of care, including TRT, counselling, explanations and information giving, such as details of support groups, will be necessary to help the patient adapt and to relieve any worries. There are more than 100 tinnitus support groups in the UK and they can be of enormous help to sufferers by providing ongoing emotional support (see 'Useful websites').

For further information on tinnitus and health anxiety, see Heath (1994).

14.5 Find out if there is a tinnitus support group in your area. If there is, try to arrange to attend one of their meetings.

Vertigo

PATHOPHYSIOLOGY

Vertigo is a disturbance of equilibrium in the absence of an external cause which creates a sensation of rotating motion of oneself or one's surroundings. It is usually caused by irritation of the vestibular apparatus and is most frequently associated with disorders of the bony labyrinth and with Ménière's disease. Cardiac, neurological or viral infections and therapeutic medications such as streptomycin can also cause vertigo.

Common presenting symptoms Vertigo is a disabling and often frightening sensation that may be transient or recurring. It is not the same as dizziness and may be relatively mild or quite severe. The motion perceived is often described as a whirling sensation, but rocking and swaying sensations are also reported. Severe attacks of vertigo may be sudden and dramatic, accompanied by pallor, nausea and vomiting.

For more information on vertigo management, see Lauder (1993).

MEDICAL MANAGEMENT

A careful history is required from the patient and must include any precipitating factors such as head and neck movements. Any other symptoms such as tinnitus or deafness should be ascertained. It is also helpful to know how long the periods of vertigo last. Details of medication and any recent trauma can also aid diagnosis. A neurological and cardiovascular examination and perhaps radiography, hearing tests and blood tests may be advisable.

Occasionally, surgery will be required to treat the particular disorder of which vertigo is a symptom, but treatment is more commonly pharmacological, or using the Eplay manoeuvre or Cooksey Cawthorne head and neck exercises, which are taught by a physiotherapist (Lauder 1993). An occupational therapy assessment of home safety may also be beneficial.

NURSING PRIORITIES AND MANAGEMENT: Vertigo

As is the case with tinnitus sufferers, the majority of individuals who experience vertigo will be distressed and incapacitated by their condition. They will usually be seen in their homes, as they are likely to feel unsafe venturing out. The first nursing priority for these patients is safety. The attacks of vertigo may be unpredictable, or may be associated with a particular head movement. For example, for one individual, a precipitating circumstance might be standing on a stepladder with their head back and to one side in order to change a light bulb; for another, it may be simply a quick movement to bend down and pick up a baby from its cot. The nurse should discuss with the patient and family how to avoid the particular head and/or other movements in order to eliminate attacks, if this is possible.

Ménière's disease

PATHOPHYSIOLOGY

In Ménière's disease, the membranous labyrinth is distended by an increase in the endolymph, at the expense of the perilymph, and the organ of Corti degenerates. The most widely held theory of its cause is that it arises as a result of local ischaemia, although it has been suggested that it may be due to viral infection, biochemical disturbance, vitamin deficiency or local physiological faults.

Common presenting symptoms Ménière's disease is characterised by four disabling features:

- vertigo
- tinnitus
- sensorineural hearing loss
- nausea and vomiting.

It may arise at any age but is most common among individuals aged 30–50. As it runs its course over a period of many years, deafness increases. Although this hearing loss may initially affect only one ear, it will, in 10% of patients, eventually affect the other as well (Becker et al 1993, McAllen 1996). Many patients have a warning that an attack is imminent, e.g. there is a feeling of fullness in the ear or the character of the tinnitus changes.

During an attack the patient will have vertigo, nausea and vomiting and will want to lie down and remain as still as possible, in order to relieve these distressing symptoms. Nystagmus may be present and, as a consequence of vagal stimulation, sweating, bradycardia and diarrhoea may occur.

MEDICAL MANAGEMENT

It may be difficult to arrive at a conclusive diagnosis of Ménière's disease, as many other disorders, e.g. labyrinthitis,

intracranial disease and acoustic neuroma, display similar symptoms. Given that, between attacks, clinical examination may prove negative, diagnosis will rely heavily on careful history taking and audiological investigations.

Treatment The most common treatment for the symptoms of Ménière's disease is the prescription of medication, e.g. a labyrinthine sedative, such as cinnarizine, and diuretics. A vasodilator such as nicotinic acid or moxisylyte may be prescribed to alleviate local ischaemia. The majority of patients respond well to medication therapy and may have long periods of respite from severe symptoms. Adherence to a low-salt diet may be advised to reduce the volume of endolymph.

Surgery may occasionally help to relieve symptoms. This may take the form of decompression of the endolymphatic sac, the creation of a fistula between the endolymph and perilymph reservoirs, or a vestibular neurectomy.

NURSING PRIORITIES AND MANAGEMENT: Ménière's disease

The main nursing priority in case of an attack of Ménière's disease is to ensure the patient's safety. Attacks are often so severe that the patient needs to lie as still as possible, and, if in hospital, may gain a sense of security if the side rails on the bed are raised. Vomiting can be so severe as to cause dehydration. If the patient cannot take fluids orally, i.v. fluids and antiemetic drugs will be necessary until oral medication and feeding can be tolerated.

Patients suffering from Ménière's disease often have to make lifestyle changes in order to cope with some of the symptoms of the disorder. The nurse should be prepared to offer advice on lifestyle adaptations. As an individual faced with the problems associated with Ménière's disease is likely to feel anxiety, it is vital that the nurse provides clear information and explanations, particularly with regard to prognosis.

The involvement of the primary health care team and of the occupational health nurse will be especially important, as it is often not until the patient is back at home following diagnosis that many questions with regard to participation in sport, driving, safety at home and in the workplace begin to be considered.

THE NOSE

ANATOMY AND PHYSIOLOGY OF THE NOSE

The principal function of the nose is to provide a passageway for air entering and leaving the respiratory tract (see Fig. 14.3). In so doing, it acts as an 'air conditioner', ensuring that inspired air is humidified, sufficiently warm and free from particulate matter.

The terminal fibres of the olfactory nerve are located in the roof of the nasal cavity. The lower two-thirds of the nose are supported by cartilage and the upper third is enclosed by bone. The cavity is divided in half by the septum which consists of cartilage anteriorly and bone posteriorly. The entrance is lined with stratified squamous epithelium and coarse hairs (termed vibrissae) and the

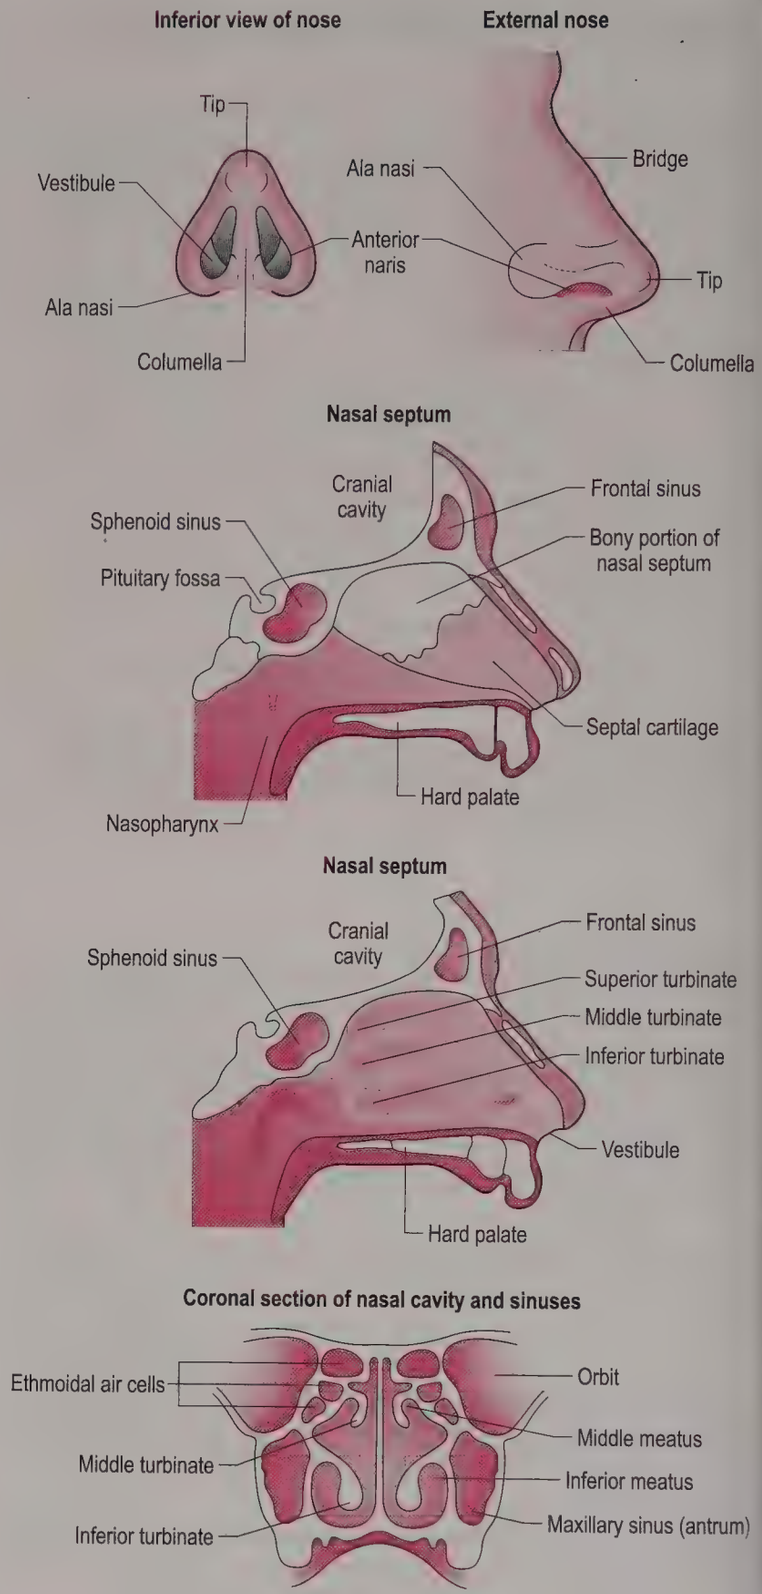

Fig. 14.3 The nose and paranasal sinuses.

passages are lined with a mucous membrane of ciliated columnar epithelium. These passages are highly vascularised. A branch of the maxillary artery supplies the lower posterior section of the cavity, and the anterior and posterior ethmoidal arteries supply the mucous membrane. All these vessels join at Little's area on each side of the septum (see Fig. 14.4).

For further information, see Becker et al (1993).

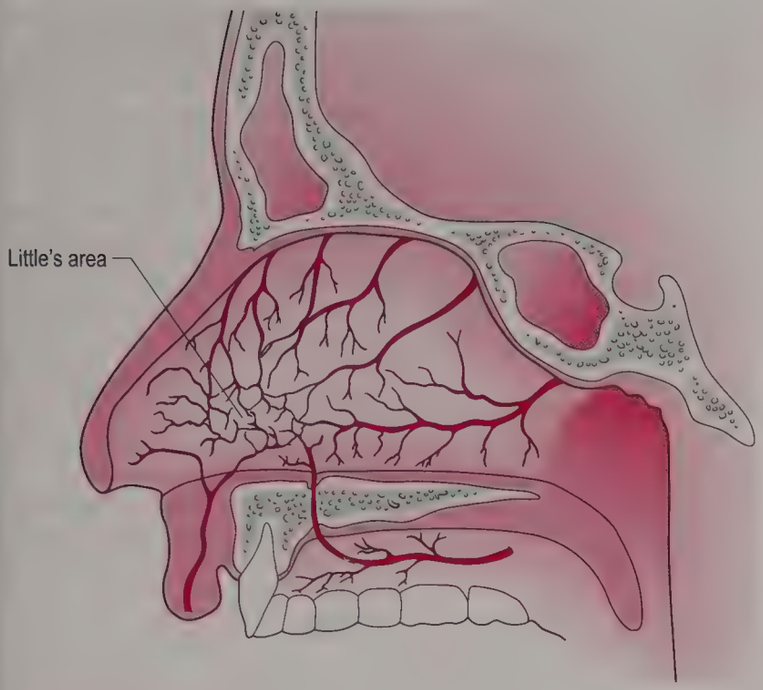

Fig. 14.4 Blood supply to nose (sagittal section).

DISORDERS OF THE NOSE

Epistaxis

PATHOPHYSIOLOGY

Epistaxis is bleeding from the nose. It is not a disease in itself but a symptom of some other disorder, which may be of a local or general nature. Local causative disorders include idiopathic, trauma caused by nose-picking, foreign bodies, a blow to the nose or surgery. More generalised disorders that sometimes give rise to nosebleeds can be:

- vascular, e.g. hypertension and cardiac failure
- congenital, e.g. haemophilia and hereditary haemorrhagic telangiectasia
- neoplastic, e.g. leukaemia
- medication-induced, e.g. a side-effect of anticoagulant therapy
- infections, e.g. influenza, rhinitis, sinusitis and the common cold.

Common presenting symptoms Epistaxis can affect males and females equally and can occur at any age but is most common in childhood and early adolescence, when it usually occurs in Little's area (see Fig. 14.4) and is often the result of trauma or infection. In middle-aged or older individuals, the bleeding is more likely to occur in the posterior part of the nose and may be associated with hypertension. This form of epistaxis may be very frightening and can be life threatening if it proves difficult to control.

Patients may refer themselves to the local emergency department when they have an active epistaxis. They may then either be admitted to the appropriate hospital ward or, if the bleeding has stopped, given an outpatient clinic appointment. One patient's experience of epistaxis is recounted in Box 14.4.

Patients often present at clinics with a history of recurrent epistaxis, but are rarely actually bleeding at that time. On examination, dilated blood vessels may be apparent. The best treatment to prevent the bleeding recurring is cautery by the use of a chemical, such as silver nitrate, electrocautery or diathermy.

Box 14.4

An experience of epistaxis

It first started on a Saturday morning. I bent down to pick up my bag from the floor and realised my nose was running. On wiping it, I saw fresh blood. Going into the bathroom, I could still feel it running and the tissue was getting soggy with blood. Remembering some first aid, I squeezed the soft front of my nose, sat down and leaned forward. At least it stopped the blood coming out of my nose, although I could taste some in my mouth now. After 10 min I stopped squeezing and the bleeding stopped. I cleaned around the front of my nose, but spent the rest of the day not daring to blow my nose in case the bleeding started again.

All was well until Wednesday evening. I'd just had a bath and was watching TV, when I felt my nose running. Again, there was blood on the tissue and dripping from my nose. Like the previous time, I squeezed my nose, but after 10 min, when I released the pressure, the blood started dripping and I squeezed again. Again, on releasing the pressure, the blood continued to drip and I now had a pile of bloodstained tissues in the bin and patches of blood all over the bathroom floor as I tried stuffing tissues up my nose as well. By now an hour had passed and still the blood dripped. I didn't think it was ever going to stop and wasn't sure what to do.

My flatmate suggested contacting my GP. She phoned and we were advised to go to the emergency department of our local hospital. So my flatmate drove me to the hospital and I took the washing up bowl to catch the blood, as I didn't want to mess up the car!

On arriving at the emergency department, my flatmate booked me in and I was seen very quickly by a nurse. On releasing the squeeze on my nose, the blood still continued to drip out and the nurse said I would see a doctor. The nurse then squeezed my nose for me. I was glad as my arms were aching from all the squeezing I had done. My blood pressure was taken and the doctor saw me.

Despite all the blood coming out of my nose the doctor sprayed it with a local anaesthetic and had a look inside. They could see a blood vessel at the front of my nose that was bleeding, so they put a stick on it, to cauterise the vessel and the bleeding stopped. It was a great relief and after an hour of no further bleeding I was allowed to go home with some nasal cream and an outpatient's appointment for 4 weeks' time.

MEDICAL MANAGEMENT

The management of epistaxis can be divided into resuscitation of the patient, arrest of the haemorrhage and diagnosis and treatment of any underlying cause (Ell & Parker 1992).

A patient with a severe active epistaxis is usually admitted to hospital as an emergency. Vital signs are recorded to monitor for shock, as bleeding may be severe enough to necessitate blood transfusion. Treatment is by insertion of a nasal pack. This usually takes the form of a nasal tampon or pneumatic packing with an inflatable balloon. Nasal

packs are usually left in place for 24–72 h. Antibiotics are given if the packs are in longer than 24 h, to prevent any risk of infection developing and spreading to the middle ear. Occasionally, when these measures fail to control the bleeding, arterial ligation is necessary. If the bleed is the result of some underlying medical condition, this will need to be investigated and treated at the same time.

NURSING PRIORITIES AND MANAGEMENT: Epistaxis

Nursing intervention will vary, depending on the site, severity and cause of the epistaxis, as well as the patient's age.

Anterior nosebleeds

Most patients with anterior nosebleeds will be children or adolescents and will be treated as outpatients in their GP's surgery or at the hospital.

NURSING PRIORITIES AND MANAGEMENT: Anterior nosebleeds

The first priority of nursing intervention will be to stop the bleeding, whilst providing psychological support. The patient should be helped to sit upright with the head slightly forward and asked to mouth breathe and spit out all blood. This helps to estimate the blood loss and prevents the blood from being swallowed and causing nausea. Digital pressure with the thumb and forefinger should be applied to the cartilaginous part of the nose and ice packs to the area above it, i.e. Little's area (see Fig. 14.4). This area has many surface arterioles which may have weakened walls. Ten continuous minutes of this pressure is usually sufficient to control an anterior nosebleed. If these first aid measures fail, or if there are recurrent nosebleeds, the patient will probably be transferred to hospital for insertion of a nasal pack or cautery of the area.

Once the bleeding is under control, the nurse should explain to the patient and, where appropriate, to the parents, how to prevent nosebleeds from recurring. Advice should be given about blowing the nose gently, avoiding picking the nose and trying to keep the nasal mucosa slightly moist by using soft petroleum jelly. An explanation of how to cope with and control a nosebleed should also be given.

Hospital treatment

This will be necessary for severe epistaxis that cannot be controlled by the above measures. By providing clear and concise information, the nurse can help alleviate the patient's anxiety and aid recovery. A specialist nurse can pack the nasal cavity or assist the medical practitioner to do so. When a nasal pack is in place, the patient will only be able to breathe through the mouth and may be afraid of suffocation. Frequent oral hygiene and plenty of oral fluids should be offered to prevent the oral mucosa becoming dry. These drinks must not be hot, as this can cause local dilatation of blood vessels and exacerbate the problem. Eye care may be necessary as the packing may obstruct the nasolacrimal duct, causing tears to overflow. Nasal packing can also cause hypoxia, with disorientation as well as alterations to vital signs. Oxygen therapy and blood gas monitoring will be needed in this situation. The systemic effects of nasal packing were investigated by Ogretmenoglu et al (2002). Their results suggested that bilateral anterior nasal packs caused hypoxia, tachycardia and hypercapnia due to hypoventilation. This led them to recommend that nasal packs be removed as early as possible, and that oxygen therapy be given routinely, especially for patients with cardiopulmonary disease, with appropriate monitoring of O_2 saturation.

Areas that have been cauterised may become encrusted. Soft petroleum jelly should be applied to such areas twice a day for a few weeks until the mucosa has healed.

Some patients admitted as emergencies with uncontrollable nosebleeds will be in hypovolaemic shock (see Ch. 18, p. 718).

For further information on first aid, read Malem & Butler (1993).

14.6 Revise the signs and symptoms of shock so that you can visualise the likely appearance of a patient admitted with severe, uncontrollable epistaxis.

Although anxieties can be reduced by answering the patient's questions and giving information, sedatives may also be prescribed. Following an epistaxis, patients are usually nursed propped up in bed to aid venous return from the area and to make it easier for them to spit out any blood. Ice packs may be applied to the nose to help constrict the vessels and control bleeding. The nurse should explain to the patient how to breathe through the mouth and an emesis basin or sputum carton should be to hand. Again, it is important to offer frequent oral hygiene, plenty of cool drinks and eye care as necessary. As these patients often have dysphagia because of the pressure of the nasal pack on the soft palate, a nutritious soft or even liquid diet may be appropriate. Bed rest is usually advised, although patients should be allowed to use the commode at the side of the bed to ease the strain of elimination.

Packing is usually removed in 2 or 3 days. If the bleeding has not been controlled, the patient will have the appropriate arteries ligated in theatre. If a deviated nasal septum (see p. 606) has been a contributory cause, corrective surgery may be performed.

If hypertension or another medical disorder has caused the nosebleed, an appropriate specialist medical opinion is sought and treatment commenced. The nurse may, in the meantime, obtain appropriate patient education booklets or information sheets in relation to the relevant disorder from colleagues working in the ward(s) specialising in the care of such patients, so that the patient can be given appropriate advice (see Ch. 2).

Community care

To prevent the recurrence of epistaxis, support should continue after the patient has returned home and resumed normal activities. If the patient is at home, the GP and practice nurse will be informed of their condition so

CASE HISTORY 14.1

Mrs E

Mrs E is 58 years old and lives with her husband, who suffers from chronic obstructive airways disease and is unemployed. They have a son and a daughter, both of whom are married and have children. Mrs E works in a television assembly factory and enjoys watching TV, going to bingo and participating in the factory social club. She smokes 20 cigarettes a day and drinks about 14 units of alcohol a week, mainly at the weekend. She often baby-sits for her son and daughter. She has to do all the housework, cooking and shopping as her husband's breathing problems leave him with little energy.

For the past few months Mrs E has been suffering from nosebleeds, but today's was very severe and could not be controlled, even with the help of the occupational health nurse at the factory. She was brought to the local hospital's emergency department (ED) by ambulance. By the time she arrived her blood pressure was 90/50 and her pulse 105; she was pale and shivering. She was also very anxious and frightened.

In the ED an Epistat catheter was inserted and an intravenous infusion commenced. Mrs E was then transferred to the ward where the staff nurse welcomed her and took her to the bed she had prepared. The staff nurse was given a report by the ED nurse and after helping Mrs E to transfer from the trolley to bed she planned to observe her infusion closely and to monitor the bleeding and her blood pressure.

On admission, Mrs E was still anxious and distressed. She was a very fastidious lady and the mess her nosebleed had made concerned her. She was also very worried about what her husband would do for his meal and how he would be kept informed of her condition.

In prioritising Mrs E's needs, the staff nurse took into account the details of her medical condition as well as other concerns that the patient herself felt to be important. She helped Mrs E into a hospital nightgown after washing the blood from her skin and put her blouse into cold water to soak. She checked the infusion and Mrs E's blood pressure, then brought the ward phone to the bedside and telephoned Mrs E's husband. As Mrs E had difficulty talking, because of the nasal catheter, the nurse assisted in a three-way conversation in which Mrs E was reassured that her husband was all right. A neighbour had made his tea for him, and Mrs E's daughter was on her way to the hospital, bringing her mother's toiletries and nightclothes. This conversation reassured Mrs E and allowed her to feel more relaxed. This in turn helped the staff nurse to concentrate on monitoring Mrs E's condition and helping to alleviate her problems.

For further information, see Becker et al (1993).

that they can encourage the patient to implement the advice received in hospital and can monitor hypertension if present.

For information on epistaxis in older people, see Ell & Parker (1992).

STOP THINK

14.7 Using a nursing model familiar to you, prioritise and plan the nursing interventions you think Mrs E (see Case History 14.1) will require over the next 24 h and say how you would evaluate her care. Discuss the plan with your teacher and/or with a qualified member of your nursing team.

DISORDERS OF THE PARANASAL SINUSES

The paranasal sinuses are a group of air spaces surrounding the nose which, it is said, make the skull lighter and add resonance to the voice. They consist of two frontal, two maxillary and two ethmoid sinuses and a single sphenoid sinus divided by a septum. These sinuses all drain into the nose (see Fig. 14.3).

Acute sinusitis

PATHOPHYSIOLOGY

Acute sinusitis is the inflammation of one or more of the paranasal sinuses. It usually develops as an infection secondary to an upper respiratory tract infection or dental disease. Because of the close anatomical connection of the sinuses with the nose, sinus infection is common. It may be acute or chronic.

Common presenting symptoms Pain is a symptom, and it may be facial, supraorbital or interocular, depending on the sinus involved. Tenderness in the area of pain and nasal obstruction may also be features, and nasal discharge may be present. The patient usually complains of general malaise and is pyrexial.

MEDICAL MANAGEMENT

A nasal swab may be taken for culture and sensitivity. Sinus radiography may also be performed to determine which sinuses are affected. Medical treatment usually consists of the prescription of mild analgesics, antibiotics and nasal decongestant drops.

NURSING PRIORITIES AND MANAGEMENT: Acute sinusitis

The patient with acute sinusitis is usually nursed at home, and will be advised to rest in bed, to drink plenty of fluids, to take mild analgesics such as paracetamol and to self-administer any prescribed nasal drops. Oral hygiene is also important as the individual will probably be mouth breathing because of the nasal obstruction. Moist steam inhalations can also bring some relief and help to loosen crusting in the nasal cavities. Many sufferers find inhalations very soothing first thing in the morning and last thing at night. After 2 or 3 days the person should have improved sufficiently to be fully active again.

Chronic sinusitis

PATHOPHYSIOLOGY

Chronic sinusitis is common and can be quite debilitating. It can develop for several reasons, including:

- inadequate treatment of an acute episode
- septal deviation or nasal polyps preventing adequate drainage of the sinuses
- pollution, e.g. cigarette smoke
- allergic nasal disease.

Common presenting symptoms The main symptoms of chronic sinusitis are purulent nasal discharge, postnasal drip, facial pain, headache and recurrent throat infections.

MEDICAL MANAGEMENT

Treatment is initially conservative, consisting of treating any infection with prescribed antibiotics and nasal decongestant sprays. Surgery may be necessary to remove all of the diseased mucosal lining and widen the opening to the nasal passage to allow more effective drainage.

This is functional endoscopic sinus surgery (FESS). FESS is the most recent advance in the surgical management of nasal and paranasal sinus disease. By means of nasal endoscopes, the surgeon is able to visualise, diagnose and treat any disease or deformity. CT and/or MRI scans are vital for both diagnostic and intraoperative use. Meticulous postoperative management and follow-up are essential in achieving effective results.

Possible complications of FESS are:

- haemorrhage
- cerebrospinal fluid leak
- visual disturbance/blindness
- periorbital haematoma.

NURSING PRIORITIES AND MANAGEMENT: Chronic sinusitis

Nursing priorities when caring for these patients are:

- to prepare the patient for surgery and to observe for any possible complications, including haemorrhage and infection
- removal of nasal packing as per the surgeon's instructions
- administration of prescribed analgesics and antibiotics.

On discharge, the patient must be advised on the correct method for instillation of nasal drops and the importance of steam inhalations.

For fuller details of FESS, see Krouse et al (1997).

14.8 Discuss with a patient the experience of nasal packing and its removal.

Nasal injury

PATHOPHYSIOLOGY

Injuries to the nose are fairly common and usually occur in sporting activities, falls, accidents and assaults. A blow to one side of the nose may fracture and displace the bone, causing deviation on the other side. A direct blow to the front of the nose can splay out the nasal bones, resulting in a depressed bridge. An injury that is sufficiently severe to fracture the nasal bones will also cause soft tissue swelling and may cause epistaxis.

MEDICAL MANAGEMENT

Investigations will involve a radiographic examination, although this does not always reveal the fracture or may simply reveal a previously undetected fracture. An examination of the nose using a nasal speculum will allow the practitioner to see if the airways are patent and if there is any damage to the septum. Palpation of the nasal bones must be carried out very gently, as they will be very tender and painful for up to 3 weeks following a fracture.

Treatment of a broken nose involves manipulating the fractured bones. Occasionally this can be done at the time of the accident, but more commonly it is done a few days later, when the oedema has subsided, usually as a day case procedure. The manipulation must be performed within 10 days of injury to prevent calcification of the nasal bones. If the corrected fracture is unstable, a plaster of Paris cast is usually taped in position over the nose for about 10 days to allow the fracture to set correctly.

NURSING PRIORITIES AND MANAGEMENT: Nasal injury

If nursing attention is available immediately, treatment of a fractured nose will probably involve first aid measures to stop any epistaxis and to limit the oedema. This involves compressing the end of the nostrils gently between the thumb and forefinger, which unfortunately will be very painful for the patient, and encouraging the patient to sit with the head slightly forward and to spit out any blood. If ice is available, an ice pack applied to the bridge of the nose can help to control bleeding and swelling. Any epistaxis which results from a blow to the nose is usually short lived.

DISORDERS OF THE NASAL SEPTUM

Deviation of the nasal septum

The nasal septum separates the nostrils. It is usually thin and quite straight. The upper part is composed of bone and the lower part of cartilage. Deviations of the nasal septum can range from a simple bulge to a marked S-shaped deformity. Most people have some degree of deviation; hence, when introducing a nasogastric tube, the patient should always be asked which nostril is easier to breathe through.

PATHOPHYSIOLOGY

Developmental problems or trauma may result in a deviated nasal septum. Patients usually complain of nasal obstruction, infection of the sinuses or chronic otitis media due to the inability of the eustachian tubes to function properly. Any combination of these symptoms may be present, or there may be no symptoms. Simply having a septal deviation is not a reason to operate on it.

MEDICAL MANAGEMENT

An assessment by the medical practitioner of the symptoms, correlated with the degree of the deformity, should be carried out before a treatment plan is agreed. Inspection of the nose with a nasal speculum should reveal the extent of the deviation.

If surgery is the chosen treatment, this is likely to be either a submucous resection or a septoplasty. There is often

some confusion as to what these procedures involve. In both operations, access to the bony and cartilaginous parts of the septum is gained by stripping off the nasal mucosa. In a submucous resection, the affected parts of the septum are removed; during a septoplasty the septum is freed, allowing it to be repositioned along the midline of the nose. A nasal pack is usually inserted following these procedures to prevent haemorrhage.

NURSING PRIORITIES AND MANAGEMENT: Deviation of the nasal septum

Septal surgery is often carried out as a day case and packs can be in place from 4 to 24 h. Nursing care in hospital will be similar to that given for epistaxis (see p. 604). Patients are usually discharged 2–4 h after the nasal packing has been removed. There will be a degree of nasal obstruction for 2 or 3 weeks after surgery, until the post-surgical swelling has subsided. Patients are usually advised to stay away from work or crowded places for 10–14 days after surgery to minimise the risk of infection. They are also advised to follow the surgeon's instructions with regard to steam inhalations, nasal douches or decongestant sprays.

Septal haematoma

This usually results from trauma, including surgery, and is a collection of blood beneath the mucoperichondrium of the septum. The patient complains of nasal obstruction and pain. Examination usually reveals a bilateral swelling in the nasal cavities. Antibiotics are given to prevent infection and it is often necessary to incise and drain the haematoma.

Septal perforation

Trauma or snorted illegal drugs are usually the cause of a hole in the septum. Although the patient is often symptom-free, excessive crusting or epistaxis may occur. Occasionally the patient complains of whistling on inspiration. If symptoms are troublesome, surgical closure may be attempted.

NASAL OBSTRUCTION

Obstruction of the nasal cavities can result from a number of causes but patients usually present with similar symptoms, the most common being obstructed breathing and increased nasal discharge. Some of the most common causes are:

- infection
- allergy
- deviated nasal septum
- foreign bodies
- polyps
- neoplasms.

Nasal obstruction resulting from the first two causes does not usually require hospital treatment. Deviated nasal septum is described above; the other causes are described below.

Foreign bodies in the nose

PATHOPHYSIOLOGY

It is usually very young children, aged 2–4 years, or those with learning difficulties, who insert foreign bodies into the nasal cavity. These objects may be organic or inorganic. Inorganic bodies include buttons, beads and small plastic or metal objects which may lie undetected for a long time, only to be found during a routine examination, sometimes as late as when the child reaches adolescence or adulthood. Organic bodies such as peas, wood, paper, cotton wool or sweets cause a local inflammatory reaction which will eventually lead to the formation of granulation tissue. The resulting nasal discharge will eventually become purulent, foul-smelling and bloodstained. Characteristically, the discharge is from only one cavity.

MEDICAL MANAGEMENT

Following a thorough examination, the foreign body is usually removed in the outpatient department. Occasionally it has been in place for such a long time that a general anaesthetic is needed for smooth and safe removal.

NURSING PRIORITIES AND MANAGEMENT: Foreign bodies in the nose

Support will be given to both the patient and the family as removal can be frightening. Epistaxis is a possible complication following removal, irrespective of the type of anaesthetic used.

Nasal polyps

PATHOPHYSIOLOGY

Nasal polyps are projections of oedematous mucous membrane and may look like bunches of grapes. They result from prolonged infection or allergy and are usually bilateral and multiple. They occur more commonly in adult males than in females.

Common presenting symptoms Patients usually complain of nasal obstruction and discharge. Occasionally the size of the polyps may cause broadening of the external nose. The patient may complain of headaches if there is sinus involvement and there may be loss of smell and taste.

MEDICAL MANAGEMENT

On examination, a characteristic glossy, greyish swelling will be visible. If probed, it will be found to be soft, insensitive and mobile. Surgical removal is the treatment of choice. This may be carried out under local or general anaesthetic. The patient who is given a local anaesthetic will require less time in hospital, but the decongestant that the local anaesthetic contains shrinks the polyps and makes them more difficult to identify and remove. With a general anaesthetic, the polyps can be removed at a less hurried pace but bleeding may be more profuse and might therefore obscure some of the smaller polyps. Recurrences are common and an attempt should be made to treat any underlying infection or allergy.

NURSING PRIORITIES AND MANAGEMENT: Nasal polyps

Nursing staff should be alert to epistaxis, which is the main postoperative complication of polyp removal. Given that polyps can be associated with allergies, many patients may also suffer from asthma and should be closely observed in this regard.

A nasal pack is usually inserted after the procedure. Appropriate nursing care is detailed on page 604. As it is fairly common for polyps to recur, the importance of attending the outpatient department for follow-up should be explained to the patient.

Common problems during nasal surgery

- *Bleeding* — this occurs because the nasal mucosa has such a rich blood supply. It can be controlled by the use of ice packs. If the surgeon suspects that the bleeding might be severe, a nasal pack may be inserted.
- *Oedema* — oedema of the mucosa is likely to occur as a consequence of manipulation. Ice packs may help to minimise swelling.
- *Watery discharge* — the irritation of the mucosa, which results from surgery, will cause the production of an excessive amount of watery discharge known as rhinorrhoea. The nurse should provide an adequate supply of tissues or apply a nasal bolster made of gauze to absorb discharge. This helps to make the problem more manageable.
- *Pain* — as the nose is blocked after surgery, the patient may experience frontal headaches, which should be alleviated by means of prescribed analgesics, e.g. paracetamol.

Neoplasms

Nasal and sinus tumours are rare. When they occur, they are usually unilateral. Malignant tumours are often infected and ulcerated, in which case they usually produce epistaxis or a profuse purulent discharge. Headache may also be a feature if there is sinus involvement.

Treatment may consist of surgery, radiotherapy, chemotherapy or a combination of these. Patients receiving radiotherapy or chemotherapy are usually treated as outpatients and may be visited by community nurses, including Macmillan nurses, if they experience any side-effects of treatment requiring nursing intervention.

For further information on nasal and sinus neoplasms and treatments, see Sigler & Schuring (1993).

THE THROAT

ANATOMY AND PHYSIOLOGY OF THE THROAT

The throat is usually considered to consist of the pharynx and the larynx. The pharynx may be divided into the nasopharynx and the oropharynx.

The nasopharynx extends from the nasal septum to the eustachian tubes and rests behind and above the soft palate. The oropharynx extends from the posterior boundary of the hard palate to the hyoid bone; it contains the uvula and the tonsils and is surrounded by lymphoid tissue.

The larynx is the organ of voice production and airway protection. It is composed mainly of cartilage and muscle and is lined with a mucosa of stratified squamous epithelium (upper part) and ciliated pseudostratified columnar epithelium (lower part).

DISORDERS OF THE THROAT

Benign tumours

These generally arise as a result of voice abuse or overuse and the patient usually presents with continued hoarseness. The tumours are usually attached to the vocal cords and vary greatly in size. Resolution of small nodules may be achieved by voice rest and appropriate speech therapy. Larger nodules may require surgical removal.

For further information on benign and malignant tumours, see Sigler & Schuring (1993).

Carcinoma of the larynx

PATHOPHYSIOLOGY

Carcinoma of the larynx is classified according to its location and extent, i.e. supraglottic (above the vocal cords), glottic (confined to the vocal cords) or subglottic (below the vocal cords) (see Fig. 14.5). It accounts for 1% of all malignant disease and is more common in males than in females. The majority of patients have a history of heavy smoking, although the disorder does occasionally occur in non-smokers. High levels of alcohol consumption can be an influencing factor. The most common form of the disease is squamous cell carcinoma. About 10% of all patients with carcinoma of the larynx have a coexisting carcinoma of the bronchus.

Common presenting symptoms Some patients with laryngeal carcinoma do not seek medical help until the disease is advanced, having ignored the symptom of hoarseness for some time. Occasionally patients are treated initially for laryngitis and by the time a tumour has been diagnosed it is advanced. Otalgia, dyspnoea, dysphagia, neck lumps and weight loss are all symptoms of advanced laryngeal carcinoma. The impact of the diagnosis and the community care needs of a patient newly diagnosed with cancer are discussed by Glover and Cameron (2004).

MEDICAL MANAGEMENT

Carcinoma of the larynx has a high rate of cure if detected early. The form of treatment offered will depend on the site of the tumour and how early it has been detected. If the tumour is confined to the vocal cords it is usually diagnosed as a result of the patient consulting their GP with a history of hoarseness. Patients who have suffered from hoarseness for more than 3 weeks should have a mirror examination of their larynx (indirect laryngoscopy) to investigate the possibility of carcinoma. Diagnosis is confirmed by an examination of the patient's larynx under general anaesthesia (direct laryngoscopy) and a histological examination of a biopsy of the tumour.

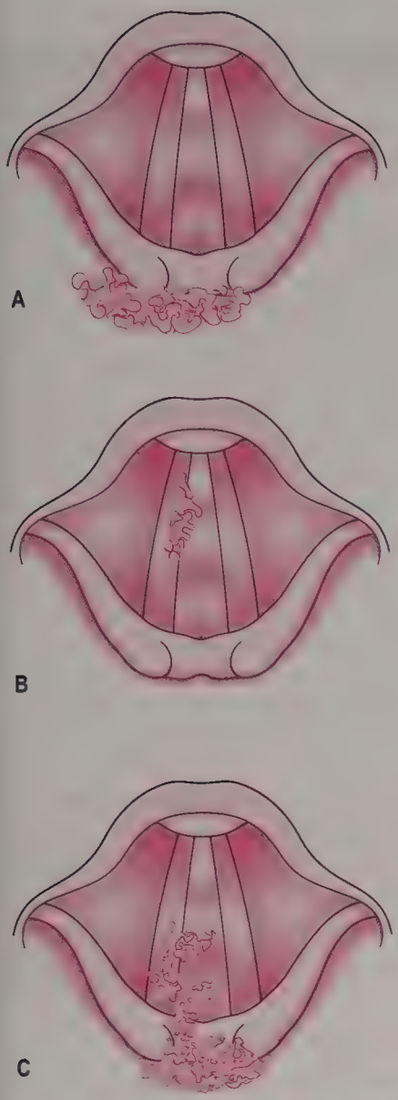

Fig. 14.5 Tumours of the larynx. A: Supraglottic tumour. B: Glottic tumour. C: Subglottic tumour — extensive spread to supraglottic area.

In recent years, in some centres in the UK, there has been increasing use of the CO_2 laser to remove laryngeal tumours, ranging from very small vocal cord (glottic) tumours to larger tumours requiring partial or hemilaryngectomy. When using the laser, it is possible effectively to remove all of the tumour but less of the normal healthy tissue, and so preserve more function. Otherwise, the treatment of choice for a glottic tumour is radiotherapy. If the disease is more extensive and/or invasive, treatment may be radiotherapy, chemoradiation or total laryngectomy.

- In chemoradiation, chemotherapy is given at various points during the radiotherapy course, for example on days 1, 22 and 43. The aim is to provide an effective treatment for the disease, while preserving the larynx.
- Total laryngectomy involves removal of the larynx and the creation of a permanent end tracheostome (see pp. 610–615).

Hanna et al (2004) undertook a non-randomised retrospective study of 42 patients, 23 of whom had had a total laryngectomy and postoperative radiotherapy, and 19 who had concurrent chemoradiation, with the aim of comparing quality of life between the two groups. Overall, the scores for both groups were similar, with no statistically significant differences noted. However, there were differences between patient experiences; for example, the surgical group reported greater difficulties with social functioning, while the chemoradiation patients reported greater difficulty coping with a dry mouth.

Laryngeal surgery may also have to be performed on patients who have a residual or recurrent tumour following radiotherapy. Nursing interventions appropriate to this procedure are outlined in the next section.

The lymphatic nodes in the neck are the most likely site for metastatic spread from a laryngeal tumour. If the nodes are involved they are treated by removal, i.e. a selective neck dissection, either as a separate surgical procedure, if the primary site is being treated by radiotherapy or laser excision, or at the same time as total laryngectomy.

Very advanced tumours of the larynx may be considered inoperable, in which case the patient may be given palliative radiotherapy and/or chemotherapy to relieve some of the more distressing symptoms of the disease (see Ch. 31). In addition, a tracheostomy is sometimes performed to relieve any respiratory obstruction and a percutaneous endoscopic gastrostomy (PEG) tube inserted to aid nutrition, hydration, administration of medications and patient comfort.

A study undertaken by Forbes (1997) indicated that the most frequent symptoms and problems experienced by head and neck cancer patients, in a palliative care situation, are pain, weight loss, feeding difficulties, respiratory problems and communication difficulties.

Laryngectomy

Preoperative preparation

Various members of the multidisciplinary team (MDT) will spend some time with the patient and family prior to surgery to explain the operation and its after-effects. This team will consist of medical and nursing staff, including the clinical nurse specialist (CNS), speech and language therapist (SALT), physiotherapist, medical social worker, dietitian and, often, former patients who have had a laryngectomy. Most centres have written information that can be used to supplement oral information. NHS policy (DH 2000) has emphasised the need for good communication between health professionals and patients. The provision of high quality information is an essential part of care.

The role of the head and neck oncology CNS is fully discussed in Semple (2002). For further details on creating information for patients with head and neck cancer, see Semple & McGowan (2002), and for laryngectomy see the NALC website (see 'Useful websites').

Physical preparation Diagnostic radiography of the neck and chest is performed and CT scan or MRI carried out. A full blood analysis is made. Total laryngectomy may also include a partial thyroidectomy, so thyroid function must be checked pre- and postoperatively (see Ch. 5).

An electrocardiograph (ECG) is ordered to check heart function (see Ch. 2). The patient will also be given a dental check-up and receive any necessary dental treatment to help circumvent the risk of pathogenic organisms in the oral cavity. Local preparation of the skin may be required, for example if the patient has a beard.

NURSING PRIORITIES AND MANAGEMENT: Total laryngectomy

Preoperative priorities

The nurse's priorities at this stage will centre on providing support and information for both the patient and the family and preparing the patient physically and psychologically for the operation (see Ch. 26; see also Research Abstract 14.2).

14.9 Consider Case History 14.2. What information would you consider it important to obtain during an initial chat with Mr G to help you plan his nursing care?

Discuss this with your colleagues and check your ideas with your teacher or a qualified member of the nursing team.

The patient is usually admitted at least one day before surgery. It is important for the patient to get to know the team members at this stage, and in some units it is possible to meet the community nurse who will be helping the patient on returning home.

RESEARCH ABSTRACT 14.2

Laryngectomy: the patient's view

This study of laryngectomy, which looked at the incidence of disability and acceptability, was carried out in Wolverhampton. Data were collected using a 10-question questionnaire. Of the 82 patients approached, 65 replied, giving a response rate of 79%. Of the 65 who responded, 54 had undergone a total laryngectomy and 11 had this operation combined with a partial pharyngectomy. The average age was 68 years, the male:female ratio was 3:1, and the time since surgery ranged from 6 months to 35 years.

Respondents had experienced a substantial number and range of problems. These included having a worse sense of smell, being unable to blow their nose, experiencing difficulties in swallowing, an increase in chest infections, and stomal crusting or bleeding. None of the respondents reported weight loss and a majority were satisfied with their voice rehabilitation. Communication methods did not include voice prosthesis so one could reasonably expect this satisfaction rate to be higher now. Generally, respondents who felt they had achieved satisfactory rehabilitation indicated no reduction in their social acceptability. Of the 54 people who replied to the question about their sexual activity, 34 said there was no restriction. Most of those who had enjoyed swimming prior to surgery (29%) expressed their unhappiness at being unable to continue. The availability of stoma swimming aids may help those anxious to swim again. A disappointing 9% of respondents continued to smoke, most having changed from cigarettes to pipe or cigars.

Despite their problems, 91% of respondents considered the operation to have been worthwhile and 78% had found a laryngectomy club to be useful.

These findings can and should be used to better inform patients preoperatively and to act as a focus for postoperative problem identification and education.

Jay S, Ruddy J, Cullen R J 1991 Laryngectomy: the patients' view. Journal of Laryngology and Otology 105: 934–938

CASE HISTORY 14.2

Mr G

Mr G is a 64-year-old retired labourer. A widower, with a married daughter Ann, who lives in Canada with her husband and two young children, he has no other family. He lives alone, but has helpful neighbours. He is a keen bowler and enjoys the social side of the bowling club. He also reads a lot and listens to music.

Mr G has been diagnosed as having a subglottic tumour with extensive spread and is to be admitted to hospital for a total laryngectomy and selective neck dissection of left lymph nodes. Ann and her family have made plans to come home and spend 2 weeks with Mr G in his own home following his expected discharge from hospital in 3 weeks' time.

Mr G arrives at the ward with his friend Mr J and is welcomed by the staff nurse, who takes Mr G to a four-bed room and explains that he will be there until his operation, after which he will be in a high dependency unit for one or two nights before returning to the ward. The nurse leaves Mr G and his friend to unpack his bag and then returns with a cup of tea for them both. She asks about his activities of living with a view to planning his nursing care. Whilst discussing his social situation and lifestyle, Mr G tells the staff nurse he smokes 20 cigarettes a day and consumes about 30 units of alcohol a week and has continued with this pattern for many years. She takes this opportunity to discuss the advantages of stopping smoking with him and, with his consent, refers him to the smoking cessation advisor with a view to him stopping smoking and starting nicotine replacement therapy the next day. Since Mr G's nearest relative is his wife's sister, who lives 200 miles away, he gives her name and that of his friend as next of kin. His friend tells the staff nurse that he and his wife will visit and do Mr G's washing for him.

For further information on helping people stop smoking, see Haw (2002).

The patient and family will need support in adjusting to the diagnosis of cancer and the altered body image which will result from this type of surgery (Price 1998) (see Case History 14.2).

Patients undergoing total laryngectomy will need to be prepared for the fact that they will have a permanent 'hole' in the neck through which they breathe. They will be unable to talk initially. They will be able to swim only under supervision and after receiving advice and guidance on the use of special stoma devices. They will lose their sense of smell because they take in air through the mouth and stoma rather than the nose. In view of these after-effects, some patients will refuse surgery altogether, a decision which may be very difficult for families and members of the health care team to accept.

To aid observation, the patient is usually nursed in a single room, being admitted into this room in order to become familiar with the surroundings. A nasogastric or stomagastric tube will be present postoperatively for feeding, as well as i.v. infusions, oxygen and wound drains. These, along with tracheal suction, humidification and practical aspects of care, need to be demonstrated and discussed preoperatively to help reduce anxiety and thereby aid recovery (Feber 1998).

An appropriate means of communication, which works for the patient, the family and the members of the

multidisciplinary team (MDT), should be arranged before surgery. For example, a pad and pencil would usually be kept close to hand, but if the patient has literacy difficulties or problems with sight, other means of communication must be sought. The establishment of a good communication scheme preoperatively will help the patient to regain confidence postoperatively and should minimise frustration.

The SALT will visit the patient preoperatively to explain their role, and may suggest that a visit from a previous laryngectomy patient would be of benefit. This visitor must be someone who has developed good speech, is an effective communicator and is well integrated back into the community. During this visit it may be suggested that the patient look at the visitor's stoma, but this issue is not forced. If well planned, these visits can be very reassuring to the patient and family. Some people refuse the offer of such a visitor and their choice must be respected.

The physiotherapist will also assess the patient prior to surgery, explaining their role in the patient's postoperative care and teaching them deep breathing and leg exercises.

In the period leading up to surgery, it is important that any malnourishment is corrected by enteral or parenteral supplements. The dietitian or nursing staff will assess the patient's nutritional state preoperatively and will explain to the patient how they will be fed postoperatively. A study by Lennie et al (2001) indicates that more preoperative information and education on what to expect postoperatively is needed (see Research Abstract 14.3). Kelsey (1997) describes a successful nutritional assessment tool. The duration of parenteral feeding is dependent on the type of surgery performed and the state of the wound.

Postoperative priorities

Immediately following surgery the main nursing priorities will be maintenance of a clear airway (see Box 14.5), observation of the tracheostome, management of pain, establishment of good communication with the patient, and reassurance and support of the patient and family.

The patient will be nursed in the semi-recumbent position initially and then gradually encouraged to sit more upright to aid respiration and neck drainage. It is important that the patient's head is flexed slightly forward to ease tension on the suture lines. When the patient is being moved, the head should always be supported.

Initially the patient's vital signs should be recorded at half-hourly intervals; as these become stable within the normal range, recordings can be reduced to 4-hourly. In the immediate postoperative period the naso/stomagastric tube should be on free drainage to prevent vomiting. This allows the pharyngeal repair to heal and prevents fistula

RESEARCH ABSTRACT 14.3

Are we preparing laryngectomy patients adequately for changes in eating habits?

This descriptive study obtained its sample from a national internet-based laryngectomy support group in the United States. There were 34 returned questionnaires (an 83% response rate); 85% of the respondents were male. The mean age was 62 years (range 47–76) with an average of 5 years since laryngectomy had been performed. The participants completed a Food Eating Experiences and Diet Questionnaire which was designed by the researchers to provide qualitative and quantitative data.

A pilot study which tested the questionnaire on five laryngectomees resulted in some modifications to content and clarity. There were five sections to the questionnaire with the first three focusing on potential changes related to different aspects of eating. The fourth section measured perception of hunger and appetite. The last section obtained perception of information given by health care professionals on potential changes in eating following laryngectomy. In each section data were collected by either or both Likert and visual analogue scales, with an area for free text to make comments or give explanations.

Ninety per cent of the participants experienced some change. Most frequently noted were decreases in smell, taste, the overall enjoyment of eating and desire to try new foods and an increase in the time it took to eat meals. Fifty per cent of the participants found they took at least 10 min longer to eat a meal. For the majority, laryngectomy did not affect their perception of hunger and appetite and the number of meals eaten each day. A large number indicated their lack of satisfaction with the information related to eating and nutrition which they had received prior to surgery. Comments indicated that the information was either insufficient or incomplete, with the loss of taste and smell in particular needing more attention. Some respondents felt the information received focused primarily on speech changes. Most participants found themselves looking for information on eating and nutrition from a variety of non-health care sources including laryngectomee support groups and websites.

The results indicated that, as well as increasing the amount and detail of preoperative information and teaching on alterations following laryngectomy, facilitating access to laryngectomy information sources and support groups was a worthwhile intervention. Solving these problems can be made easier by discussing them with those who have experienced the same or similar problems.

Lennie T A, Christman S K, Jadack R A 2001 Educational needs and altered eating habits following a total laryngectomy. Oncology Nursing Forum 28(4): 667–674

Box 14.5

Resuscitation of a 'neck breathing' patient

The principles of resuscitation of a 'neck breathing' patient are the same as those for any other patient, although a few alterations of technique apply. The ABCs of first aid — airway, breathing and circulation — are given top priority.

Initially, the stoma would be covered by the resuscitator's mouth, but as soon as possible a cuffed tracheal tube should be inserted, and inflated to prevent any leakage of the air which is being introduced by the resuscitator. The tube should then be connected to an Ambu bag and resuscitation continued as normal. The National Association of Laryngectomee Clubs has a video, *LIFE*, which demonstrates the correct methods (see 'Useful websites').

Box 14.6

Potential complications of laryngectomy

Psychosocial distress
Laryngectomy can be viewed as a series of losses which present enormous challenges and require a great deal of adaptation. It can result in psychological morbidity, including depression, low self-esteem, poor sleep, fears of isolation and rejection. Feber (2000) makes the point that, when measuring the success of their surgery, patients include social, economic and cultural as well as medical factors.

Blockage of the trachea
This potentially life-threatening complication can occur if the trachea has not been sufficiently humidified and the stoma cleaned. The potential for tracheal blockage should be stressed during the educational preparation of the patient for discharge, as it tends to occur when patients have returned to the community and have not cared for their stoma, in particular the humidification and cleansing aspects of care, as taught in hospital. As a result, mucus will have been allowed to accumulate in and around the stoma where it has dried to produce a crust which can become large enough to cause an obstruction to the airway. Postoperative radiotherapy which includes the trachea in the fields can cause mucositis of the tracheal lining and viscous secretions which can produce a similar result.

Stenosis of the tracheostome
Like tracheal blockage, this complication is potentially life threatening and may occur when the patient has returned to the community. It may be the result of fibrosis occurring as healing takes place, in which case wearing a stoma button or tube for part or all of the time can be an effective preventive method. The patient should have been made aware of this potential problem and taught that observation of stoma size, using a stoma gauge if necessary, is an essential part of daily stoma care and that help should be sought if there is any reduction in size or difficulty in breathing. Some patients may need a stomaplasty, a refashioning procedure which will increase the size of the stoma.

Failure to produce voice
Coltart (1998) discusses why, despite advances including surgical voice restoration and the use of voice prostheses, not all patients learn to speak again but become dependent on non-verbal communication.

Fistula formation
If the pharyngeal repair breaks down, a fistula may form which allows saliva and food to leak from the incision, causing excoriation of the skin and possibly leading to infection. This is usually treated by inserting a feeding tube, if one is not already in place, and ensuring that the patient does not take any oral fluids until healing has taken place. Reilly (1998) gives a comprehensive overview of enteral feeding, including techniques which can be used in this situation. Healing may take several weeks and antibiotics may be prescribed if infection is present. If the fistula does not heal spontaneously, surgical closure may be necessary.

Wound breakdown
This is most likely to occur in patients who have had radiotherapy prior to surgery. Careful wound care can help to prevent its occurrence.

formation (see Box 14.6). A stomagastric tube is inserted through a created tracheo-oesophageal fistula, which is later used for a voice prosthesis.

Once bowel sounds have been detected, usually 24 h postoperatively, the patient can commence fluids. Water is given first, then full-strength feeding is gradually established. This gradual progression is necessary to avoid the problems of vomiting and diarrhoea. The nurse must check that the naso/stomagastric tube is in the correct position. Once naso/stomagastric feeding has been established, the i.v. infusion will be discontinued.

14.10 What are the methods for confirming that the naso/stomagastric tubes are correctly positioned in the stomach? (See Ch. 21.)

Humidified oxygen is administered to the patient during the immediate postoperative period to help keep the lining of the tracheal mucosa and the inspired gases moist (Baxter et al 1993). The patient may have a cuffed (preferably with a low-pressure cuff) tracheostomy tube in position (see Fig. 14.7, p. 616). The cuff pressure must be recorded and released as soon as possible to prevent damage to the tracheal lining. The tube is usually removed 24–48 h after surgery. Some patients return from theatre without a tube in position; here careful observation of the stoma for swelling or obstruction will be necessary. Normally, excessive secretions are moved into the trachea by ciliary action and expelled by coughing. For the new laryngectomy patient, this can be difficult, and tracheal suction is necessary in the immediate postoperative period as these secretions can be excessive and the patient is able to make only limited coughing movements.

A drain will be present on each side of the neck. These drains must be patent at all times. The colour, nature and amount of drainage must be recorded. The wound is closed with fine sutures or clips and may be covered by a clear plastic dressing to aid observation. Stoma care is performed as necessary and usually at least twice daily postoperatively to prevent crusting and infection.

Good pressure area care is necessary in the first 24 h, but care must be taken when moving the patient due to the neck wound. A 2-hourly change of position should be carried out and full use made of special mattresses.

The immediate postoperative period can be very difficult for the patient and family as they realise the full implications of the surgery. Often the patient is very agitated the first time they are sufficiently awake to ask for something and discover that they have no voice. The communication skills of the ENT nurse are especially important at this time. The nurse should remind the patient of the prearranged communication plan and display patience and understanding (see Box 14.7). The patient should never be left without any means of communication or help such as a buzzer or bell. This is very important for the patient's confidence to avoid the very natural fear of requiring tracheal suction and not being able to attract attention.

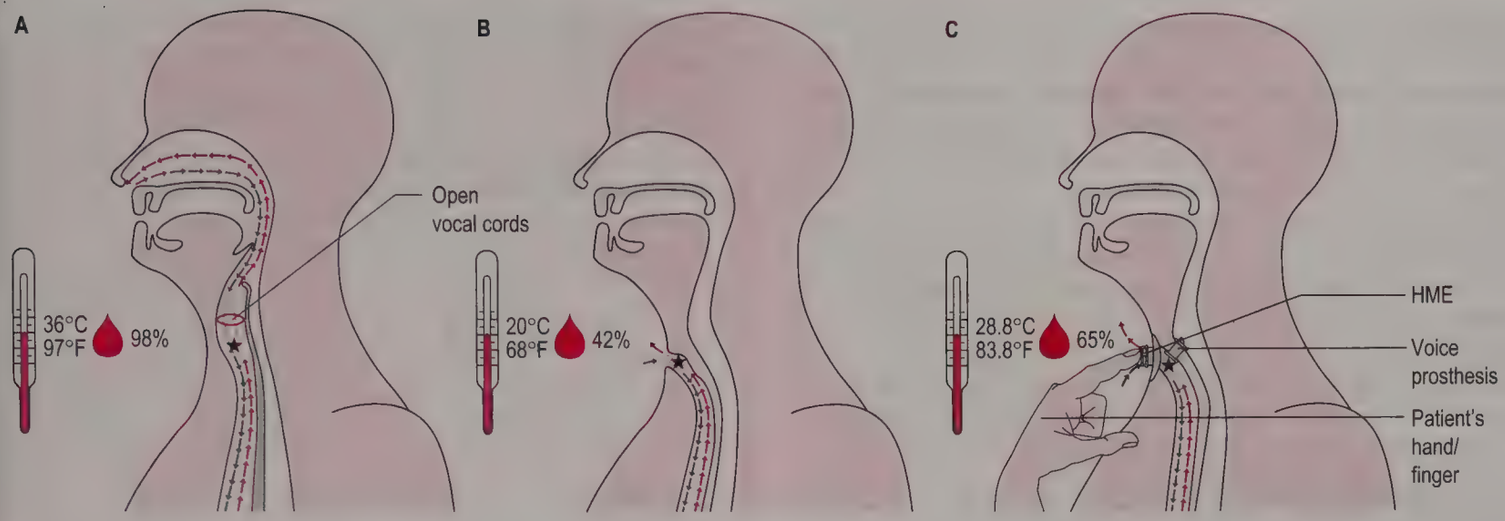

Fig. 14.6 Pre- and post-laryngectomy humidification and temperature levels, with HME and voice prosthesis in place. A: Before laryngectomy the humidification and temperature are at high levels. B: After laryngectomy they drop drastically, leading to excessive mucus production and coughing. C: With an HME a significant improvement in the humidity and temperature is obtained, reducing physical and psychological problems. The HME is being used in combination with a Provo voice prosthesis. (Adapted with kind permission from Platon Medical Ltd.)

Box 14.7

Communication with a person who has lost the ability to speak following head and neck surgery

- As much preoperative explanation and information as possible should be given in the time available.
- Adequate materials, e.g. pen, paper, picture cards or 'magic' slate, should be available, and be seen by the patient to be available, before surgery and subsequently at all times.
- Be patient, and maintain a calm and unhurried atmosphere.
- Always give encouragement and praise.
- Remember that previous hearing levels have not been altered. There is no need for you to raise your voice or write down information.
- Pay extra special attention to non-verbal communication such as facial expression, hand and body positions and movements.
- Stress that the inability to communicate is temporary; skill levels will considerably improve in almost all patients.
- Communicating by writing only is difficult for most. The following points are worth remembering:
  - — some people are unable to read or write, i.e. they are illiterate
  - — writing takes much longer than speaking
  - — writing can be disruptive of thought processes
  - — for most people it is difficult to communicate depth of emotions and feelings by the written word
  - — lack of privacy (? use 'magic' slate which can be immediately erased)
  - — never read a previously written communication unless invited to do so.
- Do not ask two questions at once.
- On occasions, ask questions that only require a yes or no answer.
- Develop your own lip-reading skills.
- Do not finish sentences for the person.
- If the person is only able to say the first few words or part of a sentence, repeat what you have understood and ask them to fill in on what you have missed.

Mouth care is particularly important while the nasogastric tube is in position. The specific mouth care given to each patient will be determined by individual assessment.

14.11 Try not speaking for a minimum of 1 h during an average non-working day. Record how you felt during this time, indicating the number of times you went to speak and the times you actually were unable to stop yourself automatically speaking. Discuss your findings with your mentor or personal tutor.

On the first or second postoperative day, the patient is usually well enough to be helped out of bed and begin walking. Over the following days the patient should be encouraged to increase activity until fully ambulant.

Naso/stomagastric feeding is continued until the patient's pharyngeal repair is fully healed, usually 10–14 days after surgery. This is tested by a SALT, who administers a swallowing assessment, which involves giving the patient a drink of dye and observing the wound for any signs of leakage. If the wound appears to have healed, the naso/stomagastric tube is removed at the surgeon's discretion and the patient is allowed to commence a soft diet. Foods should be of a gradually increasing consistency until a normal diet for that person is tolerated. However, Lennie et al (2001) found that many have significant long-term alterations to eating habits (see Research Abstract 14.3).

Wound drains are removed when drainage is minimal (approximately 3–4 days after surgery). The neck sutures may be removed around the seventh day, or later if the patient has had previous radiotherapy. Stoma sutures are usually removed after 10 days.

Tracheal suction is given when necessary, but the need for this should gradually diminish as the patient's cough reflexes become stronger. Stoma care is continuous; the nurse should encourage the patient to participate in this. Mechanical humidification may still be required at certain times (see Fig. 14.6); alternatively, a Buchanan laryngectomy protector or similar other lightweight protector may be worn. A heat moisture exchanger (HME) is a highly effective and increasingly popular means of providing humidification

(see Fig. 14.6c). It is a small, disposable, lightweight device which can fit on to a base plate over the stoma or be connected directly to a tube. The patient must be taught how to remove any crusting which may form around the stoma. Patients needing to wear a tube or stoma button must be shown how to clean and change it.

Rehabilitation of the patient should start as soon as possible; ideally, this will involve the supportive participation of the patient's family and of the community nurse. Dropkin (1989), in her seminal work on the relationship between disfigurement, dysfunction and coping ability, found that between the fourth and sixth postoperative days could be considered the most significant time in terms of accepting the defect. Acceptance may be shown by the performance of self-care tasks, which is then followed by re-socialisation behaviours. Lack of achievement in these areas indicates a need for increased nursing intervention. The patient will first need to become accustomed to their altered appearance. If appropriate, they could be given a hand mirror, perhaps on the second postoperative day, after the nurse has explained what they should expect. The presence of family members at this time might be helpful but the patient should make the decision about this. Progress in wound healing and a decrease in face and neck swelling over a period of days can be encouraging for the patient. Once accustomed to looking in a mirror, the patient should be encouraged to wipe away secretions from the stoma, gradually progressing to performing stoma care and changing the stoma tube or button by themselves. The patient must be made aware of the importance of wearing a protector for humidification purposes to prevent the formation of crusts which can cause obstruction as well as a predisposition to chest infections.

Voice rehabilitation

Coltart (1998) considers what forms of operative planning will be most appropriate to achieve the best results for the patient. The surgeon, with the SALT and other members of the MDT, will have discussed voice rehabilitation with the patient preoperatively. In selecting the most appropriate voice aid, they will have addressed the physical, social and psychological needs of the patient, as not every voice aid is suited to all patients.

Following laryngectomy, voice rehabilitation will begin when the surgeon and SALT are satisfied that the wounds are adequately healed. Some patients will be reviewed in outpatient departments for fitting of a prosthesis. The SALT will see patients on a regular basis to teach the use of the aid. It is important to advise patients that it can take time to achieve coherent speech again.

Once the naso/stomagastric tube has been removed, the SALT can begin to start voice rehabilitation by means of speaking valves or oesophageal speech. If the patient has mastered a few simple words prior to discharge, their confidence may be increased tremendously. Motivation and support are important factors in the acquisition of speech; again, the participation of the patient's family can be of enormous benefit. Following discharge the patient will continue to attend for speech therapy. Voice restoration methods available for individuals who have undergone laryngectomy are described in Box 14.8.

Box 14.8

Voice restoration after laryngectomy

Tracheo-oesophageal puncture with voice prosthesis
The voice prosthesis is a valve which can be inserted into a puncture created at the time of laryngectomy (primary puncture) or later (secondary puncture). The patient breathes in, covers their stoma with a finger, thus forcing the expired air through the valve and producing voice. Alternatively, a special housing and 'hands free' system incorporating a heat moisture exchanger (HME), which opens on inspiration and closes on expiration, can be used instead of the patient's finger (see Fig. 14.6). The speech and language therapist (SALT) and specialist nursing staff teach the patient how to care for the valve and other devices.

Oesophageal speech
Oesophageal speech was formerly the only method available to restore voice after laryngectomy. In order to master this technique, the patient should have regular sessions with a specialised SALT over a period of months at least. Success rates are very variable. If a valve has been inserted, most SALTs will still teach this method alongside the techniques used with valves, as no single method can guarantee success.

Electronic vibrator or artificial larynx
This device, when applied to the soft tissues of the neck, produces a tone, so that, when the patient articulates, sound is produced. Initially, it can take some time to find the exact place on the neck which gives the best result. The sound produced is monotonous and somewhat mechanical, and for these reasons it is unacceptable to some. It can also be of limited use if the neck is tender or painful.

Pen and paper, hand-held computer
Either of these methods is used by some people, from preference or if all of the above approaches have been unsuccessful.

Preparation for discharge

By demonstrating patience and understanding and sensitively implementing a planned rehabilitation programme, the MDT can help to build up the patient's confidence prior to discharge, to try to ensure that the patient will be able to cope with any problem that may arise. The patient should feel at ease with the stoma and be confident in caring for it and for any voice prosthesis. They should be encouraged to socialise with other patients, perhaps by moving to a multi-bed room. Most centres use a staged discharge plan with the patient going home for at least one overnight stay or weekend before discharge.

Mason et al (1992) describe a stepwise method for teaching self-care to laryngectomy patients prior to discharge, called the Nottingham system. The aim is to identify problems early, assess progress continuously and provide extra support when needed. Tracheostome care is divided into 10 different aspects of care, e.g. removing the tube, cleaning the stoma and skin care. Each element of care is then broken down into five teaching phases, commencing with the professional performing the task and ending when the patient is totally self-caring. The date of successful

completion of each phase is recorded. Before starting the teaching plan an agreement is reached between patient and professionals on the anticipated number of days required to reach competence. If a patient is found to require a considerably longer time to gain competence in any aspect of self-care, the GP is informed of the likely need for extra support. Although the Nottingham system was devised for laryngectomy patients, it can just as easily be used for those who have had a tracheostomy.

The community nursing services will be involved in preparations for the patient's return home. They will be contacted by ward staff as soon as a discharge date has been decided. The community nurse's main role is one of support and they will withdraw services slowly as the patient becomes increasingly confident at home. It is important to support the patient's partner and family as they also have just experienced challenging situations. Vickery et al (2003) found some partners experienced more distress than the patients.

A social worker is often required to help patients and their families with practical difficulties before, during and following surgery. Some individuals who have undergone a laryngectomy may be unable to return to their former employment. For example, those who were previously employed doing heavy manual labour will be unable to resume such work because, following laryngectomy, they are unable to hold their breath and increase intrathoracic pressure. Negotiation between the social worker and the employer to try to find a feasible job reallocation may allow such a patient to continue working. However, if continued employment is impossible, the social worker and/or a benefits advisor will assist patients to receive all the social security benefits to which they are entitled. The social worker or CNS may also be able to help patients and their families with travelling expenses during the treatment programme by obtaining a cancer charity grant.

Patients will attend the ENT or head and neck oncology outpatient clinic after discharge to ensure that no problems arise with which they feel unable to cope. The National Association of Laryngectomee Clubs (NALC) circulates a regular newsletter and has branches in most areas of the UK (see 'Useful websites'). The support that this Association can give is invaluable to many patients, who greatly benefit from the opportunity to share experiences and talk about problems with others in a similar situation. Many patients also form lasting friendships with those laryngectomy patient(s) who visited them preoperatively. NALC holds regular national study days for nurses and other health care professionals.

For further information on coping with dysfunction and disfigurement after head and neck cancer surgery, see Dropkin (1989, 1997). For information on promoting self-esteem after laryngectomy, see Feber (1996). More information on rehabilitation is to be found in Clarke (1998) and on post-discharge care in the community on the NALC website (see 'Useful websites').

Tracheostomy

The surgical procedure of tracheostomy involves making an opening through the skin and structures of the neck into the trachea. It is one of the earliest operations described; there is evidence that it was performed by the Egyptians in biblical times.

A tracheostomy may be short or long term and may be planned as elective surgery or performed as an emergency procedure.

Indications

The indications for a tracheostomy are as follows:

- *Airway obstruction* — this may be caused by the inhalation and impaction of a foreign body in the larynx. Severe inflammation may also cause obstruction, as might laryngeal cancer which is being treated by radiotherapy.
- *Bronchial toilet* — after head injury, drug overdose, cerebrovascular accident, coma or certain neurological disorders, the patient may require assistance with respiration and removal of bronchial secretions.
- *Need to improve respiratory efficiency* — when patients with impaired respiration are relying on their own efforts rather than assisted ventilation, the performance of a tracheostomy cuts down dead space and improves respiratory efficiency by 30–50% (Serra 1998).
- *Artificial ventilation* — if artificial ventilation is required for more than 72 h, a tracheostomy may be indicated, as it has been shown that endotracheal intubation for 72 h or longer can cause laryngotracheal damage.
- *Major head and neck surgery* — a tracheostomy will maintain the airway and protect it from haemorrhage and obstruction due to oedema both during and after surgery (see also Ch. 28).

Box 14.9 lists some of the indications for short- and long-term tracheostomies.

MEDICAL MANAGEMENT

Prior to performing a tracheostomy, the medical staff must explain to the conscious patient what is involved and the effect the procedure will have. In an emergency situation, such as when the patient presents with stridor or is unconscious, the medical and nursing staff will have minimal opportunity or time to prepare the patient pre-operatively. Consequently, a planned programme of support and explanation will be required afterwards.

Box 14.9

Indications for tracheostomy

Short-term tracheostomy
- Assisted ventilation
- Burns and scalds
- Foreign body lodged in trachea
- Major head and neck surgery
- Severe infection
- Trauma to larynx, face, mouth or oropharynx
- Vocal cord paralysis

Long-term tracheostomy
- Congenital deformity
- Trauma causing permanent damage
- Untreatable tumours, causing airway obstruction
- Vocal cord paralysis

Tracheostomy is usually carried out with the patient under a general anaesthetic, but in emergencies a local anaesthetic may be used. Tracheostomy involves making an incision into the trachea through the third and fourth tracheal rings. The percutaneous or mini-tracheostomy is infrequently used in the ENT situation.

For further information on this, see Fisher & Howard (1992).

An appropriately sized tracheostomy tube is then inserted. For the first 24–48 h, a cuffed tracheostomy tube (see Fig. 14.7) is normally used to prevent blood from the wound being aspirated and aspiration pneumonia developing. A permanent tract usually forms 2–3 days postoperatively, at which time it is possible to change the tube. Tracheal dilators must always be to hand in case the tube is expelled accidentally and it is necessary to keep the stoma open. Most hospitals have a policy regarding the first tube change, which is likely to be performed by medical staff or experienced nursing staff with medical back-up.

There are several types of tracheostomy tube available, and the most appropriate one will be chosen for each patient. As mentioned above, a cuffed tube, preferably with a low-pressure cuff, may be inserted during the operation. Single-use disposable tubes are usually employed and may be cuffed or plain. All tubes have an introducer, which is removed immediately on insertion, and an inner tube, which can be removed for cleaning without necessitating removal of the whole tube. Most tubes are made of polyvinyl chloride (PVC) and silicone, although silver tubes are occasionally used.

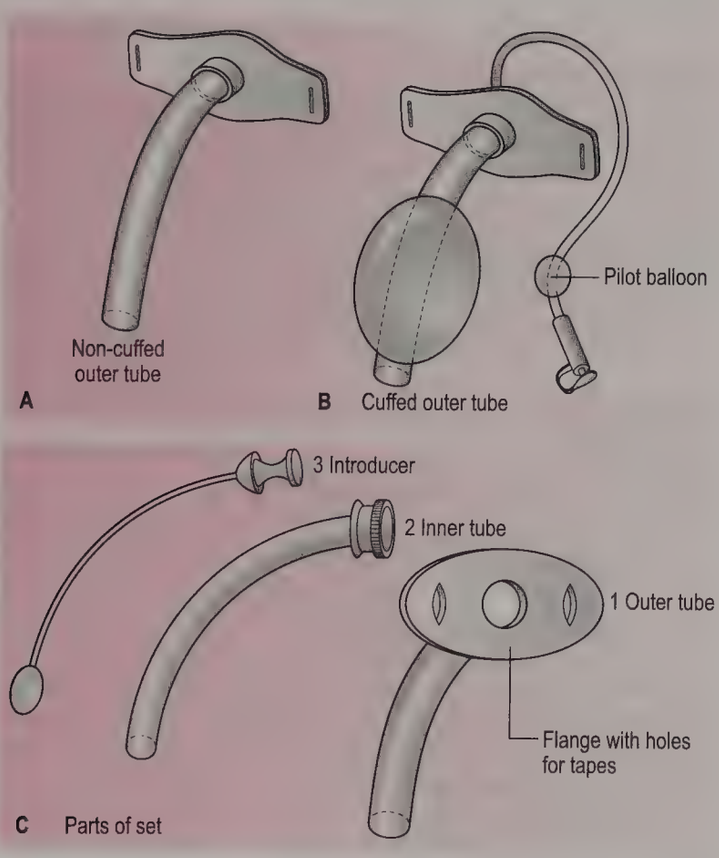

Fig. 14.7 Tracheostomy tubes in common use. A: Non-cuffed outer tube. B: Cuffed outer tube. C: Parts of tracheostomy tube set.

NURSING PRIORITIES AND MANAGEMENT: Tracheostomy

Preoperative priorities

Physical and psychological preparation of the individual for a tracheostomy is a priority of preoperative nursing care as the procedure can cause many difficulties. If the tracheostomy is short term, these problems will be of limited duration, but if it is to be long term, the patient and family will require additional information and education. They may need help in coming to terms not only with the problems presented by the stoma but also with the diagnosis, e.g. cancer, that necessitated surgery. Patients who have been well prepared for a tracheostomy tend to cope better than those who have not. Unprepared patients may become insecure, withdrawn and depressed. The main problems in the immediate postoperative period, for which the patient has to be prepared prior to surgery, are as follows:

Temporary loss of voice Air will bypass the vocal cords following the tracheostomy, making speech impossible unless a tube with a speaking valve is inserted. A system of communication whereby the patient can make themselves understood by staff and family members should be worked out beforehand (see p. 611 and Box 14.7).

Altered body image Body image is concerned with the control and function as well as physical appearance of the body. The very thought of coughing out sputum, which most people usually go to great lengths to hide, but which in the case of the patient who has a tracheostomy must be done through an open hole and tube in their neck, as well as their need for suction, is not easy to understand and accept. High quality information and education must be offered to help the patient and family adjust to the presence of a tube in the neck. A visit from a patient who has adjusted well to having a tracheostomy may help.

Increased secretions These are produced because of the irritation caused by the tube and air bypassing the nose. This should be explained to the patient along with the need for suction. It is helpful, if possible, to show the equipment required for this prior to surgery.

Ideally, a patient undergoing tracheostomy should be nursed in a single room initially and care assigned to one nurse who can gain the confidence of the patient and family.

Postoperative priorities

Maintenance of the airway

On return to the ward the patient should be nursed in a sitting position with the neck well supported; the tapes around the neck, which are fixed to the flange of the tracheostomy tube, must be tied securely in position.

Suction should be carried out when necessary. To prevent infection, it is necessary to perform this procedure with a clean technique, according to Harris (1984) and Harris and Hyman (1984), whose research has not yet been superseded (see also Ch. 28). A sterile catheter should be used each time and should touch only the inside of the tracheostomy tube. The catheter diameter should be no more than half that

of the tube to allow adequate flow of gases around it. If it is too wide, it will draw air out of the lungs more quickly than it can be replaced, which can cause atelectasis. Griggs (1998) gives a formula and chart to allow calculation of the correct catheter size.

Suction should be applied only as the catheter is being removed. Thumb-control catheters are ideal for this. Since the patient is unable to breathe during suction, it should be performed for no longer than 10–15 s; the patient should be allowed enough time to recover before it is repeated. The amount and type of secretions should be observed and recorded. A study on tracheal suction by Day et al (2002) indicated poor levels of knowledge and potentially unsafe practice among the nurses studied.

The physiotherapist will teach the patient how to cough into a tissue; as the patient becomes competent at this, the need for suction will gradually be eliminated.

Continuous humidification is given immediately post-operatively via a mechanical humidifier. When the patient begins to be up and about, a protector over the stoma will humidify inhaled air, act as a filter and have a cosmetic effect by covering the tube.

Care of the wound

The stoma into which the tube is inserted will require regular cleansing to prevent crusting and infection. A dressing beneath the tracheostomy tube can aid comfort and help to prevent sores caused by the tube and hard flanges as well as excoriation of the skin from tracheal secretions. However, these dressings can be a source of infection (Bond et al 2003). Skin can be protected with a barrier cream or film. If sutures are present, these will be removed according to local policy (see Ch. 23, p. 856).

For further information on adult tracheostomy care, see Serra (2000); for a pictorial guide, see Harkin & Russell (2001a).

Complications

The following complications may occur after tracheostomy. Hackeling et al (1998) describe a 7-year audit of complications that brought tracheostomy patients to the Emergency Department.

Blockage of tracheostomy tube Tracheal dilators and a spare cuffed tracheostomy tube must always be kept to hand in case this problem arises. Sometimes the blockage can be relieved by suction or by changing the inner tube. At other times it will be necessary to change the whole tube.

Displacement of the tube The tube can become displaced into the pre-tracheal tissue or completely out of the stoma if the tapes holding it in place have not been secured adequately. Dilators should be used to keep the stoma open until the tube can be replaced. Tapes should be checked for correct fit at least twice daily. Assessment and management of a patient in this situation are described by Seay and Gay (1997).

Surgical emphysema Emphysema is the abnormal presence of air in the tissues. Surgical emphysema is iatrogenic in origin, being a result of faulty suturing, and can be corrected by releasing the sutures.

Haemorrhage The insertion of a cuffed tracheostomy tube can help to control bleeding and prevent aspiration of blood. It is possible, however, for a major blood vessel to be eroded by a badly placed or poorly managed tube, causing a massive haemorrhage.

Dysphagia, nausea, vomiting If the tracheostomy tube is the wrong shape for the type of tracheostomy and the size of the patient, it may also tether the larynx and exert excess pressure on the posterior wall of the trachea and oesophagus, resulting in nausea, dysphagia and vomiting. These effects can be relieved by the insertion of a different type of tube.

Damage to the tracheal mucosa This can result from poor suctioning technique, badly chosen or improperly inserted tubes, or prolonged and/or overinflation of the tube cuff. Ulceration of the anterior wall or a tracheo-oesophageal fistula may result and can lead to tracheal stenosis.

Infection A wound or respiratory tract infection can result from poor technique when performing stoma toilet, changing the tube or applying suction, or from inadequate maintenance of respiratory status.

Changing the tracheostomy tube

The first tube change should be performed by experienced medical or nursing staff, as it takes 2–3 days for a tract to form and there is a danger of the tube being displaced or inserted into the pre-tracheal tissues. Two people should always be present for this procedure. One will remove the old tube and the other will immediately insert the new one. The tapes are then securely tied.

Decannulation or removal of the tube

The tube can be removed without any preliminaries, but usually the patient is gradually reintroduced to breathing through the nose and mouth. A tube with a speaking valve allows the patient to breathe in through the tube and out through the larynx. Once the patient has become accustomed to this, the tube can be replaced by a 'blocker' so that the patient has to breathe in through the nose and mouth. Once able to tolerate this continuously for 24 h and oxygen saturation levels are satisfactory day and night, the tracheostomy tube can be removed. Another method of achieving decannulation is to insert a smaller tube each time it is changed.

Whichever method is used, after removal of the tube a dressing must be applied to allow the tracheostomy site to heal. This can be a very anxious time for patients and support and encouragement are necessary. The stoma should shrink rapidly and close off in a short time.

Humidification

Humidification will prevent the tracheostomy patient breathing in cold dry air, which could cause the secretions of the trachea to become dry and difficult to remove and eventually lead to infection and blockage of the tube. A selection of aesthetically pleasing covers, which humidify and filter the air, are available and the patient should be introduced to these before discharge. A HME can be worn under these covers.

Preparation for discharge

Before discharge can take place, the patient and family must be well prepared for all foreseeable difficulties and should be proficient in total care of the tracheostomy tube. The teaching of self-care techniques can begin with the nurse demonstrating procedures while the patient watches in a mirror. Rudy and McCullagh (2001) describe a nurse teaching programme initiated in order to help non-specialist nurses develop skills and confidence in identifying barriers to learning and motivation when teaching tracheostomy care to their patients. It is wise to teach not only the patient but also the family how to care for the tracheostomy in case the occasion arises when the patient is unable to do this themselves (Mason et al 1992). However, some surgeons do prefer their patients to report to the ward or unit for a weekly tube change.

For an outline of outpatient nursing care, see Minsley & Wrenn (1996).

The community nurse will be actively involved in the patient's discharge and reintegration into the community. Ideally, they will visit the patient in hospital and arrange for suction apparatus to be installed in the home if necessary. After discharge, they should visit the home regularly to ensure that the patient is coping with the stoma and altered body image. Barnett (2005) gives an overview of the care needed by a patient living with a tracheostomy in the community.

Tonsillitis

The tonsils are composed of lymphoid tissue and lie between the faucial pillars (see Fig. 14.8). During early childhood they enlarge in response to upper respiratory tract infections and in adulthood should become reduced in size. In old age they normally atrophy. It is generally agreed that tonsils have a role to play in the body's defence system against infection.

Each year an average of 12 000 people in the UK undergo the surgical procedure of tonsillectomy. The majority of these patients are 14 years of age or younger. Among people aged 15–25, more females seem to require this surgery than males. Among the older population the tonsils are usually removed as a treatment for tumour.

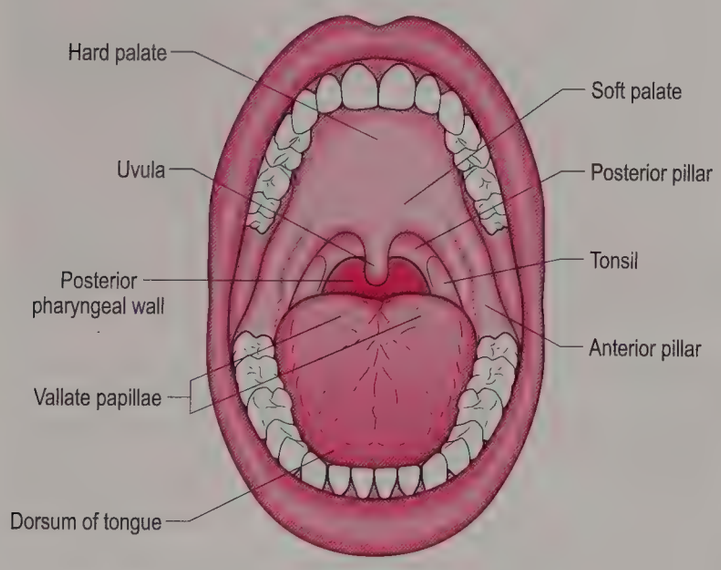

Fig. 14.8 Tonsils and surrounding area.

PATHOPHYSIOLOGY

Common presenting symptoms Patients usually present with a sore throat. Tonsil pain increases with swallowing and is often referred to the ear because of the involvement of the trigeminal nerve, which supplies both sites. They may also present with pyrexia, inflamed tonsils with exudate, lethargy and the absence of a cough (Scottish Intercollegiate Guidelines Network 1999).

Recurrent bouts of infection are the most common reason for the removal of tonsils. Infection may take the form of acute tonsillitis, acute otitis media (see p. 598) or a peritonsillar abscess (see p. 619). Streptococci, staphylococci and *Haemophilus influenzae* are the organisms most commonly present.

Patients with tonsillar tumours normally present with dysphagia. These patients usually also complain of weight loss and may have speech problems. They may also suffer from facial pain and deafness because of the involvement of cranial nerves. Tonsillar tumours are rare.

MEDICAL MANAGEMENT

There is some controversy among medical practitioners about when tonsil infections should be treated conservatively and when tonsillectomy, with or without adenoidectomy, should be performed. The size of the tonsils is not usually the main criterion, but rather the history of the effect of repeated infections on the general health of the patient. Consideration is also given to absence from school or work, loss of appetite, speech defects, nasal catarrh or colds, hearing loss, breathing problems and abdominal pain, the last a sign of mesenteric adenitis, which occurs because of transmission of infection through the lymphatic system (Scottish Intercollegiate Guidelines Network 1999).

Tonsillectomy is an elective operation and is not considered in the presence of respiratory tract infections, during the incubation period after contact with an infectious disease, or if there is tonsillar inflammation. Tonsils are removed by dissection and any bleeding vessels are ligated or diathermy is applied. There remains a debate about the use of disposable instruments for tonsillectomy.

NURSING PRIORITIES AND MANAGEMENT: Tonsillectomy

Postoperative priorities

Airway

On returning from theatre, patients should be positioned in the post-tonsillectomy position, i.e. semi-prone, as this allows any blood or saliva to flow out of the mouth and helps keep the airway clear.

Haemorrhage

Half-hourly recordings of pulse and blood pressure and observations of breathing, pallor, restlessness and frequent

swallowing are carried out to ensure early diagnosis of haemorrhage. Frequent swallowing is one of the first signs of tonsil haemorrhage and can go unnoticed unless the patient is closely observed. Particular attention must be paid to the sleeping patient.

Chewing and swallowing

Encouraging the patient to eat regularly (Cook et al 1992) and to swallow is important, as the exercising of the throat muscles seems to help keep the tonsil bed free from infection and to prevent the occurrence of secondary haemorrhage.

Infection

Pyrexia is not uncommon on the first postoperative day, as part of the general metabolic response to the trauma of surgery, but if it continues, antibiotics should be prescribed and the source of infection sought.

Analgesics

Prescribed analgesics should be administered and their effectiveness observed. They should be administered before meals, before going to sleep and first thing in the morning. Good pain management is vital in ensuring the patient has a comfortable and uncomplicated postoperative recovery.

Preparation for discharge

Patients are usually discharged from hospital within 24 h. They are advised to avoid dirty, dusty atmospheres for approximately 2 weeks and to take a similar amount of time away from work or school/college. An advice sheet should be given on discharge with a contact number to ring should any difficulties be experienced at home, including bleeding, pyrexia and otalgia (earache). Research Abstract 14.4 discusses post-tonsillectomy morbidity after discharge.

Post-tonsillectomy pain control and pain relief following discharge and the adequacy and accuracy of preoperative information and advice were the topics of a study by Stone (1996).

RESEARCH ABSTRACT 14.4

Early post-tonsillectomy morbidity

This prospective study was undertaken to assess the amount and nature of post-tonsillectomy morbidity within 2 weeks of discharge from hospital. Complete follow-up data were obtained from 149 patients (103 children under 16 years and 46 adults) when they attended a follow-up review with one of the authors. All patients were admitted on the day of surgery, had their tonsils removed by dissection and, with two exceptions, were discharged within 24 h. The two exceptions were discharged within 36 h when pyrexia had subsided and oral antibiotics had been commenced.

Following verbal advice from medical and nursing staff, all patients were discharged with oral analgesics and a written information sheet, which advised different actions for specific problems. In spite of this, a surprisingly large number of patients contacted their GP. Whether these patients were adults or children is not stated. Forty patients (27%) were responsible for a total of 53 GP consultations, 23 were prescribed antibiotics and two were prescribed mouthwashes. Throat pain was the commonest reason for consultation. Two out of five patients who consulted for otalgia were inappropriately prescribed a topical steroid and antibiotic. The responses to secondary haemorrhage were particularly worrying. Nineteen patients had this potentially fatal complication. Despite clear advice to the contrary, only seven patients sought advice or care.

The inability to recognise expected symptoms, such as throat pain, or to seek advice for haemorrhage, despite the information given, led the authors to suggest that all patients who experienced any operation-related problems should telephone the ward in the first instance. The need to improve or reinforce information was recognised, as well as the very real increase in workload for GPs and increase in antibiotic prescriptions. Other suggestions for improvement included routine assessment by a nurse practitioner and giving patients a review appointment which could be cancelled if all was well.

As the number of day case patients and early discharges continue to rise, the need to provide patients with information which can be clearly understood, remembered and accepted, so as to enable patients to recognise problems and act appropriately when they do occur, is essential. General practitioners must also become familiar with normal symptoms and responses to tonsillectomy.

Kuo M, Hegarty D, Johnson A, Stevenson S 1995 Early post-tonsillectomy morbidity following hospital discharge: do patients and GPs know what to expect? Health Trends 27(3): 98 –100

Peritonsillar abscess (quinsy)

PATHOPHYSIOLOGY

This is a very painful condition and can be life threatening. It usually occurs as a complication of acute tonsillitis. Pus forms in the space behind the capsule of the tonsil. The abscess is usually unilateral and affects males more than females.

The patient presents with a pyrexia high enough to cause a rigor. There is usually a history of an episode of acute tonsillitis which has subsided, only to return on one side. There is acute pain radiating to the ear on the affected side, trismus (spasm of the jaw muscles) is present and swallowing is so difficult that saliva dribbles out of the mouth. The voice becomes muffled because of the large swelling which affects the function of the palate. The neck glands on the affected side will be enlarged and tender.

MEDICAL MANAGEMENT

Antibiotic cover must be prescribed and the abscess may need to be incised and drained. Usually it is necessary to administer i.v. fluids, and antibiotics are always given parenterally for the first 24 h. Analgesics will be required when the pain is severe. Very rarely the swelling will be so severe that it will obstruct the airway; it may then be necessary to perform a tracheostomy to allow the patient to breathe.

NURSING PRIORITIES AND MANAGEMENT: Peritonsillar abscess

Nursing care of the patient with peritonsillar abscess will include:

- physical and psychological support of the patient
- administration of analgesics, antipyretics and antibiotics
- administration of prescribed i.v. fluids
- ensuring good oral hygiene
- observation and recording of the patient's airway, temperature, pulse, blood pressure, fluid intake and output
- care of the tracheostomy if this has been performed (see p. 616).

Patients who require admission to hospital will be very anxious, agitated and in pain. They will require explanations, reassurance and swift administration of analgesics. As many will be unable to swallow, observations must be made for signs of dehydration; if dehydration is present, it will be necessary to administer i.v. fluids as prescribed by medical staff.

Good oral hygiene is important, especially once the abscess has been drained, as the patient will have had to spit out pus and will have a foul taste in the mouth. Once the pain has been relieved by analgesics and drainage of the abscess, the patient will be able to commence oral fluids and gradually begin taking a normal diet. Oral antibiotics will be substituted for the i.v. administration.

The patient is usually discharged once able to eat and drink normally and has been apyrexial for 24 h. If the abscess has been severe enough to require a tracheostomy, this would be removed and the patient would be discharged only when the wound had healed. Patients are often sent home before they have finished their course of antibiotics; the importance of completing the course must therefore be clearly explained to them. Most patients who have a previous history of tonsillitis are re-admitted in 6–8 weeks to have a tonsillectomy performed as peritonsillar abscesses have a habit of recurring.

For further details of the management and care of a patient with a peritonsillar abscess, see McCall (1993).

Snoring/obstructive sleep apnoea (OSA)

Over the last few years, the issue of snoring in association with OSA has been addressed as it has been recognised that these individuals may have a contributing anatomical defect.

PATHOPHYSIOLOGY

The patient may show signs of chronic sleep deprivation. The patient's partner and/or family may complain of loud snoring and periods of breath-holding when the patient is asleep. This may be as a result of the tissues of the soft palate and pharynx collapsing and causing a temporary obstruction of the oropharynx. When the patient breathes, this tissue, including the uvula and possibly large tonsils, may vibrate, resulting in loud snoring. Patients may hold their breath due to this obstructing tissue. This condition can be dangerous, due to the possible development of severe hypoxaemia and systemic and pulmonary hypertension (Shenwell & Wilson 1994).

MEDICAL MANAGEMENT

Investigations Admission to hospital for a sedation nasendoscopy will be necessary. By means of a nasendoscope the medical staff can view the oropharynx of the sleeping patient and observe the activity and position of the tissues and structures. At this time monitoring of oxygen saturation levels is also possible.

Many centres now carry out sleep studies, which record the patient's breathing, snoring and pattern of electrical activity during overnight sleep.

Treatment A variety of treatments is available. These include weight loss in overweight people, change of sleeping position, mandibular advancement splints and the use of nasal decongestants. Continuous positive airway pressure may also be used (see below).

If it is obvious that there is collapse of excess tissues in the oropharynx, then the surgical technique of uvulopalatopharyngoplasty, with or without tonsillectomy, may be performed at a later date. This involves tightening of the soft palate and pharyngeal tissue, removal of the uvula and possible tonsillectomy. Correction using a laser or punctate diathermy is an alternative procedure (Macdougald 1994, Whinney et al 1995).

Lasers are used for a wide range of problems in ENT, not only sleep apnoea. For fuller details, see McKennis & Waddington (1993).

NURSING PRIORITIES AND MANAGEMENT: Obstructive sleep apnoea (OSA)

Uvulopalatopharyngoplasty

The priorities and management are the same as for tonsillectomy (see p. 618). Patients may experience nasal regurgitation on swallowing. This will usually resolve over a short period of time.

Continuous positive airway pressure (CPAP)

This treatment avoids surgery and can be carried out by the patient at home each night. The patient requires a considerable amount of education and supervision during the initial stages and continuous ongoing support. This education and support are usually provided by a specialist nurse who plays a key role in coordinating and implementing continuity of care from the initial sleep investigation stage and throughout.

Nasal CPAP works as a pneumatic splint, as the continuous positive pressure stops the pharynx collapsing and vibrating. At night the patient wears a well-fitting nasal mask which is connected via tubing to a small machine which delivers the positive pressure airflow. The mouth is left uncovered. The nasal cavity needs to be free of obstruction.

Most patients tolerate CPAP well, despite occasional problems with nasal and face irritation. It is most commonly used for moderate to severe OSA.

For further information on sleep apnoea, see Macdougald (1994), Shenwell & Wilson (1994) and Kendrick (1995).

CONCLUSION

The specialty of ENT care is a continually evolving one that presents many challenges to the nurse, who will encounter patients of various ages and backgrounds, each with specific needs in regard to the intensity, duration and setting of treatment. The ENT nurse is likely to encounter a wide range of disorders, some of which will have profound implications for the patient's ability to function within family, work and social spheres and which will require thorough assessment and individualised care planning. As always, the nurse's ability as communicator will do much to determine the effectiveness of these interventions. In this specialty, in which many patients will suffer from disorders that will impair hearing and/or the ability to speak, the need for skill and inventiveness in communication is especially important.

Nurses in various fields can make an important contribution to health education and preventive care as these relate to, for example, smoking and potential and existing ENT disorders. By helping to implement programmes for vaccinations, community and school nurses help to prevent the hearing impairment often seen in children whose mothers contracted rubella during the early months of their pregnancy. A knowledge of how to evaluate noise levels can help occupational health nurses to protect workers from noise-induced hearing loss, and school nurses can alert young people to the fact that personal stereos are capable of producing the same volume of sound as a pneumatic drill, and thus present a serious risk of hearing impairment. For patients with a chronic condition, such as Ménière's disease or tinnitus, hospital and community nurses can provide ongoing psychological support, practical advice on day-to-day coping and information about local support groups. As the causes of certain ENT disorders become better understood, and as pharmacological and surgical treatments make further strides forward, ENT nursing will continue to offer challenges and rewards for nurses in a variety of care settings.

Most large ENT units also care for patients suffering from head and neck cancer. The implementation of the recommendations for cancer units and centres made by Drs Calman and Hine in *A Policy Framework for Commissioning Cancer Services* (HMSO 1995) and the NICE Guidance on commissioning cancer services (NICE 2004) have implications not only for where these patients should receive their care but also for the education and training needs of the nurses who care for them.

INTRODUCTION

The mouth is central to many activities of daily living which we often take for granted until some minor but painful problem such as toothache or an aphthous ulcer reminds us of the importance of the condition of the mouth to our general feeling of well-being. The mouth is the source of the infant's first pleasurable activity, the sucking reflex being present at birth and perhaps, during teething, of the first experience of *dis*-ease. For individuals approaching the end of life, or for anyone who is acutely ill, good mouth care can give much comfort and relief and help to preserve dignity.

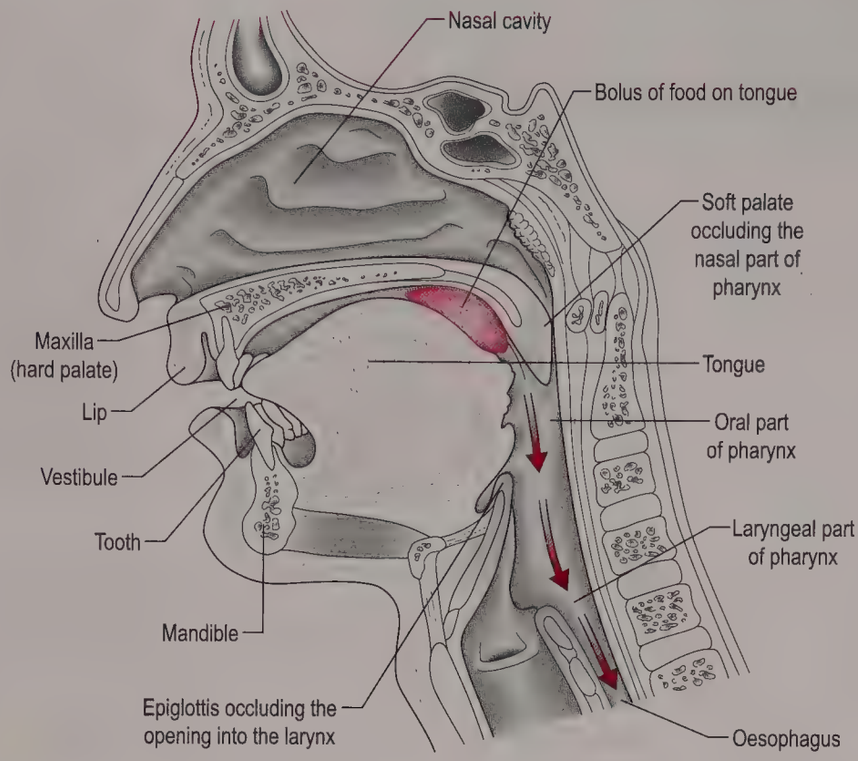
Oral health is defined as:

> *... a standard of health of the oral cavity and related tissues without active disease. This state should enable the individual to eat, speak and socialise without discomfort or embarrassment and contribute to general well-being.*
>
> *Scottish Office Department of Health (1995).*

Although this book addresses adult health, it is important to realise that good oral health practices laid down in childhood can only influence adult health in a positive way, and the nurse can help to encourage these (see Box 15.1, p. 629). Nurses can also contribute to prevention and detection of oral cancer (Macpherson et al 2003) and alleviate the misery caused by iatrogenic mucositis. However, McGuire (2002) notes that: '... there are a number of barriers that prevent patients from receiving needed care. These barriers range from a lack of knowledge, to inconsistent practice, to administrative and environmental issues. Indeed, a remarkable number of individuals and settings do not appear to regard this problem as significant.' She highlights the financial implications of mucositis in cancer care. Miller and Kearney (2001) suggest that 'unfortunately, mouth care has become a ritualistic and banal activity, a topic of conflicting advice and subjective conclusions from sporadic research'.

Mouth care should not be regarded as a standard procedure, but must be adapted to meet the needs of individuals in various care settings throughout life, and at various points on the health–illness continuum. The mouth is often the first indicator of generalised systemic disease or disease in adjacent structures. In addition, its immediate visibility gives any dysfunction a particular significance for the individual, who may be acutely aware of any disfigurement, whether cosmetic or functional. This can give rise to many difficulties affecting the person's self-perception and quality of life.

15.1 From your own experience, how many activities of daily living (see Roper et al 2000) are affected, and in what ways, after a dental procedure, e.g. a filling or extraction requiring local anaesthesia? Now consider how much worse it would be for a patient if any of these activities were affected in the long term or even permanently.



ANATOMY AND PHYSIOLOGY

The mouth or oral cavity has evolved as a 'workshop', where much activity associated with chewing (mastication), drinking and speaking takes place (see Fig. 15.1):

- Entrance is between the lips (red, muscular and sensitive) through the vestibule, a small space immediately before the inner entrance which consists of gums (gingivae) covering alveolar ridges of maxillae and mandible, into which are set teeth.
- The opening (parotid duct) from the parotid gland, one of the salivary glands, is into the vestibule.

1(A) Oral stage: preparatory phase
(Time taken varies)

Lips open; saliva is stimulated
Liquid or portion of food is taken
↓
Solid material is broken down by teeth, moistened by saliva
↓
Strenuous movements of jaw and cheek muscles and mobile tongue against the hard palate, teeth and alveolar ridges form food into bolus
↓
Tongue tip gathers stray food particles from between lips and teeth and from the floor of the mouth and incorporates them into bolus
↓
The lips must be closed. The soft palate is lowered and bolus or liquid is propelled backwards by strong humping movements and funnelling of the tongue

1(B) Oral stage: executive phase
(Time taken should not exceed 1 s)

The bolus of food on the tongue is propelled towards the oropharynx. The soft palate rises to close the nasopharynx and so prevent nasal regurgitation
↓
The bolus must contact pillars of fauces and the posterior oropharyngeal wall to trigger the swallow 'reflex' and initiate:
↓
2 The pharyngeal stage
(Normally lasts 0.75 s)
↓
The bolus passes the laryngeal part of the pharynx, through the open cricopharyngeal sphincter, and so to:
↓
3 The oesophageal stage
(2 s)

Fig. 15.1 The importance of oral competence to the process of feeding, chewing and swallowing.

- The roof of the mouth is formed by bony hard palate (maxilla) and muscular soft palate.
- Lateral walls are formed by the muscles of the cheeks.
- The floor of the mouth is almost entirely filled by the muscular tongue, which is very mobile and sensitive. Tiny projections on it, called papillae, contain nerve endings of taste. There are also openings from two pairs of salivary glands: submandibular and sublingual.
- The rear exit to the oropharynx is under the border of the soft palate, through two archways (palatoglossal and palatopharyngeal) which enclose the palatine tonsil. The area posterior to the molar teeth is known as the retromolar trigone.
- The entire oral cavity is lined with mucous membrane, much of which is stratified epithelium to cope with 'wear and tear'.

The mouth is situated close to many other structures, and disease or injury of the mouth may also affect, for example, the eye, ear, nose, maxillary sinuses, pharynx, larynx and neck. The face and neck are richly supplied with arteries, veins, nerves, muscles, lymph vessels and nodes, and knowledge of all these is important to understanding the effects of trauma or disease arising in, or affecting, the mouth.

The stages of normal swallowing

Only in the mouth is there normally any voluntary control over the process of digestion. The first stage (oral) must be accomplished (see Fig. 15.1) so that the swallowing reflex is triggered when the bolus reaches the posterior pharyngeal wall, and the second stage (pharyngeal) then commences. During this and the third stage (oesophageal), swallowing is involuntary.

A deficiency in the mouth may cause difficulty in the later stages of the swallowing mechanism.

Several cranial nerves (CNs) are involved in the acts of swallowing and voice production (see Table 15.1).

Normal swallowing is discussed in detail by Langley (1989).

A means of communication

The lips, tongue, hard and soft palate and teeth, together with throat and facial muscles, all manipulate sound to give quality and resonance to speech. The mouth also contributes to other expressions of emotion, e.g. smiling, laughing, whistling and kissing. Thus any disturbance to the norm caused by trauma, cerebrovascular accident or surgery can cause diminution or failure of these very basic functions and so reduce quality of life. Understanding some of the changes that may occur will help the nurse to assist the patient's recovery (see 'Orofacial trauma', p. 635, 'Tumours', p. 641, and Ch. 4).

Saliva

This is formed by a combination of secretions from the parotid, submandibular and sublingual glands and from the mucous membrane. Saliva keeps the mouth moist; without it, oral functions are very difficult. Salivary amylase is the enzyme that assists with digestion of food.

For a discussion of the physiology of salivation, see Holmes (1998).

Teeth

Teeth are important structures for biting and chewing food. Children have 20 temporary or deciduous teeth, which are gradually replaced by 32 permanent teeth between the ages

Table 15.1 Cranial nerves involved in stages of swallowing. Damage to any of these nerves may affect the ability to eat

Nerve	Type	Function
CN I	Olfactory	Sense of smell
CN V	Trigeminal	Sensory to gums, cheek, lower jaw and muscles of mastication; motor to muscles of mastication
CN VII	Facial	Taste from anterior two-thirds of the tongue; motor to muscles of face
CN IX	Glossopharyngeal	Secretion of saliva; sensory to posterior one-third of tongue, soft palate, pillars of fauces and pharynx; taste from posterior tongue; motor to pharynx
CN X	Vagus	Sensory to larynx; motor to palate, pharynx and larynx
CN XI	Accessory	Motor to laryngeal and pharyngeal muscles, and muscles of head control
CN XII	Hypoglossal	Motor to muscles of tongue

Note: CN II, CN III, CN IV, CN VI and CN VIII are not involved in motor or sensory functions of swallowing.
Adapted from Langley (1989) and Waugh & Grant (2001).

of approximately 6 and 24 years. Time of eruption can be a measure of developmental age.

Overcrowding of teeth may necessitate extraction of third molars (wisdom teeth) during young adulthood. However, impaction of wisdom teeth is now more commonly seen at a later age because fewer molars are now extracted (Scottish Intercollegiate Guidelines Network 2000a).

The importance of good orodental health throughout life is discussed later in the chapter.

See Chapter 4, Waugh & Grant (2001) and, for a more detailed account, Johnson & Moore (1997).

Bones of the face (see Fig. 15.2)

Many of these bones are complex and fragile, and hence trauma to the mouth may result in a complicated injury (see 'Orofacial trauma', p. 635).

DISORDERS OF THE MOUTH

Disorders of the mouth can be broadly classified into five categories:

- derangement of orofacial tissues
- orodental disease
- infections and inflammatory conditions (localised or systemic)
- traumatic injury
- tumours.

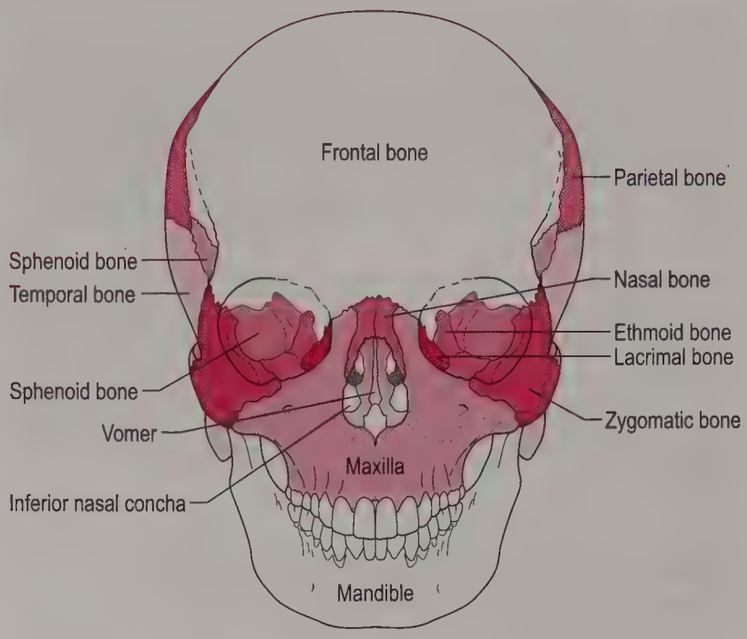


Fig. 15.2 The bones of the face.

DERANGEMENT OF OROFACIAL TISSUES

Defects involving the mouth may require a series of corrective procedures and may present the individual with physical, social and emotional problems in childhood, young adulthood and maturity (Cheng et al 1998). The most commonly occurring congenital malformations of the mouth are dental and jaw disproportion. Cleft lip and cleft palate together have an incidence of approximately 1 in 700–1000 live births. Of this number, roughly one-third are cleft lip, one-third cleft palate, and the remaining third cleft lip and cleft palate. Other deformities of the face and mouth are comparatively rare, but can be devastating for both child and parents, and may involve dilemmas for parents if diagnosed prenatally (Moss 2001).

Problems associated with dental/jaw disproportion, cleft lip/palate and other deformities of the face or mouth may concern:

- appearance
- dentition/occlusion
- eating and drinking
- speech
- hearing
- mid-face growth
- psychosocial adjustment.

PATHOPHYSIOLOGY

Cleft lip and palate result from an embryonic developmental failure 6–12 weeks after conception (Waugh & Grant 2001). Cleft lip may be unilateral or bilateral and can vary in severity from a slight notch to complete division of lip and gum. Cleft palate can result in inability of the soft palate to meet the posterior pharyngeal wall, and close off the nasopharynx. If uncorrected, speech is affected, producing a typically 'nasal' delivery in which certain consonants, particularly C, D, K, P, S and T, cannot be properly enunciated.

For information on rarer deformities of the mouth and face, see Wray et al (2003).

MEDICAL MANAGEMENT

Treatment The medical management of oral defects requires a multidisciplinary approach extending from infancy to adulthood. Treatment protocol will depend on the extent of the deformity and on the age of the child.

For management of cleft lip/palate, see Ray (2003) and Table 15.2.

Orthognathic surgery, i.e. surgery to correct major facial deformities, is an important and developing area of maxillofacial work and is carried out in only a few units in the UK. It requires a team approach involving neuro-, maxillofacial, plastic and ophthalmic surgeons, and assessment and correction take place throughout life (Moos 2003).

NURSING PRIORITIES AND MANAGEMENT: Congenital orofacial derangement

Nursing considerations

Referral Although any deformity may be discovered by prenatal screening, nevertheless the experience for parents of such a newborn child may be very traumatic, and the provision of sensitive and supportive counselling should not be delayed. Parents should be referred within a few days of their child's birth to the relevant specialist professionals, e.g. specialist nurse, orofacial consultant, orthodontist, speech therapist, genetic specialist (see Ch. 6), and should be given information on their local branch of the Cleft Lip and Palate Association (CLAPA) (see 'Useful websites', p. 651) or other appropriate self-help group. Professional psychological support may also be required as there can be great family stress (Martin 1995, 1998).

Oral hygiene Nurses should emphasise to parents the importance of good dental hygiene as there is a higher risk of caries and infection, and parents may mistakenly feel that, compared with gross abnormality, the loss of a few teeth due to dental caries is inconsequential.

Table 15.2 Treatment of cleft lip and palate

Procedure	Timing/patient's age
Lip repair	0–6 months
Palate repair	4–24 months
Bone graft to alveolus	9–11 years
Osteotomy (for correction of defect of hard palate) Rhinoplasty (for nasal defect)	Around 18 years
Pharyngoplasty (to correct the pharynx) Myringotomy revision procedures	As and when necessary
Orthodontic treatment	Throughout childhood and into adulthood
Speech therapy	As and when necessary

Pre- and postoperative nursing care of patients undergoing major corrective surgery will take into account the general considerations discussed in Chapter 26, incorporating the specialised skills and techniques demanded by each procedure; Chapter 6 provides a discussion of genetic disorders and their management.

ORAL HEALTH AND ORODENTAL DISEASE

Dental and periodontal disease affects about 95% of the population of the UK in varying degrees and accounts for the largest proportion of disorders of the mouth (Morris et al 2001). Because most of this disease is preventable, this discussion of orodental disease will begin with a consideration of dental health, first with respect to recent trends and then with regard to the promotion of orodental care.

Changing patterns of dental health

Incidence of dental caries can be measured in terms of the number of decayed, missing and filled teeth; dmft indicates the status of deciduous teeth and DMFT that of permanent teeth. From the early 1970s, there was a substantial improvement in dental health in the UK. More people retained their natural teeth into later life, and there was a marked decrease in dental caries in children. By 1998, dentate adults had fewer missing teeth and more sound, untreated teeth on average than in 1978. However, improvement in children's dental health appears to be falling off and there was no improvement in 2001/2002 compared to the two previous years. Moreover, dental caries appears to increase as the child grows older (Nunn et al 2003). In the UK, 40% of children have dental decay, but there is wide regional variation ranging from dmft = 0.94 in the West Midlands to dmft = 2.55 in Scotland (Pitts et al 2003). There is also a direct correlation between dental caries and social deprivation. There are serious implications for health in later years if dental disease remains untreated in childhood (Fayle et al 2001).

15.2 Consider why regional variations might exist.

Promoting oral health

Nurses in all spheres of practice (see Box 15.1) can help with early education in the simple preventive measures that are the key to oral health. A nurse-led initiative described by Black (2000) is aimed at educating children and their parents to improve their diet and dental health, and to identify orodental problems early (Scottish Intercollegiate Guidelines Network 2000b, Scottish Executive 2003).

See Wray & Gibson (1997) and Scully & Cawson (1999) for illustrations of oral soft tissue disease, and Sweeney & Bagg (1997) for an interactive programme on the mouth.

Oral hygiene Parents should introduce a dental hygiene routine as soon as their child's first teeth appear, using a soft, baby toothbrush. Most children will require supervision until they are 7 or 8 years old.

The teeth should be brushed last thing at night and, ideally, after every meal. The toothbrush should be held

Box 15.1

Contribution of nurses and midwives to orodental health

Health visitors and public health nurses
Encourage oral hygiene in childhood and visits to dentist and orthodontist. This is a primary preventive function of the health visitor, school nurse and public health nurse. Educate on oral cancer prevention (smoking, alcohol and other substance abuse). Demonstrate dental hygiene. Alert parents to the need for children's visits to the dentist. Encourage healthy eating principles (Scottish Executive Health Department 2001).

Occupational health nurses and practice nurses
Educate on adverse effects of smoking and excessive alcohol. Raise awareness of symptoms of intraoral cancer. Advise on good handwashing practices and healthy eating.

District nurses
Identify potential problems in older people. Advise on continued dental examination. Raise awareness of oral cancer.

Nurses caring for older people
As above. Increase mouth comfort and self-esteem.

Nurses working with those with learning disability
Supervise early and continued dental care and thus minimise need for restorative dentistry.

Midwives
Give dental care advice in pregnancy.

All nurses
Encourage and/or assist with oral hygiene for patients' comfort and health. Have dental/oral health literature available (Scottish Executive Health Department 2001).

at an angle of 45° and the teeth brushed horizontally to avoid damage to the gums. All exposed surfaces of the teeth should be brushed.

Toothbrushes should be renewed every 3 months, and hard brushes should be avoided as they can damage tooth enamel and gums.

Toothpaste with added fluoride is recommended, except in areas with fluoridated water. Current advice is that it is unnecessary to rinse, thus leaving a film of fluoride toothpaste (Park & Ross 2002). Toothpaste with sugar added to improve flavour should be avoided. Sensitivities to certain toothpaste ingredients, e.g. cinnamon-aldehyde, menthol and peppermint occur occasionally and will resolve spontaneously when use is discontinued (Francalanci et al 2000).

Dental floss with or without added fluoride may be used to clean between the teeth. Overzealous use can damage the gums and it is best not used by children. Similar care should be taken in the use of toothpicks.

Disclosing tablets can be useful to demonstrate how plaque is left after inadequate brushing. Chewed after cleansing, the tablet produces a stain on any teeth still covered with plaque. Correct brushing should then remove the plaque.

Common misconceptions Chewing gum after meals to increase saliva is of limited value in reducing decay. To be of any benefit, sugar-free gum must be chewed for 20 min and be backed up by other forms of dental care.

Chewing an apple after a meal does not clean the teeth. Rather, it leaves an acidic deposit, which encourages development of plaque.

Diet There is a direct correlation between the incidence of caries and availability of sucrose. There appears to be a vicious circle of deprivation in which poor diet, i.e. high in sugar and fat, combined with inadequate intake of fruit and vegetables, predisposes to dental decay in children. Eventually, as people age, poor dental status may affect nutrition and as a result may contribute to the risk of vascular disease, which appears to follow the north/south axis of deprivation (Bates et al 2001). Continued health promotion is needed to improve the diet of schoolchildren, especially in Scotland. It may be that adults, whose dental health is now on average better than adults of 20 years ago, are unaware of the need to reinforce good eating habits for the future. Nurses could contribute to health education in this area, and emphasise the cariogenic action of non-milk sugars, which include fruit juices, honey and table sugar, especially when consumed by young children last thing at night (Levine 2001).

For information on diet and a list of resources, see Oral Health Group (2003) and Scottish Executive (2003).

15.3 Examine the contents labels of the prepared foods you normally buy. Do any of these products contain more sugar than you had realised?

Access to dental care Often, the dental surgery is the first remembered clinical setting for health care. If these first visits are reasonably pleasant, then a positive attitude may be created towards future regular dental check-ups, and subsequent serious disease can then be diagnosed early (Fayle et al 2001).

Early access to orthodontic services, particularly for those with congenital abnormalities, will help to minimise problems in later life.

In the adult population, changes from institutional living to community-based housing for those with learning difficulties may be associated with reduction in dental attendance and treatment (Stanfield et al 2003). Older housebound people face similar problems (Simons 2003), especially those with a depressive illness (Friedlander et al 2003).

However, the future dental health of the nation may be affected by factors including regional variation in accessibility of NHS dentistry, increased treatment charges and changes in funding of dental services (McGrath & Bedi 2003, Tickle et al 2003). Seventy-five per cent of British adults consider oral health as being important to quality of life (McGrath & Bedi 2002). However, Nuttall et al (2001) found that only 59% of adults were likely to attend for regular dental check-ups, while younger adults (16–24 years) were less likely to do so than 5 years previously.

15.4 Consider why young adults are less likely to attend a dentist regularly. How could nurses influence this?

Fluoride is a substance naturally present in some areas in water. It is taken up by growing teeth and makes enamel

harder and more resistant to the development of caries. There is strong evidence that caries is considerably reduced in areas of naturally occurring fluoridated water (Stephen et al 2002). However, much controversy still continues over the practice of adding fluoride to the water supply (Cross & Carton 2003).

Fluoride supplements can be given to children from the age of 6 months. Dentists, pharmacists and health visitors should be able to advise on the correct amount required locally. Overdosing causes fluorosis, which can cause 'mottling' of teeth, i.e. brown spots with white opacities.

For further information on dental health education, see Levine (1996a,b).

Dental and periodontal disease

PATHOPHYSIOLOGY

Plaque is a firmly adherent, non-calcified deposit of bacteria, mucus, food particles and cellular debris which accumulates on the surface of a tooth, particularly at the base. It forms rapidly in the absence of good oral hygiene and reacts immediately with sugar to form an acid which can attack and erode tooth enamel, leading, if unchecked by adequate saliva combined with good dental hygiene, to gum disease and dental caries.

Calculus is hard mineralised plaque which requires removal by a dental surgeon or dental hygienist.

Caries is progressive, localised decay of teeth caused by bacterial action. It is characterised by demineralisation of the inorganic portion and destruction of the organic substance of the tooth.

Gingivitis — inflammation of the gums Normal gums are pink, e.g. in Caucasians, or brown, e.g. in Asian or African people, and are firm. In gingivitis, the gums are purple–red, soft and puffy, tender, and may bleed easily. Regular oral hygiene and dental care reduce this reversible stage of gum disease.

Untreated, gingivitis can lead to gum recession and the formation of pockets (found in 75% of dentate adults) around the base of teeth, in which plaque and calculus can collect. Further infection from bacteria in plaque may lead to periodontitis.

Periodontitis is characterised by gradual loss of the supporting membrane of the teeth and erosion of supporting bone. Membrane and bone, once destroyed, cannot be replaced and subsequent loosening of teeth occurs.

Acute ulcerative gingivitis is an uncommon condition caused by a mixed infection of a bacillus and spirochaetes, associated with poor oral hygiene, smoking, throat infections, stress and HIV infection. The gums are sore and bleed easily and ulcers develop which may spread more deeply. There is foul-smelling halitosis, and cervical or neck lymph glands may be enlarged.

Common presenting symptoms The patient commonly presents to the general practitioner (GP) or dentist with a combination of symptoms which may include toothache, bleeding gums and emission of pus from the gums (pyorrhoea). If oral hygiene has been habitually poor, the patient is more likely to wait until pain is severe before presenting. Many people fear going to the dentist and delay for as long as possible.

MEDICAL MANAGEMENT

Investigations include X-rays, sialograms (see Appendix 1) and relevant blood tests.

Dental surgery or outpatient procedures Most orodental problems are treated in dental surgeries (NHS or private practice). Treatments such as extractions, fillings, root treatment for dental abscess, and restorative work such as fitting crowns and dentures are carried out with the patient under a local anaesthetic administered by the dentist. Some procedures necessitate general anaesthesia, which is administered by an anaesthetist. Treatment of gingivitis is with mouthwashes and metronidazole or penicillin. Scaling, i.e. removal of plaque and calculus, is carried out when swelling has subsided.

Inpatient or day-case procedures Procedures which can be classed as minor oral surgery but which may require hospital treatment include:

- removal of impacted wisdom teeth
- removal of dental cysts
- removal of salivary glands or ducts
- apicectomy — excision of apex of tooth root
- pre-prosthetic surgery
- placement of implants.

Patients may be referred to a dental hospital/school or to an oral/maxillofacial unit.

Patients with certain conditions or who are taking certain types of medication will require hospital admission and special monitoring as follows (Stenhouse & Wray 2003):

- Diabetes mellitus — insulin dosage must be monitored; there is a risk of delayed healing
- Heart valve disease — monitoring is very important as infection can lead to bacterial endocarditis (see Ch. 2)
- Corticosteroid medication — must be monitored; healing may be delayed
- Anticoagulants — must be monitored; there is increased risk of haemorrhage.

NURSING PRIORITIES AND MANAGEMENT: Orodental disease

Nursing considerations

Outpatient care Individuals treated in dental surgeries or as hospital outpatients will require reassurance and advice on aftercare at home. The nurse should make available written information such as that presented in Box 15.2 and ensure that the patient understands and can carry out instructions for self-care and knows where to call for advice should problems arise.

Box 15.2

Information for patients having minor oral surgery

Following surgery to your mouth, you can expect some swelling and discomfort. This may last for some days. The following information will help you in the postoperative period.

On the day of treatment

1. Rest for a few hours. You do not necessarily have to lie down, however.
2. Avoid strenuous exercise for 24 h.
3. Avoid rinsing your mouth for 24 h, even if it tastes unpleasant. Rinsing may disturb any blood clots and start up bleeding.
4. Your lips and/or tongue may be numb. Be careful not to bite or burn them inadvertently.
5. Avoid hot fluids, alcohol, hard foods and cigarettes.
6. Pain or soreness can be relieved with a mild painkiller, e.g. co-codamol or paracetamol (no more than eight tablets in 24 h for an adult).
7. Should the wound begin to bleed, apply a compress (a clean cotton handkerchief rolled up is ideal). Place this on the bleeding point and bite firmly on it for 10 min, or longer if necessary.
8. If you are at all worried, or if anything untoward occurs, such as prolonged bleeding, excessive pain or swelling, please telephone the oral surgery department where you received treatment.

On the day after treatment

A mouthwash can now be used to cleanse the mouth. It is not necessary to purchase a proprietary mouthwash, although you can if you wish. It is the mechanical action of washing out the mouth which is of importance, rather than the substance used.

Warm salty water is very effective to cleanse and freshen the mouth. Dissolve half a teaspoon of salt in a tumbler of warm water. Hold a mouthful of the solution in the mouth for a minute or two and then spit it out. Finish the tumbler in the same way. Repeat the procedure several times a day for 5 days.

Follow-up

You will have been given another appointment if further treatment is necessary. If you have any problems please contact the oral surgery department for advice.

Inpatient care Many patients are treated as day cases. However, stay may be longer if any of the above conditions apply.

The preparation of patients for anaesthesia is described in Chapter 26. Because of 'dentist phobia', patients undergoing dental surgery often experience anxiety which may seem disproportionate to the size of the procedure, and need much reassurance.

Postoperatively, the patient may experience considerable pain, swelling and bruising. Nursing Care Plan 15.1 gives an example of the care that is required following a wisdom tooth extraction.

On discharge, the patient should be given clear, adequate information on self-care and a number to call should further advice be needed.

Promoting oral health and comfort in special client groups

Most people are able to maintain good oral hygiene independently throughout much of their lives. Others, for reasons of physical or cognitive disability, or infirmity due to illness or advanced age, will need supervision and assistance in carrying out dental and periodontal care routines. The importance of this aspect of daily care must not be minimised, as poor orodental health can seriously compromise the individual's well-being, both functionally and socially.

Physically disadvantaged and those with learning difficulties

Individuals with limited motor control or manual dexterity may require help with brushing teeth. Toothbrushes with adapted handles are available to aid gripping and the nurse should be aware of how these can be obtained, often from an occupational therapist. Many people with limited movement depend on the mouth and teeth to hold or control equipment; it is thus especially important that their teeth are kept in good condition. Occasionally, it is difficult to gain the cooperation of a disadvantaged person who needs dental treatment; in such cases, general anaesthesia may be required even for a simple procedure. The practice of good oral hygiene is obviously preferable to repeated general anaesthesia.

The older person

Adequate dental care for older people can greatly enhance quality of life with regard to comfort, self-image and social interaction (Fiske et al 1990). However, Holmes (1996) commented that 'much of the care is not supported by research, and oral-care practices have remained unchanged for many years' (see p. 636 for a review of mouth care products).

Many older people now retain their natural teeth and regular dental check-ups should be encouraged by community nurses. Good oral hygiene and regular assessment of oral/dental health for older people in hospital should form part of any nursing care plan. However, Samaranayake et al (1995) found considerable unmet dental need among a group of 147 older people in five long-stay wards.

Older people in general have specific problems relating to oral health as follows (the figures in parentheses are from Samaranayake et al 1995):

- Gum retraction/resorption — this occurs naturally, causing root surfaces to be exposed, and with natural wear of the teeth can necessitate repair work.
- Dry mouth (35%) — this can lead to a coated tongue (56%) and increases the risk of decay.
- Ill-fitting dentures (45%) — as a result of the natural resorption of the alveoli when teeth are lost. Continuous wearing of dentures can lead to the development of *Candida*-associated denture stomatitis (19%) (see 'Infections and inflammatory conditions of the mouth', p. 632). Dentures should therefore be removed at night, cleaned and kept in water or a weak solution of Milton or other proprietary cleanser. Dentures left dry for any length of time can shrink.
- Angular cheilitis (25%).

Nursing Care Plan 15.1 Care of a patient following removal of impacted wisdom teeth

Nursing considerations	Action/intervention	Expected outcome
1. Pain due to manipulation of jaw	• Administer adequate analgesics and monitor their effect	Patient is free of pain
2. Risk of haemorrhage	• Withhold mouthwashing overnight	Blood clot left undisturbed; bleeding minimised
3. Vomiting because of swallowed blood from tooth socket	• Give constant reassurance; stay with the patient or allow privacy according to patient's wishes	Patient is comforted; dignity and self-esteem respected
4. Personal hygiene	• Provide frequent sponging, especially of face and hands	Comfort maintained
5. Oral hygiene	• Provide gentle, warm saline mouthwashes the morning after; gentle brushing, avoiding socket	Mouth is freshened; debris removed; haemorrhage avoided
6. Risk of infection	• Administer antibiotics if prescribed • Implement special precautions for patients at risk	Infection avoided; normal healing takes place
7. Discharge	• Evaluate outcome of treatment and postoperative care • If the patient is fit for discharge: give aftercare information; refer to community nurse and hygienist; arrange return appointment	Patient is confident about performing self-care; professional supervision is continued

- Loss of appetite — older people who have lost interest in meals should be examined for any of the above and for early indications of intraoral cancer. Specialist opinion should always be sought for any ulcer which does not heal within 2–3 weeks (Macpherson et al 2003).
- Reduced manual dexterity and general weakness.

15.5 Consider the nursing care of older patients. Is the same quality of care given to teeth as to washing face and hands and combing hair? Carry out a thorough examination of the oral cavity (see Macpherson et al 2003).

Jamieson et al (2002) describe mouth care in detail; Macpherson et al (2003) give a detailed, illustrated description of examination of the oral cavity. See also Sweeney & Bagg (1997), Wray & Gibson (1997) and Scully & Cawson (1999) for illustrations of oral disease which the nurse might encounter during routine oral inspection and which would warrant seeking specialist advice.

Acutely ill people

During the acute phase of any illness, the patient may require assistance or supervision in carrying out oral hygiene, but the objective should be to encourage optimum independence as far as possible.

Many acutely ill people suffer from stomatitis (mucositis) and/or candidosis and will require special measures. These are further discussed in the following section.

INFECTIONS AND INFLAMMATORY CONDITIONS OF THE MOUTH

These can give rise to considerable pain and discomfort, and the individual, already often ill, debilitated and poorly nourished, can become more so if the oral condition is not reversed. The mouth may be affected by the following:

- local and systemic infections (see Table 15.3)
- oral manifestations of a generalised systemic disease:
  - — gastrointestinal and nutritional disorders (see Chs 4, 20 and 21, and Table 15.4)
  - — blood (haemopoietic) and endocrine disorders (see Chs 5 and 11)
  - — dermatological disorders (see Ch. 12).

For further information and illustrations of the above conditions, see Wray & Gibson (1997) and Scully & Cawson (1999).

Stomatitis

PATHOPHYSIOLOGY

Stomatitis, or inflammation of the mouth (stoma), is also called mucositis and can be caused by:

- vitamin deficiency (B_{12}, folic acid)
- viral infection, including HIV
- radiotherapy to head and neck
- chemotherapy

Table 15.3 Common local and systemic infections affecting the mouth

Infection/organism	Oral presentation	Cause/effect
Candidosis is an opportunistic oral infection most commonly caused by *Candida albicans;* can be broadly divided into three types (Wray & Bagg 1997)	Different presentations are recognised and may be found at the same time, especially in terminal illness, and when associated with HIV and AIDS. Anorexia is common (Ventifridda et al 1998)	Destruction of normal oral flora due to immunosuppression caused by, e.g. antibiotics, cytotoxic drugs, radiotherapy to head and neck, HIV, severe debilitation post-surgery, anaemia and other blood disorders, diabetes mellitus, terminal illness (identified in 75–89% of patients) (Ventifridda et al 1998)
(a) Pseudomembranous candidosis ('thrush')	White–yellow plaques like milk curds, easily wiped off, leaving painful, bleeding surface; patient may complain mucosa feels rough and tender, and of dryness and a metallic taste	May also occur in oropharynx (? a cause of anorexia); in infants (poor hygiene) is highly infectious; and in advanced HIV (Palmer et al 1996)
(b) Erythematous candidosis	Minimal white plaques, painful erosion of dorsum of tongue, generalised erythema and oedema	Often related to use of broad-spectrum antibiotics (antibiotic stomatitis)
	There may be clear demarcation from normal tissue; may be asymptomatic and thus undiagnosed	May be seen in areas in contact with dentures (denture stomatitis, and associated with poor oral hygiene, xerostomia, smoking. Occurs in 50% of denture wearers
	Erythema with no obvious predisposing factors	May indicate HIV infection
(c) Hyperplastic candidosis or candidal leukoplakia	Firm adherent white patches or tiny nodules on erythematous base	Have potential to become malignant
	Hairy leukoplakia has corrugated appearance	Usually associated with HIV
Candidal cheilosis (often found with chronic candidosis)	Soreness, redness and cracks at corner of mouth	Habitual licking, nutritional deficiencies, diabetes mellitus
Chickenpox (varicella)	Occasionally vesicles develop on oral mucosa, similar to characteristic vesicles on skin	May result in loss of appetite and nutritional deficiencies
Herpes labialis (cold sore), herpes simplex virus type 1	Vesicular eruption on lip; patient is not always aware of infective nature — virus present in saliva	Often follows primary herpetic infection, stress, fever, local irritation. Exposure to sunlight may reactivate the virus
Herpes zoster (shingles), varicella-zoster virus	Affects one or more branches of trigeminal nerve (CN V), usually unilaterally	Mainly affects older or immunocompromised people
Herpangina, Coxsackie virus group A	Multiple ulcers and erythema affecting palate and fauces	Mild, short-lasting
HIV infections/AIDS (see also candidosis, particularly pseudomembranous)	Oral disease present in 80% of patients with AIDS and 50% of patients with HIV (Palmer et al 1996). Oral manifestation may be first clinical sign; may present as hairy leukoplakia (Epstein–Barr virus has been isolated)	Early management is advised so as to avoid serious complications when immune system is further suppressed, and to maintain quality of life (Scully & Cawson 1999)
Kaposi's sarcoma (KS)	Red–blue or purple patches on skin of cheek or oral mucosa, especially palate (Palmer et al 1996)	50% of patients with KS have oral lesions
Bell's palsy — usually a viral infection of facial nerve (CN VII)	Drooping of mouth, unable to close eye or wrinkle forehead	Very disfiguring; patient feels stigmatised

Illustrations and further information on treatment of these and other oral conditions can be found in Wray & Gibson (1997) and Scully & Cawson (1999)

- bone marrow transplantation (BMT) and graft-versus-host disease (GVHD)
- liver failure
- renal failure.

Common presenting symptoms In this condition, cell regeneration in the epithelium of the mucous membrane cannot keep pace with the rate of destruction which occurs as a result of any of the above. The mucosa becomes thin and there is erythema and some loss of taste. Later, oedema develops and the mucosa breaks down at the slightest trauma, giving rise to haemorrhage and ulceration (Wells 2003).

The pain caused by stomatitis can be excruciating. One patient described drinking water as 'like swallowing

Table 15.4 Gastrointestinal and nutritional disorders affecting the mouth

Disorder	Oral presentation	Cause/effect
Bulimia nervosa	Erosion of teeth due to exposure to gastric acid from self-induced vomiting	Tooth erosion may be first indication of disorder
Crohn's disease	Irregular swelling of lower lip, angular cheilitis and folded thickening of oral mucosa	Mainly due to lymphoedema Sensitivity to foods, flavouring, dyes and preservatives
Coeliac disease	Recurrent oral ulceration	Caused by folic acid deficiency
Pernicious anaemia	Generalised papillary loss with mucosal atrophy	Caused by vitamin B_{12} deficiency
Iron deficiency anaemia	Atrophic glossitis	Less severe than that due to folic acid or vitamin B_{12} deficiency

Illustrations and further information on treatment of these oral conditions can be found in Wray & Gibson (1997) and Scully & Cawson (1999).

broken glass'. A sore mouth is one of the side-effects that makes chemotherapy, radiotherapy to the head and neck area or preparation for bone marrow transplantation (BMT) an unhappy experience for many people (Coleman 1995, Wells 1998, and see Ch. 31). In health, saliva normally helps to clear the mouth of harmful pathogens; however, in these patients saliva becomes increasingly viscoid, resulting in xerostomia (dry mouth) which upsets the normal pH balance (Holmes 1998), creating an ideal environment for invasion by *Candida albicans*.

Candidosis (thrush)

PATHOPHYSIOLOGY

Candidosis, candidiasis, or moniliasis is caused by infection with *Candida (Monilia) albicans*, a yeast-like fungus normally found in the respiratory, alimentary and (in females) genital tracts of healthy people. Oral candidosis is very common in people who are ill, debilitated, older or terminally ill. Presentation and predisposing factors are summarised in Table 15.3.

Systemic diseases showing oral manifestations

These include blood disorders such as leukaemia (bleeding gums), polycythaemia vera (bright red oral mucosa) and thrombocytopenic purpura (petechiae on tongue). For greater detail on these conditions, see Chapter 11. In dermatological conditions (see Ch. 12), examples of oral symptoms are Koplik's spots in measles and oral vesicles in chickenpox (varicella).

Burning mouth syndrome

Although this condition is neither inflammatory nor infective, it is relatively common, particularly among older women. The oral mucosa appears entirely normal, but the sufferer complains of a continuous or intermittent burning sensation on tongue, palate, lips and lower alveolus.

Aetiological factors include vitamin deficiency, allergies, haematological disorders, undiagnosed diabetes, xerostomia and cancer phobia, the last, in particular, causing much anxiety. Although Scala et al (2003) contend there is no consensus on the diagnosis and there is no definitive cure, Lamey (1996) considers the problem can usually be readily managed and patients should be advised to seek specialist advice.

MEDICAL MANAGEMENT OF INFECTIONS AND INFLAMMATORY CONDITIONS

Treatment begins with the identification of the pathogen by culture swab or saliva washings. An appropriate antibiotic or antifungal agent is prescribed. All patients having radiotherapy, chemotherapy or preparation for BMT should be referred for dental assessment before treatment starts (Ali 2003). If being treated for a systemic disease, the patient's medication should be reviewed, with appropriate consideration of drug interactions. Only if the symptoms become severe will causative treatments such as radiotherapy be withdrawn temporarily.

Appropriate mouthwashes may be prescribed; again, drug interactions should be avoided (Barkvoll & Attramadal 1989).

NURSING PRIORITIES AND MANAGEMENT: Infections and inflammatory conditions of the mouth

Many patients with these conditions are already ill people; to have to cope with an excruciatingly painful mouth can often overwhelm them completely and lead to total demoralisation. Nurses write frequently about oral care, but despite that, Miller and Kearney (2001) comment, 'Rarely do experts teach it, and it frequently is delegated to the most junior (inexperienced) members of the nursing staff'.

Nursing responsibilities for oral care

Much of the traditional ritual of oral care is unsuited to a sick person with xerostomia, acute stomatitis (mucositis) and/or candidosis, and it is difficult to encompass the many aspects of care in a limited text, but the student should

consider the following when caring for individuals and challenge inappropriate practice.

Self-care should be encouraged whenever possible as patients know what their own mouths will tolerate (Little 1996) and are more likely to cooperate.

Assessment The condition of the oral cavity may change from day to day; frequent assessment is vital, using a tool and chart to record changes. Thorough examination (Macpherson et al 2003) is necessary and although the patient may find it intrusive, it can be used as an opportunity to supervise and offer encouragement. Holmes and Mountain (1993), Coleman (1995) and Wells (2003) evaluate oral assessment tools which have benefits in different care settings.

Frequency There is general agreement that care should be regular, but opinions vary as to frequency. Four times daily may be adequate for some patients, but those able to tolerate only rinsing or even just moistening, may benefit from half-hourly care. This may be an opportunity for relatives to contribute to care (Watson 1989). Cleaning before meals may improve appetite (Roberts 1990).

Regimen A simple regimen is advocated. If possible, dentate patients should continue using toothbrush and toothpaste; a soft brush and toothpaste with added fluoride are recommended (Park & Ross 2002). If there is fragile mucosa, foam sticks may remove debris but will not remove plaque. Gauze swabs held in forceps or wrapped around a finger are too rough and may remove a layer of regenerating epithelium. Irrigation with a syringe may be appropriate in some circumstances, but forceful use may damage mucosa. Following intraoral surgery, a patient may find it difficult to adapt to the changes inside the mouth because of alteration to contour and presence of insensate flaps (Little 1996), so supervision may be necessary to ensure removal of debris.

Oral care preparations A mouth with acute stomatitis can be regarded as an open wound, and the nurse must consider whether or not some traditionally used oral care products are appropriate treatment.

Evidence for and against some oral care equipment and preparations described over almost three decades is summarised in Table 15.5.

Other esoteric recommendations for oral care in a palliative care setting include pineapple chunks, cider and soda mouthwash for a 'dirty' mouth, and semi-frozen tonic water and gin (1:1), or fruit juice (Regnard et al 1997). There is no evidence to support use of any of these for radiation-induced mucositis or xerostomia.

From the information contained in Table 15.5, it can be seen that there is considerable variation in the opinions of practitioners and researchers, but in the absence of compelling evidence, Park and Ross (2002) consider best practice to include brushing with fluoride toothpaste for natural teeth, use of chlorhexidine mouthwash to prevent plaque and Biotene Oral Balance system for xerostomia.

For a discussion of related research, see Wells (2003).

Temperature is important. Ice cubes may seem soothing if a mouth feels inflamed, but may delay the healing process. Warm solution is recommended for wound irrigation (Hollinworth 1997); it should assist in healing a damaged mouth and is often preferred by patients.

Analgesics must always be adequate and timed appropriately, e.g. to give maximum benefit at mealtimes and to cover periods away from the ward or home when receiving treatment. Opioids may be appropriate; topical anaesthetic agents including benzydamine mouthwash, Mucaine or lozenges containing local anaesthetic may be used (Regnard et al 1997, Wells 2003).

Dignity and self-esteem Consideration should be given at all times to the importance to the patient of maintaining dignity and self-esteem. A sore mouth can be a further demoralising factor for a patient already under stress. All nursing care plans for oral care must form part of holistic care and must consider any therapeutic measures being implemented by other members of the multidisciplinary team.

Reference should also be made to oral hygiene as described earlier in this chapter, in Chapters 26–33 and in Jamieson et al (2002), considering each individual's needs.

OROFACIAL TRAUMA

Traumatic injury to the mouth or face typically gives rise to much anxiety concerning disfigurement. Moreover, because of the high vascularity of this area, blood loss at the time of injury may be considerable and the patient, together with companions or relatives, are likely to be very alarmed.

A national survey (Hutchison et al 1998) estimated that about 500 000 people in the UK suffer facial injuries, with a decrease in those from road traffic collisions (RCAs) being offset by a marked increase in assaults (Magennis et al 1998). Soft tissue injuries to the face range from simple lacerations, knife wounds and bites to multiple injuries resulting in tissue loss. Bone injuries include fracture of the mandible and fracture of the maxillae, malar (zygomatic) and nasal bones (middle third fracture). The signs and symptoms of different types of fracture are summarised in Table 15.6.

Causes

Violence

Approximately 125 000 people in the UK suffer facial injury annually as a result of assault (Magennis et al 1998). Many of these are teenagers and young adults where alcohol is often associated with either victim or assailant. Figures for 1995–98 show 75% of assaults were on men, but there is a rising trend in assaults on women and those of both genders aged 18–30 (Sivarajasingam & Shepherd 2001). It is now thought that in the past there has been considerable under-reporting by the police of offences. Injury data now being supplied by emergency departments show an increase of between 25 and 50% compared to previous police statistics (Sutherland et al 2002). Emergency department data are now being used to monitor violence prevention initiatives such as closed circuit television and the use of strengthened glass in bar glasses.

Table 15.5 Mouth care equipment and preparations: evidence for and against

Preparation/strength of evidence	Evidence	Observations from clinical practice
Toothbrush, hand or electric, with soft head (strong evidence for)	Familiar to patients and recommended by several authors since Howarth (1977), removes plaque (Pearson & Hutton 2002, Sadler et al 2003)	Hard brush will damage fragile mucosa, small soft brush recommended (Miller & Kearney 2001)
Foam sticks (some evidence for)	Less effective than brushing, but will reduce plaque and control gingivitis (Pearson & Hutton 2002)	Used with chlorhexidine for fragile mucosa, or for edentulous patients
Toothpaste/dentifrice with added fluoride (strong evidence for)	Fluoride is proven to reduce caries (Mouatt 2003)	
Chlorhexidine mouthwash (strong evidence for)	Recommended by Ferretti et al (1987); said to be the 'gold standard' of antiplaque and gingivitis agents by Moshrefi (2002); antimicrobial, prevents plaque formation, decreases incidence of mucositis	'Burning' of mucosa and staining of teeth (Roberts 1990) can be reduced by dilution with water 1:1 (Park & Ross 2002). Some proprietary mouthwashes such as Corsodyl contain alcohol and are not recommended for radiation-induced mucositis (Miller & Kearney 2001)
Fluoride mouthwash, topical gel (strong evidence for dentate patients)	Fluoride is proven to reduce caries (Mouatt 2003)	Frequent use needed; requires time to be absorbed by tooth enamel
Benzydamine hydrochloride (Difflam) mouthwash (evidence equivocal)	Studies, including Epstein et al (2001) and Cheng & Chang (2003), have reported varying benefits	Can relieve mucosal pain, but may cause initial stinging and may require dilution 1:1 with water
Fluconazole (Diflucan) — antifungal (strong evidence for) not to be confused with Difflam (benzydamine hydrochloride)	Effective in treating oral *Candida albicans* and more efficacious than amphotericin (Finlay et al 1996)	One daily dose leads to better patient cooperation with treatment
Nystatin suspension — antifungal (some evidence for)	Efficacy reduced by chlorhexidine (Barkvoll & Attramadal 1989), so 1 h should elapse between taking these to allow each to be effective	Poor patient cooperation; to be effective, at least 20 min should elapse after application before eating or drinking
Water mouthwashes (some evidence for)	Recommended by Howarth (1977), Feber (1995). Increased intake will maintain hydration and help xerostomia (Wells 2003)	Patients can acceptably carry a bottle and use frequently (Sadler et al 2003)
Saliva replacement, range of commercial preparations, e.g. Biotene Oral Balance system, BioXtra, Saliva Orthana (some evidence for)	Varying reports of efficacy (Miller & Kearney 2001, Meyer-Leuckel & Kielbassa 2002); optimal substitute for saliva not yet discovered (Sadler et al 2003); Biotene Oral Balance found to be superior to other agents (Epstein et al 1999)	Mucin-based preparations are said to be better tolerated (Davies et al 2001) but mucin is derived from porcine gastric mucosa, so is unsuitable for Jews, Muslims and other groups (Miller & Kearney 2001)
Pilocarpine (Salagen) (some evidence for)	Increases salivary flow only if some salivary gland function remains (Taylor 2003)	Side-effects include sweating; often discontinued for this reason (Miller & Kearney 2001)
Ascorbic acid (insufficient evidence)	Used in palliative care settings (Milligan et al 2001) No evidence of benefit for radiation xerostomia or mucositis	
Sodium bicarbonate mouthwash (insufficient evidence)	Used traditionally but no confirmatory controlled studies (Sadler et al 2003). Is not antimicrobial Said to remove crusted mucosa (Roberts 1990); Tombes & Gallucci (1993) advise against its use	
Saline mouthwash (insufficient evidence)	Used traditionally but no confirmatory controlled studies (Sadler et al 2003) Recommended for patients having oral radiation (Feber 1995)	
Lemon and glycerine (evidence against)	Causes demineralisation of teeth (Meurman et al 1996) Being anhydrous, will aggravate xerostomia (Sadler et al 2003)	
Hydrogen peroxide (evidence against)	No scientific or clinical evidence (Krishnasamay 1995) Astringent, exacerbates xerostomia, unpleasant taste (Davies et al 2001)	

Table 15.6 Characteristics and management of maxillofacial fractures

Fracture	Signs and symptoms	Management
Fractured nasal bones	Nasal deviation or flattening; bruising	Manipulation of nasal bones and septum; nasal pack and plaster of Paris for 1–2 weeks
	Septal haematoma causing obstructed breathing	Drainage of haematoma
Fractured malar bone	Black eye; swelling over cheek, sometimes flattening; anaesthesia of areas supplied by injured nerves (infraorbital and superior dental); inability to open mouth; diplopia	Elevation of malar bone through incision in temporal region. May require fixation by wiring of bone
'Blow-out' fracture of malar	Periorbital haematoma; diplopia	Insertion of implant to orbital floor to stop eye dropping
Fractured maxilla/middle third fracture	Grossly swollen face; failure of teeth to occlude properly; bilateral periorbital haematoma; fractured nasal bones; teeth may be loosened; CSF rhinorrhoea	Intermaxillary fixation (IMF) eyelet wires, Gunning splints, etc. Open reduction and internal fixation (ORIF) using wires, screws, plates
Fractured mandible with/without other fractured facial bones	Displaced or undisplaced; local pain and swelling; severe pain on opening mouth, sublingual haematoma	Undisplaced: usually no treatment Displaced: reduction with wires, splints or plate depending on site of fracture

NB: there will be considerable variation in presentation and in the timing of manipulative procedures, in accordance with the exact site and combination of fractures.

Domestic violence is often unreported by the victim, and Lydon (1996) suggests the following reasons for this:

- fear due to repeated psychological abuse
- fear of reprisals
- fear for their children's safety or that they will be taken into care
- financial dependence on the assailant.

Lydon comments that domestic violence is often trivialised and challenges nurses to be proactive in trying to bring to the fore this serious issue in our society. The Zero Tolerance campaign (theme: 'Violence against women and children is a crime'), which started in Edinburgh and spread country-wide, is a very successful example of raising awareness of this issue (see Women's Aid, 'Useful websites', p. 651).

15.6 Discuss how you would react if you suspected that someone presenting to the Emergency Department had been assaulted by someone they know well.

Road traffic collisions (RCAs)

Incidence of facial injuries was reduced following the introduction of seat belt legislation (Department of Health and Social Security 1978), and the more recent introduction of airbags has reduced fatalities and severity of injuries to the head (Frampton et al 2002).

Industrial injuries

Accidents in the workplace involving machinery or equipment are often followed by claims for compensation. Nurses should therefore not comment on the circumstances of any incident, either in person or by telephone, other than by using standard statements agreed by hospital policy (Nursing and Midwifery Council 2004).

Sports injuries

These are usually the result of a collision or fall and are most commonly soft tissue injuries (Hill et al 1998). Wearing helmets or gum shields may reduce the severity of injury.

Accidents

Accidental falls are common among older people, often resulting in facial injury. The underlying cause of the fall may require investigation (Chew & Edmondson 1996).

Burns

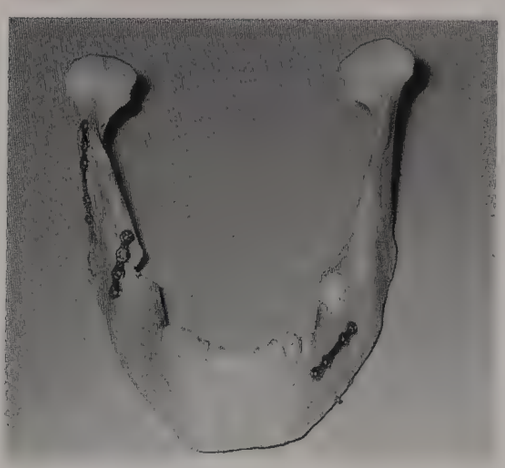
The treatment of burn injuries is discussed in detail in Chapter 30. It is emphasised here, however, that to assist in the prevention of contractures of the mouth and subsequent difficulty in function or administration of a general anaesthetic, patients with burns should be encouraged to drink from a cup as early as possible and to avoid the use of straws.

15.7 Take a few sips of a drink directly from a cup and then with a straw. What do you observe about the maxillofacial movement required for these two actions?

MEDICAL MANAGEMENT

Immediate intervention Emergency treatment will involve whatever resuscitative measures are required to maintain the patient's airway, breathing and circulation and to prevent the development of clinical shock (see Chs 18 and 27). Priorities for intervention will have to be set, as cerebral and pulmonary injuries are often associated with maxillofacial injuries in severely injured trauma patients (Alvi et al 2003, National Institute for Clinical Excellence 2003). A full physical examination will involve neurological observations and X-rays as appropriate, and will be followed

by referral to the appropriate specialists, e.g. maxillofacial, orthopaedic or ophthalmic surgeons. Cannell et al (1996) state that, in using an injury assessment tool (Ali & Shepherd 1994) when assessing multiply injured patients, maxillofacial injuries often tend to be underscored and that a maxillofacial surgeon should be involved as soon as possible to minimise facial deformity. However, the person with a maxillofacial injury with minimal displacement of bone and no symptoms of head injury may delay attending for treatment until, eventually, swelling and bruising make the injury appear more alarming.



Treatment of maxillofacial injuries The signs and symptoms of maxillofacial injuries, together with appropriate treatments, are summarised in Table 15.6.

Soft-tissue injuries require thorough cleansing. This may entail scrubbing of the wound under general anaesthesia, to remove glass, debris, gravel or dirt. Failure to clean the injury adequately will lead to 'tattoo scarring', i.e. a permanent blue–grey scar. Facial suturing should adhere to plastic surgery techniques (McGregor & McGregor 2000).

Bone injuries The objectives of treatment are to restore pre-existing anatomy, functional occlusion of teeth and facial appearance. The most common method of immobilisation now employed is open reduction and internal fixation (ORIF) when the fracture is exposed, reduced (i.e. repositioned) and fixed with wires, screws, a rigid plate or mini-plates. Plates (see Fig. 15.3) may be left in situ permanently or removed after 3 months. However, other methods of fixation using the patient's bite, known as intermaxillary fixation (IMF), may still be used successfully, for example:

- *Eyelet wiring* — wires are twisted around the upper and lower teeth, leaving a loop (eyelet). The teeth are then brought into proper occlusion and wired together (see Fig. 15.4).
- *Arch bar wiring* — this technique is similar to eyelet wiring but is used when fewer teeth exist.
- Gunning splint and cast cap splints are other methods of IMF and are described in Wray et al (2003).

Undisplaced fractures of the mandible generally require no surgical treatment.

638 Fig. 15.3 Interosseous plating.

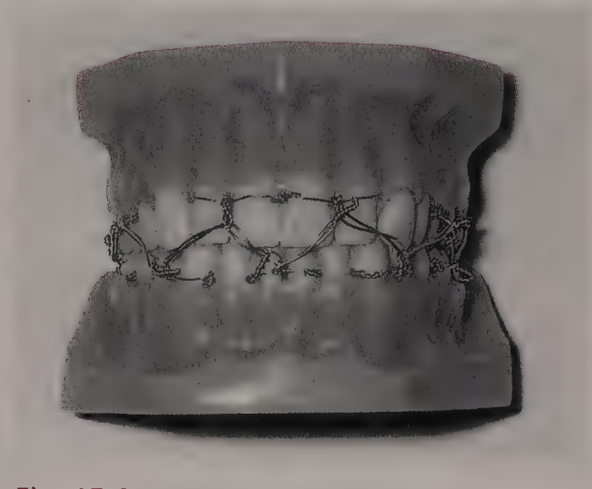


Fig. 15.4 Eyelet wiring.

A fractured maxilla can be immobilised internally (ORIF) or externally (IMF), depending on the precise nature of the injury. Internal fixation can be achieved by means of metal plates or with internal suspension wires. The latter hold the maxilla and mandible in occlusion and are fixed to the malar or frontal bone.

External fixation is now less commonly seen but may be achieved by inserting rigid pins into the bones via the skin. These are then secured externally with rods and joints. This method may be used for more complicated injuries.

Treatment of a fractured malar (zygoma) may take the following forms:

- Elevation through incision in the temporal region
- Wiring or plating of the fracture
- Kirschner wires (K-wires) — rigid wires which may be inserted into the bone in one or more directions, and the ends cut just clear of the skin
- An implant may be necessary to repair a shattered orbital floor.

Fractured nasal bones may also form part of a compound facial injury. Here, the fracture is reduced by manipulation of the nasal bones and may be immobilised by a plaster of Paris splint.

For further information on orofacial trauma, see Wray et al (2003).

NURSING PRIORITIES AND MANAGEMENT: Orofacial trauma

Orofacial injuries vary widely both in presentation and in their impact upon the individual's lifestyle and psychological well-being. Case Histories 15.1 and 15.2 outline the experiences of two patients admitted to hospital after receiving blows to the face. Each has different needs, priorities and concerns, and hence different requirements for nursing care. While the treatment of individuals who have suffered orofacial trauma must take into account a range of physical and emotional considerations, only that care which is specific to the mouth and face will be described here. General pre- and postoperative care is discussed in Chapter 26; reference to other chapters will be made as appropriate.

CASE HISTORY 15.1
Ms Y

Ms Y, aged 23, was brought to the Emergency Department by a neighbour who heard a disturbance and found her dazed. She was found to be suffering from concussion, a fractured malar bone and facial lacerations, and was admitted to the ward. Ms Y explained that she received these injuries when she tripped and fell against a door.

Ms Y was advised that she would have to have the fractured malar reduced and stabilised under anaesthetic. She was assured that the operation was not a major procedure, but that the fracture would simply be fixed by means of wires. She was also given general information on preoperative procedures and postoperative care. She was advised not to use a mouthwash too vigorously.

She was able to take a soft diet, however, and was advised to continue with soft foods for 7–10 days and to take as much protein as possible to promote healing.

After the incident, Ms Y was also suffering from diplopia (double vision) as a result of a slight displacement of one eye. This persisted and she was later referred for orthoptic exercises.

While she was on the ward, Ms Y began to disclose some of her domestic problems, first to her primary nurse and then to the medical social worker who, with Ms Y's agreement, had become involved. Ms Y indicated that she would consider accepting assistance from a women's support group. The social worker arranged for Ms Y's children to be cared for until she was ready for discharge.

Ms Y's discharge was planned well in advance. Through liaison with women's support agencies, she was assisted in reviewing her home circumstances and was offered alternative accommodation with her children.

Life-threatening concerns

Harrahill and Eastes (2000) discuss the risk of injuries which may be missed, and the importance of skilled nursing observation. For patients who have suffered maxillofacial injury, the immediate priority of intervention is likely to be to maintain the airway. Respiratory difficulty and haemorrhage will require immediate care.

Respiratory difficulty

This problem can vary in severity and may be due to swelling of the tongue caused by oedema or haematoma, or to the patient's inability to control the tongue because of disturbance of the muscle attachments. If conscious, the patient should be sat up and propped forward as soon as possible, if other injuries allow. The airway must be kept clear. If the maxilla is fractured, it may be necessary to insert two fingers into the patient's mouth and hook behind the hard palate to re-establish the airway. In severe cases, early intubation or tracheostomy may be necessary.

Haemorrhage

There may be significant haemorrhage from middle third fractures resulting in cheek swelling, and nasal packing may be required. Bleeding may also be profuse when soft tissue injury has occurred, and immediate measures may be necessary, e.g. applying pressure on a bleeding point or pressure point until ligation of the damaged vessel can be performed. Bleeding can also be controlled by holding the skin edges together with Steri-strips until suturing can be carried out.

Shock

Nursing and medical staff must be alert to the warning signs of shock and should be prepared to take urgent action (see Ch. 18).

Major nursing considerations

Observation and monitoring

Vital signs Temperature, pulse, pulse oximetry, respiration, blood pressure and pain should be recorded at regular intervals. Neurological observations may be appropriate (see Ch. 9).

Rhinorrhoea The nurse should also watch for the presence of rhinorrhoea (nasal discharge) caused by leakage of cerebrospinal fluid (CSF). This can occur in fracture of the maxilla if the cribriform plate of the ethmoid bone is disturbed. CSF gives a positive reaction to Dextrostix.

Eye integrity/vision (see Ch. 13). The nurse should check for abnormal pupil reactions, proptosis and acute pain. Vision should be checked hourly at first, especially if the patient cannot open the eyes because of oedema. The nurse should gently open the eyes and check pupil reaction. Any rapid decrease in visual acuity can indicate retrobulbar haemorrhage, which can lead to blindness and requires urgent action. Double vision can indicate a fracture of the orbital floor.

Major patient problems

Pain

Pain must be assessed (see Ch. 19) but is not normally a major early problem. It is important, however, not to underestimate the patient's pain and to explain why analgesics may have to be withheld initially while investigations are carried out (see Ch. 27).

Anxiety

Anxiety caused by fear of disfigurement and scarring may be the first concern of many patients and relatives. An injury to the eye will be a source of further anxiety.

Patients and relatives should be given the opportunity to talk about their fears, particularly in the early stages when profuse bleeding may make the injury look horrific. Nurses should offer the reassurance that healing is usually rapid and that as much as possible will be done to minimise scarring. However, it is equally important not to raise expectations unduly. Some people have unrealistic ideas about the results that surgery can produce, and it is unfair to allow them to imagine that what existed before can always be fully restored. Scars can fade and may be camouflaged, but it is not always possible to disguise the disfigurement caused by major tissue loss or bone displacement and it may be appropriate to introduce psychological support at an early stage (Rumsey et al 2002).

Other considerations

Every effort should be made to clean blood and debris from the patient before relatives arrive, in order to avoid

unnecessary distress. Dirty clothing should be removed, observing local policy for the care of patients' property.

Oral hygiene should be carried out within the limitations of the patient's condition. For example, a blood clot should be left undisturbed as far as possible to minimise further bleeding, but broken teeth, debris and so on should be removed if this has not already been done. Gentle irrigation with warm saline may be helpful.

Nursing care in surgical interventions

Patients who have soft tissue injury without bone damage will have suturing and/or reconstruction carried out as soon as possible.

Many patients with maxillofacial fractures will require surgical intervention to reduce and stabilise the fracture. The timing of this surgery will vary according to the patient's overall condition and the amount of localised swelling which may make assessment of the fracture difficult. In many cases, fixation is best left for a few days; if the general condition permits, the patient may be discharged home for the interim. Alternatively, direct transfer to a specialised unit may be arranged.

Postoperative management

The overall aim of postoperative management is to assist as necessary with the activities of daily living and to help the patient achieve independence in these activities as soon as possible.

Monitoring vital signs In the initial postoperative period, the patient's vital signs should be recorded every 15 min. As the condition stabilises, the patient can gradually be raised to a sitting position to aid respiration, help drainage and minimise oedema. The patient should be encouraged to maintain an upright position even at night. Moving and handling advisors now counsel against pillows placed in armchair fashion. A reclining armchair, if available, can be useful later if other injuries permit.

Respiration The patient may have a nasal airway in situ to assist breathing and this will need occasional suction to ensure it remains patent. The mouth may also need gentle suction if the patient is afraid to swallow saliva for fear of choking. The patient should be encouraged to relax and to practise gentle swallowing movements.

Oral hygiene It is very important to help the patient maintain good oral hygiene. If the jaws have been wired, a soft toothbrush or Q-tips can be used to keep the anterior surface of the teeth and splints clean. The inside of the mouth can be cleansed with mouthwash taken through a straw (or a feeding cup with a spout) and squeezed out between the teeth. An alternative method is to have the patient lean forward and to irrigate the mouth through gaps between the teeth, using a monojet syringe, letting the fluid run out.

Preventing wound infection The skin entry points of external fixation should be kept free of crusting by cleaning with normal saline. An ointment such as sterile petroleum jelly may be applied.

Sutures to facial lacerations can be kept clean with normal saline and removed in 3–4 days to minimise scarring. Supporting Steri-strips may then be applied over the wound for a further 3–4 days. Any intraoral lacerations are usually repaired using catgut, which will be absorbed, but the mouth should be checked in case any non-absorbent sutures have been used, e.g. inside the lip.

Maintenance of fixation The guiding principle of the treatment of maxillofacial fractures is, as for any other types of fracture, to obtain healing in the optimal position, e.g. that which maintains proper occlusion. In order for callus to form, and thus for healing to take place, the bone must remain immobile. Many patients will have fractures fixed with internal metal plates. However, if the jaw is immobilised by other means, appropriate instruments for releasing the fixation, i.e. wire cutters, or scissors for elastic bands, must always be available at the patient's bedside for immediate use should any danger of airway obstruction arise.

Instruments for tightening screws should also be at hand, and the fixation checked at regular intervals. Most patients will be aware if it becomes loose, but older people or those with head injury may not be. To avoid confusion, only those instruments appropriate for loosening or tightening the individual's particular type of fixation should be available at the bedside.

Nutrition (see also Ch. 21). A nasogastric tube may be inserted to allow for postoperative aspiration and/or drainage of old blood. Oral feeding should be encouraged as soon as possible, and there are particular problems if the jaws must be kept wired for several weeks. A liquid diet must be taken, which may make it difficult for the patient to consume sufficient calories to maintain body weight. All food must be liquidised and supplemented with 'sip feeds', of which a wide variety is now available. Frequent, small meals should be taken throughout the day.

The dietitian should be consulted, ideally before the surgery takes place, to assess the patient's dietary requirements. Older patients with a low body mass index (BMI) will require special monitoring and encouragement. This is especially important if food is served by non-nursing personnel who may not appreciate the significance of unfinished meals.

15.8 How can a calorie intake adequate to promote healing be provided within the constraints of a hospital setting for Ms Y (Case History 15.1), who has no interest in food, and Mr J (Case History 15.2), whose injuries prevent him from eating solid food?

Allaying fears Nursing staff should bear in mind that the patient is likely to be very alarmed on recovery from anaesthesia to find that interdental or external fixation is in place, even if previously informed that this would be necessary. It is important that the patient is given some means of expressing feelings and concerns and is briefed fully on how to manage basic functions such as eating and how to avoid choking if coughing up phlegm or vomiting.

Communication will be frustrating for the patient initially if the jaws have been fixed, but most difficulties will be

CASE HISTORY 15.2
Mr J

Mr J, aged 30, was assaulted while returning from an evening out with friends. He was unconscious for a short time after the incident. He was brought to the Emergency Department in the recovery position to prevent blood from inside his mouth trickling down the pharynx (and potentially the trachea) and causing respiratory distress. Fortunately, he had not suffered pneumothorax, in which case he might not have been able to lie in this position. It was difficult to restrain him as he was restless from the combined effects of blows to the head and the alcohol he had taken. He was found to be suffering from a middle third fracture, a fractured mandible, fractured ribs and facial lacerations.

Mr J was advised that his jaws would have to be wired together and external fixation applied, but he had difficulty concentrating and absorbing information. His wife was present during the discussion. She was very anxious and mentioned that she had been concerned by the fact that her husband had been drinking more lately.

When he awoke from the anaesthetic, Mr J was quite frightened, as he did not remember much of what had been explained to him preoperatively. The nurse in the recovery ward told Mr J to breathe deeply and encouraged him to relax. She then explained again what had happened and what was preventing him from opening his mouth. She explained why it was important for him not to disturb the fixation, but also assured him that if it ever became urgent for him to release his jaw, the necessary equipment was at hand. She then stayed with Mr J until the feeling of the wires became more familiar to him, and ensured that adequate analgesics and sedation were being administered (see Ch. 19).

Mr J had some problems in the first few postoperative days when he turned in bed and accidentally knocked his frame. He was somewhat apprehensive about having a visit from his active 2-year-old daughter.

He was able to take only a liquid diet, and so liquidised meals were provided with supplementary drinks. He was advised that he could obtain a prescription from his GP for high-calorie drinks during the time when the wiring was in place.

Mr J was surprised at how quickly the appearance of his injury improved. His facial wounds healed quite rapidly and he was encouraged that within a few months the scars would fade and become less noticeable.

While he was still in hospital, he was encouraged to review his alcohol intake and was given information on the effects of alcohol abuse and on local self-help groups from whom he and his family could obtain support as he addressed his dependency problem (see Ch. 36).

overcome by otherwise healthy people, given sufficient encouragement and reassurance in the early stages. Writing pads, 'magic' slates, picture cards and other aids may be used to facilitate communication. Special care will be needed for patients with learning difficulties.

Mobility When and how well the patient will be able to return to normal activity will depend on the nature of any other injuries incurred. Patients with facial injuries can be up on the day following surgery, but there are obvious restrictions if a maxillocranial frame is in place.

15.9 Stop and reflect on how your own activities would be affected if you had metal rods protruding from your head.

Body image Disfigurement caused by facial injuries is of great concern to most patients, and for the majority scarring will be a source of continuing anxiety.

Many people will be reluctant to look at themselves in a mirror following surgery and should not be forced to do so (see Case History 15.2). It might help for the nurse to ask the patient if he would like her to describe how his face looks to her; if her account is matter-of-fact and accepting, he may be more willing to look at himself. Unfortunately, for many people, disfigurement will give rise to deep feelings of grief and loss which may never be completely resolved, and specialist help may be needed (Robinson et al 1996).

Alcohol Smith et al (2003) showed the benefit of a nurse-led psychological intervention on alcohol consumption and misuse in young males following alcohol-related facial injury (Scottish Intercollegiate Guidelines Network 2003).

Discharge planning

Patients who are fit and who can maintain adequate self-care can be discharged when postoperative swelling has subsided. They should be provided with written instructions on diet and oral hygiene, and given a telephone number to call in case of emergency. Referral to the community nurse should be made for care of wounds, checking of fixation and assessment of diet. A follow-up appointment should be made for the patient to return after 4–6 weeks to have the fixation removed.

Post-traumatic stress disorder (PTSD)

There is growing awareness of the psychological impact of a traumatic event (Joy et al 2000, Sen et al 2001), and of the need to address the long-term psychological problems which many trauma patients, regardless of age, experience. In particular, older patients who are already frail may never recover fully from maxillofacial injury and surgery. Some who are fit to go home may well be too afraid or self-conscious to go out of their house. The community nurse is in an ideal position to encourage such individuals to venture into the outside world again. Some may require long-term care, whether within the family, in sheltered housing or in an appropriate care home.

TUMOURS OF THE MOUTH

Oral cancer is more common than is often realised, the mortality rates being comparable with malignant melanoma and cervical cancer (Soutar 2003), and attempts are being made to raise awareness (www.mouthcancerawareness.org.uk). The mortality rates could be much reduced, as early diagnosis should lead to cure (Macpherson et al 2003), and nurses in their role as health educators can make a significant contribution to this reduction (see Box 15.1, p. 629).

Treatment of intraoral tumours is frequently carried out in specialised units. However, as the use of advanced reconstructive techniques becomes more widespread and patients are discharged into the community at an earlier stage, often to continue treatment as outpatients, nurses in more general areas of practice are likely to encounter these patients. To help to ensure continuity of care from hospital to the community, it is important for general nurses to have an understanding of the long-term problems faced by these

patients (Espie et al 1989, Freedlander et al 1989, Rogers et al 2002, Kelly 2003).

Treatment plans vary from centre to centre and there are different schools of thought within the medical profession as to which treatment schedule best promotes survival and, also important, a good quality of life (Robertson et al 2001). However treated, it is likely that many patients will suffer some disruption of several basic mechanisms which control the functions of eating and speaking. Patients may be left with short-term, long-term or permanent malfunction, which will vary greatly from patient to patient and is dependent on many factors. Table 15.7 indicates some of the malfunctions following surgery and/or radiotherapy.

It must be stressed that each patient is very much an individual whose needs and priorities will differ significantly from those of another patient with a seemingly similar problem. There can therefore be no set plan of care, and nurses must be ready and equipped to modify their ideas, working in conjunction with the other members of the multidisciplinary team and with the patient, to meet that individual's needs. As rehabilitation may take many months or years, it is often necessary for this multidisciplinary liaison to continue for some considerable time to ensure the best possible quality of care (Kelly 2003).

The pathophysiology and common presenting symptoms of tumours of the mouth are described under the following headings:

- tumours of the lips
- tumours of the floor of the mouth and tongue
- tumours of the palate
- tumours of the salivary glands.

However, because the separate functions of the mouth, e.g. speaking, chewing and swallowing, are frequently interdependent, medical and nursing management will be discussed with reference to the whole mouth.

Tumours of the lips

PATHOPHYSIOLOGY

Benign tumours, including granulomata, are treated by simple excision.

Malignant disease may take the form of basal cell carcinoma (BCC, often called 'rodent ulcer' because of its pattern of 'eating' or 'gnawing into' tissue) or squamous cell carcinoma (SCC). Malignant melanomas may also rarely occur on the lips (see Ch. 12).

Predisposing factors include prolonged, unprotected exposure to sunlight, e.g. among outdoor workers, fair skin and pipe smoking. The lower incidence of lip cancers among women may possibly be due to the barrier effect of cosmetics.

Common presenting symptoms Basal cell carcinoma may appear as a nodule or as a small, unstable ulcerating area with persistent crusting. It may also be diffuse and invasive. The patient often reports: 'I thought it had healed up, but I kept knocking the top off it.' The ulcer may have 'pearlised' rolled edges. These tumours are generally slow

Table 15.7 The effects of intraoral disease and treatment on the mechanisms of eating

Normal mechanism and cranial nerves involved	Disruption caused by intervention	Effects
Teeth bite and chew food, powered by muscles of jaw and supplied by trigeminal nerve (CN V)	Teeth may be extracted due to caries or to give access to tumour	Soft food only can be taken until fitting of dentures, if this is possible
Saliva secreted by parotid gland (CN IX), submandibular and sublingual glands mixes with food	Glands may be excised during surgery or damaged by radiotherapy	Dry mouth (xerostomia) Stomatitis Thrush
Tongue and teeth powered by muscles of jaw break down food and form it into bolus	Muscles damaged or weakened by surgery and trauma	Re-education of eating skills will be needed
Mouth kept closed by superficial facial muscles (supplied by CN V and CN VII); buccinator prevents food gathering in cheek pouches	Internal contours of mouth are altered; lack of control Temporomandibular joint malfunction	Drooling Food gathers in mouth Trismus — mouth cannot open
Tongue helps propel food to back of mouth and into contact with oral part of pharynx	Excision of part or whole tongue Tongue becomes fixed or insensate	Patient needs to push food to oropharynx
Simultaneously with above, muscles of soft palate elevate and tighten, straightening out to close off nasal cavity and preventing food from entering it	Damage to palate and nerves allows food to enter nasal space	Food, liquids come down nose unless obturator (see Box 15.3) can be fitted
Larynx rises under shelter of epiglottis to close off airway, preventing entry of food	CN IX damage causes paralysis of pharyngeal muscles	Aspiration of fluid to lungs necessitates permanent tracheostomy and gastrostomy

growing and do not metastasise, although occasionally a tendency to multiple BCC is seen.

Squamous cell carcinoma is more aggressive and, if untreated, may assume the 'cauliflower' look of a malignant ulcer and will eventually fungate and cause severe pain.

Tumours of the floor of the mouth and tongue

PATHOPHYSIOLOGY

Tumours of the tongue account for approximately one-third of all intraoral tumours in the UK. Others included in the category of the floor of the mouth are found on the lower alveolus, tonsillar fossae and retromolar trigones, and about 90% are of the SCC type (Lewis 2003). Fifty years ago the male to female ratio was 5:1; it is now 2:1 in Scotland and incidence and mortality are also rising in almost all EU countries (Soutar 2003).

Spread usually involves the local lymph nodes, e.g. cervical, submandibular and submental. Distant metastases occur rarely in the lung.

Predisposing factors Heavy smoking combined with excessive alcohol consumption is associated with these cancers. However, there is an increase in younger people with no history of smoking or excess alcohol consumption (Llewellyn et al 2003), and it is now accepted that oral cancer may occur in any age group. Other risk factors are deprivation and diets poor in fruit and vegetables. There are also connections with anaemia, vitamin deficiencies and chronic oral infections, e.g. syphilis, herpes simplex virus, human papilloma virus and HIV (Soutar 2003).

Common presenting symptoms These cancers may become apparent in a variety of ways. In the early stages, intraoral SCC is easily mistaken for infection, irritation from dentures or a simple aphthous ulcer. Dysplasia, i.e. abnormal mucosa which presents as white patches (leukoplakia) or red patches (erythroplakia), is a precancerous condition which can revert to normal if the individual stops smoking. Unchecked, this condition will often become malignant. More advanced tumours are usually unmistakable, but many patients present late for various reasons, including fear, misdiagnosis and self-neglect (Lewis 2003).

Tumours of the hard and soft palate

PATHOPHYSIOLOGY

These tumours may arise from the epithelium of the mucous membrane (SCC), in the maxillary sinuses, in the maxilla or in the minor salivary glands in the palate. They are less common than tumours of the floor of the mouth, but are potentially more disfiguring, as spread may occur locally to the floor of the orbit or to the eye.

Common presenting symptoms Onset may be insidious. The patient may notice a dull ache for some time and may complain of 'sinusitis'. The pain will eventually increase and swelling may develop over the cheek. There may be some displacement of the eye (proptosis) in advanced cases. Rarely, a malignant melanoma appears as a pigmented lesion of the palate and goes unnoticed until the individual presents with a secondary tumour of the cheek or neck.

Tumours of the salivary glands

PATHOPHYSIOLOGY

The most common cause of swelling of the parotid gland is mumps (acute parotitis), an infectious, inflammatory condition that usually resolves without treatment. Mumps may, however, be relatively severe in adults and lead to pancreatitis or orchitis.

Benign (pleomorphic salivary adenomas, PSAs) or malignant tumours may develop in the parotid, submandibular, sublingual and other minor salivary glands. Salivary gland ducts may become blocked by small accretions (see 'Orodental disease', p. 630).

Common presenting symptoms The patient presents with a swelling, which is often asymptomatic and therefore sometimes long-standing, in the area of the affected gland. If left untreated, a parotid gland tumour may involve the facial nerve (CN VII), resulting in facial palsy, a severe disfigurement.

MEDICAL MANAGEMENT OF TUMOURS OF THE MOUTH

Tests and investigations A treatment plan for malignant tumours will be devised on the basis of careful staging of the cancer (see Table 15.8 and Ch. 31). Investigation may include the following:

- history
- physical examination — visual and by palpation
- blood tests
- diagnostic X-rays — face and jaw, chest and spine as appropriate
- orthopantomogram (OPT or OPG; see Appendix 1)
- sialogram (see Appendix 1)
- computed tomography (CT) scan
- magnetic resonance imaging (MRI); see Chapter 31
- positron emission tomography (PET) scan, if available
- examination under anaesthetic (EUA)

Table 15.8 TNM classification for lip and oral cavity

T: Primary tumour	
T1	Tumour ≤2 cm
T2	Tumour >2–4 cm
T3	Tumour >4 cm
T4	Tumour invading adjacent structures
N: lymph nodes (neck)	
N1	Ipsilateral single node ≤3 cm
N2	Ipsilateral single node >3–6 cm Ipsilateral, multiple nodes ≤6 cm Bilateral, contralateral nodes ≤6 cm
N3	Node >6 cm
M: distant metastases	
M0	No distant metastases
M1	Distant metastases

Adapted with permission from Sobin & Wittekind (2002).

- videofluoroscopy
- fine needle aspiration
- biopsy — results are essential for staging disease and planning treatment
- sentinel node biopsy (SNB) to evaluate spread of cancer to the neck (Ross et al 2002) (see Appendix 1).

The patient's age, general physical condition and mental outlook will also be taken into consideration.

Treatment Patients are often seen at a combined clinic, where many medical and other professional personnel may be present, and this can be very stressful (Telfer & Shepherd 1993). At this clinic different specialist consultants, e.g. surgeons and oncologists, liaise to plan treatment, which may be radical, i.e. intended to effect a cure, or conservative, i.e. intended to alleviate pain, prevent fungating tumours and subsequent haemorrhage. Radical treatment may involve extremely difficult adjustments for patients and, for some, a significant reduction in the quality of life (Espie et al 1989, Freedlander et al 1989, Rogers et al 2002).

The treatment options for oral tumours are radiotherapy, surgery and, less commonly as first-line treatment, chemotherapy. These treatment modes may be used singly or in combination; sequence and timing vary from one centre to another (McMahon 2003).

Chemotherapy is usually given concurrently with other treatment. It may be used to reduce the bulk of some tumours prior to surgery or in cases of recurrent tumours (see also Ch. 31).

Radiotherapy can be given as the sole treatment, or pre- or postoperatively. It may take either of the following forms:

- teletherapy (external radiation) by means of megavoltage machines or supervoltage machines
- brachytherapy, in which a radioactive source is placed in or near the tumour, e.g. interstitial needles to tumours of the lip or oral cavity. This treatment is being used increasingly in tongue cancer to try to maximise quality of life (Sandhu et al 1999).

Many tumours, e.g. SCC, are highly curable by radiotherapy. Sarcoma and malignant melanoma, on the other hand, are less radiosensitive (Holmes 1997, and see Ch. 31).

Surgical excision Treatment by this method ranges from small local excisions with direct closure, to major operations with full reconstruction. Benign tumours are usually excised.

Some centres carry out excision of tumours initially, with secondary reconstruction later; others carry out immediate reconstruction (Hislop & Soutar 2003). Table 15.9 summarises current surgical procedures.

Both radiotherapy and surgery treat SCC successfully, either independently or in combination, but there is lack of agreement among medical practitioners as to the best timing of each. Gene, viral oncolytic and antibody therapies are being researched (Ganly 2003).

Nurses should be aware of the effect of radiation on the epithelium (Little 1996, Holmes 1997, Wells 2003, and see Ch. 31). Following radical radiotherapy, healing after surgery may be delayed; occasionally, orocutaneous (between mouth and skin) fistulae may develop. A late effect may be bone necrosis (osteoradionecrosis).

Follow-up and aftercare will require outpatient appointments at regular intervals for at least 5 years. Dental and/or prosthetic provision may include dentures, obturators (see Box 15.3) and other prostheses provided by members of the multidisciplinary team as and when necessary. Referral to other consultants, e.g. ENT, ophthalmic, thoracic and neurological specialists, will be made as

Box 15.3

Obturators

Obturators are prostheses which are designed to fill a defect in the palate after maxillectomy. They are fitted in three stages:

1. *Surgical splint* — fitted during surgery to hold a skin graft in place and/or avoid collapse of the cheek and upper lip. After about 2 weeks, it is replaced by a temporary obturator.
2. *Temporary obturator* — used throughout radiotherapy. This allows the patient to become accustomed to wearing and handling an obturator.
3. *Definitive obturator* — fitted after shrinkage of defect. It may be composed of a soft malleable 'bung' which fills the defect, and a denture which fits over the bung.

Without the obturator, the patient will be unable to speak or eat properly, and fluid will run into the nasal cavity. With a well-fitting obturator, the patient can eat and speak normally.

The obturator must be removed after meals and cleaned by brushing or by immersion in a proprietary cleaning solution (if the obturator has been 'built up', cleanser should not be used). The mouth must be rinsed after all food to prevent accumulation of plaque, debris, etc.

Table 15.9 Surgery for tumours of the mouth

Site	Excision	Reconstruction
Superficial lesion of lip, leukoplakia	Shaving	None
Lip, parotid gland, T1 tumour of mouth	Simple excision	None: direct (primary) closure
Lip	Wedge excision	Direct closure
Tongue	Local excision	Split-skin graft
Lip, alveolus, tongue	Local excision	Local flap: many varieties — Abbé, tongue, buccal, nasolabial, etc. (see Soutar & Tiwari 1996)
Mouth/pharynx (all sites), cheek, neck	Local/wide excision ± neck dissection	Free flap common in many centres
As above (especially for recurrent tumour as palliative procedure)	As above	Pedicled flap (deltopectoral, pectoralis major)

appropriate. Speech therapy and dietary advice will be essential for many patients.

NURSING PRIORITIES AND MANAGEMENT: Tumours of the mouth

The presence of an oral tumour may not give rise to immediate life-threatening concerns, except where a long-neglected tumour causes respiratory distress or haemorrhage.

Patients will vary widely in the symptoms with which they present, and usually require much reassurance when a biopsy confirms the diagnosis. They will be admitted as soon as appropriate treatment has been arranged, or immediately if the disease is advanced. A gastrostomy (see Ch. 21) may be planned if swallowing difficulties are anticipated. The nurse may require to be the patient's advocate, to ensure adequate understanding before consent to treatment. Referral to the primary care team and/or Macmillan or Marie Curie home care nurses will be beneficial to many patients for support before definitive treatment starts.

Immediate nursing priorities

Nursing intervention in the early stages of treatment will focus on controlling pain (see Ch. 19), relieving anxiety, encouraging self-care in oral hygiene, and nutritional assessment (see Ch. 21). Supplementary feeding may be necessary, as weight loss is common among this group of patients. Existing physical conditions must be taken into account in any nursing plan. An additional concern may be the assessment and control of alcoholism. Excessive consumption of alcohol is a causative factor in many cases of oral cancer, and advice and information on limiting the intake of alcohol may be given by nurses (Scottish Intercollegiate Guidelines Network 2003, Smith et al 2003, and see Ch. 36).

Preoperative preparation

Giving information

All patients will require adequate and honest information about the proposed treatment and its implications (see Ch. 31). In view of the many variations in procedures, and the diverse presentations and responses to treatment that are possible, nurses should be wary of giving information based on limited knowledge of apparently similar cases. What is feasible for one person may not be possible for another, and expectations or anxieties should not be raised unduly.

The patient should, however, be allowed to voice any concerns about the disease and its implications for normal functioning, e.g. speaking and eating, and for appearance. Many patients also have a deep fear of cancer and may have misconceptions about prognosis and the likely course of the disease. It is important for their needs to be recognised and any unfounded anxiety relieved.

Information giving is discussed by Ream (2000).

A multidisciplinary approach

A successful outcome will depend in part on the continuity of care provided by the multidisciplinary team. Along with medical staff, the nursing team will include ward, theatre and high dependency unit nurses, specialist nurses, community nurses and possibly Macmillan and Marie Curie nurses. The following professionals also contribute to care, and the nurse must be aware of each team member's role and facilitate liaison wherever appropriate:

- Dietitian — assesses dietary intake and advises staff and patient on maintaining adequate nutrition; liaises with pharmacy, the nutritional support person in the commercial companies and the community dietitian for provision of enteral feeding equipment (Dawson et al 2001)
- Speech and language therapist — advises patient on pre- and postoperative exercises to assist with speech and swallowing difficulties; advises on alternative means of communicating if loss of voice is permanent (Jackson et al 1999) (see Ch. 14)
- Physiotherapist — gives instruction and assistance with pre- and postoperative exercises to assist breathing, expectoration, limb and shoulder movements
- Dentist (associate specialist) or prosthodontist — assesses need for dental care, especially when radiotherapy is part of treatment, and fits obturator and/or dentures (Ali 2003)
- Dental hygienist — advises patient on care of teeth and oral hygiene, especially during radiotherapy and/or chemotherapy
- Maxillofacial technician — advises on whether provision of a prosthesis is realistically possible; designs, constructs and fits this when appropriate for each individual patient
- Medical social worker — gives information and advice on availability of grants for special needs; arranges home help, day care
- Hospital chaplain or other religious counsellor — gives spiritual comfort and practical help
- Voluntary support agencies — provide emotional and practical support for patient and family.

15.10 Discuss the ways in which each member of the team would be able to contribute to the care of the patient described in Case History 15.3 while in hospital and in the community.

Postoperative care

The postoperative nursing care of individuals who have undergone major surgery for intraoral cancer is highly specialised and combines the skills of many specialties. There will be variations in procedures and approaches among centres, and each patient will require a highly individualised plan for care.

Many centres reconstruct facial defects using free tissue transfer. Figure 15.5 outlines nursing procedures for the monitoring of free flaps.

Soutar & Tiwari (1996) describe free flaps. See also Coull & Wylie (1990), Coull (1992) and Haskins (1998) for discussions of nursing responsibility for monitoring free flaps.

Participation of relatives

Oral tumours and the effects of treatment may have far-reaching consequences not only for the patients concerned

CASE HISTORY 15.3
Mrs C

Mrs C, a 45-year-old housewife with two teenage children, was referred to an oncology unit from a dental hospital after she reported that she had had a lump in her mouth for some weeks. No lymphatic nodes were palpable in her neck and Mrs C was not too concerned that she might have cancer because she had never smoked and rarely took alcohol. She and her husband were consequently very shocked when they were given the result of a biopsy which showed squamous cell carcinoma.

Mrs C was assured that the disease was treatable and was advised to have surgical excision in the first instance, possibly followed by radiotherapy. Liaison was immediately set up with a Macmillan nurse, who visited her at home and discussed with Mrs C and her family their fears about cancer.

Mrs C felt that she did not want her husband to visit her until 3 or 4 days after the surgery. Her husband, however, felt anxious at not seeing her and came to visit of his own accord on the first postoperative day. The nurse prepared him for how his wife would look, and although he was initially shocked by her appearance, he felt that the result was not as bad as he had anticipated. He was also able to appreciate the rapid improvement which had taken place by the second day.

For herself, Mrs C was glad that he had visited. She felt more alert than she had believed possible. She also noticed the relief on her husband's face on his second visit and was able to believe him when he said she looked much better. On the third day, having prepared them, he brought their two children.

Three years later, Mrs C is attending the outpatient clinic for regular follow-up appointments. She has upper and lower dentures, which she wears all day, and is able to chew, swallow and speak well. She is socially very active and has adjusted well to the effects of her surgery, although she feels anxious every time she visits the clinic. Even after 3 years, she admits, 'I worry in case they find anything'.

but also for their families (Espie et al 1989, Freedlander et al 1989, Diamond 1999, Walton 2003). Relatives must often provide care for the patient after discharge. They are likely to experience much anxiety and to need maximum support. Nurses must help them through this very stressful time (see also Nicholson & Wells 2003).

Relatives will need constant reassurance, especially during the early postoperative days, and should be counselled before the first postoperative visit, which is usually very stressful (see Case History 15.3). It is advisable to reinforce and supplement verbal advice with written information, particularly with regard to oral hygiene, diet, radiotherapy, chemotherapy and local support groups. Local written information is now often available and general information booklets are also available, e.g. BACUP, Macmillan Cancerline (see 'Useful websites').

Altered body image

The impact of surgery to the face and mouth upon day-to-day function is visible to everyone. Basic activities such as breathing, eating and drinking may have to be performed with some loss of dignity. This, together with the disfiguring effects of the surgery, will require the patient to accept an altered body image, which can be a very difficult adjustment to make. Below, a patient describes, in a diary shared with the author (Kelly 1987), how she feels about her swollen face:

> *He said I was 'round the corner' — but I don't really feel like it. I asked about my face which is freakish and he said when I start walking about, gravity would reduce it. I feel a bit shy about it. I feel a freak especially when I see in a mirror — avoid mirrors meantime!*

This patient also refers to being 'unleashed' from drainage and feeding tubes —another assault on body image.

Another patient who had undergone several operations, commented: 'Each time, I feel I am a little less of the person I once was.' Remarks such as 'Of course, until I get my teeth, I can't go anywhere' are also frequently heard. It is worth noting that for many patients, after this type of surgery, dentures (if they can be worn) may be purely cosmetic rather than functional (Ali 2003). Many patients, e.g. those who have had a tracheostomy, will be temporarily unable to speak following their surgery. It is important for nurses to bear in mind that it may be difficult for these individuals to convey their emotions in writing and that it may be necessary to 'read between the lines' in order to fully appreciate the extent of their emotional pain. The effects of a permanent tracheostomy are discussed in Chapter 14.

15.11 Consider how Mrs C in Case History 15.3 is likely to feel about her condition and the consequences of treatment. How is her body image likely to be affected?

Robinson (1997) describes research into coping with disfigurement. For vivid descriptions of the impact of oral cancer on life, read Diamond (1999).

Discharge planning

Prior to the patient's discharge, liaison should be established with the GP and community nurse and appropriate appointments and home visits arranged. In many cases a Macmillan nurse will visit the patient in the ward and will continue to give support at home. Each of these professionals will coordinate subsequent visits through the local health centre according to assessment of the patient's needs and should be encouraged to contact any member of the hospital team for help and support at any time.

Particular advance planning will be required if the patient's social circumstances are less than optimum; for example, many patients live alone or in hostel accommodation, and early liaison with social workers will ensure that the best possible social support is provided.

Rehabilitation

Following discharge after major oral surgery and radiotherapy, the process of rehabilitation may not be complete for a period of some months or even years. Patients will need ongoing support as they learn to cope with changes in lifestyle and in the activities of daily living (see Ch. 34). Planning for rehabilitation should start from the day of admission and must take into account the following considerations:

- *Living arrangements* — the patient may need to live with relatives temporarily or permanently, or may need rehousing if they are to live alone. Long-term nursing support, e.g. from Macmillan and Marie Curie nurses,

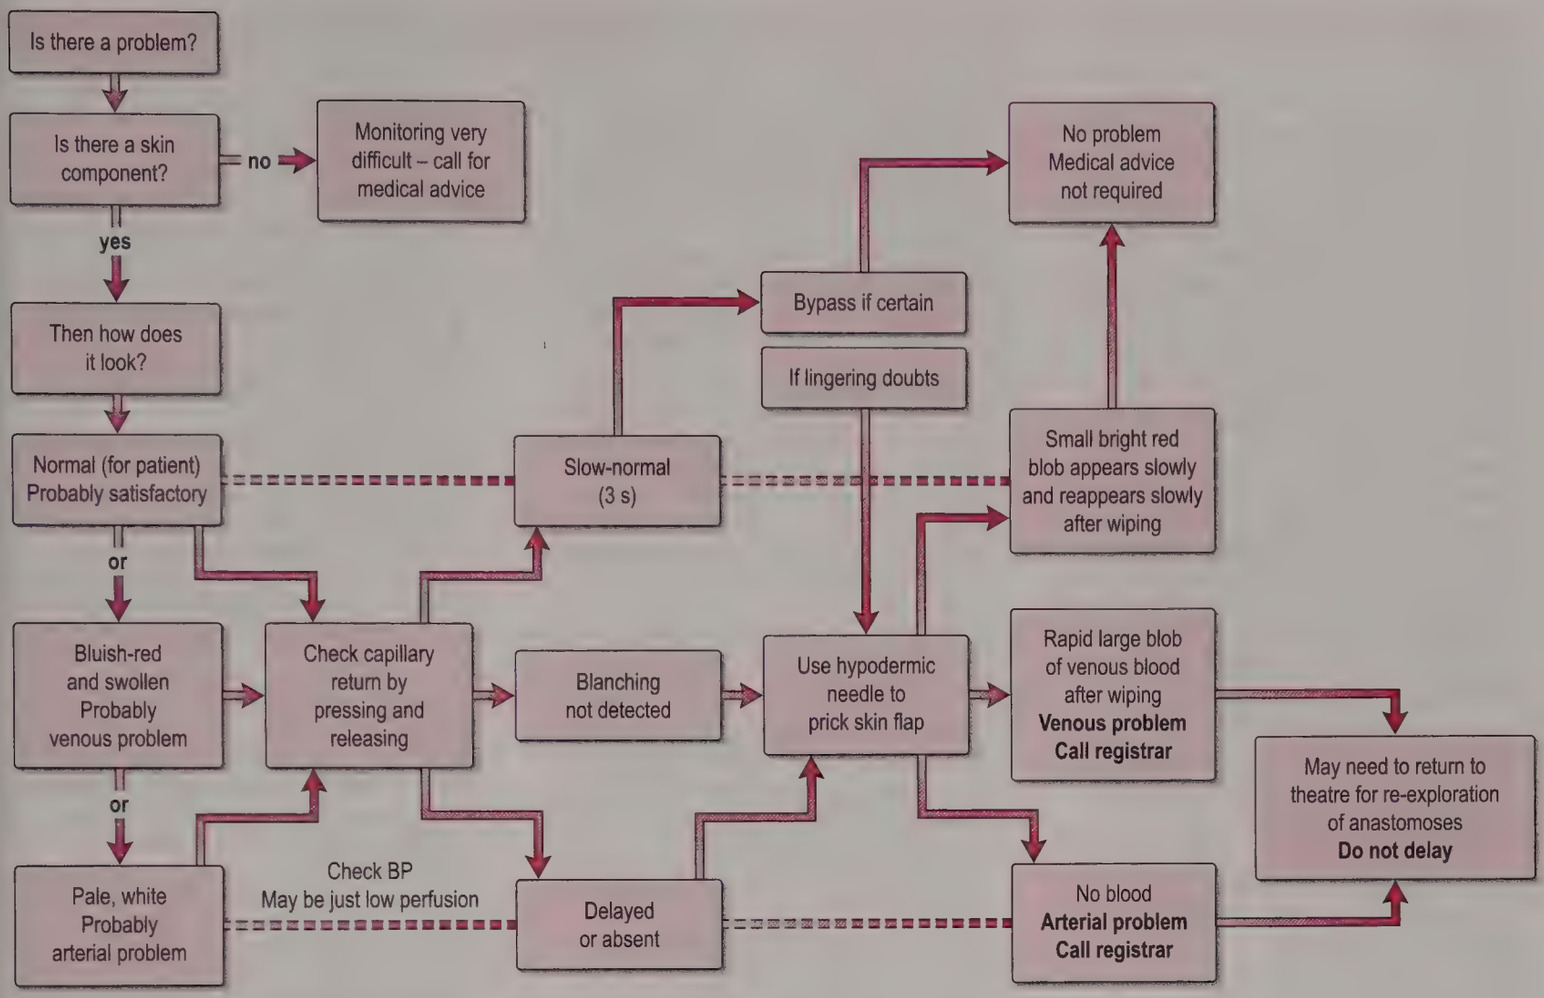

Fig. 15.5 An algorithm for monitoring free flaps.

and community-based services, e.g. Meals-on-Wheels, may need to be arranged.

- *Breathing* — patients with a tracheal stoma will need to be instructed in its management and will need support in adjusting to their altered appearance.
- *Oral hygiene; eating and drinking* — the patient (or carer) will need to be proficient in maintaining oral hygiene and using special equipment for giving enteral feeds if necessary.
- *Communication* — training in alternative forms of communication will be needed to compensate for a loss in speech.
- *Psychological support* — the patient should receive pre-discharge counselling to help in adjusting to an altered body image. Ongoing professional support may be needed for some time after discharge as the patient readjusts to life in the community (Robinson et al 1996), and both the patient and family should be able to contact members of the hospital team for support and advice.
- *Work* — the patient will need help in adjusting to new employment circumstances, whether changing jobs, stopping working or returning to a previous job, and in learning to cope with a changed appearance and function and with the reactions of colleagues.
- *Education* — the patient may need information on such matters as nutrition, giving up smoking and reducing alcohol intake (Scottish Intercollegiate Guidelines Network 2003).

The patient and family should be informed about local self-help groups where they can obtain practical and psychological support.

15.12 Consider how you might go about planning the long-term rehabilitation of Mrs C in Case History 15.3.

Nursing and stress

Caring for patients with intraoral tumours can give rise to considerable stress and nurses may find this area of care quite harrowing. Unfortunately, ward nurses frequently see patients return with a recurrence of the cancer, and some may question whether radical treatment has in fact been justified. Liaison with outpatient clinics will make it apparent, however, that many patients do in fact survive to lead fulfilling lives for many years after treatment.

For a discussion of staff support in cancer nursing, see Magnusson & Robinson (2000) (see also Chs 17 and 31).

Palliative care

In cases of advanced disease, only approximately 10% of patients with oral cancer survive over 5 years; there is therefore a need to address issues of palliation, often from time of diagnosis (Scottish Intercollegiate Guidelines Network 2000c, McDougall 2003; see also Ch. 33).

15.13 After reading this chapter, consider the different priorities you may have to set in delivering effective oral care throughout different stages of the health–illness continuum.

INTRODUCTION

The immune system is a complex and fascinating network of cells and proteins which is programmed to respond to the many challenges presented to it by foreign particles, microorganisms such as bacteria, viruses, fungi and protozoa, and tumour cells. Its function is to protect the body from anything that could be harmful. In order to carry out this function, it has to be able to recognise 'self' from 'non-self', which it attacks and attempts to eliminate or destroy.

Human beings and animals have a number of non-specific barriers to foreign substances; for example, the intact skin protects the body from invasion and substances in some body fluids help to kill microorganisms (see Fig. 16.1). It is when these barriers fail or are compromised that the specific immune responses come into play.

Healthy individuals can fight off infection by immune mechanisms, and in many cases immunity to a disease occurs after a single encounter with the infectious organism. Sometimes, the system is unable to function normally because of an immune deficiency or a functional disorder. When a large number of microorganisms enter the body, the immune system may function normally but still be too slow to prevent the person from developing the infectious disease. Immune suppression can occur as result of other disease; it can also be iatrogenic, resulting from medication, including chemotherapy, or radiotherapy.

Health care-associated infection (HAI) and infectious diseases

There is heightened concern and activity in the UK, and globally, in relation to health care-associated infection in particular and to the prevention and control of all infectious diseases. Health care-associated infection (HAI or HCAI), previously known as hospital-acquired infection and in some countries as nosocomial infection, is the term used to refer to infection acquired during receipt of some form of health care. New infections such as Legionnaire's disease, human immunodeficiency virus (HIV) and severe acute respiratory syndrome (SARS) and long-standing infectious diseases such as *Mycobacterium tuberculosis* and influenza continually pose challenges to public health as well as to health care settings, as do more commonly occurring infections, such as methicillin-resistant *Staphylococcus aureus* (MRSA). For the purposes of this chapter, health care settings where HAI must be controlled include hospitals, care homes and primary care facilities; however, the guidance given applies also to patients who are being cared for in their own homes.

Measures developed and applied at local settings and national levels aim to reduce the burden of HAI, and other infectious or communicable diseases, on individuals, health care organisations, and within the National Health Service as a whole. The Health Protection Agency, Health Protection Scotland and Departments of Health in all UK countries

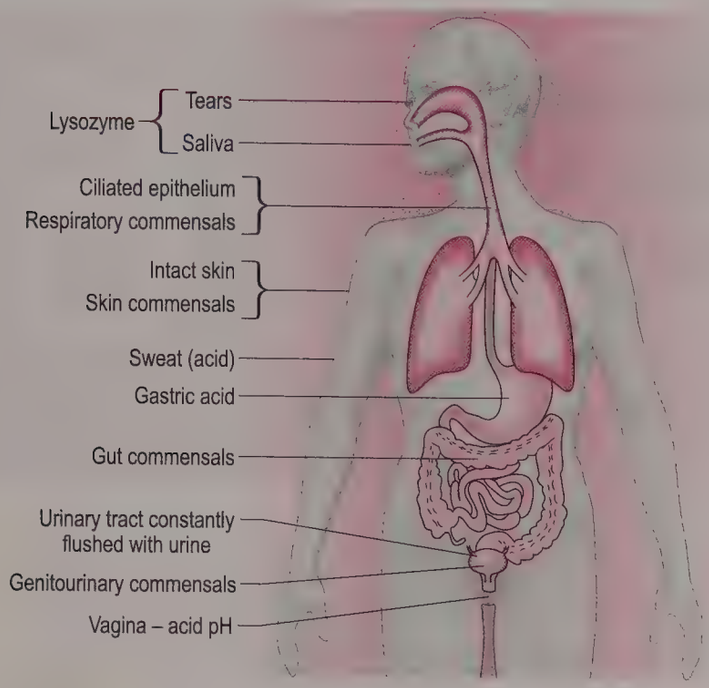

Fig. 16.1 Barriers to infection.

coordinate many activities, such as national surveillance and control programmes, in order to highlight and act upon the actual burden in specific settings (see 'Useful websites', p. 689).

For further information on the national burden of HAI, see Plowman et al (1999), National Audit Office (2000, 2004) and the UK Health Department websites (see 'Useful websites', p. 689).

It is thought that up to one-third of all HAI is preventable. Nurses must consider not only how they can address infection prevention, control and management within health care settings, but also how they might influence the wider public health arena.

Epidemiology

Epidemiology is the study of disease in relation to populations, e.g. who is being affected by MRSA, or by SARS, and when and where they are being affected. A population considered at risk, for example from MRSA, could be monitored using epidemiological methods to gather information which relates the disease to the population by studying both ill and healthy individuals. Epidemiology is closely linked with risk assessment and management, and results of studies can help to influence structures, processes and outcomes, including control measures and action plans.

In order to identify infectious diseases including HAI, methods must be in place to gather the appropriate information to inform knowledge of the distribution of such diseases. There are various ways to monitor disease.

- *Incidence* is the number of new cases in a defined period within a specific population, e.g. incidence of wound infections postoperatively in all patients undergoing surgery in the next financial year.
- *Prevalence* is the number of cases that occur either at a particular time (point prevalence) or over a defined period of time (period prevalence), e.g. the number of patients with urinary tract infections at any one time within a hospital.
- *Surveillance* is 'the ongoing systematic collection, collation, analysis and interpretation of health data essential to the planning, implementation and evaluation of public health practice, closely integrated with the timely dissemination of these data to those who need to know. The final link of the surveillance chain is the application of these data to prevention and control' (Centers for Disease Control 1998).

Data collected over time show the changing patterns of infectious diseases in our society, providing information on newly emerging diseases and identifying specific problem areas, e.g. outbreaks and seasonality of diseases. Risk management not only contributes to the prevention of infection but also assists in the control of outbreaks of infection. To fully appreciate infection control principles, including immunology, the relevant anatomy and physiology must be understood.

ANATOMY AND PHYSIOLOGY

The lymphoid system

The lymphoid (or lymphatic) system consists of organs and tissues made up of cells which are involved in the immune response. These structures may be described as being either primary or secondary, as follows.

Primary lymphoid organs

The thymus gland and the bone marrow are known as primary lymphoid organs. Lymphocytes develop in the bone marrow (see Ch. 11): T lymphocytes differentiate in the thymus gland; B lymphocytes differentiate in the bone marrow. It is in the organ where they differentiate that lymphocytes acquire the surface receptors which enable them to recognise antigens.

Secondary lymphoid organs

The spleen and lymph nodes are known as secondary lymphoid organs, as are other areas of lymphoid tissue which are associated with mucosal surfaces in the body, such as in the respiratory, gastrointestinal and genitourinary systems. The spleen contains white blood cells, or leucocytes (see Chs 4 and 11), and is involved in the breakdown of erythrocytes, leucocytes and platelets. The lymph nodes are small collections of lymphoid tissue (1–25 mm in diameter) which are found all over the body, often where lymphatic vessels branch. Lymph nodes act as filters, trapping any foreign materials or antigens so that they can be attacked and destroyed by specialised white blood cells which accumulate there in large numbers.

For further information, see Waugh & Grant (2001).

Types of immune response

Two types of immune response are involved in recognising and eliminating any 'foreign' material which enters the body:

- *Non-specific or innate immunity* — by which any foreign cell or particle is identified as such and attacked. Even

tumour cells which arise in the body's own tissues can be recognised as foreign and may be destroyed. This response is non-specific in that it is the same whether the foreign particle or antigen is a bacterium, a particle of asbestos or other agent. The response occurs as soon as the antigen is encountered. No 'memory' is involved and a second contact with the same antigen will produce the same response at the same rate.

- *Specific or adaptive immunity* — in which special cells (B and T lymphocytes) are programmed to respond to recognised antigens. This response is highly specific: each lymphocyte is equipped to recognise only one antigen. Once contact has been made with that antigen and it has been destroyed, some 'memory' cells (see p. 657) remain in the body. If the same antigen is encountered again, these cells are stimulated to reproduce, and the response is both faster and greater.

Cells and chemicals involved

Cells

The cells involved in the immune response are white blood cells (leucocytes) (see Box 16.1). These may be granular (granulocytes or polymorphonuclear leucocytes) — neutrophils, basophils and eosinophils, or non-granular (agranulocytes) — mononuclear phagocytes, i.e. monocytes and macrophages, and lymphocytes. In this section these cells will be described according to their function.

Phagocytes

have the ability to recognise foreign material and to engulf and digest microorganisms by a process called phagocytosis. Three cells are classed as phagocytes: neutrophils, monocytes and macrophages.

Neutrophils

are small cells and live only for a few days. They originate in the bone marrow and circulate in the blood.

Box 16.1

Components of the immune system

Cells

Leucocytes (white blood cells)

- Granular (granulocytes or polymorphonuclear leucocytes)
  - — neutrophils
  - — basophils and mast cells
  - — eosinophils
- Non-granular (agranulocytes)
  - — Mononuclear phagocytes (monocytes and macrophages)
  - — Lymphocytes
    - B lymphocytes
    - T lymphocytes

Chemicals

Complement
Cytokines, e.g. interferons
Inflammatory mediators, e.g. histamine
Antibodies (immunoglobulins)

Monocytes

are approximately the same size as neutrophils. They also originate in the bone marrow and circulate in the blood, but they may enter the tissues, where they become macrophages.

Macrophages

are larger than neutrophils and monocytes. They are long lived and are found in the tissues, principally in the liver, spleen, lymph nodes and lungs. Mainly involved in non-specific immunity, they are also activated by lymphokines, which are produced by T cells in the cell-mediated immune response (see p. 658). Phagocytosis can take place only if the invading cell becomes adherent to the surface of the phagocyte. This occurs by a chemical attraction between the surface of the phagocyte and antigen. The process can be assisted by complement (see p. 656) and by antibodies.

Accessory cells

function by releasing chemicals which are harmful to invading organisms. This group of cells comprises basophils, eosinophils and mast cells.

Basophils and mast cells contain histamine and other chemicals which give rise to an inflammatory response when released. They are important in allergies, e.g. hay fever. Basophils circulate in the bloodstream. Mast cells, although similar in function, are located in connective tissues and mucous membranes.

Eosinophils are capable of phagocytosis, but their main function is to attach themselves to larger parasites such as helminths (worms) and destroy them by releasing harmful substances. They may also help to control the inflammatory response by breaking down histamine. There is an increase in the number of eosinophils in people suffering from allergic conditions and parasitic infections.

Lymphocytes

originate in the bone marrow as stem cells and subsequently differentiate into B and T cells.

B cells are the lymphocytes which produce antibodies. They differentiate in the bone marrow and then mature in the secondary lymphoid tissues. The antigen receptor on their surface is specific for one antigen only. B lymphocytes are capable of 'memory' and are specialised to deal with microorganisms which do not, of their own accord, enter host cells, e.g. circulating bacteria.

T cells have various functions. They originate in the bone marrow and then mature and differentiate in the thymus gland. They are also antigen-specific and have an antigen receptor which is similar in structure and function to that of the B cells. T lymphocytes are capable of 'memory' and are specialised to deal mainly with microorganisms which invade host cells, e.g. viruses.

T cells can be broadly divided into two groups:

- T-helper cells
- T-cytotoxic cells.

T-helper cells are subdivided into the cells which interact with B cells, helping them to produce antibody, and the cells which assist the mononuclear phagocytes, helping them to destroy intracellular pathogens.

T-cytotoxic cells destroy host cells which are infected by viruses or other intracellular pathogens.

Chemicals

Complement

is the collective name for a group of proteins which induce chemical reactions and are involved in the control of inflammation. Their three main functions are:

- To coat microorganisms with a substance which phagocytic cells can recognise. This ensures that the microorganism adheres to the surface of the phagocytic cell.
- To activate the destruction of the microorganism inside the phagocyte once ingestion has taken place. Complement also participates in the acute inflammatory response by inducing vasodilatation and increasing the permeability of the capillary endothelium.
- To assist in the lysis of invading cells.

Cytokines

are molecules of mainly proteins, whose function is to signal between cells during the immune response. Interferons are one example. There are many different interferons and they protect cells of the same species from viral attack. They are synthesised by virally infected cells and secreted into the extracellular fluid. Here they bind to specific receptors on other, non-infected cells, which 'surround' the infected cell and prevent the spread of virus.

Histamine

is released by mast cells when they degranulate after adhering to a microorganism. This gives rise to increased vascular permeability, arteriolar dilatation, smooth muscle contraction in the respiratory and alimentary tracts, and increased secretion of respiratory mucus.

Antibodies

are the principal substances involved in the adaptive or specific immune response. Collectively known as immunoglobulins, they are proteins capable of recognising and binding to their own specific antigen, usually a microorganism.

Antibodies are produced by B lymphocytes and, once formed, circulate in the plasma. They have three functions:

- to bind to antigens
- to bind to phagocytes
- to activate the complement pathway.

There are five classes of antibody: immunoglobulin G (IgG), IgA, IgM, IgD and IgE. Each of the five classes may be produced with specificity for a single antigen. Their structure varies according to function and they are present in different amounts in the bloodstream (see Box 16.2).

Box 16.2

Immunoglobulins

Immunoglobulins are proteins with known antibody activity. They form the central component of the immune system and are synthesised by lymphocytes and plasma cells. The five classes of immunoglobulins are as follows:

- IgM — the first immunoglobulin to appear in the bloodstream in the primary response to infection. Since it disappears fairly quickly after the antigen disappears, it is an indicator of current or very recent infection.
- IgG — produced in large quantities in both the primary and secondary responses to infection. It is also important as a defence against infection in the first few weeks of life, being the only immunoglobulin which crosses the placenta to the fetus.
- IgA — secreted onto the luminal surface of the respiratory, alimentary and genitourinary tracts and present in saliva, tracheobronchial and genitourinary secretions as well as in the serum. It is important in preventing the entry of microorganisms from the external orifices of the body.
- IgE — normally found on the surface membrane of basophils and mast cells. It is associated with allergic reactions such as hay fever.
- IgD — present in small quantities bound to B cells where it aids in the 'memory' function.

Immunoglobulins can be taken from a donor by plasmapheresis and given:

- to someone who has been exposed to a pathogen and is not immune, e.g. antitetanus immunoglobulin (Humotet)
- as short-term prophylaxis, when exposure is anticipated and there is not time for vaccine to take effect, e.g. tickborne encephalitis
- to someone who is heavily immunosuppressed, following exposure to a pathogen which could cause serious infection because of an inadequate immune response.

Passive immunisation with immunoglobulins does not confer long-term protection: this requires vaccination (see p. 657).

The non-specific immune response

When a foreign substance enters the body, the first line of defence is the non-specific immune response, which comprises the following components:

- mechanical barriers, e.g. the skin, cilia in the upper respiratory tract
- phagocytes
- chemicals, e.g. complement, the interferons
- substances found in body secretions, e.g. lysozyme, gastric acid.

These defences can be effective on their own, but help is sometimes needed from adaptive or specific immune response mechanisms.

Disadvantages of the non-specific response are as follows:

- The cells can differentiate between 'self' and 'non-self' but cannot recognise specific antigens.
- Adaptation does not occur after exposure, i.e. the same level of response is produced for each exposure to an antigen.
- There is no 'memory' and so developing the same infection a second time cannot be prevented.

The specific immune response: natural immunity

The specific immune response involves the lymphocytes and comprises the humoral or antibody-mediated response, initiated by B lymphocytes, and the cell-mediated response, initiated by T lymphocytes. These responses are described separately here, but they interact with each other as well as with non-specific factors. The humoral response deals mainly with extracellular organisms, and the antibodies which it produces are present in the serum. The cell-mediated response is important for dealing with intracellular organisms.

Specificity

When first exposed to an antigen, the circulating lymphocytes differentiate to recognise and bind to that one particular antigen. This recognition and binding is like a lock and key mechanism on a door. Many different keys may go into the same lock, but only one will fit closely enough to turn in the lock and open the door, the primary response.

On re-exposure to the antigen, perhaps many years later, the remaining progeny of that cell (memory cells) will be stimulated to replicate as a secondary response.

Antibody-mediated immune response

This response may be described in terms of its primary and secondary phases.

Primary response The first time an antigen is encountered in the body it takes approximately 2 weeks for a corresponding antibody to be detected in the blood. The production of this antibody is called the primary response. Although the immune system reacts immediately to antigens, the synthesis of antibodies takes some time.

An antigen binds to its specific receptor on the surface of the B lymphocyte, triggering the following sequence of events:

- The B lymphocyte is stimulated to develop into a plasma cell and to undergo multiple divisions so that identical plasma cells are formed.
- The plasma cells synthesise antibodies.
- Some B lymphocytes differentiate to become memory cells, which persist and replicate in the body long after the invading antigen has been dealt with (see Fig. 16.2).
- Once sufficient quantities of an antibody have been produced to destroy all the antigen, the plasma cells die, leaving memory cells ready to respond to a future attack by that antigen.
- Antibodies bind to the antigen, activating the complement system (see p. 656).
- When several antibodies bind to one antigen, the complex thus formed is chemically attracted to the surface of phagocytic cells, resulting in the formation of an antigen–antibody–phagocyte complex.
- The presence of antibodies triggers the phagocyte into action, resulting in ingestion and digestion of the bacterium.

The time interval between contact with the antigen and the production of antibodies (IgM), however, may allow disease to develop in the individual due to the effects of the antigen, e.g. infection from microorganisms.

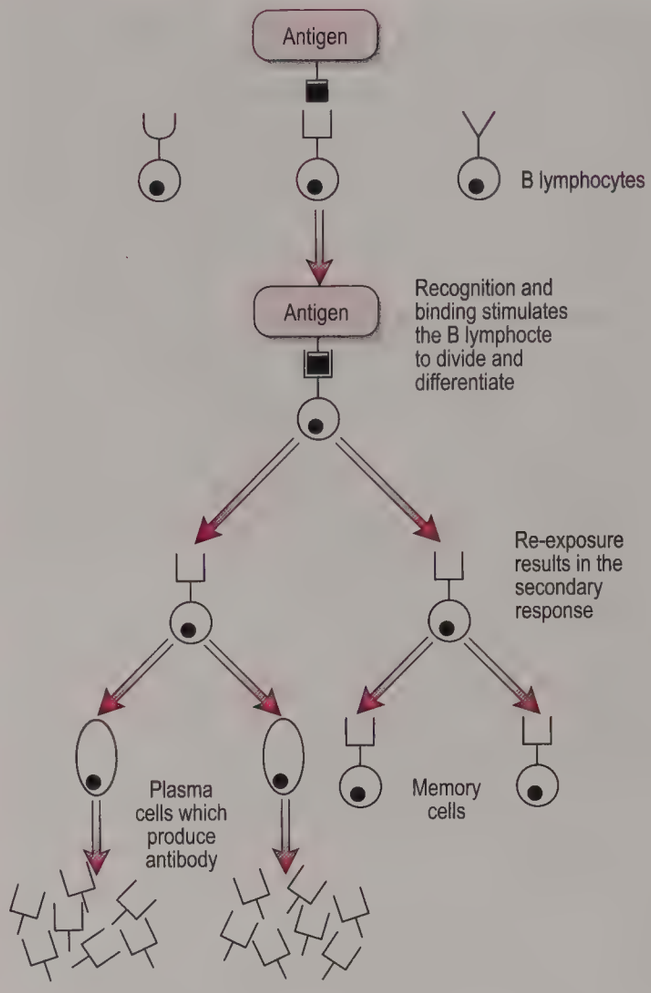

Fig. 16.2 The primary immune response.

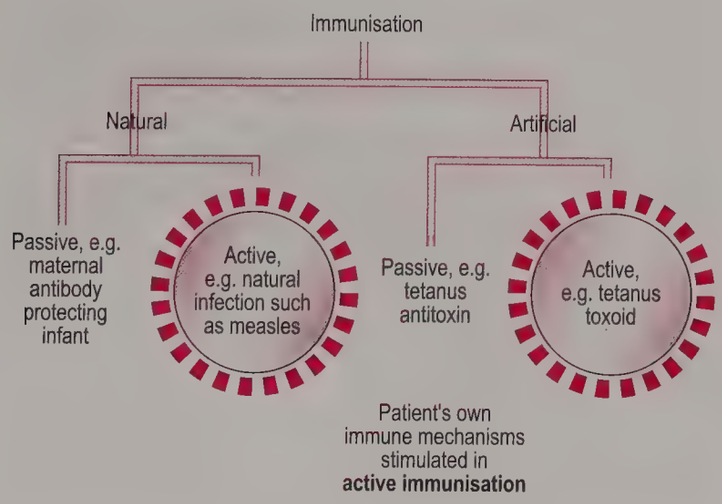
Secondary response When the body encounters an antigen for the second time, the memory cells respond rapidly by producing plasma cells, which then produce antibodies. This response occurs within a few days and, together with any residual antibody from the primary response, usually prevents disease from developing. In other words, the individual has developed an immunity.

Immunisation: artificial immunity

Vaccination or immunisation is a means of artificially invoking a primary immune response to a particular microorganism (antigen) so that when the antigen is subsequently encountered, the individual will be immune to it. The principle of immunisation is to introduce altered microorganisms or toxins into the body so that the individual does not develop the disease, but does mount an immune response. In other words, it mimics the natural response to infectious disease. Booster doses may be required months or years after the first dose of a vaccine in order to maintain an adequate level of memory cells. There are three types of vaccine:

- *Live attenuated vaccines.* Laboratory cultures of virulent strains of some organisms lose their virulence. These are then capable of inducing immunity without causing disease. The bacille Calmette–Guérin (BCG:

tuberculosis) and rubella vaccines are of this type. However, live attenuated vaccines should not be given to someone who is immunocompromised or taking long-term corticosteroid medication, as their immune system cannot mount the appropriate response.



- *Toxoids*. The toxin produced by the bacterium is chemically modified by the use of formalin so that its toxicity is lost, but its antigenicity is retained, and is therefore capable of producing an immune response. The tetanus toxoid is an example of a toxoid.
- *Killed vaccines*. These are preparations in which the organisms have been killed by heat or chemicals; the whooping cough vaccine is one example.

Immunity can therefore be natural, i.e. acquired in utero or after infectious disease, or artificial, i.e. acquired after immunisation. Figure 16.3 illustrates the processes involved in natural and artificial immunity.

Cell-mediated immune response

As it is not possible for antibodies to reach microorganisms which live inside host cells, for example viruses, a different system, known as the cell-mediated immune response, carries out this function. In order that a T lymphocyte recognises an infected cell, a major histocompatibility complex (MHC) is involved. The MHC is a group of molecules which are important in interactions between cells in the immune system, in particular in the recognition of infected cells. One of these molecules is present on the surface of the cell in association with antigen, and the T cells recognise and bind to this on the surface of the macrophages, producing cytokines (see p. 656) which activate the macrophage and kill the intracellular microorganism. Cytotoxic T cells are also antigen-specific, having acquired a specific antigen receptor during their maturation in the thymus gland. They recognise antigen in association with the MHC on virally infected cells, which they destroy.

Once all the antigen has been destroyed, the immune response is 'switched off' until the next time. The involvement of other cells (e.g. mast cells) in the immune response has been discussed on page 655.

658 Fig. 16.3 Natural and artificial immunity.

Understanding of all immunology processes will help to ensure that patients and clients are assisted in fighting infection, particularly while receiving health care.

PREVENTION, CONTROL AND MANAGEMENT OF INFECTION

History

Infection control measures have been adopted to help prevent the spread of infection for centuries. In the 14th century, the Venetians applied quarantine to ships arriving at their port in order to contain diseases such as the bubonic plague. In the 19th century, Semmelweiss, a Hungarian obstetrician, realised that infection was being passed on the hands of health care workers to patients and showed that mortality rates could be greatly reduced by handwashing. Equally, Florence Nightingale emphasised the importance of cleanliness and hygiene in preventing and controlling illness. Also in the 19th century, separate hospitals for infectious diseases were first established.

Developments in the understanding of the micro-organisms which cause disease are landmarks in the history of health care. The invention of the microscope allowed the study of minute organisms, invisible to the naked eye. In 1676, van Leeuwenhoek designed a primitive version of this piece of now indispensable equipment, whereby bacteria could be seen. Since then many advances have been made in analysing and studying the structure of bacteria. Modern techniques are attributed primarily to Pasteur, Lister and Koch for their work on microorganism activity, the prevention of bacterial invasion in tissues and techniques for diagnostic bacteriology.

Infection control measures are essential in everyday clinical practice today. The occurrence of antibiotic-resistant organisms, such as MRSA, vancomycin-resistant enterococci (VRE) and multidrug-resistant tuberculosis (MDRTB), thought to be attributed to many years of use and misuse of antibiotics, has greatly increased and is of concern internationally.

Jenner introduced vaccination in 1796 but it was not until the 20th century that it became routine. Vaccination has controlled 10 major diseases throughout the world: smallpox, diphtheria, tetanus, yellow fever, pertussis, *Haemophilus influenzae* type b, poliomyelitis, measles, mumps and rubella. However, in an age when there is heightened awareness of the risks from bioterrorism, the threat of infections familiar only to older generations, for example smallpox, is again causing great concern. The threat from disease spread through accidental or deliberate release of microorganisms raises the issue of herd immunity in populations that have not had to consider the protection they enjoy through acquired immunity, i.e. vaccination. Governments internationally are preparing both for the re-emergence of diseases that have previously been eradicated or controlled and for the emergence of new diseases.

16.1 All health care workers receive hepatitis B vaccination. If, after a primary course of three injections over a period of 6 months, the antibody titre is inadequate, what course of action will be taken?

For further information on hepatitis B immunity, see www.who.int/vaccines/en/hepatitisb.shtml.

The threat from microorganisms continues in the 21st century. As new species are identified, existing ones genetically mutate to ensure their survival in a changing environment. These minute organisms continue to cause significant disruption to our health. Influenza and norovirus (winter vomiting and diarrhoeal disease) are prime examples of infections that have been in existence for many years and cause major disruption most winters. Concern continues that a world pandemic of influenza will occur, as it did in 1918, when it killed millions.

The understanding of microorganisms must continue to develop as they themselves develop, particularly if nurses are to be alert to such threats in the environment.

The infection control team

Health care workers, patients, relatives and carers together have a contribution to make in the prevention, control and management of the spread of infection. Those involved include nurses, doctors and dentists, allied health professionals, health care assistants, domestic and catering services, estates management, sterile services staff, administrative and management staff, education and training staff. The role of the infection control team is well defined and includes the utilisation of the risk management approach (see p. 661) to ensure that appropriate measures and action plans are in place. The structure for infection prevention and control programmes of work at organisation level is guided by national and local requirements. The infection control doctor and infection control nurse have clear responsibilities within this structure.

The microbiology laboratory is an important partner. Laboratory staff are a key resource in the process of obtaining, analysing and reporting on samples from patients.

Many settings also have infection control link nurses/personnel to enhance the effectiveness of the work of the team. The link person in a ward, department or community team will have received additional education to improve the communication between infection control teams and the clinical setting and may assist with clinical audit and awareness of clinical staff in relation to standard infection control precautions (see p. 664). The work of the team is guided by the Control of Infection Committee which is responsible for strategic and operational decisions about infection control.

The nurse's role in infection control

Nurses can contribute to the application of all aspects of prevention measures by acting as role models and by educating others. Nurses have a pivotal role in managing infection in acute or primary care settings by:

- containing and controlling the sources of microorganisms
- preventing infection and the potential spread of microorganisms that can cause harm
- treating and managing identified infections
- promoting the most fundamental aspects of patient care.

Nurses have a duty of care as stated in the Health and Safety at Work Act (1974) to prevent, control and manage infection. Nurses, as the largest staff group in health care, have a responsibility to prevent the spread of infection and act accordingly to ensure they do not put themselves and others at unnecessary risk from infection (NMC 2004). Nurses must therefore understand physiology, immunology, fundamental infection control measures and how a risk management approach operates within the field of infection prevention, control and management, an approach that has become increasingly popular in health care overall.

Nursing assessment is vital to health and control of infection, whether the health care setting is the home, the hospital, the clinic or the care home, as it can reveal crucial information about patients, their surroundings and their behaviours. Nursing models and processes must incorporate approaches to prevention, control and management of infection, for example within care plans and pathways.

The health of the nurse while at work is also important. The nurse should:

- stay away from work if unwell, particularly if the illness could be communicated to others, e.g. influenza
- be aware of their immune status regarding infectious diseases such as rubella, chickenpox, measles, tuberculosis, tetanus, hepatitis B and poliomyelitis. Nurses can obtain advice from their general practitioner (GP) or from their employer's Occupational Health Department
- discuss other health concerns that may have an impact upon the ability to work, or upon others, with the Occupational Health Department, e.g. skin conditions that may be caused by supplies used during work and that may harbour and spread microorganisms.

How infection spreads

The terms 'infection process', 'cycle of infection' or 'chain of infection' are often used to describe the circumstances that can lead to patients or others acquiring HAI or any infectious disease. The rationale for application of recommended precaution measures to prevent spread is based on this chain of events. It is crucial to understand how microorganisms spread and infection occurs. The infection process is related to:

- the presence of an infectious agent, i.e. microorganisms that are capable of causing infection
- a reservoir or source where microorganisms can be found. Within health care settings this may include the environment, e.g. dust, bedding, equipment, furniture, sinks, washbasins, bedpans and surfaces; and humans, e.g. patients, staff and visitors, especially on hands
- the potential for microorganisms to be transmitted from sources. These are often called portals of exit and include the means by which microorganisms might spread, such as exhalation, aerosolisation, secretion and excretion
- a means or route of transmission for microorganisms, categorised as blood borne, droplet, airborne, contact, food and water borne (common vehicle) and vector borne

- portals of entry — for microorganisms to enter susceptible sites, commonly through a variety of invasive devices, e.g. intravenous lines, urinary catheters, respiratory devices or any device that breaches the normal immune defences (see Fig. 16.1), as well as wound sites, open skin lesions, mucous membranes and ingestion
- a susceptible host — anyone who, for whatever reason, is at risk from microorganisms that would not normally cause them harm. Factors that affect the body's natural ability to fight infection include:
  - — the presence of underlying disease, e.g. diabetes mellitus
  - — immunocompromised status, e.g. HIV, chemotherapy treatment
  - — poor nutritional status
  - — extremes of age, i.e. the very young and the very old.

The principles of all precautions and measures taken in order to prevent and control infection are based on the interruption of this process. If measures are not taken, a cycle will continue and patients, staff and others may be exposed to potentially pathogenic (disease-causing) microorganisms.

Microbiology

Microbiology is the study of microorganisms such as bacteria, fungi, protozoa, viruses and helminths. In recent years, minute protein particles called prions have also been identified that cause transmissible spongiform encephalopathies (TSEs), e.g. variant Creutzfeldt–Jakob disease (vCJD).

Bacteria

Bacteria, including variations of the microscopic beings such as mycoplasmas, rickettsiae and chlamydiae, are small microorganisms of simple primitive form. Bacteria are commonly found living within our bodies and in our environment, for example in soil and water. Bacteria constitute the normal commensal flora within the body (see Table 16.1). However, such bacteria can become disease-producing organisms (see p. 662).

Viruses

Viruses are a group of parasitic infective agents so small that they are visible only through electron microscopy. Viruses have no independent metabolic activity and may replicate only within the cell of a living plant or animal.

Fungi

Fungi are simple plants that are parasitic on other plants, animals and humans. A few can cause fatal disease and illness in humans. They are classically opportunistic, e.g. in a postoperative patient, where antibiotic therapy may not only eradicate the infective organism, but also protective normal flora. Fungi can proliferate and cause infection such as *Candida albicans* (see Ch. 15).

Protozoa

These are the smallest single-cell organisms, many species of which can cause human disease. Most are harmless; however, some cause particular problems in hot climates, e.g. *Plasmodium*, the protozoa which causes malaria.

Table 16.1 Normal commensal microorganisms

Site	Organism
Skin	*Staphylococcus epidermidis* Diphtheroids *Corynebacterium* sp.
Mouth and throat	Staphylococci Streptococci Anaerobes *Neisseria* sp.
Nose	Staphylococci Diphtheroids
Gut	*Escherichia coli* *Klebsiella* sp. *Proteus* sp. *Streptococcus faecalis* *Clostridium perfringens* Yeasts *(Candida)*
Kidneys and bladder	Normally sterile
Vagina	Lactobacilli Streptococci Staphylococci Anaerobes

Helminths

These are large parasites — worms — which can be a major cause of morbidity, mainly in developing countries.

For further information, see Gould & Brooker (2000) and Humphreys & Irving (2004).

Routes of transmission

Clear understanding of the most common routes or means of transmission can ensure that no matter what the microorganism, the spread can be controlled:

- *Blood borne* — through sexual transmission, injury or inoculation. The main concern within health care settings or for health care workers in the community is the transmission of HIV and hepatitis B and C through sharps injuries or blood splashes. Many different organisms besides blood-borne viruses can be spread unwittingly by health care staff while caring for patients, e.g. through blood and body fluids, secretions, excretions, non-intact skin or mucous membranes. Standard infection control precautions, which have superseded Universal Precautions, apply at all times in all health care settings (see p. 664).
- *Airborne* — through inhalation. Airborne transmission is by small particles that can remain suspended in the air for long periods of time and can be widely dispersed by air currents.
- *Droplet* — through inhalation. Droplet transmission differs from airborne as the particles are larger and therefore do not remain suspended in the air. Spread is therefore through close contact with infected persons who may be sneezing, coughing, talking or undergoing airway procedures such as intubation or bronchoscopy.

The droplets can settle in the environment close to where they have originated, e.g. within 1 metre of an infected coughing patient.

- *Contact* — direct or indirect. This is regarded as the most common route of transmission related to HAI. Direct is the transfer of organisms by contact with people, primarily contaminated hands. Indirect is the transfer of organisms through the environment and the items within it, e.g. fomites (any inanimate object that can carry disease-causing organisms), and patient care equipment.
- *Food and water borne* (also known as common vehicle) — food and water can be the most common reservoirs for microorganisms, but the term 'common vehicle' also includes transmission through medication, blood or other solutions.
- *Vector borne* — usually spread via insects such as mosquitoes and ticks but cockroaches, ants and flies can also transmit infection. This mode of transmission is not common in the UK but should be considered in pest control policies.

Certain organisms can be transmitted through more than one of these routes and all modes of spread must be considered when carrying out risk assessments and providing care. Bacteria tend to cause the most concern while health care is being provided as they can often be avoided (see Table 16.2).

Diagnostic sampling

Sample taking is an important element of a nurse's role. Sampling provides identification of microorganisms for diagnosis, relevant treatment and screening purposes, e.g. on admission, transfer or discharge; preoperative or other pre-procedure screening; for 'clearance' purposes, e.g. to exclude previous known infections; and in contact tracing, e.g. to identify or exclude transmission of infection often in unsuspecting, otherwise healthy individuals. Health care settings will have a screening policy, e.g. some settings will screen on admission when patients are having elective orthopaedic surgery, due to the high risks related to such surgery and the implications of joint replacement failures due to infection. There are various sources and types of sample. For example, samples may be taken from the respiratory tract including the ear, nose and throat and the eye using a swab, a fluid (including sputum) aspirate or a tissue, or from the gastrointestinal tract and biliary system by sampling faeces, fluid or tissue (samples of vomit are not normally sent for testing as the results are of limited analytical value).

In order to avoid false-positive and false-negative results, it is important to ensure that there is no contamination from other microorganisms while obtaining samples, that an adequate amount of a sample is taken and that it is sent promptly to the laboratory. The value of swab sampling is frequently questioned, but it is a common, convenient and inexpensive option in clinical practice. If contamination occurs, for example from intact skin surrounding a suspected infected surgical wound (false positive), or not enough sample is sent to the laboratory, for example a dry swab is used to sample a small patch of dry skin for microbiological screening purposes (false negative), analysis will be limited and results will not be meaningful. Accurate completion of laboratory forms is also essential.

THE RISK MANAGEMENT APPROACH

The risk to health from infection is one of many risks to be managed in health care settings. The risk management approach to HAI was developed during the 1970s as part of the growing health and safety agenda around the developed world. The World Health Organization (WHO) definitions provide a basis for the risk management approach in relation to infection control:

- *Hazard* — a biological, chemical or physical agent with the potential to cause an adverse health effect
- *Risk* — a function of the probability of an adverse health effect and the severity of that effect associated with exposure to a hazard.

Hazards and risks from microorganisms are present in our environment at all times. Once they are identified, appropriate control measures and action plans must be adopted to ensure that the greatest time and resource is spent in the areas with the greatest risks of infection. For example, a risk assessment is carried out when a chemical disinfectant must be used to decontaminate a piece of equipment. Guidance on how to use and handle safely the disinfectant and the equipment is provided for the health and safety of both patients and staff. A review of the decisions made must be undertaken within a defined timescale as the use of the disinfectant may change over time and the risks may change, requiring updated guidance on control measures for staff.

For further information, see www.hse.gov.uk/coshh — Care of Substances Hazardous to Health Regulations produced by the Health and Safety Executive.

In summary, the correct systems, management and culture must be in place to ensure that actions are effective in preventing, controlling and managing HAI:

- *Systems* include structures and processes at national, organisational and individual practitioner level, e.g. guidance given through policies and procedures, education and training, and frequent planned monitoring of outcome through audit, surveillance and research.
- *Management* includes the appropriate support being available and a clear commitment towards addressing the risks of infection, considering these alongside the many other pressures faced within health care. Ensuring that the correct processes are in place to achieve this must be a management priority and education on this is mandatory in many areas.
- *Culture* includes the continuous improvement of quality through individual behaviour, whereby nurses can be seen as role models, aware of the systems and processes to manage hazards and risks from infection. Good infection control practice by health care and associated staff helps maintain an overall culture of good practice, making it easier for all to comply, especially during periods of stress.

Table 16.2 Examples of common bacteria encountered while providing health care

Organism	Main sources	Main mode of spread and means of entry	Examples of resulting disease/conditions
Staphylococcus aureus including MRSA	People, skin, wounds, and at times in sputum Environmental dust	Direct and indirect contact with persons carrying the organism or from the environment. Entry through e.g. open wounds	Wound and skin infection Bacteraemia, endocarditis Osteomyelitis and septic arthritis
Clostridium difficile	In the animal and human lower bowel, therefore faeces and any faecally contaminated areas. Especially found in hospitalised patients who have received antibiotic therapy that has disturbed their normal bowel flora Also soil	Direct and indirect contact with persons carrying the organism or from the environment, especially as it can form spores that survive for long periods in the environment. Often also called faecal–oral spread if ingestion occurs resulting in further GI upset/infection	GI infection, characterised by loose, foul-smelling green stools and abdominal pain The most common cause of HAI diarrhoea Can lead to pseudomembranous colitis
Streptococcal infections	Found in humans, at various sites, and in the environment	Direct and indirect contact with persons carrying the organism or from the environment Through droplets from infected respiratory tracts	Pharyngitis Wound infection, rarely necrotising fasciitis Septicaemia Toxin-mediated disease, e.g. scarlet fever, toxic shock syndrome Pneumonia and associated bacteraemia
Enterococci, including vancomycin-resistant enterococci (VRE) *Pseudomonas aeruginosa*	Mainly environmental sources but also in the human GI tract. In the lower bowel of animals and humans, most commonly in hospitalised patients who have received antibiotic therapy Moist sites in the environment, but especially poorly draining shower areas and open fluid containers Also soil	Direct and indirect contact with persons carrying the organism or from the environment	Urinary tract infection Wound infection Endocarditis Eye and ear infections Wound infections, e.g. in burns Septicaemia Respiratory infections, especially in the immunocompromised, e.g. cystic fibrosis patients
Mycobacterium tuberculosis (TB)	Found in humans, animals and in the environment	Through the airborne route when respiratory infection is present Through direct contact when other systems are infected	Respiratory or pulmonary TB; can be termed as open TB Closed TB, where another system or site of the body is infected. It can infect any organ in the body (see Ch. 3)
Escherichia coli	Found in humans, particularly the GI tract, and in the environment	Direct and indirect contact with persons carrying the organism From the environment or from food From poor hand hygiene	GI infection Urinary tract infection

Policies and procedures

Underpinning much of the work undertaken in clinical practice are the policies and procedures that guide best practice, for example related to hand hygiene, isolation of infectious patients, aseptic technique and insertion of urinary catheters. These must be current and have planned timescales for review. Many nurses are involved in framing policies, including those at management, specialist and general level. However, it is not enough to have an infection control policy manual; the recommended practices must be learned, applied and monitored with feedback given to ensure continuous quality improvement for up-to-date patient care. It is part of accountable practice that each member of the multidisciplinary team adheres to policies and procedures; failure to do so is considered breach of the Health and Safety at Work Act (1974).

16.2 Locate the infection control policy manual in your area of work and familiarise yourself with the guidance it provides, related to your nursing duties. How do you contact the local infection control team for further guidance if needed?

Antibiotic prescribing and use

Another important area of practice in which policy should be available to guide many health care practitioners is antibiotic prescribing and use. This is now of particular concern to those nurses who have a role in prescribing, as antibiotic resistance (see Box 16.3) is increasing and strategies and recommendations have been published by WHO and in many countries to combat the problem. There have recently been cases around the developed world where patients have died from infections that could not be treated, as the causative microorganism was resistant to all the available antibiotics. This is of great concern in a world that has relied heavily upon the benefits of antibiotics.

For further information, see Department of Health (2000).

Box 16.3

Antibiotic use and resistance

- Antibiotics can work in different ways to treat infections. They can be bacteriostatic — stopping bacteria from multiplying, or they can be bactericidal — interfering with the cell wall of bacteria, thus killing them.
- Bacteria mutate and change to protect their cell structure against antibiotics, thus becoming resistant. Drug-resistant organisms can not only spread and cause further harm but can also transfer their resistance to other organisms. As new antibiotics are developed it is anticipated that bacteria will continue to protect themselves by mutating and again become resistant.
- Misuse and overuse of antibiotics are thought to have contributed to the problem. Pressure from patients to be given antibiotics, the contribution of topical antibiotics to antibiotic resistance and over-the-counter availability of antibiotics in many countries outside the UK are all considerations. Some resistance, however, will be inevitable.
- Policies should include guidance on the appropriate use of antibiotics for treatment in all clinical eventualities, including the use of 'broad spectrum' and 'narrow spectrum' antibiotics, and the length of time antibiotics should be taken. Guidance on use of antibiotics for prophylaxis is equally important, e.g. the use of antibiotics before, during and after surgery to prevent rather than treat infection (Scottish Intercollegiate Guidelines Network 2000).
- Nurse prescribing and its role in antibiotic resistance is important at this time when nurse prescribing is being extended. Points for consideration include the difficulties associated with diagnosing infection accurately, awareness of allergies to and toxic effects of antibiotics, the potential side-effects and the reduction in effectiveness of other medications when taking antibiotics, e.g. the oral contraceptive pill. Patient education is also important, e.g. there is often no point in taking antibiotics for viral complaints such as a sore throat, and completing an entire course of antibiotics as prescribed is essential.
- Antibiotic resistance has a major impact upon demands for services within health care as additional elements are required to care for those affected, e.g. isolation facilities.

Outbreak management

When an outbreak of any infectious disease occurs, at times even when guidance has been followed, a well-coordinated, multidisciplinary response will minimise the impact of the outbreak by controlling and managing the impact and ongoing risks. Outbreaks may have minimal impact or major, widespread implications, including death or serious illness. Local infection control policies state the response that will be mounted when an outbreak is suspected or confirmed, with the definition of what is considered an outbreak within the area also being clearly stated, as this can vary between settings. Policies should include details of the people involved and their roles during the incident, the communication processes and the actions to be taken, including risk assessments. Communication is crucial in these situations, as it is within all health care provision. Meetings are established during these times to facilitate the response and this might include extraordinary meetings of the Control of Infection Committee.

Outbreaks may happen in health care facilities as well as in the community, but those within health care settings receive most attention, particularly in the media. Outbreaks in the community often spread to health care settings, where more immunocompromised patients are present in an environment already conducive to spread of infection (see Box 16.4).

Food hygiene

Infection spread via the food-borne route can have a major impact upon health care and the community. The Stanley Royd Hospital outbreak in 1984, in which a number of older

Box 16.4

Examples of microorganisms causing outbreaks

Norovirus infection

- This is a commonly occurring gastrointestinal infection that usually causes seasonal outbreaks of vomiting and/or diarrhoea.
- Although the illness tends to be short lived and less severe than other forms of gastroenteritis, the disruption caused in hospitals and long-term care facilities is extensive if a ward or department has to be closed to further admissions or if the occurrence of symptoms among staff results in staff shortages.

MRSA

- Outbreaks of MRSA are frequently encountered, often not causing significant harm but certainly causing disruption. The impact upon patients, staff, resources and budgets, both locally and on the NHS as a whole, can be significant.
- In large outbreaks, wards or areas may be closed to admissions, surgery may be cancelled and patients and staff may be affected, directly or indirectly.
- If the outbreak is significant, staff may be screened for the microorganism to prevent further spread, depending on the local screening policy.
- There are many strains of MRSA, but if microbiology reference laboratories identify the strain, specific risk assessments can be carried out and actions taken.

people died and many staff and patients became ill, led to Crown immunity being removed from health care settings in order that they could be monitored and instructed on best practice in relation to food hygiene; previously, they had been exempt from prosecution if they were deemed to be at fault. The *Escherichia coli* outbreak, spread through meat in a butcher's shop in Wishaw, Lanarkshire, in 1996, resulted in the death of many people in that community and attracted much media interest over hygiene controls in food premises.

In hospitals and care facilities, guidance on effective food preparation, production and distribution techniques is vital for effective infection control. Major outbreaks of food-borne illness have led to the incorporation of the Hazard Analysis and Critical Control Point (HACCP) risk management system as a preventive mechanism for the safety of foodstuffs. The system identifies possible safety risks in a food production facility and attempts to control that risk at critical points.

The nurse's role in food hygiene often involves basic measures such as the care of fridges, microwaves and eating utensils. However, awareness of the importance of food hygiene overall, as well as the other elements of best practice, is essential.

For information about those infectious diseases that require to be 'notified' for monitoring purposes, whether an isolated case or during an outbreak situation, see www.hpa.org.uk/infections and www.isdscotland.org.

STANDARD INFECTION CONTROL PRECAUTIONS

Standard infection control precautions (SICPs), first recommended in the USA, incorporate fundamental infection prevention and control measures that help to interrupt the chain of events that can lead to infection, whether the risk management approach has been adopted or not. Elements of these precautions should always be included in guidance, policies and procedures. Before the introduction of SICPs, published recommendations on elements of infection control had become more common following the introduction of health and safety legislation, and had specifically featured general infection control guidance under such terms as 'safe working practice' and 'body substance isolation', but most widely under the heading of 'universal precautions'. Universal precautions were first introduced during the initial HIV epidemic in the 1980s, to protect patients against exposure to blood and body fluids regardless of their blood-borne viral status. These precautions appeared to motivate and greatly improve compliance with general infection control measures and ultimately had a major impact on health care, for example, the increased use of gloves in practical care procedures. During the 1990s, however, wide variation in the interpretation and implementation of universal precautions became apparent and steps were taken to outline practical, feasible recommendations for preventing cross-infection at all times and to further encourage standardisation of precautions throughout all health care settings. Universal precautions were at this point replaced with standard precautions, which throughout this chapter are referred to as standard infection control precautions (SICPs), in order to take into account the many micro-organisms that can be spread while providing care and not only blood-borne viruses such as HIV.

SICPs are a set of recommendations for the care of all patients regardless of their infection status, when exposed to any:

- blood
- body fluids, e.g. serous fluid, lymph fluid
- secretions or excretions (except sweat), e.g. sputum, urine
- non-intact skin
- mucous membranes.

There are nine elements to standard infection control precautions (see Table 16.3).

Hand hygiene

People's hands are considered the most common vehicle by which microorganisms might be transported and cause infection to those who are susceptible. Therefore, all of the steps that lead to adequate hand decontamination must be considered and applied in practice in all settings (see Table 16.4). Guidance related to hand hygiene for the very specific work carried out in specialised areas such as theatres should additionally be available at local and national level. The terms hand hygiene, hand decontamination and hand washing are used interchangeably in today's health care (Gould 2004, Rickard 2004).

For recommended hand washing technique, see Gould (2004), NHS Education for Scotland (2004) and Royal College of Nursing (2004a).

Environmental prevention, control and management of infection

A clean environment contributes to the prevention of infection. It is common sense and good practice to ensure that the environment is clean so that infection is not spread and patients are reassured that standards of cleanliness and hygiene are high.

In hospital

The responsibilities for ensuring the patient's environment is clean must be made clear to all. Cleaning is usually conducted using a general purpose detergent, warm water in a clean receptacle and clean or disposable cloths or mops. Drying is also important, although large surfaces, e.g. floors, may have to be 'air-dried'. Wet environments are not acceptable for patients who are at particular risk, e.g. in transplant units, intensive care units and burns units. Stagnant moisture or fluid can be a focus for micro-organisms and lead to HAI, e.g. *Pseudomonas aeruginosa* from eye- and mouth-care solutions left next to intensive-care patients. Disinfectants may be used when particular risks are known, under guidance from infection control teams and from policies and procedures.

If any contamination of the environment is observed, decontamination must take place immediately. Particular attention must be given to horizontal surfaces, e.g. bedrails, bedside cabinets, chair arms, tables, floors or health care equipment such as pumps, especially those that are

Table 16.3 Standard infection control precautions

Element	Action/timing	Rationale
1. Hand hygiene	At the right times In the most appropriate way for the situation (see Table 16.4)	Frequently called the single most important action to prevent, control and manage infection
2. Personal protective equipment (PPE)*	Gloves (powder-free): — non-latex alternatives should be available and their use is being increasingly encouraged due to the adverse affects of latex Aprons, gowns, footwear Eye and mouth protection	To protect mouth and eyes in particular, and the skin of the face, hands and the rest of the body with the use of clothing and equipment in order to avoid contamination/soiling/splashing and potential exposure to harmful microorganisms, originating from patients, the environment or even live vaccinations The use of gloves does not negate the need for hand decontamination and all PPE must be disposed of safely and properly immediately after being removed Often this is into clinical waste
3. Prevention of occupational exposure to infection	Cover all breaks in skin Avoid sharps injuries: — never resheath sharps such as needles — utilise sharps receptacles close to the point of use — never try to retrieve any items from sharps receptacles Avoid splashes with blood or body fluids by using PPE when exposure is anticipated Report any exposure incidents following local policies (see www.riddor.gov.uk/info.html)	To additionally protect health care workers, carers and others from exposure to microorganisms that cause infection, e.g. hepatitis B, C, HIV, MRSA
4. Management of blood and body fluid spillages	Utilise cleaning products and disinfectants (often found in 'spillage kits') immediately spillages occur, following local policies	To protect all of those in the surrounding area from exposure to microorganisms found within spillages that could cause harm and to protect the environment from contamination
5. Management of equipment utilised during care	Prevent reuse of single-use devices Prevent single-patient use devices being used on other patients Ensure reusable devices are handled safely and decontaminated between use on the same patient and before use on others, following local policies: — basic cleaning measures are a vital part of health care and should also be performed before any required disinfection processes	To ensure that items used during care are not a factor in the spread of potentially infectious microorganisms directly to patients or a factor in the contamination of patients' environment leading to indirect spread of infection
6. Environment control	At the right times and in the most appropriate way for the situation Cleanliness and maintenance must be kept at the optimum level	To ensure that the care setting, its fixtures and fittings and other items within it are adequately decontaminated and maintained to prevent cross-infection occurring through this route
7. Safe disposal of waste, including sharps	Waste is categorised by regulations so that it will be segregated and subsequently destroyed safely and effectively: — clinical waste generated in the home and community is often dealt with differently from that generated in hospital settings; local policies reflecting current regulations must be followed — the area around the opening of clinical waste bags and sharps containers is often the most contaminated in health care settings and should never be touched. 'Hands-free' waste sack holders, e.g.foot-operated, must always be in place	To prevent the risk of inappropriate, avoidable exposure to the microorganisms found contaminating clinical waste in particular, thus protecting all health care workers and others The use of PPE when handling waste is essential

Continued

Table 16.3 Standard infection control precautions *(Continued)*

Element	Action/timing	Rationale
7. Safe disposal of waste, including sharps *(Continued)*	Attaching waste bags to other pieces of furniture, e.g. trolleys, is not generally acceptable, nor is overfilling of bags	
8. Linen	Safe handling, transport and processing of bags: — linen should never be held against the body or shaken, even if protective clothing is worn — linen should always be disposed of into appropriate receptacles immediately after being removed and never placed on the floor	To prevent the risk of inappropriate, avoidable exposure to microorganisms when linen is being handled or reused, thus protecting health care workers and others and preventing contamination of the environment Linen can be heavily contaminated with potentially pathogenic microorganisms; items such as urinary catheters, needles, etc. are often found in linen by laundry staff, putting them at unnecessary risk Use of PPE when handling used linen is essential
9. Appropriate patient placement	Choosing the most appropriate site/area to care for a patient must be considered using a risk management approach at all times, e.g. consider the route of transmission of any known or suspected infections/colonisation, how these might then spread to others, the potential outcomes of this spread, the availability of resources to site patients in the best place	To prevent exposure of others and the environment to potentially infectious microorganisms and to protect the patient as far as possible

*Also known as protective clothing.

Table 16.4 Hand hygiene

	Action	Rationale
Provision of hand decontamination facilities	Access to adequate hand hygiene facilities and supplies is an essential element of SICPs in all settings where exposure to microorganisms might occur The use of 'hands-free' tap systems, e.g. elbow taps, is recommended wherever possible in health care as this ensures that hands are not contaminated during the process of turning taps on or off and potentially becoming a source for further contamination of patients or the environment Also important is the use of mixer taps to ensure water of the right temperature can be provided as well as the absence of plugs to discourage washing in filled sinks where microorganisms can harbour	By providing adequate facilities, hand decontamination should be carried out in the correct manner at the correct times to prevent cross-infection from occurring
	Where running water cannot be accessed, the use of alcohol hand decontamination products, e.g. gels, is a useful alternative	Alcohol gel is appropriate if hands are not soiled; it is inactivated by organic matter

	Level 1 Social handwash	Level 2 Hygienic handwash	Level 3 Surgical scrub
***When* to wash or decontaminate**	**Before** commencing/leaving work, eating/handling of food/drinks, preparing/giving medications, general patient/client contact	**Before** aseptic procedures, contact during all patients'/clients' care procedures, leaving isolation rooms (all levels of transmission-based precautions)	**Before** surgical/other invasive procedures **Between/within** the above described procedures if any contamination occurs

Continued

Table 16.4 Hand hygiene *(Continued)*

	Level 1 Social handwash	Level 2 Hygienic handwash	Level 3 Surgical scrub
***When* to wash or decontaminate** *(Continued)*	**After** visiting the toilet; patient/client contact, handling laundry/equipment/waste, blowing/wiping/touching nose *NB* even if gloves have been worn	**After** contact with isolated patients/clients, any potential contact with body fluids/ excretions/secretions, etc. *NB* even if gloves have been worn **Between/within** the above described procedures if any contamination occurs **In high-risk areas at all times:** infant nurseries/special care baby units, infectious disease units/ intensive care/therapy units, wards/ departments during outbreaks of infection	
***Why* decontaminate**	To render the hands physically clean and to remove microorganisms picked up during activities (transient microorganisms)	To remove or destroy transient microorganisms and to provide residual effect	To remove or destroy transient microorganisms and also to substantially reduce those which normally live on the skin (resident microorganisms)
***How* to decontaminate** When washing hands for whatever purpose, the tap should first be turned on and the hands wet before applying the soap. A good lather should be evident for undertaking the steps, with all areas of the hands being covered (and forearms when surgical scrub is being undertaken). Following this, hands should be rinsed well Cleansing solutions' instructions should give guidance as to the volume of solution to be used; this also applies to alcohol hand products.	Using soap, preferably liquid, wash hands Alternatively, where hands are not soiled, utilise alcohol hand products using the same steps	Using an approved antiseptic hand cleanser or soap, wash hands If hands have any contact before or during a procedure, but are not soiled with any body fluids and, therefore, do not require hand washing with soap or an antiseptic hand cleanser, alcohol hand-rub can be used, using the same technique. Any soilage can inactivate the activity of alcohol and therefore hand washing in these circumstances is essential *NB* Alcohol hand-rubs/gels can also be used following hand washing, e.g. when performing aseptic techniques	Using an antiseptic hand cleanser carry out Level 2 hygienic hand wash for 2 to 3 min, ensuring all areas of hands and arms are covered (The time used for surgical scrub is often debated and local policies must be followed)

	Action	Rationale
***How* to dry**	Using clean disposable towels, dry each area of the hand thoroughly each time after washing. This should be done by drying each part of the hand, remembering all of the steps included in the hand washing process If 'hands-free' taps are not available, the disposable towels should then be used to turn off the tap	Hand drying is an important process in removing any remaining transient microorganisms on the hands and hands that are not dried properly can become dry and cracked, leading to problems Recontamination of the hands following drying should be avoided as far as possible Other forms of hand drying, e.g. hot air driers or reusable towels, are available but are not considered acceptable in ensuring that the whole hand decontamination process is effective Reusable towels that are freshly laundered are sometimes acceptable in the home
Additional points Gloves	It may be necessary to change gloves and decontaminate hands between tasks on the same patient	To ensure that contamination of gloves/hands does not lead to microorganisms coming into contact with an area/site of the body where they would not normally be present and might cause infection

Continued

Table 16.4 Hand hygiene *(Continued)*

	Action	Rationale
Cuts and abrasions	Cover all cuts and abrasions with a waterproof dressing, even when gloves are being worn	To prevent inadvertent exposure to blood or body fluids and to protect the patient from exposure to the blood or body fluids of the health care worker
Soap	Liquid soap dispensers should be kept clean and the 'topping up' of solutions into bottles should not take place If bar soap must be used in home care settings, it should be kept on a rack that facilitates drainage	To prevent microorganisms from harbouring in dispensers and spreading to those using them and subsequently to patients Liquid soap solutions can become contaminated when a 'topping up' system is used
Nail brushes	Do not use nail brushes to scrub nails or any part of the hands during social or hygienic hand washing	Most microorganisms can be easily removed by hand washing and scrubbing can break the skin, leading to increased risk of picking up microorganisms or dispersing skin scales that may cause harm to others
Nails	Nails must be kept short and clean Nail polish or artificial nails should not be worn	To prevent the harbouring of microorganisms which may then be spread It has been shown that nails and chipped nail polish can harbour potentially harmful bacteria
Hand creams	Communal hand creams should not be used unless in a wall-mounted pump dispenser that undergoes a maintenance and cleaning regimen If a particular skin problem is experienced, advice should be sought from your GP or Occupational Health Department	To protect skin from drying and cracking, where bacteria can harbour Communal tubes or tubs of hand cream can become contaminated with microorganisms from the hands of those using them, therefore only individual tubes of hand cream should be used or those that are in contained dispensers Hand skin problems should be appropriately treated to try to ensure broken skin is not a problem when being potentially exposed to microorganisms in the workplace
Jewellery	Wrist and hand jewellery should be removed at the start of each shift if there will be close personal contact with patients during this time	To prevent contamination of jewellery, particularly those with intricate parts such as stones, with microorganisms and subsequent spread to health care workers or patients

SICPs, standard infection control precautions.

frequently touched or are used for eating. Other surfaces frequently touched by health care workers, e.g. hand rails, telephones, keyboards and door handles, are also important, and while recent media headlines have implicated items such as lift buttons, those items closer to patient care are probably more crucial in environment control and protection of patients.

Cleaning schedules must reflect specific risks, e.g. the volume of activity, the condition of the patients and the procedures being undertaken. This applies to clinical areas as well as local or central storage areas for supplies such as personal protective equipment (PPE), waste and linen. PPE or other clean or sterile equipment must never be stored in sluice areas, unless they are specifically for use there, and cleaning equipment must never be stored in communal areas, e.g. bathrooms. Supplies must always also be stored off the ground. Items used for cleaning must also have a schedule so they do not harbour microorganisms. Cleaning of soft furnishings such as curtains, chairs and carpets should include vacuuming. Increasing the frequency of cleaning and of reviewing methods of cleaning is essential during outbreaks or when there is increased risk of cross-infection, e.g. from incontinent patients or the presence of multidrug-resistant organisms.

Schedules for the pick-up of linen and waste bags are also important and must be agreed, recorded and monitored. If waste bags are not picked up frequently, this can lead to increased contamination of the environment, and storage of waste bags in communal areas such as corridors is not acceptable.

New items, such as invasive scopes, and large areas/items such as flooring or furniture, must be given specific decontamination attention with the involvement of the infection control team.

Schedules should also be drawn up for care of ventilation (air) systems, particularly in high-risk areas such as theatres and transplant units, and for water- and ice-dispensing machines, which can be a focus for microorganisms.

At home

In the home environment, risk assessments must be carried out and the most appropriate and common-sense approach used; for example, asking a patient's partner to wear full PPE when cleaning up a urine or vomit spillage may be unrealistic. Education and support from the community nurse are essential to provide people at home with the information necessary to prevent the spread of infection.

Many disciplines are involved in environment control and service level agreements can ensure that all are aware of the standards to be achieved and tasks to be undertaken. Many reports have been published (Auditor General 2000, 2003) about the lack of cleanliness and hygiene in health care, often focusing on the reduced numbers of dedicated cleaning staff, particularly in acute areas. Roles such as the modern matron, directors for infection prevention and control, and infection control managers, as well as infection control teams, can create a positive culture towards cleaning.

SICPs and respiratory infection

The spread of respiratory infection worldwide, e.g. SARS and influenza, has put respiratory hygiene and cough etiquette on the health agenda. Health care workers and patients need standard procedures, especially during seasons when outbreaks are more common, such as:

- covering the mouth and nose when coughing or sneezing
- using disposable tissues and disposing of them directly into bins
- performing hand hygiene after any contact with respiratory secretions or used tissues.

The proximity of patients to one another in areas such as waiting rooms is also a consideration for the spread of respiratory infections and regularly updated guidance will be made available to address such ongoing concerns, particularly from the Health Protection Agency and Health Protection Scotland.

Key points representing good practice in preventing infection are shown in Box 16.5.

16.3 Think about a patient you have cared for recently. Identify how you considered their risks for infection during provision of routine daily care, bearing in mind the steps in the cycle of infection. Also think about which SICPs you applied, or should have applied, and why you did or did not apply them.

Decontamination of reusable medical devices

Health care workers require specific guidance on decontamination of reusable medical devices, such as surgical instruments (see Fig. 16.4). Decontamination encompasses cleaning, disinfection and sterilisation. The main areas to consider when undertaking decontamination include:

- the risk of HAI from a reusable device and the most appropriate technique to protect patients from infection. Transmissible spongiform encephalopathies (TSEs), including CJD and vCJD, present a serious risk and need particular guidance
- general patient and staff safety to protect them from potentially infective microorganisms where devices are in use and to ensure that devices are safe to be handled and only used following decontamination, e.g. free of potentially harmful chemicals used during disinfection

Box 16.5

Good practice in preventing infection

- A good standard of personal hygiene
- Appropriate wearing of uniforms, e.g. those working in hospital should change clothing before leaving and follow local policies on the best way to launder uniforms
- Appropriate placement of flowers in clinical areas, especially high-risk areas, where microorganisms may breed and spread infection (particularly harmful to immunocompromised patients)
- Appropriate care of animals when patients are present; animals may spread infections to patients — and vice versa, as it is thought that animals too may now harbour MRSA
- Avoiding sitting on or placing clinical items on patients' beds as beds may be contaminated with microorganisms and therefore can easily contaminate items placed on them, including uniforms and intravenous equipment
- Appropriate wearing of jewellery, as it may lead to cross-infection
- Long hair should be tied back away from the face and neck
- Appropriate use of white coats and other overcoats which, if not properly laundered, can be a source of microorganisms. Many doctors have stopped wearing white coats as they do not serve any personal protective equipment (PPE) purpose
- Ensuring reusable, communal items, e.g. stethoscopes and tape, are stored in a clean area and decontaminated where appropriate after use. Keeping items such as tape and scissors in uniform pockets poses an unacceptable infection risk

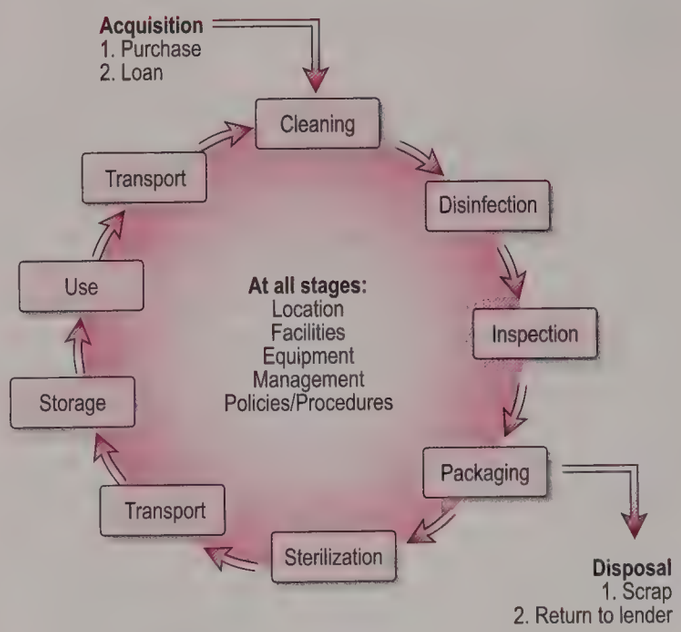


Fig. 16.4 Decontamination cycle.

- recognition of the symbols that guide health care workers handling and reprocessing medical devices, e.g. the symbols for 'do not reuse', 'single use only' and 'sterile', which can be found on the packaging of all items.

Many health care workers, including nurses, are responsible for handling and packaging items before sending them to a reprocessing department, e.g. central sterilising unit, returning them to stores for redistribution or sending them for repair. Training on sterilising unit policies is essential for those responsible for reprocessing surgical instruments to avoid decontamination failures that can lead to HAI. Automatic washer disinfectors and ultrasonic cleaners should be used. If cleaning is not carried out correctly, failures will occur, even in sterilised items. Cleaning prior to sterilisation is as important as sterilisation itself. Manual cleaning is discouraged, both to protect health care workers from cross-infection and also because the automated process is often more efficient. Where manual cleaning of instruments is essential, guidance must be sought from the infection control team and from the most up-to-date policies, including the use of appropriate PPE. Items with hollow bores and areas that are hard to reach are particular harbours of microorganisms.

Additional precautions

Transmission-based or expanded precautions, incorporating isolation procedures, previously often known as barrier nursing, should be applied when highly transmissible or antibiotic-resistant microorganisms are present in a patient. The procedures are commonly categorised by the organism's route of transmission, the most common being:

- droplet
- airborne
- contact.

Knowledge of the route of transmission will make the precautions to be taken clear and easy to understand without the need for more in-depth knowledge of the specific microorganism or infection. This makes it possible for all disciplines and others involved to apply the appropriate precautions.

People under isolation precautions may be embarrassed or depressed because they feel that they are in some way 'dirty'. Nurses are legally responsible for keeping patient information confidential and may divulge such information only if it is essential for the benefit of the patient or the safety of others. Nurses should explain this to patients to minimise embarrassment or unease. It is also helpful to inform the patient about infection control procedures. Maintaining patient confidentiality should not hinder measures such as isolation. Patients in circumstances such as isolation often require increased psychological support.

Full details of the measures to be adopted in addition to SICPs should be available within local infection control policies and from infection control teams. Although the recommendations, accepted internationally, are specific with regards to measures to prevent and control the spread of infection through identified routes of transmission, slight variations may occur due to local situations and facilities.

Table 16.5 shows examples of infectious diseases, their means of spread and precautions to be employed.

For further information, see Garner (1996).

How to set up and maintain isolation for MRSA

(see Fig. 16.5 and Box 16.6)

Appropriate equipment for effective isolation care in single side-rooms must be provided at the door to the room, i.e. gloves, aprons and other PPE, alcohol hand products and waste disposal receptacles. When isolation facilities are limited or not available, patients with the same infectious disease should be cohorted following a risk management approach. This practice is sometimes necessary within health care settings to contain a specific infection, for example when numerous patients are infected with norovirus and there are not enough single rooms. During and following isolation of a patient, cleaning of their environment often causes anxiety among those involved in this process. Keeping such areas — whether at home, in hospital or in care homes — clutter free is essential, so that cleaning can be carried out efficiently. Thorough terminal cleaning of all areas, including soft furnishings, e.g. curtains, may be required, following local policies and procedures or a risk assessment, usually aided by the infection control team. Specific cleaning equipment must be dedicated to isolation rooms/areas and not used for other areas. Linen and waste are often 'double-bagged' to avoid any further contamination when they are removed and linen should be sent to laundries in water soluble bags.

Anxiety again can occur over delivery of meals and care of utensils and crockery when patients are known to have specific infections and reassurance and guidance will be needed. Guidance states that patients should be treated the same whatever the infection and that adherence to SICPs and appropriate additional measures should generally be adequate. Risk assessments may be carried out by infection control teams in some circumstances and specific guidance given if required. Visitors, whether they be other health or social care workers or relatives or friends, including children, can be as anxious as the patients they are visiting in isolation or at home with a specific infection. They must be advised about appropriate contact with the patient and their environment and good hygiene in order to avoid becoming contaminated during visits and to ensure cross-infection does not occur. Often infection control teams will provide staff with supporting information and guidance, including information for children.

Where patients with airborne infections such as pulmonary TB are being cared for, it is recommended that they are placed in a negative-pressure isolation room which has the necessary ventilation to aid the prevention of spread. The converse is a positive-pressure ventilation room which is used when trying to protect immunosuppressed patients from circulating air which may harm them in their compromised state, e.g. those who are neutropenic.

Aseptic and clean techniques

Aseptic and clean techniques can prevent the entry of microorganisms into susceptible sites, for example surgical sites and insertion sites of invasive devices.

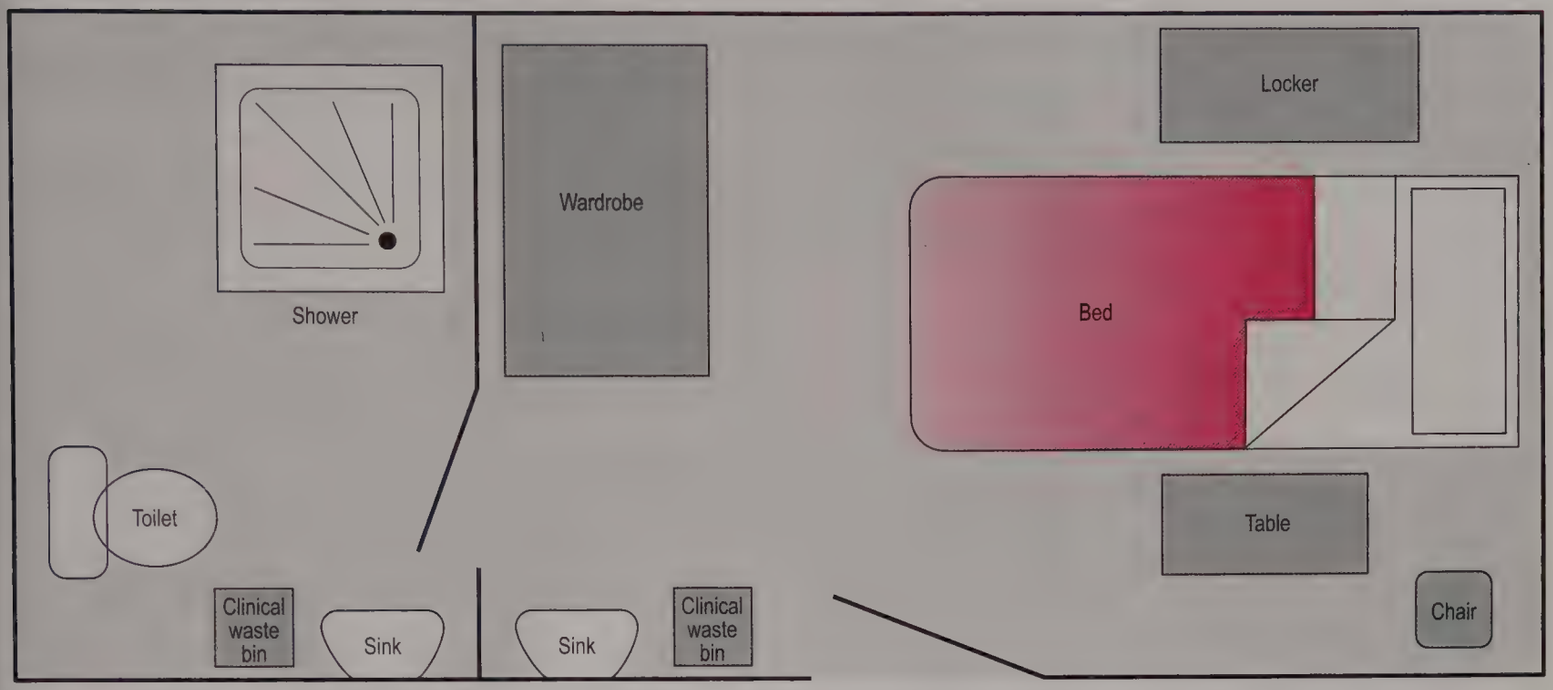

Fig. 16.5 Accommodating a patient with MRSA — room, equipment and appropriate arrangement. (See also Box 16.6.)

Box 16.6

Accommodating a patient with MRSA

Single room with closable door and attached bathroom

- Minimal belongings and equipment in the room
- Handbasin with liquid soap and alcohol rub/gel and disposable hand towels both inside and outside the room door
- Aprons and gloves available outside the door
- Foot-operated clinical waste bin next to the sink, in the cubicle by the door
- Table/trolley on the door-side of the bed, kept clean and clutter-free
- Own vital signs machine or blood pressure cuff and thermometer if possible
- Red water soluble linen bags outside the door
- Sign on the door making it clear to adopt contact precautions (see p. 670). NB: Also recorded on report sheet and reiterated at the nursing handover report
- Sign on the door advising visitors to ask a nurse before entering
- Advice from nurse re MRSA, gloves, aprons and hand washing, given without breaching confidentiality or causing anxiety to those who do not understand such infections

Bathroom

- Own washbasin
- Soap, alcohol rub/gel and disposable hand towels available
- Gloves and aprons available
- Foot-operated clinical waste bin

Informing the patient

- Advise the patient about MRSA and why they are being isolated; provide reassurance and ensure they understand
- Explain they can still have visitors and that they also will receive advice
- Make sure the patient understands any treatments for MRSA, e.g. nasal cream, and the importance of adhering to the regimen
- Information leaflets should be used

Actions when nursing the patient

Before entering

- Collect all necessary equipment
- Wash and dry hands, put on gloves and apron
- Open the door using outside handle

Whilst in the room

- Make sure only gloves and apron surface make contact with the patient or the environment

Leaving the room

- Open the door with inside handle. As you reverse out and before exiting, remove apron first, then gloves and put them in the clinical waste bin within the cubicle, using the foot pedal
- Leave without touching anything further
- Close door with outside handle
- Decontaminate hands

NB

- If any equipment has been brought out of the cubicle it must be washed/wiped appropriately immediately
- If the general ward's observation equipment is being used for this patient, their observations should be done last and the equipment always cleaned after it has been used
- Catering staff must be advised as to appropriate measures when delivering meals

With thanks to Hannah O'Regan, Student Nurse, University of Edinburgh for her contribution to Fig. 16.5, and Box 16.6.

Table 16.5 Examples of infectious diseases, their means of spread and the precautions to be employed

Main mode of transmission	Characteristics	Summary of main prevention measures
Droplet Diphtheria Influenza virus *Legionella* Meningococcal disease MRSA (occasionally) Respiratory syncytial virus Rotavirus Small round structured virus *Streptococcus pyogenes*	Coughing, sneezing, talking (within 1 metre) Splashing, potential aerosolisation during procedure (could be further than 3 feet)	Surgical mask for patients and health care workers Ensure distance between patients and others and utilise barriers to facilitate this, e.g. single room Remember importance of PPE for patient care procedures, including eyewear *NB* eyeglasses can be protective against direct splashes; however, where aerosol occurs, more extensive eyewear is required, e.g. wrap-round goggles
Airborne Chickenpox (varicella) Influenza virus Measles Smallpox *Mycobacterium tuberculosis*	Smaller particles that are suspended in the air longer and further, then entering through the respiratory tract	Negative pressure ventilation rooms (the gold standard is considered to be a single room, with adjoining toilet and anteroom with its own hand washing facilities) Use of respirator-type devices (surgical masks are not considered adequate) and other PPE Limit high-risk aerosol procedures, including avoidance of nebuliser use
Contact Chickenpox (varicella) Food poisoning, e.g. *Salmonella, Campylobacter* Hepatitis A Influenza virus MRSA Poliomyelitis Rotavirus Shingles (varicella) Small round structured virus *Streptococcus pyogenes* Vancomycin-resistant *Enterococcus*	Hands as the main vehicle of transmission Environmental contamination is also common	Utilisation of barriers to prevent spread, e.g use of single rooms Hand hygiene critical Frequent environmental decontamination (as per local policies) Remember importance of PPE for patient care procedures

PPE, personal protective equipment.

Aseptic technique

Asepsis involves ensuring that:

- all equipment used is sterile
- the setting, e.g. the dressing trolley, is prepared by washing it with detergent and water and drying it. A disinfectant wipe with 70% alcohol is then recommended for the surface
- SICPs are adopted by personnel involved
- the patient is prepared for the procedure. Skin cleansing is a major factor in the prevention of infection and up-to-date guidance on this should be available within local policies
- items are disposed of or reprocessed appropriately following the procedure
- appropriate documentation is completed to describe the procedure and any findings.

Aseptic technique should be employed for:

- wounds healing by primary intention, e.g. surgical incisions, fresh breaks in the skin or burns
- insertion of cardiovascular invasive devices, e.g. central venous catheters, peripheral venous catheters
- insertion of indwelling urinary catheters
- percutaneous endoscopic gastrostomy and jejunostomy tubes
- tracheostomy tubes and chest drains
- vaginal examination using instruments.

Clean technique

This is a modified aseptic technique that can be employed when managing certain wounds healing by secondary intention, for example chronic leg ulcers, which are often heavily colonised with microorganisms in the first instance. Avoiding the unnecessary entry of other microorganisms into the site is still essential, although on certain occasions sterile equipment such as gloves may not be necessary; clean gloves may be adequate. A non-touch technique is vital to ensure that no non-sterile items come into contact with the site. A risk management approach will determine the appropriateness of adopting a clean as opposed to an aseptic technique. Liaison with the infection control team or other nurse specialists, for example tissue viability nurses, before proceeding may be advisable.

Dressings also prevent invasion of microorganisms in susceptible sites, as does appropriate maintenance and care of invasive lines and tubes. Dressings should keep a wound or insertion site free from potential contamination and

infection and be impermeable to bacteria. Dressings used on wounds where slough or necrotic tissue is present should minimise or remove this dead tissue (see Ch. 23).

Guidelines for care: key areas of concern in relation to HAI

Evidence-based or best practice guidelines, derived from systematic or critical reviews, are a fundamental part of nursing care. Guidelines often focus on the highest risk areas, such as intensive care units, burns units and long-term care homes, as well as on specific priority diseases such as MRSA. If clear guidance is not available, a common-sense approach is important, for example continuing to provide high quality standards of care until further, more specific evidence is available.

High-risk procedures have become a focus for the production of guidelines, applicable in all settings. HAI can be prevented by managing high-risk procedures appropriately. A review (Harbarth et al 2003) suggests that emphasis should be placed on key areas with HAI reduction potential (see Table 16.6).

The prevention of urinary tract infections

Urinary tract infections are known to account for approximately 30–40% of all HAIs and are considered the most common.

For further information, see Chapter 8 (this volume) and Department of Health/Hospital Infection Society (2001a,b).

The prevention of surgical site infections

For further information, see Chapters 23 and 26 (this volume), Mangram et al (1999) and Dougherty & Lister (2004).

The prevention of cardiovascular line infections

Insertion of cardiovascular lines invades the epithelial barrier, which protects the skin from potential invasion. Bacteraemia (bacterial blood infection) caused by these devices contributes significantly to HAI.

Risks present from many sources while cardiovascular lines are in situ. These include:

- contamination of the device itself while it is being inserted or manipulated
- contamination of the dressing used to cover the device. Preferred dressings are semi-permeable polyurethane, which allows visual inspection and prevents unnecessary disturbance, e.g. it can be left in place for bathing, and minimises the risk of bacteria at the invasive site
- microorganisms present in stopcocks, extension sets, taps, filters — these adjuncts should be used only where appropriate and the use of stopcocks and taps in particular should be avoided
- contamination during attachment of administration sets, and any of the above adjuncts, to the device and/or to the infusion container
- contamination of additives to infusion fluids
- contamination that may present in pre-packaged infusion fluids, administration equipment, or even infusion devices or dressings themselves.

Patients who require a cardiovascular device are often already compromised in their health, which is a risk factor. The use of multilumen catheters, the type of catheter and the insertion site are also risk areas. For example, insertion of lines into the internal jugular vein or the femoral artery poses a higher risk due to their position near a hair line and in the groin, which are ideal environments for bacterial growth. Disturbance of devices and their attachments must be kept to a minimum and they should be replaced at optimum times.

For further information, see Department of Health/Hospital Infection Society (2001c).

The prevention of respiratory tract infections, particularly those associated with artificial adjuncts

Reducing the incidence of HAI pneumonia within health care settings is also being considered. The use of devices to facilitate artificial breathing and support respiratory distress is a key factor in the potential for HAI. Areas for consideration, particularly related to nursing care, include:

- care and dressing of insertion sites such as tracheostomies and chest drain tubes
- the correct technique for suctioning of respiratory secretions
- the correct use and care of nebulisers when administering saline or water for loosening secretions, or medications (see Box 16.7)
- humidification systems
- artificial respirator bags
- intubation with endotracheal tubes — some nurses trained and competent in advanced life support may insert endotracheal tubes

Table 16.6 The preventable potential for key HAI areas

HAI type	Reduction potential (%)	Setting details
Catheter-associated urinary tract infections	46–60	All specialties
Surgical site infections	24–34	Surgical specialties
Central venous catheters associated with bloodstream infection	14–71	70% neonatals 56% adult critical care
Ventilator assisted pneumonias	38–70	Intensive care units

Box 16.7

The use of nebulisers and associated risks

A newspaper article revealed that a patient had acquired *Legionella* following a hospital stay. Following investigation of the source of this infection, an alert was distributed from the Medicines and Healthcare Products Regulatory Agency in England and Wales and Scottish Healthcare Supplies in Scotland, stating the importance of the care of nebulisers, in particular cleaning them after use. Manufacturers' instructions should be followed and recent reviews have highlighted sufficient evidence to recommend cleaning them with sterile water rather than tap water to avoid contamination from microorganisms such as *Legionella*. *Legionella* can cause disease in humans following inhalation from contaminated water vapour. If water sources are adequately treated and managed for home and health care setting consumption, *Legionella* should be avoided. Immediate drying and storage of nebulisers are equally as important so that they do not become a source of infection between uses on the same patient; nebulisers are considered single-patient use items.

- breathing circuit tubing
- anaesthetic machine tubing and connections.

All the above points must be considered in the community setting, although the focus for infection rate reduction programmes is frequently on acute settings.

For further information, see Chapters 3, 13 and 29 (this volume), Tablan et al (2003) and www.devices.mhra.gov.uk.

A common feature of all guidelines is the use of antiseptics to prepare sites prior to insertion of devices or breaches in the skin (see Box 16.8).

Box 16.8

The use of antiseptics

- The use of antiseptics is often debated, particularly in relation to wound care and preoperative skin preparation. Many studies have shown the benefits of using them appropriately
- Like antibiotics, not all antiseptics will kill or inhibit all microorganisms
- Resistance to antiseptics may occur as it has with antibiotics
- Antiseptics, whether in fluid, lotion, cream or dressing format, should be used after a risk assessment; misuse must be prevented as, like any medicine, they can have adverse effects
- Patients can have allergies to certain antiseptics or contraindications to their use, for example povidone–iodine
- 'Topping-up' of bottles that contain fluids or lotions, such as antiseptic solutions, rather than disposing of the used bottle and replacing it completely, can allow microorganisms to build up within the solution, which can be a source of infection when used on the skin of health care workers or patients

Guidelines for the prevention of sexually transmitted infections and for the prevention of gastrointestinal infections, including the introduction of feeding systems such as nasogastric tubes, are also important and available.

Transition from home to hospital and hospital to home

Effective communication between staff working within primary and acute care settings is vital if infections that might be introduced to the home from hospital or to the hospital from home are to be prevented, controlled and managed appropriately. Nurses should liaise between settings, disciplines and agencies to influence and inform decision making in relation to infection control. Whether working in the NHS, in education as a school nurse or lecturer, in the prison service, general practices, independent hospitals or care homes, or with commercial companies providing health care products, nurses must consider ways in which the potential for infection can be managed across the spectrum of health care services. Communication in all its forms is core to this.

16.4 Discuss with a community nurse how the control of infection can be achieved in the patient's home, e.g. hand hygiene, use of protective clothing, aseptic techniques and disinfection of equipment.

INFECTIOUS DISEASES

'Infectious' (or 'communicable') diseases are illnesses caused by microorganisms which are not normally present in or on the body, such as salmonellosis, hepatitis B and tuberculosis. Such infections contrast markedly with those which are acquired as a result of poor asepsis in invasive techniques or as a consequence of antibiotic therapy, immunosuppressive drugs or inadequate hand washing, normally thought to be HAI. Infectious diseases can be caught by anyone, at any time, in any place, and do not usually result from a particular nursing or medical procedure. This does not mean, however, that they cannot be spread from person to person; this presents a particular danger when patients with infectious disease are nursed in hospital.

Causes

Infectious diseases are generally caused by:

- bacteria, e.g. salmonellosis, meningococcal meningitis
- viruses, e.g. hepatitis, chickenpox
- protozoa, e.g. malaria, toxoplasmosis, amoebic dysentery.

Knowledge of the organism that is causing the disease is important in the planning of care.

Transmission

Most infectious diseases are ingested (e.g. hepatitis A), inhaled (e.g. tuberculosis) or inoculated (e.g. hepatitis B). Inoculation in this context refers to blood or body fluid entering a cut or skin abrasion or being splashed onto

mucous membranes; it can also occur following needlestick injury. The organisms can be transmitted directly, i.e. straight from one person to another through direct contact with the infectious body substance, or indirectly, i.e. deposited on hands or surfaces where they can be picked up by touch.

Some infectious diseases are so common in the population that only general care is needed. Many people suffer from cold sores (herpes simplex), but the common-sense precautions of avoiding mucous membrane contact until the sores have healed, careful handwashing and washing of cutlery and cups, and not sharing toothbrushes, razors or face cloths are usually enough to prevent transmission.

Diseases such as chickenpox are so common and so easily transmitted through inhalation, particularly in children, that special precautions to prevent their spread in the community are rarely necessary, although these may need to be enforced in settings such as hospitals where there are particularly susceptible individuals. Other common diseases are prevent-able by an active immunisation programme; for example, immunisation against diphtheria, pertussis (whooping cough) and tetanus; poliomyelitis; measles, mumps and rubella and *Haemophilus influenzae* type B is now offered for all infants. It is still advisable, however, for pregnant women because of the risk of damage to and/or infection in the fetus during pregnancy, and for people who are immunosuppressed to keep away from anyone known to have an infectious disease.

Immunity to infectious diseases

Immunisation against many diseases is carried out during childhood, with booster doses being required only in later life. A booster dose is a smaller dose of a vaccine which boosts the level of memory cells, specific to the given antigen, circulating in the bloodstream (see Fig. 16.2).

Nurses and health visitors have an important role to play in encouraging parents to have their children vaccinated. Vaccination should be carried out by staff that are aware of the risks and the benefits. Some parents are afraid that their child might develop an adverse reaction to a vaccine; however, this is an uncommon occurrence and few of the children so affected have developed serious complications. In the late 1970s in England and Wales, the percentage of infants vaccinated against whooping cough fell dramatically due to public concern about vaccine-damaged children, although such cases were very rare. There was a concurrent rise in the number of whooping cough cases reported, a proportion of whom had serious systemic complications.

16.5 Identify recent trends for vaccination uptake for measles, mumps and rubella.

SALMONELLOSIS

PATHOPHYSIOLOGY

Salmonellosis is caused by one of about 200 serotypes of the genus *Salmonella* which cause disease in humans and animals (Payne 2000). Only a few of these are commonly encountered in the UK. The organism is ingested; common sources are contaminated meat and poultry products and untreated milk. The incubation period is 12–72 h (Heymann 2004). Some salmonellae, e.g. *S. typhi* and *S. paratyphi*, can cause enteric fever.

Common presenting symptoms

are highly variable, ranging from mild symptoms to life-threatening septicaemia. Normally, the effects of infection are acute enterocolitis with diarrhoea, blood in the stools, abdominal pain and nausea; less frequently, they include vomiting, fever, headache and toxaemia. Rarely, arthritis, cholecystitis, endocarditis, pyelonephritis, acute renal failure, meningitis or pneumonia occur.

MEDICAL MANAGEMENT

Investigations

Diagnostic investigation includes stool bacterial culture while diarrhoea persists. If enteric fever, septicaemia or a focal infection is suspected, blood cultures during the acute stage of the illness are done. Serological tests are of little value except in the detection of a 'carrier'.

Treatment

Rehydration and electrolyte replacement may be necessary in the treatment of severe enterocolitis. Antibiotics are not generally given in uncomplicated intestinal infection as they tend to prolong the excretion of the organism. They are given if the disease is severe with evidence of systemic spread and/or a vulnerable patient, e.g. a frail or older person. Antibiotics are absolutely indicated in enteric fever caused by *S. typhi* and *S. paratyphi*. Ciprofloxacin is exceedingly active and is the drug of choice in all cases of salmonellosis and enteric fever. It is not licensed, however, for use in pregnancy or in those under 18 years of age. Chloramphenicol is a useful alternative, although it can be associated with side-effects such as severe haematological disorders.

NURSING PRIORITIES AND MANAGEMENT: Salmonellosis

Many people with salmonellosis become ill at home, often after eating an undercooked meal or after eating infected poultry. Eggs may also be contaminated. Most people will wait to see if the symptoms subside before contacting their GP, but if a particular item of food is suspect they may seek help earlier.

Institutional outbreaks can and do occur and are usually a result of defects in food hygiene, either at kitchen or at ward level. Cross-infection in the ward can occur, either directly from a patient with salmonellosis to another person, or via nurses' hands if hygiene is poor. However, the exact cause of such outbreaks is not always identified.

The nurse is unlikely to be involved in caring for a patient at home with acute salmonellosis, unless there are concurrent problems. The community nurse or health visitor may be involved in helping to obtain faecal specimens from other members of the family and in trying to trace the source of infection, in conjunction with, in England and Wales, the Environmental Health Officer and the Consultant in Communicable Disease Control (CCDC) and, in Scotland, with the Consultant in Public Health Medicine (CPHM Communicable Diseases and Environmental Health). Such

visits are an excellent opportunity for health education in general and about food hygiene as part of a planned programme which takes into account family needs. SICPs must be applied and patients should be advised that the prescribed course of antibiotics must be completed.

Life-threatening concerns

Those that may arise are septicaemia, focal sepsis, severe fluid and electrolyte imbalance, dehydration and acute renal failure.

Major patient problems

These include skin excoriation from severe diarrhoea, fever, abdominal pain, nausea, loss of appetite and weakness because of constant diarrhoea.

Further considerations

Specific ongoing nursing care

Ongoing care comprises the following aspects:

- Preventing the spread of infection through the adoption of SICPs and provision of guidance about hand washing. Care with faeces will be needed in hospital and in the home, with particular attention paid to surfaces which may be contaminated; regular cleaning regimens should be in place. Contact precautions may also be applied in health care settings.
- In hospital, designating one nurse on each shift to look after the patient. It is important for nurses to spend time with the patient giving information and reassurance about isolation procedures to counteract the loneliness of isolation.
- Ensuring that fluid intake is adequate (see Ch. 20).
- Ensuring that nutrition is adequate (see Ch. 21), while trying to accommodate the patient's wishes; this can be difficult in hospital, where there is central catering and where meals are delivered at specific times.
- Keeping the anal region clean and dry and applying a 'for use by this patient only' barrier cream to prevent excoriation.
- Ensuring that the patient can get to the toilet or has a commode at the bedside and has the opportunity to wash their hands afterwards.
- Trying to ensure privacy as far as possible.
- Being sensitive to any odour problem; discussing this with the patient might help.
- Encouraging visitors to visit at different times of the day and providing guidance about hand washing.
- Identifying key carers at home and providing guidance about infection control.
- Encouraging self-care and independence.

HEPATITIS B

Hepatitis B is a viral infection which is transmitted from mother to child mostly at birth, sexually, by blood contact, especially injecting drug users (see Chs 36 and 37) and needlestick injury. It is endemic in some parts of the world. The virus, HBV, has been found in most body secretions and excretions, but only blood, saliva, semen and vaginal secretions have been shown to be infectious (Heymann 2004). Hepatitis B was formerly seen in people who had received blood and blood products and in people who had been given injections with contaminated needles. These risks have largely been eliminated in the developed countries by the screening of blood donors, the testing of donor blood and the single use of sterile syringes and needles. The main risk to health care workers is that of inoculation with infected blood, either through needlestick injury with a contaminated needle or by being splashed with infected blood on skin abrasions or mucous membranes.

PATHOPHYSIOLOGY

The virus is made up of several components, each of which is capable of inducing an immune response. HBsAg (hepatitis B surface antigen) is the first antigen to appear in the blood after infection. The presence of anti-HBs antibodies in the blood is the best measure of immunity to the virus.

Acute hepatitis B may have one of four outcomes:

- complete recovery
- fulminant hepatitis — rare but frequently fatal
- carrier state — HBsAg-positive
- chronic hepatitis — may lead to cirrhosis of the liver and to hepatocellular carcinoma (see Ch. 4).

Some people become infected with the hepatitis B virus without developing the acute disease. This is known as subclinical infection and such individuals are more likely to develop the carrier state. These individuals may be unaware of the infection and of their potential for transmitting the virus to others.

The incubation period for hepatitis B is 45–180 days (Heymann 2004). Onset is insidious.

Common presenting symptoms

are highly variable, ranging from unapparent infection or malaise, with abnormal liver function tests, to cases of fatal acute hepatic necrosis. Normally, anorexia, nausea, vomiting, abdominal discomfort and fever occur, followed perhaps by arthralgia, urticaria or glomerulonephritis caused by antigen–antibody complexes, progressing to jaundice.

MEDICAL MANAGEMENT

Investigations

are serological. HBsAg is indicative of infection and infectivity and occurs both before and during the acute illness. This finding must be interpreted with caution, however, as HBsAg may still be present in carriers and the chronically infected who have become jaundiced from some other cause. Carriers are of high infectivity when HBeAg is present (a marker of replication in the liver) and of low infectivity when anti-HBeAg is present. HBV DNA is a more sophisticated measure of replication, infectivity and the progression to chronic liver disease. IgM anti-HBc is an antibody to the 'c' or 'core' antigen which may be present during the diagnostically difficult 'window' when HBsAg and anti-HBs are in equivalence and neither is detectable in the serum. Serial estimation of these, other antigens/antibodies, other viruses such as hepatitis D and the liver

enzymes may be necessary to establish the stage and progression of the disease.

Treatment

There is no effective treatment for the acute disease. Bed rest is not of proven value. Chronic hepatitis B may be treated by immunosuppression with a tapering course of corticosteroids such as prednisolone for 6 weeks, but now recombinant interferon or interleukin-2 is favoured. Liver transplantation, however, may still be the last recourse for a patient with advancing chronic disease.

Effective vaccines are available and are recommended for health care personnel working with patients, particularly high-risk patients, and those in contact with blood, particularly when handling sharp instruments. Prophylaxis (vaccination and/or specific immunoglobulin) is also given after inoculation accidents and other significant exposure accidents and to sexual contacts of HbsAg-positive persons as well as to infants born to HbsAg-positive mothers.

Some health care staff, e.g. surgeons and midwives, are required to demonstrate their immunity to hepatitis B virus before they are allowed to perform 'exposure-prone procedures' (EPP) where their gloved hands may be in contact with sharp objects such as needles, instruments or spicules of bone, inside a body cavity or wound and where their hands are not always completely visible.

For up-to-date information on immunisation against infectious disease, see the most recent version of The Green Book published by the Department of Health (www.dh.gov.uk/publicationsandstatistics).

NURSING PRIORITIES AND MANAGEMENT: Hepatitis B

Since there is no treatment for acute hepatitis B, nursing priorities are to alleviate symptoms and to support the patient until the disease has run its course. People with acute hepatitis B may stay at home, requiring admission to hospital only when they are too ill to be looked after at home or when they require specific medical intervention (Chislett 2003, Christopher 2003). SICPs must be applied.

Life-threatening concerns

Fulminant hepatitis will lead to gross liver failure and all of the associated problems (see Ch. 4).

Major patient problems

These include lethargy, weakness, nausea, vomiting and anxiety about transmission.

Further considerations

Specific ongoing care

This includes the following interventions:

- preventing the spread of infection through the adoption of SICPs
- encouraging the patient to rest; lethargy and weakness are often the first symptoms to arise and the last to go away
- ensuring that fluid intake is adequate (see Ch. 20)
- accurate recording of fluid balance
- ensuring that nutrition is adequate (see Ch. 21)
- providing skin care and regular change of position
- ensuring that the patient can get to the toilet or has a commode at the bedside
- ensuring that the patient does not share razors and toothbrushes with others
- designating one nurse per shift to look after the patient in hospital; loneliness and dejection can be minimised by ensuring that time is taken to talk with the patient and to discuss their needs — access to a telephone, television and other diversions may be important
- encouraging relatives and friends to be flexible about their visiting times
- encouraging self-care and independence.

PULMONARY TUBERCULOSIS

Pulmonary tuberculosis is now the most common form of tuberculosis infection, although other systems are sometimes affected, e.g. the genitourinary or skeletal systems. It is more common in immigrants from countries which have a higher prevalence of tuberculosis than the UK (Baker 2001). This disease is notifiable in the UK.

PATHOPHYSIOLOGY

Pulmonary tuberculosis is a bacterial infection caused by *Mycobacterium tuberculosis*, also known as the tubercle bacillus. The bacteria enter the body by being inhaled; once they reach the epithelial surface of the alveolus, they cause swelling of the epithelial cells and local capillary dilatation. Although some organisms will be engulfed by alveolar macrophages (see p. 655), they will not be destroyed and will continue to multiply; some will escape and may enter the bloodstream, with the potential to infect any other organ in the body (miliary TB). Lymph nodes are often infected.

Invasion of the lung tissue gives rise to an inflammatory reaction in which the infected alveoli fill with fluid, macrophages and bacteria. The resultant lung damage eventually leads to fibrosis, which will be visible on a chest X-ray. The primary lesion in the lung is often asymptomatic and confined to one area. Healing of the lung tissue occurs, sometimes leaving an area of calcification.

The patient becomes Mantoux-positive 4–6 weeks after primary infection and also following immunisation, i.e. they will develop a hypersensitivity reaction to an injection of tuberculin. A chronic cough with bloodstained mucopurulent sputum develops as the disease becomes more advanced.

Dormant bacilli may be reactivated by an alteration in immunity resulting from advancing age, malnutrition or other diseases. People with HIV (see Ch. 37) are prone to developing tuberculosis. People with pulmonary tuberculosis are considered to be infectious until they have had 2 weeks of appropriate medication.

Common presenting symptoms

Normally the initial infection is unapparent. Pulmonary disease is characterised by cough, fever, fatigue and weight loss, and less frequently by haemoptysis, chest pain or erythema nodosum. Extrapulmonary disease is less common but can involve most organs of the body, causing, for

example, meningitis, lymphadenitis, pericarditis, pleurisy, nephritis, cystitis, osteomyelitis, arthritis, laryngitis or peritonitis.

MEDICAL MANAGEMENT

Investigations

Diagnostic investigation includes chest X-ray, often with tomograms and CT scans. Microscopy and culture of sputum, gastric washings, urine, CSF, aspirate or biopsy material are performed as appropriate. Histology of biopsy material is undertaken. Skin testing with tuberculin may be performed, especially in the young.

Treatment

Normally, pulmonary tuberculosis is initially treated with a combination of isoniazid, rifampicin, ethambutol and pyrazinamide to avoid emergence of bacterial resistance. If the isolate is shown to be sensitive, one or two of the medications may be discontinued after 2 months. Other antibiotics may be used when resistance is present or likely to be a problem, and particularly in patients from abroad. Ethambutol is not normally given to patients under 5 years of age or to very old people. Therapy continues for at least 6 months.

NURSING PRIORITIES AND MANAGEMENT: Pulmonary tuberculosis

The main aims in nursing patients with pulmonary tuberculosis are to establish medication and to encourage adherence to the treatment regimen. The underlying health of these patients may not be good and their nutritional status is often poor. The prospect of having to take a large number of tablets regularly over a long period of time is daunting and the side-effects of some medications mean that some people stop taking them. A great deal of support and encouragement will be needed.

Once a person is diagnosed as having pulmonary tuberculosis, it is important that they are kept away from anyone who is immunosuppressed until no longer infectious. Contacts may require follow-up; in the case of staff, this is done by the occupational health department. Non-staff contacts such as family members can be referred to a TB liaison nurse or a chest physician.

A sputum specimen sent to bacteriology will be examined directly under the microscope for the presence of tubercle bacilli. If these bacilli are seen, the report will state 'AAFB (acid alcohol fast bacilli) seen on direct film', 'film positive', 'smear positive' or 'ZN (Ziehl–Neelsen) positive', and the patient will be considered to have 'open' pulmonary tuberculosis. This means that there are enough bacilli in the sputum for them to be seen easily in a small sample, and therefore that the sputum is infectious to others. Culture of the organism may take 6–8 weeks and is necessary to make a firm diagnosis; there are mycobacteria other than *M. tuberculosis*. Infectivity also depends on whether or not the person is 'productive'; a person who is highly productive of sputum and is film-positive is much more likely to infect others than someone who is film-positive and not coughing up any sputum at all (King 2001, Negus et al 2004).

Life-threatening concerns

Respiratory failure may develop if the patient is too weak to cough. Tuberculosis in people who are immunocompromised, such as those with HIV, can result in serious illness.

Major patient problems

These include difficulty in maintaining the medication regimen and in learning how to prevent the spread of droplet infection when coughing.

Further considerations

Specific ongoing care

Nursing care and physiotherapy for people with pulmonary tuberculosis are similar to those for patients with any other respiratory infection (see Ch. 3). The dietitian may be asked to advise on appropriate diet.

The risk of spreading the infection to others is greatly reduced when the person remains at home, in which case care with sputum is usually all that is necessary. Isolation precautions are required for patients with pulmonary tuberculosis in hospital. Recent advice from the British Thoracic Society (see 'Useful websites') recommends that the patient who is smear-positive should be segregated in a single room, preferably with negative pressure, as such patients are infectious. Because of this, in addition to SICPs, airborne precautions should be taken, e.g. wearing a specific type of mask as respiratory protection when caring for the patient. Masks should be carefully removed and discarded, and the hands washed afterwards.

Staff who have been in close respiratory contact with patients with open pulmonary tuberculosis may be screened by Mantoux and Heaf tests and, if necessary, by chest X-ray. Other staff contacts may receive TB contact cards.

Patients are sometimes found to have pulmonary tuberculosis when they are being investigated in hospital for chest disease. Other patients who have been cared for in the same area may be notified through their GP or the TB liaison nurse.

There may be difficulties in explaining the importance of medication, particularly if English is not the patient's first language. Tracing and follow-up of contacts of people with pulmonary tuberculosis is important. Those relatives and friends of the patient who have been in close respiratory contact are generally referred to an infectious diseases physician for examination and follow-up. The British Thoracic Society recommends that there should be trained tuberculosis health visitors or nurses to provide support in implementing policies for screening, follow-up and contact tracing (Oxtoby 2003).

16.6 Miss A is a 78-year-old woman who has lived alone since her sister's death a year ago. Recently, she lost her appetite and developed a persistent cough. A sputum specimen was taken and open pulmonary tuberculosis diagnosed. Normally a pleasant, cooperative person, Miss A was grumpy and resentful when the nurse visited her at home, and there were soiled tissues strewn all over the bed and floor. Devise a care plan to prevent the spread of infection from sputum and saliva.

MENINGOCOCCAL INFECTION

Infections caused by a Gram-negative bacterium, *Neisseria meningitidis*, are commonly known as meningococcal infections. There are five common serotypes: A, B, C, W-135 and Y. In the UK, vaccination against meningococcal serogroup C is recommended and available for all under 25 years. Meningococcal disease is an important medical emergency demanding early diagnosis and prompt treatment (Boyne 2001). Meningitis may also be of viral origin, usually presenting in a less severe form.

PATHOPHYSIOLOGY

The organism is frequently inhaled and carried in the nasopharynx. More rarely, it then enters the bloodstream, giving rise to meningitis and/or septicaemia. Meningococcal group B is the most common cause of bacterial meningitis in the UK (Haslett et al 2002).

Common presenting symptoms

are highly variable. Early recognition is essential. Meningitis may present with severe headache, neck stiffness, photophobia, fever, vomiting, drowsiness and non-blanching rash. Seizures may also be seen. Septicaemia may present with a non-blanching rash, fever, vomiting, cold hands and feet, shivering, rapid or unusual breathing, stomach/joint pains and drowsiness. Late signs of septicaemia in meningitis are impaired consciousness, hypertension, cyanosis and raised intracranial pressure. Fulminating cases may present with sudden shock, extensive purpura and disseminated intravascular coagulation (see Ch. 18). Delirium and coma may supervene.

MEDICAL MANAGEMENT

Investigations

Blood, CSF (if the patient is stable) and pharyngeal swab samples should be taken, in addition to aspirates from other sterile sites, if appropriate. Molecular methods of polymerase chain reaction (PCR) testing are becoming increasingly important.

Treatment

The medication of choice in the treatment of meningococcal infections in the UK is benzyl penicillin, given in high dosage parenterally, commenced as soon as the diagnosis is suspected. If the bacteriological diagnosis cannot be established with certainty, or when there is allergy to penicillin, then broad-spectrum treatment is often given to cover other bacterial pathogens; this usually consists of a high-dose injectable cephalosporin such as cefotaxime. Close household and respiratory secretions/salivary contacts are given a short course of rifampicin or ciprofloxacin to eradicate nasopharyngeal carriage. This is also given to the index case, as penicillin does not eradicate carriage. MenC vaccine should be offered to all cases and unimmunised close contacts where serotype group C is confirmed. Vaccines can also be offered for close contacts of cases with A, W-135 and Y cases. SICPs and droplet/contact precautions apply.

NURSING PRIORITIES AND MANAGEMENT: Meningococcal infection

Life-threatening concerns

The meningococcus bacteria invade the bloodstream and endotoxins initiate the release of a complex cascade of chemical mediators which may lead to the manifestations of septic shock — hypotension, hypovolaemia, vasodilatation and severe capillary leak and metabolic acidosis. This leads ultimately to multiorgan failure and, if all life support interventions fail, death (see Ch. 18).

16.7 The initial flu-like symptoms of meningococcal meningitis can quickly progress to septicaemia, even when detected early. What are the clinical indicators that would alert you to this potentially mortal progression? What is the pathophysiological significance of the haemorrhagic rash that develops in some, but not all, cases of meningitis?

Major patient problems

Meningeal irritation may result in neck stiffness. Vomiting and sweating may lead to dehydration and electrolyte imbalance (see Ch. 20).

For further useful information, see the Meningitis Research Foundation and the Meningitis Trust (see 'Useful websites').

CHICKENPOX AND SHINGLES

Chickenpox and shingles are caused by the same virus, known as the varicella zoster virus (VZV). Primary infection causes chickenpox (varicella), and most people have chickenpox only once, since infection usually confers lifelong immunity. The virus remains latent, however, and recurrence in a different form — shingles (herpes zoster) — can occur months or many years after the initial infection and on more than one occasion.

Chickenpox is highly infectious, from both respiratory droplets and skin lesions. Although common in children, susceptible adults can also be infected, sometimes causing more complications. Disease is more severe and sometimes fatal in the immunocompromised, in unborn babies before 20 weeks' gestation and in neonates infected in the perinatal period. Shingles is usually seen in older people (50–80 years of age) and only the skin lesions are infectious. People can develop chickenpox after contact with someone suffering from shingles; but shingles cannot be contracted from a person suffering from chickenpox. This is because shingles occurs as a result of reactivation of the VZV, whereas primary infection results in chickenpox (which may be subclinical). Contact with chickenpox or shingles, in someone who is not already immune, can result in primary infection.

Vaccination against varicella is now recommended for all non-immune health care workers who have direct patient contact. This is to protect susceptible health care workers and also to protect vulnerable patients from acquiring chickenpox from an infected member of staff.

Chickenpox

PATHOPHYSIOLOGY

The incubation period of chickenpox is 2–3 weeks, commonly 14–16 days. A case is infectious for at most 5 days (usually only 1–2 days) before the onset of the rash and until all vesicles have crusted over, usually about 5 days after the last crop.

Common presenting symptoms

Initial symptoms are usually a slight fever and the development of a skin rash which is maculopapular at first, becomes vesicular and then forms a scab. The lesions do not all occur at the same time but in succession, so that on different parts of the body they may be at different stages. Areas of the body that are normally covered by clothing often have more lesions than exposed parts.

MEDICAL MANAGEMENT

Treatment

There is specific treatment for chickenpox with aciclovir but this is usually not recommended for uncomplicated disease. Antibiotics may be given for secondary infection of vesicles. Zoster immunoglobulin can be given to those at special risk (e.g. the immunocompromised) who have been in contact with the disease and have not had it themselves.

NURSING PRIORITIES AND MANAGEMENT: Chickenpox

Life-threatening concerns

Rarely, chickenpox can cause severe illness. The most common cause of death in adults with the disease is primary viral pneumonia, which is treated with parenteral antiviral agents. Children may develop septic complications or encephalitis. The disease can be severe or even fatal in the immunocompromised.

Major patient problems

The rash may cause irritation and discomfort, and secondary bacterial infection of lesions can occur.

Further considerations

Chickenpox is highly infectious, both from respiratory secretions and from skin discharges. Strict isolation, following airborne and contact precautions as well as SICPs will be required until the period of communicability is over. PPE must be worn for every entry to the room, the door must be kept closed and negative ventilation used if available. Decontamination of the room is also essential.

Shingles

PATHOPHYSIOLOGY

Common presenting symptoms

The first symptoms the person notices are often pain and paraesthesia in the affected area; this is usually the trunk but can be the face or a limb. A rash appears, starting with a macule on which vesicles develop over several days. The vesicles, which are a grey colour, dry up and crust over, usually in a week or so. The rash is characteristically restricted to the area supplied by the sensory nerves of one or an associated group of dorsal root ganglia. Subsequent healing may take several weeks, and residual or prolonged pain occurs in about 10% of cases.

MEDICAL MANAGEMENT

Treatment

involves administering analgesics, aciclovir and sometimes applying idoxuridine paint to the vesicles in the early stages. Early aciclovir treatment may prevent development of severe disease.

NURSING PRIORITIES AND MANAGEMENT: Shingles

Shingles can flare up spontaneously or may follow treatment for another disease, e.g. radiotherapy, where the patient is immunocompromised.

Major patient problems

Pain and discomfort may result from the lesions, which may persist for a long time. The patient may experience anxiety and depression if the condition fails to improve; this is especially common among older patients. A sympathetic and optimistic attitude can do a lot to make the symptoms more bearable (Williams 2002).

Further considerations

Care of the skin condition is similar to that for other skin disorders (see Ch. 12); it should be borne in mind that the lesions will be susceptible to secondary bacterial infection. SICPs must be applied.

If the person is in hospital, they should be kept apart from other vulnerable patients. Isolation precautions may be necessary until the lesions have crusted over, especially if lesions cannot be adequately covered to prevent contamination of outer clothing or bed linen. Only immune staff should nurse patients with shingles (see Box 16.9).

DISORDERS OF IMMUNITY

Four types of immunity disorder can be identified:

- immunodeficiency
- hypersensitivity
- autoimmune disease
- graft rejection after transplantation.

In this chapter, only the first three are addressed.

IMMUNODEFICIENCY

Immunodeficiency may be primary or secondary in nature.

Box 16.9

Staff contact with infectious diseases of childhood

The following questions should be posed in determining which staff members should provide nursing care for patients with diseases such as measles, mumps, rubella and chickenpox:

1. Are the staff members known to be immune (e.g. rubella antibody-positive) or have they been immunised? In the case of a disease that produces lasting immunity, have they had the disease themselves?
2. Are they working with susceptible patients, e.g. neonates, young children, the seriously ill or the immunosuppressed?

If the answer to '1' is 'yes', it is usually all right for the staff members to work as usual.

If the answer to '1' is 'no' and to '2' is 'yes', the staff members should be reassigned to a non-susceptible area until the incubation period is over.

In circumstances where there is any doubt, the control of infection or occupational health department should be consulted.

Primary immunodeficiency

Primary immunodeficiency states are very rare, but may arise under either of the following two conditions:

- there are not enough cells available
- the number of cells is adequate but they have a functional defect.

These problems will be discussed in relation to the cells and proteins involved, i.e. impairment of phagocytes, B lymphocytes or T lymphocytes.

16.8 Recall the cells and proteins that are involved in the immune response.

Impairment of phagocytes

Phagocyte impairment may occur in the following forms:

- *Neutropenia* — a low number of neutrophils (see p. 655). This condition can be congenital (very rare), secondary to drug or radiation therapy (see Ch. 31) or overwhelming infection, or associated with the autoimmune diseases (see p. 683).
- *Functional defects* — abnormalities in phagocyte structure or function. These can result in the inability of phagocytes to localise in an inflammatory site, or in their inability to ingest and digest microorganisms.
- *Failure of complement activation*. There are many steps in the complement pathway, and many components are involved or created during complement activation. Some appear to be more important than others (Roitt & Delves 2001). Absence of one of the complement components can make phagocytosis difficult, as it is easier for the granular leucocytes to ingest microorganisms if their outer surface is coated with complement.

16.9 Recall the function of B lymphocytes and try to work out what will happen if they are deficient.

Impairment of B lymphocytes

Occasionally B lymphocytes fail to mature properly in the bone marrow, resulting in B-cell deficiency and therefore diminished antibody production. People with B-cell deficiency are particularly prone to bacterial infections, e.g. *Staphylococcus aureus* (Roitt & Delves 2001).

Impairment of T lymphocytes

T-cell deficiency occasionally occurs in children in whom absence of the thymus gland means that the cells cannot differentiate to become T lymphocytes. People with T-cell deficiency are particularly prone to some viral infections, e.g. varicella (Roitt & Delves 2001).

Secondary immunodeficiency

This occurs as a result of some other condition; an individual suffering from secondary immunodeficiency is sometimes called a 'compromised host'. This term simply means that the person's immune defences are in some way reduced or compromised, making them particularly susceptible to infection.

The commonest clinical situations in which this happens are AIDS (see Ch. 37), chemotherapy, intercurrent infection (such as HIV infection, TB, chickenpox) and in people who are post-transplant.

Other factors that contribute to patients being more susceptible include extremes of age, general health status, nutritional state, underlying conditions such as diabetes mellitus, immunosuppressive medication and previous exposure to infection.

HYPERSENSITIVITY

An excessive immune response, hypersensitivity, can result in damage to normal tissue. This response may be immediate or delayed. Four types of hypersensitivity reaction have been described: types I, II and III are antibody-mediated; type IV is mediated mainly by T cells and macrophages (Roitt & Delves 2001).

Type I: anaphylactic or immediate hypersensitivity

In this type of immune response, excessive IgE production results in IgE binding to mast cells which, when the antigen is encountered, release histamine, giving rise to an acute inflammatory reaction. This type of response usually develops within minutes of exposure to the antigen and will recur on subsequent encounters.

The reaction can be local, as in asthma (see Ch. 3), hay fever and eczema, or systemic, as in anaphylactic shock. Typical antigens are the house dust mite, pollen, latex and foodstuffs such as shellfish, eggs and nuts; the increasing number of people with allergy to nuts has resulted in many food labels indicating whether the product contains nuts. The nature of the symptoms will depend on whether the antigen is encountered locally or systemically, or absorbed via the intestine.

Atopy is a term used to describe the tendency of 10–15% of the population to suffer from allergic diseases such as asthma, eczema, hay fever, urticaria and food allergy. There is often a familial (genetic) disposition to this condition.

Type II: antibody-dependent cytotoxic hypersensitivity

In this type of response, antibodies react to normal tissue cells, which then bind to complement or to phagocytes, resulting in lysis or phagocytosis of the cell. This can occur as a result of 'foreign' antigens entering the body, e.g. a mismatched blood transfusion (see Ch. 11) or a transplant, or can be induced by medications or infections which appear to alter cell surface antigens such that an attack by native antibodies ensues.

Type III: immune-complex-mediated hypersensitivity

In this form of hypersensitivity, large immune complexes, i.e. antigens bound to antibodies (see p. 657), form in excess and are deposited in the capillary endothelium of the kidney, joints, skin and other sites. They may activate complement and attract phagocytes, resulting in mast cell degranulation and local or general inflammation. The inflammation may be acute, as in serum sickness; chronic, as in glomerulonephritis; or both, as in farmer's lung. This type of hypersensitivity resembles an anaphylactic reaction, but takes longer (several hours or more) to develop.

Type IV: cell-mediated or delayed hypersensitivity

In this type of immune reaction, sensitised T cells, on repeat contact with an allergen (antigen), release cytokines (soluble chemicals) which attract phagocytes and function without the presence of antibodies. These reactions cause chronic and sometimes extensive inflammation and are apparent a few hours after exposure to the antigen.

This type of immune response is the basis of the Mantoux test (see p. 677), which is given to find out whether a person has tuberculosis, has developed immunity to tuberculosis or is not immune. It also gives rise to contact dermatitis (see Ch. 12) and sarcoidosis (see p. 683), and contributes to graft rejection.

Anaphylactic shock (type I)

Anaphylactic shock is a sudden and severe form of type I hypersensitivity reaction, where there is an inappropriate or excessive response to some foreign material such as an antibiotic or other medication, a vaccine or a bee sting (Ferns & Chojnacka 2003, Reading 2004).

PATHOPHYSIOLOGY

IgE antibodies are the mediators of this reaction. The mechanism is similar to that of hay fever, except that the response is systemic rather than localised.

Common presenting symptoms

The characteristic feature of anaphylactic shock is collapse within seconds or minutes after exposure to the offending allergen. Usually this follows an injection or, less commonly, ingestion of the offending antigen. Laryngeal oedema manifests as swelling in the throat, hoarseness or stridor. Examination of the patient may show an urticarial skin rash which may be localised or widespread. The rash is itchy and can coalesce to form giant hives. In anaphylaxis, urticaria is part of a life-threatening condition. However, urticaria can present independently as a mild type I hypersensitivity and can be alleviated by the application of antihistamine creams.

Angioedema resulting from a sudden increase in vascular permeability can lead to oedema of the skin, respiratory obstruction and severe hypotension, the result of which may be fatal.

MEDICAL MANAGEMENT

There is not usually time for investigations in patients with anaphylactic shock. The diagnosis must be made rapidly. Treatment in mild cases is with subcutaneous adrenaline to restore blood pressure and relax the airways. This can be repeated at 3-min intervals. Severe cases require intensive cardiovascular and respiratory support with adrenaline given intravenously.

Antihistamines may also be given to counter the harmful effects of the histamine released by mast cells. Corticosteroids are sometimes given but have a delayed effect, as they act on the immune system and do not counter the chemicals already released.

NURSING PRIORITIES AND MANAGEMENT: Anaphylactic shock

Life-threatening concerns

Anaphylactic shock may occur suddenly and unexpectedly and is life threatening, especially in circumstances where emergency facilities are not available. Death may ensue if prompt action is not taken. Maintenance of airway, breathing and circulation is paramount. Emergency procedures are as follows (see also Ch. 18):

1. To help restore blood pressure, place the patient flat in the left lateral position and insert an airway to prevent respiratory obstruction.
2. Give adrenaline intramuscularly, unless the patient's condition is good and there is a strong central pulse.
3. Give oxygen by face mask if it is available.
4. Send for medical aid (GP or hospital doctor) or ambulance (dial 999); ask a relative, if present, to stay with the patient while you do this.
5. Be prepared to institute cardiopulmonary resuscitation.
6. Check pulse and blood pressure regularly and after any medication.

Major patient problems

Should the patient survive, severe anxiety after the event is likely. The question of how to prevent a similar occurrence will need to be explored and the cause of the reaction investigated. People with frequent unpreventable attacks should have a MedicAlert card or bracelet, and the patient and relatives should be supplied with, and taught how to administer, adrenaline using, for example, the autoinjector pre-filled adrenaline 'pens'.

For further information on emergency medical treatment of anaphylactic reactions for first medical responders and community nurses, see the Resuscitation Council (UK) guidelines (www.resus.org.uk/pages/guide.htm).

Transfusion reaction (type II)

This is a type II antibody-dependent cytotoxic hypersensitivity. An adverse reaction to a blood transfusion can occur when the immune system mounts an antibody response to the transfused blood. For details of this kind of reaction and the associated medical and nursing care, see Chapter 11.

Serum sickness (type III)

This condition is a type III immune-complex-mediated hypersensitivity reaction to foreign antigens, i.e. that of another species. It occurs when the immune system recognises the proteins in an introduced serum as foreign and produces antibodies against them. Antigen–antibody complexes, known as immune complexes, form and may be deposited in the skin, joints, heart and kidneys, resulting in a temperature rise, urticarial skin rash, swollen lymph glands/nodes and swollen and painful joints. Serum sickness was common in the days when horse serum was used as a source of immunoglobulin (Roitt & Delves 2001). Its occurrence led to the development of blood transfusion-derived products such as Humotet (human antitetanus immunoglobulin). Insulins used in diabetes mellitus are now produced by genetic engineering to avoid allergic reactions to non-human insulin components (see Ch. 5).

Sarcoidosis (type IV)

This is a type IV hypersensitivity reaction, the cause of which is as yet unknown.

PATHOPHYSIOLOGY

This disease may take a subacute or chronic form and is characterised by disturbances in cell-mediated immunity in which the balance between the different types of T lymphocyte is altered. Lesions or granulomas may develop in the lungs, liver, spleen, parotid glands, joints, skin, eyes, mediastinal and superficial lymph nodes, and phalangeal bones. In the subacute form, often discovered incidentally on routine chest X-ray, the lesions usually resolve spontaneously without treatment; however, in chronic sarcoidosis they may lead to the production of fibrous tissue causing permanent damage, e.g. interstitial fibrosis in the lungs, myocardial damage leading to cardiac arrhythmias, skin rashes and damage to the iris, possibly leading to blindness. Although the disease may involve other organs, the severity of their involvement is variable. The disease is primarily pulmonary (Baughman et al 2003).

Common presenting symptoms

Most patients have pulmonary symptoms, i.e. dyspnoea on exertion and unproductive cough, in addition to general malaise, weakness, loss of appetite, fever and weight loss. Lymph node enlargement may also be detected on examination.

MEDICAL MANAGEMENT

Investigations

Diagnostic investigation includes chest X-ray and lung function tests (see Ch. 3). Biopsy of the lung or other tissue can confirm the diagnosis. In some cases, a Kveim test is used to confirm the diagnosis. Intradermal infection of sarcoid tissue produces a characteristic microscopic appearance on biopsy 4–6 weeks later (typical of type IV).

Treatment

of chronic sarcoidosis occasionally involves the administration of corticosteroids to suppress the immune (type IV) reaction, often for several years. Oxygen may be given in acute or severe cases involving the heart and lungs.

For further information on sarcoidosis, see the British Lung Foundation (www.lunguk.org/sarcoidosis).

NURSING PRIORITIES AND MANAGEMENT: Sarcoidosis

The priorities in nursing care will depend on the level of impairment caused by the granulomatous lesions. Commonly, there is respiratory impairment and occasionally a potential for cardiac arrhythmias. Vision may be affected and liver function disturbed. Sarcoidosis may not be the prime reason for admission to hospital but must not be neglected in setting priorities for care.

AUTOIMMUNE DISEASES

These disorders occur when the body's tolerance to 'self' breaks down and autoantibodies, i.e. antibodies against 'self' antigens, are formed. Autoimmune disorders may be:

- organ-specific, focusing on one tissue
  —Hashimoto's thyroiditis
  —pernicious anaemia (see Ch. 11)
- generalised
  — rheumatoid arthritis (see Ch. 10)
  — systemic lupus erythematosus (SLE)
  — sarcoidosis.

Why autoantibodies sometimes cause disease is not yet completely understood. Their production may be initiated by minor changes in cells or by the exposure of previously 'hidden' cells as a result of damage, infection or genetic mutation, resulting in 'new' surface antigens being presented to the immune system. Autoimmune diseases may also involve a hypersensitivity reaction, whether immediate or delayed.

Goodpasture's syndrome (anti-GBM disease)

PATHOPHYSIOLOGY

People with this rare disorder develop antibodies to their own kidney glomerular basement membrane (GBM). These antibodies bind to the glomerular membrane, fix complement and cause glomerulonephritis. They may also be deposited in the basement membranes of the lung alveoli. The cause of this disease is not known. It is potentially fatal and is commoner in young men. Fortunately, it is rare.

Common presenting symptoms,
which may be acute and severe, include:

- haematuria, mild or severe
- haemoptysis, dyspnoea, cough.

MEDICAL MANAGEMENT

History and examination
The onset can be rapid, with symptoms of nephritis and pulmonary haemorrhage.

Investigations
Urinalysis will confirm haematuria and proteinuria, and a chest X-ray will determine the degree of lung involvement. The diagnosis is confirmed if serology or kidney or lung biopsy reveals the presence of anti-GBM antibodies. Blood chemistry shows raised serum creatinine and blood urea nitrogen. Urine collection will demonstrate reduced creatinine clearance, indicating some degree of kidney failure.

Treatment
This disease must be treated urgently, as renal and respiratory failure can occur. High-dose parenteral corticosteroids, e.g. prednisolone, are given, sometimes in conjunction with a cytotoxic medication such as azathioprine or cyclophosphamide. Plasmapheresis may be carried out to remove circulating anti-GBM antibodies. If renal failure develops, dialysis will be undertaken. Kidney transplant may be required but can be attempted only after intensive plasmapheresis to ensure that no circulating anti-GBM antibodies remain. Oxygen therapy and assisted ventilation (see Ch. 29) may be required if respiratory failure develops.

NURSING PRIORITIES AND MANAGEMENT: Goodpasture's syndrome

Patients with Goodpasture's syndrome will present with both respiratory and renal failure which may require intensive nursing support (Fox & Swann 2001).

Myasthenia gravis

This rare autoimmune disease is thought to be caused by a disorder of the thymus gland, whereby it produces defective T lymphocytes. It usually occurs in individuals aged between 15 and 50 years, and is more common in females than in males.

PATHOPHYSIOLOGY
The defective T cells stimulate B cells to produce antibodies to the acetylcholine receptors in the neuromuscular junction. Acetylcholine allows the normal transmission of impulses from the motor nerves to voluntary muscle (see Chs 9 and 10).

The autoantibodies react with the acetylcholine receptor, blocking the attachment of the acetylcholine neurotransmitter and thus impairing or preventing normal muscular activity.

Complement fixation may also result in destruction of the receptors.

Common presenting symptoms
The classic symptom of myasthenia gravis is that some muscle groups tire quickly (Kittiwatanapaisan et al 2003). Movement may be strong at first but rapidly weakens. Localised symptoms include diplopia or ptosis (see Ch. 13) due to weakness of the extraocular muscles, as well as weakness in chewing, swallowing, talking and moving the limbs. The muscles around the shoulder girdle are those most commonly affected.

Symptoms are often worse at the end of the day or after exercising. Double vision or progressively quieter speech may be early symptoms. Respiratory muscles may be affected, resulting in a weakened cough. Relapses sometimes occur after infections or following emotional disturbance.

MEDICAL MANAGEMENT

History and examination
The patient presents with a history of muscle weakness and inability to sustain muscle power, e.g. difficulty in brushing hair. Anti-acetylcholine receptor antibodies can be detected in the serum.

Investigations
Diagnosis is assisted by giving an intravenous injection of the short-acting anticholinesterase, edrophonium, allowing acetylcholine to accumulate. Muscle power improves within 30 s of the injection and often persists for 2–3 min as a result of the temporary increase in acetylcholine at the damaged neuromuscular junction.

Treatment
Therapy usually begins with cholinesterase inhibitors, e.g. pyridostigmine. If necessary, immune-directed treatment is added, beginning with either thymectomy or high-dose corticosteroids. Short-term therapies, e.g. i.v. immunoglobulin or plasmapheresis, may be effective in the early stages of treatment or later during an exacerbation (Richman & Agius 2003).

NURSING PRIORITIES AND MANAGEMENT: Myasthenia gravis

Life-threatening concerns

There are two potential crisis situations: a myasthenic crisis reflects an acute exacerbation of the condition; a 'cholinergic crisis' may occur as a consequence of a toxic response to medication. The patient becomes paralysed, pale and sweaty, salivates excessively and has persistently small pupils. This occurs as a result of excessive acetylcholine, which causes hyperstimulation of the acetylcholine receptors. It requires urgent medical attention. The consequences of a myasthenic or cholinergic crisis are life threatening. Paralysis of the respiratory muscles can rapidly lead to severe hypoxia; consequently, the patient may require resuscitation and ventilation (see Ch. 29). Baseline and repeat peak flow monitoring may be necessary. Some drugs, including common antibiotics, can cause deterioration.

Major patient problems

These include fatigue and muscle weakness. Patients may need help with eating, drinking, washing and dressing. Difficulty with swallowing can lead to choking and reduced mobility may lead to pressure ulcers (see Ch. 23).

Further considerations

Most people suffering from myasthenia gravis live independently at home for as long as possible. Their nursing care, when required, will depend on the severity of symptoms. The potential seriousness of their condition may not be obvious. The educational aspect of community care for family and friends will be a priority. Advice on a nutritious diet is particularly important where chewing and swallowing are impaired. Small mouthfuls of food should be chewed slowly before swallowing. Soft, moist food is usually easiest to manage. Choking is a danger, but can often be avoided by helping the patient to concentrate on chewing and then swallowing. Eye care may be required if blinking is impaired; this may include the use of eye drops to prevent dryness of the cornea (see Ch. 13). If breathing is made difficult by respiratory muscle fatigue, the patient may be more comfortable sitting up or propped up in bed.

Useful advice is available from the Myasthenia Gravis Association (see 'Useful websites').

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is an uncommon multisystem disorder in which autoantibodies against a variety of cellular antigens are produced. Thus any cell or tissue can be affected. Women are more often affected than men, and onset usually occurs in young adulthood. It is commoner in people of Afro-Asian and Chinese origin.

PATHOPHYSIOLOGY

The cause of this disease is not yet known, although both genetic and environmental factors, e.g. the effect of sunlight, medications, hormone levels or viral infections, have been suggested. Damage is caused by the deposition of immune complexes in the tissues (a type III hypersensitivity reaction) and by the autoantibodies reacting directly with normal tissue cells (a type II hypersensitivity reaction).

Common presenting symptoms

are often vague and non-specific, so that other illnesses or psychological problems may be considered responsible. Joint symptoms, e.g. arthritis, polyarthralgia, and fever, rashes and Raynaud's phenomena are common features. Fatigue is a common non-specific symptom, and skin rash, usually on areas which are exposed to sunlight such as the face, neck and scalp, may occur; characteristically, this is a 'butterfly rash' across the nose and cheeks. Nephritis is common, along with decreased urine output.

Vasculitis, especially in the smaller blood vessels, can give rise to skin rash or ulceration, nephritis, neuropathy or stroke. There may be poor peripheral perfusion, due to inflammation and consequent occlusion of small blood vessels. There may also be cardiopulmonary symptoms, including decreased cardiac output due to pericarditis, myocarditis, endocarditis and pulmonary infarction.

Occasionally there is cerebral inflammation leading to confusion, epilepsy or psychiatric symptoms.

MEDICAL MANAGEMENT

History and examination

As the symptoms of SLE are diverse, and their severity highly variable, a thorough history will be required. There may be external signs of tissue damage such as skin rash, which will assist the doctor in making a diagnosis. Some patients will have lymphadenopathy and an enlarged spleen. Other features will depend on the specific organs involved.

Investigations

In the course of diagnostic investigation, the erythrocyte sedimentation rate will usually be found to be raised. Antinuclear antibodies will be found in the serum of most patients with this disease. Some patients will have detectable anti-DNA antibodies and circulating immune complexes. Anaemia, leucopenia and thrombocytopenia (see Ch. 11) may be present on haematological examination. Depending on the organs involved, renal, cardiac or respiratory function may be altered.

Treatment

is aimed at relieving symptoms and preventing organ damage. Non-steroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen may help to alleviate joint pain and other symptoms. Antimalarial drugs are sometimes used, as they can reduce the frequency of exacerbations of skin and joint lesions. Corticosteroids, e.g. prednisolone, are given when major organs such as the heart, lung, kidney and brain are involved.

NURSING PRIORITIES AND MANAGEMENT: Systemic lupus erythematosus

The specific care of patients with SLE depends very much on the stage of the disease and on the organs involved. In any event, the aim is to alleviate symptoms as they present (Sohng 2003, Tretheway 2004).

Life-threatening concerns

Depending on the nature and severity of organ involvement, myocardial infarction, respiratory failure and renal failure may ensue. Appropriate resuscitative measures are described in Chapters 2, 3 and 8.

Major patient problems

As fatigue is common, the patient should be encouraged to have adequate rest. For patients who have experienced alteration in bowel habit, dietary advice may help. Patients may experience confusion, depression due to CNS involvement or fears about prognosis. Epilepsy may also occur.

Poor peripheral circulation leading to cold hands and feet may develop. Patients are also likely to become susceptible to infection due to the debilitating effects of the disease process and the immunosuppressive effects of treatment.

Further considerations

Both pregnancy and the contraceptive pill have exacerbating effects on this disease. Patients suffering from photosensitivity should be encouraged to minimise exposure to sunlight and to protect the skin when exposure is unavoidable. Emotional support will be needed as this is a chronic disease of uncertain progression. Patient information is available from www.rheumatology.org/public/factsheets.

CONCLUSION

This chapter has introduced the immune system, disorders of immunity and infectious diseases. Infectious diseases, including those that cause HAI, affect patients in many ways and health care staff and carers must take account of patient susceptibility, sources of microorganisms, their routes of transmission and the many measures available to prevent, control and manage all of these. Nurses are in a key position to rise to the many challenges infectious diseases and HAI present today. They must be effective role models and demonstrate strict adherence to SICPs and other recommended practice at all times. All nurses, including those with a specialist qualification in infection control, should seek to enhance local infection control practice and to influence nationally, even globally, the prevention and control of infection in hospital and in community settings. In order to do this, nurses must have a sound understanding of immunology, the infection process, ways of preventing, monitoring and controlling infection and of risk management, and be able to contribute effectively to multidisciplinary teams within this rapidly developing field of health care.

CASE HISTORY 16.1

Mr B

The following condition is commonly encountered both in the community and hospital settings. Recognising the susceptibility of this patient to infection from the information available, and considering how his immune system will cope with further interventions while in hospital, is the first step in a scenario that will challenge your thinking on prevention and control of infection.

Mr B arrives in the ward for total hip replacement surgery. He is 62 years old with type 2 diabetes, on hypoglycaemics. He is assessed on admission and worked up for surgery. The significant factors noted are: he is overweight and is a smoker, he states that he eats well and controls his diabetes, his skin is dry in places and he is a social drinker.

His wife is in attendance with him and is recovering from a hysterectomy, for which she was discharged from hospital 4 weeks ago. It later transpires that she is continuing to see the practice nurse for an ongoing postoperative wound problem.

Mr B is found to have a foot ulcer and his diabetic control is examined more closely. During further examination of Mr B's foot ulcer, samples are taken and sent to the microbiology laboratory. This decision was taken as signs and symptoms of infection were present around the site on the foot, e.g. erythema (redness), swelling and heat, with evidence of scanty serous exudate. He is experiencing no pain from this wound site as his ability to sense pain is impaired by his diabetes and it is established that this is why the ulcer has developed thus far without being identified. The multidisciplinary team are eager to manage and treat the ulcer appropriately in order to progress with Mr B's proposed hip surgery and are considering antibiotic therapy on results of the samples taken.

Dressings are applied to the wound in order to protect it and encourage healing but also to prevent any potential spread of microorganisms to the environment and other patients, especially as there are many patients with exposed postoperative wounds in his ward.

16.10 What do you think are the risks to Mr B from his existing foot ulcer and how might this wound pose a risk to others around him at this stage?

The results from Mr B's admission screen and foot ulcer yielded a moderate growth of MRSA. The infection control team visit the ward to discuss this information. They enquire as to Mr B's background situation, advise on his isolation care and give further explanation, including a patient information leaflet, to Mr B and his wife.

16.11 What do you think the advice for patient care would be and why, taking into account Mr B's and the other patients' risks as discussed earlier, particularly considering the risks from MRSA?

16.12 What further information do you think the team would collect to try to ascertain the epidemiology of the MRSA infection? Do you think any specific discussions would take place with Mrs B?

16.13 Think about a situation where you have or should have isolated a patient and applied additional precautionary measures to ensure the spread of infection was minimised. Were the facilities and resources available to enable you to do this? Did everyone involved appear to adhere to the same high standards of infection control measures?

Treatment for Mr B's foot ulcer leads to some improvement and the surgical team decide to operate, especially as MRSA is not isolated from any other sites on his body.

Mr B is anxious and asks many questions about the 'additional' measures that are being taken during his care. The infection control nurse visits the ward again and clarifies the control measures for MRSA and similar infections, prior to, during and after surgery, including:

- being cared for in an isolation room, with the door closed and a sign on the door
- all staff who enter wearing plastic aprons and, when performing care, gloves
- staff removing their gloves and aprons before they leave the room and decontaminating their hands at the sink or with alcohol gel from the containers mounted by the door

Continued

CASE HISTORY 16.1
Mr B *(cont'd)*

- being taken straight into the theatre and not spending time in the pre- and postoperative areas
- certain items for care remaining in his room at all times for his use alone, but other items being removed to keep the room clutter-free.

While discussing these infection control measures with Mr B, Mrs B comments on her recent hospital admission and that she had heard someone in her ward had MRSA. On further discussion, the infection control nurse learns about Mrs B's ongoing problems with her surgical wound and suggests that, as healing is delayed, she talk to her practice nurse about screening for MRSA, if this has not already been done.

Mr B's surgery is successful and his foot wound is almost healed when he is told he will be discharged. At this time Mrs B receives word from her general practice that she does indeed have a light growth of MRSA within her wound and she will get further advice when she attends.

The ward staff and the infection control team provide Mr and Mrs B with advice for discharge:

- that their family can visit them as normal
- that hand hygiene and environmental cleanliness are the most important points
- that their laundry can be washed in their own washing machine at as high a temperature as possible, separating towels and bedding from other clothing, as these items are often where MRSA is most likely to harbour
- that their cooking utensils and crockery can be washed as normal in a dishwasher or with hot, soapy water.

They also provide a discharge letter including a summary of the infection control instructions to Mr B and an additional letter containing guidance given to Mrs B to be passed onto their general practice, especially as they will both continue to have dressing changes to foot and abdomen respectively.

16.14 What measures do you think would be taken to ensure Mr B's room is safe to be used by the next patient? Do you think, given today's pressures upon health care, enough time is dedicated to preparing rooms or bed spaces before a new patient goes into them?

16.15 What measures do you think the practice nurse would take to ensure Mrs B's MRSA does not spread through the practice?

16.16 Think about the fact that Mrs B has no information about how she first acquired the MRSA in her wound. How might she feel and what could be done about this situation to try to ensure that those involved have learned and acted upon this information?

INTRODUCTION

'Stress' is a word that frequently enters into everyday conversation as people remark on the difficulties and challenges of life. Most people would probably describe themselves as being 'stressed' from time to time, but what does this really mean? Is stress something that resides within the environment, in situations that are threatening, harmful or unpleasant, or is it essentially an internal state, an effect of the individual's perception of what is happening to them. Benner and Wrubel (1989), in their seminal text, defined stress as 'the disruption of meanings, understanding and smooth functioning so that harm, loss or challenge is experienced and sorrow, interpretation, or new skill acquisition is required'.

Stress may have physiological or psychological origins and research into stress is a highly complex field involving a number of sciences, including biology, physiology, psychology and sociology. These disciplines take different approaches to the definition, observation and measurement of stress. When biologists and physiologists talk of sources of stress, they are referring to empirical phenomena. Their interest is in examining identifiable events and their measurable effects upon the organism or system being stressed. Anything which affects the equilibrium of the organism may be described as a stressor; this would include bacterial or viral infections, dehydration, excessive cold or heat, inadequate food, and so on. Therefore stress can be viewed as a disturbed homeostasis that manifests itself via certain physiological and psychological imbalances (Watson & Fawcett 2003). The impact of stress occurs only when the cumulative effects of stressors surpass the individual's ability easily to return to equilibrium. However, despite the popular connotations, not all stress is a bad thing. Stress comes in two types, described as eustress or distress. Having the optimum amount of pressure to keep us happy and performing at our best is called eustress. Distress means that our functional capability is impaired in some way; this can take many forms, such as anxiety, depression or physical illness. Some of the most commonly associated triggers related to stress are listed in Box 17.1.

Social scientists view stress in terms of the pressures upon the individual to conform (or not) to societal norms. The inherent values expressed in a society's organisation and functioning may themselves be a source of stress to the individual. Modern industrial society, for example, provides

Box 17.1

Common triggers of stress

- Bereavement
- Illness, injury or trauma
- Interpersonal conflict
- Environmental factors
- Financial issues
- Uncertainty/change
- Work overload

Adapted from the Stress Management Society.

food, safety and shelter for its members in return for a commitment to work, often at some sacrifice to personal interests, leisure and family life.

Psychologists view stress from the perspective of the interaction of individuals and groups with the environment, describing the effects of stress on cognition, emotional well-being and behaviour.

It is important for nurses to have a clear understanding of the concept of stress as they endeavour to provide the best possible care for their patients. It is essential to appreciate why patients might be feeling stressed and how their stress might be alleviated. In relation to the nurse's own well-being, an understanding of stress and its effects is equally important. Nursing is physically and emotionally strenuous work, and it is vital for nurses to be able to recognise the signs of stress in themselves and to know how to go about managing stress in their daily work.

This chapter begins by outlining some definitions of stress as a type of stimulus, as a response, or as an interaction between an individual and their environment and the effects of stress upon physiological systems. The second section of the chapter introduces some of the more influential models that seek to describe and explain stress. This provides a basis for the third section, which examines the relationship between stress and disease.

The discussion then turns to the concept of coping, and various cognitive and behavioural mechanisms which people commonly employ to deal with stress. A description of the therapeutic strategies that are available to assist the individual in managing stress is then given.

PHYSIOLOGICAL RESPONSES TO STRESS

The physiological response to stress is normally seen in response to stressors such as illness, perceived danger or trauma. The stress response enables the individual to meet the challenges set by these situations and involves:

- activation of the sympathetic nervous system
- increased secretion of several hormones.

The stress response

In 1935, Cannon summarised the response of an individual, or animal, to external threat as the 'flight, fight or fright' reaction, often referred to as the 'acute stress response'. Real and imagined psychosocial stressors are an essential component of living and, when present to a moderate degree, have been described as 'eustress' since they optimise performance and improve learning. It is when a threat is perceived to be of an order which endangers either a person's sense of self-worth or even life itself, that the full manifestations of the acute stress response are seen. After events such as a car crash, bomb explosion or unexpected physical attack, rapid physiological adaptations of the acute stress response are activated. This can, in some circumstances, be life saving. Consider, for example, the situation in which smoke suddenly appears in a room and, all too soon, the first flames begin to spread; a person will often find a sudden unexpected ability for rapid action to deal with such an emergency. Along with a surge of physical strength, there will be an increased ability to tackle the flames and a marked enhancement in the ability to run and thereby escape the danger. Such a response is enabled by a release of hormones brought about by activation of the sympathetic nervous system and the adrenal medulla.

An alarm reaction of lesser magnitude is a common occurrence in the more ordinary trials of life. This occurs, for example, in such circumstances as running out of petrol on the motorway en route to an important engagement, losing one's front door keys, or being with someone who unexpectedly becomes acutely ill. The severity of the alarm reaction varies considerably between different individuals and also between different occurrences of a similar situation. Thus, when a person's car breaks down on the motorway for a second time, they may feel even more distressed than on the first occasion. Alternatively, they may be more confident in their ability to deal with the event and consequently be less 'stressed'.

The manifestation of stress is derived not merely from external problems or dangers but from the way in which people attempt to manage these problems. Ostell (1991), amongst others, described stress as the state of affairs that exists when the way in which people attempt to manage problems taxes or exceeds their coping resources. When the response to a stressor is severe, normal social relationships can be affected, as aspects of the 'flight, fight or fright' response potentially impinge upon rational behaviour.

As indicated, aversive physical stimuli that provoke stress events include excessive noise, cold or heat, and physiological imbalances such as those associated with sleep deprivation, lack of food or chronic pain. Such stressors not only act to bring about hormonal changes associated with the acute stress response, but also have their own selective effects on physiological functioning.

An example of such a selective effect can be seen in the body's response to cold, as it strives to maintain homeostasis. In cold conditions, the blood supply is redistributed to less exposed areas in order to limit heat loss and, via the mechanical act of shivering, the body temperature can be increased (see Ch. 22). In addition, the secretion of thyrotrophin-releasing hormone from the hypothalamus is increased, thereby stimulating the pituitary gland to secrete thyroid-stimulating hormone (TSH). This in turn causes enhanced release of the thyroid hormones thyroxine and triiodothyronine, which raise basal metabolic rate and hence increase heat production and core temperature.

To maintain homeostasis when threatened by a stressor, the body employs a range of physiological mechanisms. Some stressors are short lived, in which case the body may be able to react to the situation and quickly resolve the disturbance evoked by the stressor. Other stressors may last for days, months or even years. There are many examples of this chronic form of stress, for example when people must live with chronic disease or social disharmony. Where there has been repeated exposure to a particularly stressful or aversive event, there can be a further reaction, characterised by a conditioned fear response to any neutral stimulus experienced at the same time as the previous stressor. This effect is responsible for many of the anxiety reactions or acts of avoidance some people show in response to specific harmless objects.

The general adaptation syndrome (GAS)

Hans Selye, in his seminal work on the response-based model of stress, noted that the diverse noxious stimuli which challenged the ability of the body to maintain homeostasis induced a common pattern of effects (Selye 1936, 1976).

Selye deduced that, whatever the nature of the stressor, it resulted in a pattern of non-specific responses that formed part of what he described as a general adaptation syndrome (GAS). These responses, providing they were not overwhelming, enabled a physiological adaptation to take place (Selye 1976).

The syndrome is considered to have three phases. In the first phase 'the alarm reaction', the sympathetic nervous system and the adrenal glands are activated. Together they prepare the body for flight or fight. If the stressor continues, the triggering of neural and endocrine responses in the alarm reaction is followed by the second phase of 'resistance'. Stimulation of the hypothalamo-pituitary–adrenal axis results in increased secretion of corticosteroids, the endocrine response. In this phase, the internal responses of the body mobilise resources and enable tissue defences to achieve the maximum adaptation possible. The third and final phase of the general adaptation syndrome is 'exhaustion', in which the body may succumb to the stressor.

The general adaptation syndrome is criticised for providing a somewhat simplistic, stereotypical model of the responses of the body and failing to take full account of the individual variations of psychological and physiological responses. Lazarus (1966) argued that there is a circularity about Selye's model, in so far as something about the stimulus elicits a particular stress response while something about the response indicates the presence of a stressor.

17.1 Identify five stressors in each of the following categories:
(a) emotional
(b) physical
(c) environmental
(d) societal.

The acute stress response

During the alarm reaction to stress, a series of physiological responses involving limbic and brain stem structures are triggered (Fox 2004). Neural pathways from the amygdaloid nuclei in the limbic system mediate responses to emotional stress, and pathways from the reticular formation in the brain stem mediate responses to physiological stressors such as pain and injury. This activates the hypothalamo-pituitary–adrenal axis and results in the secretion of a range of hormones.

An immediate response to threat or stress involves the neural connections from the hypothalamus to the sympathetic outflow, activating both postganglionic and preganglionic sympathetic nerves passing to the adrenal medulla. This is the emergency reaction which was first described by Cannon (1935). In the adrenal medulla, acetylcholine released at preganglionic sympathetic nerve terminals activates the chromaffin cells to secrete adrenaline and noradrenaline. In humans, adrenaline is secreted in greater amounts than noradrenaline. The release of these hormones takes place in a matter of seconds or minutes.

The hormones liberated from the adrenal medulla have many effects which facilitate emergency reactions. For example, adrenaline and noradrenaline improve cardiac and respiratory function. Heart rate and force of contraction are increased. Bronchioles are dilated and the depth and rate of respiration are increased. Blood flow is redistributed to areas of need, i.e. the heart and skeletal muscles. Blood glucose and basal metabolism are raised and blood clotting facilitated. The increase of blood glucose is due mainly to the actions of adrenaline on the liver to promote glycogen breakdown and enhance gluconeogenesis from fatty acids and proteins. Adrenaline also acts on the pancreas to inhibit insulin secretion. The piloerection and pupillary dilatation, so characteristic of the behaviour of fighting cats, represent yet another physiological consequence of hormone release from the adrenal medulla. Sweating by the eccrine glands is increased. In the meantime, functioning of the digestive tract is reduced and urinary sphincters are closed.

The physiological effects of adrenaline and noradrenaline are explained in Chapter 5. Adrenaline acts on α- and β-adrenoceptors, whereas noradrenaline acts predominantly on α-adrenoceptors.

In the more long-term responses to stress described by Selye, the centre of activity passes from the adrenal medulla to the adrenal cortex, and to the hypothalamus and pituitary, which are responsible for activating the adrenal cortex. Corticotrophin-releasing hormone (CRH) is secreted by the hypothalamus as well as by extrahypothalamic sites in the brain. CRH acts on the anterior pituitary gland, stimulating the secretion of adrenocorticotrophic hormone (ACTH) and beta-endorphin. Beta-endorphin is produced by the pituitary gland and hypothalamus of vertebrates.

Beta-endorphin reduces susceptibility to pain and is probably one of the means by which stress and the stimuli of conditioned fear give rise to endogenous analgesia. Opiates act in a similar way to endorphins, but are not rapidly degraded by the body, as natural endorphins are, and thus have a long-lasting effect on pain perception and mood (Pert 1997).

Other factors influence the release of ACTH, including antidiuretic hormone (ADH) and hypothalamic vasoactive intestinal peptide (VIP). The ACTH liberated by the anterior pituitary acts to stimulate cells in the adrenal cortex to secrete corticosteroids.

Glucocorticoids secreted by the adrenal cortex play a key role in adaptation to stress (Bowman & Rand 1996). Cortisol (hydrocortisone) accounts for approximately 95% of the glucocorticoid activity of the adrenal cortex. Glucocorticoids modify metabolism so as to increase blood glucose concentrations. They do this by mobilising tissue protein and amino acids and by these actions may induce a negative nitrogen balance. Glucocorticoids are needed to enable other hormones to bring about mobilisation and metabolism of fat. These metabolic effects of glucocorticoids ensure the supply of adequate fuel to the cells when the body is under stress, and in this respect the adrenal cortex provides an important back-up system for the adrenal medulla. In addition, glucocorticoids play important roles in the proper functioning of many organ systems and tissues in the body, including the cardiovascular system, the nervous system, lymphoid tissue and skeletal muscle.

Glucocorticoids, such as cortisol and corticosteroid, possess appreciable mineralocorticoid activity, retaining sodium chloride and indirectly increasing extracellular fluid volume, although they are much less potent in this respect than aldosterone. The secretion of aldosterone is not regulated by ACTH, and so its release is independent of the stress response. Mineralocorticoid activity by hormones such as cortisol may in part underlie important, though poorly understood, actions on the cardiovascular system. An increase of extracellular fluid volume can be of great importance under circumstances when stressors induce shock or when there is loss of body fluids after haemorrhage or burn injury.

Additionally, glucocorticoids can decrease the number of circulating lymphocytes, eosinophils and basophils and, at pharmacological concentrations, suppress the immune response. In addition to their direct effects, the corticosteroids exert an enabling influence on the actions of several other hormones and are necessary for the body to show a full response to the adrenaline and noradrenaline released from the adrenal medulla. As a result of its wide-ranging functions, especially in the maintenance of fluid and electrolyte balance, the adrenal cortex is essential to life (see Box 17.2).

Box 17.2

Hormonal mediators and effects of short- and long-term stress

Short-term stress

Mediated by the catecholamine release of adrenaline and noradrenaline from the adrenal medulla, short-term stress leads to:

- increased heart rate
- bronchodilatation
- increased blood pressure
- liver conversion of glycogen stores to glucose for release into the bloodstream
- altered blood flow patterns to increase arousal and decrease digestive and urinary activity via selective vasoconstriction
- increased platelet aggregation
- pupil dilatation and piloerection
- increased metabolic rate
- sweating from eccrine glands.

Long-term stress

Mediated by the release of glucocorticoids and mineralocorticoids from the adrenal cortex, long-term stress leads to:

- gluconeogenesis whereby proteins and fats are broken down to form glucose
- increased blood glucose levels
- retention of sodium and water by the kidneys (aldosterone effect)
- increased blood volume and blood pressure via the above plus vasoconstriction and reduced fluid shift
- increased coagulability and viscosity of the blood
- suppression of the immune system and inflammatory response
- altered blood biochemistry, e.g. in serotonin, endorphin and dopamine levels.

The chronic stress response

Clearly, as Selye (1976) established, there are limits to the body's ability to maintain its phase of resistance and adaptation in the face of continuing stress; environmental stressors can be toxic and physiologically overwhelming. Where the person is physiologically challenged but not overwhelmed, in conditions of prolonged stress, enlargement of the adrenal glands and thymicolymphatic atrophy will occur. When stress persists beyond a certain period of time, disturbances occur in the homeostatic balance of the body and there is an ever-increasing danger that disease processes will be precipitated.

An important part of the body's defence mechanism in the phase of resistance is the pituitary secretion of ACTH, which in turn stimulates the adrenal cortex to release corticosteroids. One of the early signs of the body's inability to meet the demands of unremitting stress is a blunting of the amounts of ACTH released by the anterior pituitary in response to that stress. Under these circumstances, the adrenal cortex frequently shows hyperplasia, which persists despite the reduced secretion of ACTH. This blunting of the ACTH response to stress also occurs in long-standing timidity, which is possibly due to high arousal together with slow habituation to the stressors. This is coupled with an associated enlargement of the adrenal glands and hypersecretion of adrenal steroids under comparatively non-threatening circumstances. Likewise, blunting of the ACTH responses to stressors is seen in depressive illness and in many forms of anxiety. In depressed individuals, there is frequently a high corticosteroid excretion associated with enlargement of the adrenal glands and an increase in the concentrations of CRH in cerebrospinal fluid.

Emotional as well as hormonal changes characterise chronic stress. These include emotional exhaustion, a decreased sensitivity to rewards and a withdrawal from decision making, which is characteristic of fatigue. This can progress to the condition known as 'burnout', a complex phenomenon involving extreme physical and emotional distress which, for the individual, is often linked to organisational factors (Hall 2004). In burnout, the physical and emotional fatigue may be manifest as a lack of involvement with, or sympathy or respect for, colleagues and clients. At its final stage, chronic stress may result in total collapse. Long-lasting stress in which there is a poor coping strategy is correlated with increased occurrence of a variety of diseases (Levi 1971, Cooper 2004, Hesselink et al 2004). These may be described as diseases of adaptation and are related to deranged secretion of adaptive hormones in the phase of resistance. These conditions include digestive disturbances, hypertension, myocardial infarction, allergies and sleep disturbances. Such chronic stress may also lead to anxiety, depression or behavioural disturbances, such as appetite disorders or increased usage of alcohol, tobacco, caffeine or even illegal substances.

Due to the prevalence of cardiovascular disease in Western society, particular attention has been paid in recent years to the relationship of stress to hypertension, myocardial dysfunction leading to unexpected sudden death, and to coronary atherosclerosis and myocardial infarctions (Cooper 2004, Critchley et al 2004).

Unexpected sudden death arising from cardiac failure has been found frequently to follow emotional upheaval or

shock. It may be caused either by adrenosympathetically induced ventricular fibrillation or by apparent vagal stimulation and cardiac standstill. The increase in blood concentrations of glucocorticoids, mineralocorticoids and catecholamines as a result of stress can derange the vital myocardial electrolyte equilibrium. In a series of unexpected sudden deaths, the postmortem catecholamine concentrations in the blood were found to be excessively high, almost as high as in fatal adrenaline poisoning.

Increase in the blood concentrations of adrenaline, by its enhancement of platelet aggregation (see Box 17.2), can promote thrombus formation in atherosclerotic coronary arteries and thus lead to myocardial infarction. Statistical data show a close correlation between the high incidence of ischaemic heart disease in professional persons exposed to demanding occupational stress and in the 'Type A' individual, characterised by time consciousness, irritability and driving ambition (Yousfi et al 2004).

Based on the evidence of the serious consequences of excessive or prolonged stress, in combination with poor coping strategies, it can be seen that improvements to the working environment and social milieu, together with 'stress education' to lessen reactivity to adverse circumstances, should be encouraged. These measures may have as profound an impact on the health of a community as did the improvements to diet and sanitation in the mid-19th century.

MODELS OF STRESS

The physicist Robert Hooke (1635–1703) used the word 'stress' in the 17th century to refer to the ratio of an external force (created by a load) to the area over which that force was exerted. The resultant strain created a deformation or distortion of the object by what became known as Hooke's Law.

There is an interesting similarity between this use of the word stress and its modern application in the realm of human emotion and behaviour; indeed, people frequently use words such as 'weight' and 'strain' when describing their feelings of anxiety and stress.

During the 20th century, the adoption of the concept of stress by the biological and behavioural sciences resulted in the formulation of a number of models to describe stress and its effects, including the:

- stimulus-based model
- response-based model
- systems model
- general adaptation syndrome
- transactional model
- phenomenological approach.

Each of these models and its implications for nursing practice will be described in the following sections.

The stimulus-based model

In this model the person is viewed as being constantly exposed to external or environmental 'stressors' in their daily life, e.g. the demands of work, family responsibilities, bereavement or disablement, or to more specific stressors such as smells or poor lighting. These stressors have the potential, however, to cause distressing feelings and/or physical symptoms and to undermine well-being.

In the stimulus-based model, stress is a state that can generally be empirically observed, measured and evaluated, and which can potentially be removed or altered to reduce the individual's stress: it is possible, in theory, to persuade noisy neighbours to be quieter, make a cold working environment warmer, or poor lighting conditions more satisfactory. As an approach to identifying areas that might be improved in order to increase productivity, this model has some appeal for industrial planners and managers (Sutherland & Cooper 2000).

Limitations of the model In many situations, such as a bereavement or disablement, the original stressor cannot be changed or adapted to reduce distressing feelings. Even in relatively simple situations such as that illustrated in Case History 17.1, removing the stressor is not necessarily a straightforward matter. It quickly becomes apparent that the stimulus-based model has substantial shortcomings when considered in relation to the breadth of human experience (Sutherland & Cooper 2000).

Whilst it has some application in limited contexts, such as certain working environments, it does not explain why some people experience stress in certain situations while others, in similar circumstances, do not. Nor does it explain why a given situation may be stressful for a person at one time but not at another. Moreover, this model offers no explanation as to why a person may be stressed in response to apparently neutral stimuli such as birds, spiders or aeroplanes. Lazarus (1966), in a seminal text, argued that it is not possible to evaluate the human experience of stress objectively; only a personal account of feelings and experiences can adequately convey the nature of an individual's stress.

The response-based model

In this model, the word 'stress' is used to describe the experience of a person who feels they are in a threatening or difficult situation. Stress is thus a person's response to threat which, as in the stimulus-based model, is not

CASE HISTORY 17.1

J

A health visitor could not understand initially why her client, J, an unsupported mother of two, appeared to be tense and unhappy when they met at the child surveillance clinic. She asked how J was feeling, and J described how she had new neighbours in the flat above her who played loud music until early in the morning, preventing her and her two children from getting enough sleep. She had tried to talk with them but they had been hostile towards her and made her feel apprehensive. She didn't dare complain to them again. The lack of sleep was affecting J and her children.

J had difficulty concentrating at work and felt like crying frequently during the day; the children were overtired and generally irritable, making it even more difficult for her to cope.

The health visitor asked J if she could intervene by contacting the housing department on her behalf, but J said that she was afraid that this would make matters worse.

necessarily inherent in the environment or situation. By using the response-based model, it is possible to make sense of an individual's unique stress responses and even of responses that might seem, within the stimulus-based model, to be irrational, such as a fear of birds, spiders or of flying.

The systems model

A response-based model that considers the human stress response as 'a multifactorial, interactive, dynamic, phenomenon' is the systems model described in seminal work by Everly and Sobelman (1987). In this model the stress response is defined as consisting of six components:

1. Environmental stimuli Some environmental stimuli, or stressors, activate the stress response as a direct consequence of their physical or biochemical properties, i.e. their effects are not mediated by cognitive–affective evaluation. Examples of such stressors are caffeine, nicotine and extremes of heat and cold. Many environmental stimuli are not, however, intrinsically harmful but are perceived as such by the individual and, in this way, set the stage for activation of the stress response.

2. Cognitive–affective domain Everly and Sobelman (1987) described this as 'the critical "causal" phase in most stress responses', in that it is the individual's interpretation of the environment that gives rise to most stress reactions. The perspective that the individual takes towards their environment will be determined by 'biological predispositions', 'personality patterns', 'learning history' and 'available resources'. Everly and Sobelman (1987) argued that cognitive appraisal precedes emotional response.

3. Neurological triggering mechanisms The locus coeruleus, limbic system and hypothalamic nuclei are the anatomical sites for 'the integration of sensory, cognitive, affective, and visceral activity' (Everly & Sobelman 1987). In response to cognitive–affective appraisal, these structures trigger neurological and endocrine reactions. They also seem to be involved in a feedback system in which visceral and somatic efferent messages are relayed in response to emotional arousal. Everly and Sobelman suggested that 'these centers seem capable of establishing an endogenously-determined neurological tone that is potentially self-perpetuating' and which 'may, over time, serve as the basis for a host of psychiatric and psychophysiologic disorders'.

4. The physiological stress response axis The stress response itself occurs sequentially along the neurological, neuroendocrine and endocrine axes and results in neural and hormonal activity directed at target organs.

Neurological axis Neurological activity is especially evident in reactions to sudden acute stress and results in direct activation of the sympathetic nervous system, seen as raised heart rate and blood pressure, and the parasympathetic nervous system, seen as constricted pupils, increased salivation and urinary bladder contraction, and in the transmission of messages to skeletal muscle, resulting in contraction.

Neuroendocrine axis This is based in the adrenal medulla and plays an important role in longer-term arousal. Release of the catecholamines noradrenaline and adrenaline by the adrenal medullae results in such sympathetic responses as increased cardiac output and diminished blood flow to the skin and gastrointestinal system.

Endocrine axis This axis also plays an important role in chronic arousal. The hypothalamus, pituitary gland, adrenal cortex and thyroid gland are stimulated serially to release into the circulatory system the range of hormones described earlier in this chapter.

5. Coping In this final phase of the stress response, the individual attempts to reduce their level of arousal by manipulating the environment or making cognitive adjustments.

6. Target-organ effects If coping is unsuccessful and arousal is either excessive or prolonged, the physiological processes of the stress response are likely to lead to target organ dysfunction or disease.

Limitations of the model. One of the problems in viewing stress purely as a response is that this can lead to the assumption that the occurrence of stress in the life of the individual is solely their own responsibility. The descriptive term 'coping', used in a technical sense by stress researchers to describe physiological and psychological ways of adapting to stress, can also be used in an emotive way in everyday discourse to describe an individual's lack of mastery in stressful circumstances. Thus, someone who 'copes' with stress masters a situation in a positive way, whilst someone who does not 'cope' is seen to be lacking in this ability. Such judgements on self or others can have a harmful emotional effect on the individual.

Hans Selye's general adaptation syndrome

Hans Selye's extensive physiological research as an endocrinologist (Selye 1936, 1946a,b, 1976) was largely based upon the response-based model of stress.

The transactional model

A behavioural model of stress that incorporates a dynamic view of the individual and their interaction with the stress in their environment is called a transactional model. The person appraises, or seeks meaning in, what is perceived to be a potentially threatening situation in an attempt to respond in a way that minimises the distress. The process of appraisal is highly individual; each person will perceive a threatening situation differently and attach their own meanings to it (Lazarus & Folkman 1984). Moreover, the relationship between the individual and their environment is a dynamic one which constantly changes as the process of appraisal continues.

Nursing application. Case History 17.2 highlights how the transactional model of stress has clear advantages for the clinical nurse. Although Mr P's feeling of terror was related to the stressor of being in hospital and the prospect of surgery, these circumstances in themselves did not fully account for his state of mind. His feeling of stress derived from his appraisal of the situation, and this appraisal reflected his childhood experience. The transactional model

CASE HISTORY 17.2

Mr P

Nurse T was asked to interview Mr P on his admission to the ward for minor dental surgery the following day. Mr P, a 30-year-old engineer, was married and had two children, a girl and a boy. He lived with his family near the hospital and worked in a factory in a nearby town. During the interview, Nurse T noticed that while Mr P appeared to be in good health and to have a clear understanding of the surgery he was about to undergo, he seemed uneasy. Knowing that many patients feel apprehensive before having surgery, she asked him how he was feeling. Mr P replied: 'I feel silly, stupid and embarrassed about it but I am very scared — have been since I got the appointment in the post — can't understand why! I haven't been able to sleep for the past week and when I do I have awful dreams.'

The nurse talked further with Mr P about his feeling of fear. She asked him if he had ever been in hospital before and he recalled with some difficulty how, as a small child, he had been admitted as an emergency for a circumcision. As he talked he realised how frightened he had been at that time and that when he had been readmitted for an inflamed wound, his fear had become even greater. He remembered that his mother had been unable to stay with him.

The following day Mr P had his surgery. Before leaving the ward he said to Nurse T that he had felt better after talking with her. He had still felt afraid but the powerful feeling of terror had gone.

of stress recognises that a person such as Mr P, rather than being a passive recipient of stress, interacts actively with a situation.

Cox's man–environment model

Cox et al (2002) defined five stages within a man–environment model:

1. Source of demand where a situation is perceived as threatening
2. The individual's perception of demand, and coping based upon personality and early experiences
3. Psychophysiological changes in response to the perceived threat
4. Coping responses and consequences, i.e. how the individual sets about dealing with the threat
5. Feedback, both physiological and psychological.

The 'demand' is described as arising from the individual's psychological and physiological needs. The individual attempts to understand the demand and their ability to do this determines the way they set about coping. Stress may occur at a time of hopelessness, when the person understands the nature of the threat but is unable to respond in a way that diminishes or removes it. At this time, physiological responses also become active as methods of coping with stress. At each stage of the model, the individual receives evaluative feedback.

Limitations of the model. Given the complexity of individual experiences and coping strategies, it is extremely difficult to subject transactional models of stress, such as Cox's man–environment model, to empirical evaluation.

17.2 Discuss with your lecturer or mentor how the terms 'stress' and 'stressor' are used differently within various models of stress.

The role of appraisal

How individuals appraise, or find meaning in adversity, is crucial to how they withstand it. The concept of resilience (see p. 700) may explain why some people, e.g. patients with cancer or AIDS (Polk 1997), can withstand and survive the adversity whilst others cannot. Appraisal is crucial to the individual's ability to continue a healthy life after catastrophe or illness, and, as with resilience, the personal traits of the individual will influence their ability to find meaning in what is happening to them.

Appraisal then becomes an interpretative process involving perception, intuition and reason, by which the person feeling stressed distinguishes between safe and threatening situations. While not all situations involving feelings of stress are severe, it is worth remembering that people experiencing stress may be 'in extremis' or very seriously ill. The cognitive process of appraisal as described here may, in fact, be a spontaneous emotional reaction rather than a well thought-out process.

People are unique in their experiences and personalities, and because no two people, and no two situations, are exactly the same, the appraisal will be about the meaning that the person finds within the circumstances.

The phenomenological approach

Phenomenological approaches to knowledge emphasise the importance of the object as it appears within a context, rather than the object in itself. Thus a phenomenological approach to stress rests largely upon the description given by the individual of their own experience of stress. The writings of phenomenological philosophers such as Merleau-Ponty and Heidegger describe human experience as 'being-in-the-world' whereby each person is defined by their own thoughts, feelings, memories, relationships and social settings. Mind and body are not described as separate but as one integral whole (Benner & Wrubel 1989). This topic is further examined under psychosomatic problems (see p. 701). The body is the physical means of knowing and sensing the world and, with disablement or disease, the experience of the person will be impaired (Benner & Wrubel 1989). Whether the impairment is of the mind or the body, the whole experience of the person will be affected.

This view of human experience invites the nurse to use an intuitive approach when working with people who are distressed, because it acknowledges the complexity of individual responses, and recognises that providing the right kind of help is, similarly, a complex and subtle task.

Case History 17.3 underlines the fact that a solution to a problem which may seem reasonable to one person may present insuperable difficulties to another. In order to understand Nurse R's rejection of the suggested option, Nurse D would need to know more about why R overeats. If it were possible to ask R about her feelings, she might offer one or more reasons for her behaviour. For instance:

- she may feel anxious and unhappy as a student and feel reassured when she eats sweet foods

CASE HISTORY 17.3
D and R

D, a student nurse, notices at mealtimes that her colleague R often mentions her distressed feelings about her weight. Knowing that she frequently eats sweets and cakes, D suggests to her that all she would need to do to lose weight would be to stop eating between meals. R, however, rejects this option as being too difficult to carry through.

- she may have started overeating as a child at a time of family distress
- she may have been abused as a child
- she may feel sexually unattractive and find eating a means of gaining consolation
- she may feel constantly hungry.

Nursing application The description of human experience from a phenomenological viewpoint attributes to the person a wisdom about themselves and their problems that cannot easily be gained from an 'objective' position (Benner & Wrubel 1989). But does this mean that the nurse is merely a passive observer when working with distressed people? If suggestions and advice cannot be offered in any but the most uncomplicated situations, then what help can be offered?

The most effective help that can be given by the clinical nurse is support in enabling the person to identify what is causing their stress and to deal with it in their own way. This does not entail the nurse, however subtly, suggesting what they think the patient should do. Rather, it involves being aware and respectful of the person's right to choose what they feel is appropriate for them. This is not a passive position for the nurse to take but is a highly interactive and enabling one (Rogers 1974, Egan 1997, Kennedy & Charles 2002).

In Case History 17.4, L, a health visitor, does not attempt to deal with the situation by taking action or giving suggestions, even though her concern that Mrs H had not eaten or moved for some time might have prompted her to do so. L's support and concern do, however, enable Mrs H to talk about how she feels and then to accept help in dealing with the body of her cat.

This example also underlines a further facet of stress, i.e. that people often experience stress when they are not themselves being threatened. Stress can arise as an empathic response through the perception of the stress experienced by another. When L perceives the intense distress of her client, she too may experience that distress.

Phenomenology, appraisal and the role of stress

In a sense, all appraisal is phenomenological, because it rests upon the individual's own attribution of meaning to a situation (Lazarus & Folkman 1984). Personality can, however, play a large part in determining what features of their environment an individual attends to, and what they attend to is a feature of the meaning that a situation has for them (Lazarus & Folkman 1984, Benner & Wrubel 1989). Rather than describing the individual as 'appraising' a situation, however, Benner and Wrubel (1989) prefer to speak of the person 'being in' a situation. They emphasise that the attribution of meaning to a situation is unique for every individual, even though many people's interpretations appear to coincide. Taking this even further, they argue that there are no situations with an objective reality beyond the highly individual interpretations that are put upon them.

CASE HISTORY 17.4
Mrs H

L has been an experienced health visitor for a number of years, working with a general practice in a rural area. She had been visiting Mrs H for a year or two and had been alerted by the home help to the possibility that Mrs H was not eating as regularly as she ought. Mrs H was 84 years old and had lived alone for 20 years, since her husband died. She had always been fiercely independent, but her home help telephoned on Thursday morning to ask if Mrs H could be visited urgently.

When L arrived she found Mrs H sitting in her kitchen with her elderly cat on her lap. It was apparent that the cat had died. Mrs H's home help thought that she had been sitting with her cat throughout the night and was worried that she had not eaten or moved. L did not know what to do and so sat quietly beside Mrs H for some time. She felt it would somehow be wrong to try to separate her from her lifelong friend.

After a while, Mrs H and L talked quietly about her cat and how he had become ill and died during the night. Mrs H said that she did not know whether she would be able to live without him. Much later, however, she agreed to put the cat out in the garden and allowed a neighbour to come and bury him. When the village heard what had occurred, many people came forward to give Mrs H sympathetic support and to keep her company.

For Benner and Wrubel (1989), stress is woven into the fabric of our 'being in the world' and is not 'out there' to be dealt with. From this point of view, it would be harmful to suppress painful emotions, as these assist us in our interpretations of the world. Emotions such as anger or guilt give guidance to people about what is happening to them in the world. To teach people to relax may give them some short respite from painful tension until they are ready to confront their problems again and may be useful for this reason, but to teach relaxation as a way of dealing with problems may be misguided. Stress is part of the person's self, their concerns, thoughts, feelings about the past and future, memories and relationships to others and to objects.

The concept of resilience

An interesting and developing concept for nurses is that of resilience in individuals, which enables them to 'spring back' following distressing events (Jacelon 1997). The research indicates that people who can spring back have a constellation of personality traits such as above-average intelligence, interest in life, a positive outlook and flexibility. Those who can visualise their own future are also more likely to be resilient.

The notion of resilience as a process is less well researched, although nurses will recognise the individual learning and change described by Polk (1997) as 'survival, recovery and rehabilitation'. Those able to undergo this process are more likely to be members of social groups, to have friends and family, hope and the ability to find meaning and purpose in their experience of life.

Box 17.3

Physical and mental factors associated with stress

- Headaches
- Altered bowel function
- Insomnia
- Recurrent fatigue
- Depression
- Anxiety
- Reduced self-esteem
- Poor concentration

The important thing to be learned from this research for nurses working clinically is how to identify ways to enable those without the personality traits or social systems in place (Dewar & Morse 1995) to be helped towards rehabilitation, education and consolation.

17.3 What are the developmental aspects of a person's life that create a more resilient personality?

For further information on the concept of resilience, see Jacelon (1997).

STRESS AND DISEASE

Research has shown that stress can be a contributory factor in disease presentation. There are several physical and mental factors which are commonly associated with stress. These are listed in Box 17.3.

A relatively new area of behavioural medicine, psychoimmunology, looks at how the body's immune system is affected by psychological factors, such as stress. It is well recognised that heart disease and duodenal ulcer may result from excessive stress and psychoimmunologists believe that many other diseases may result from an impaired immune system's ability to deal with stress. These include inflammatory bowel disease, cancer, allergies and arthritic disorders, all of which may be related in some way to the body's inability to defend itself from stress.

In the following section the role of stress in several common disorders is examined.

PSYCHOSOMATIC PROBLEMS

The term psychosomatic means mind ('psyche') and body ('soma'). A psychosomatic disorder is one which therefore involves both mind and body. Most disorders do involve both the mind and the body; however, the term psychosomatic disorder is mainly used to mean 'a physical disease which is thought to be caused, or made worse, by psychological factors'. Some physical diseases are thought to be particularly prone to be worsened by factors such as stress, e.g. irritable bowel syndrome (IBS), psoriasis, eczema, peptic ulcer, hypertension and heart disease. It is thought that the physical element of the illness, e.g. the extent of a rash, the level of the blood pressure, can be affected by psychological factors.

It is well known that the mind can cause physical symptoms. For example, when we are afraid or anxious we may develop a fast heart rate, a tremor, nausea, fast breathing, sweating, dry mouth, chest pain, headaches and a 'knot in the stomach'. These physical symptoms are due to an 'overdrive' of nervous impulses sent from the brain to various parts of the body, and to the release of adrenaline into the bloodstream. When physical symptoms are caused by mental or emotional stress it is called 'somatisation'. For example, many people have occasional headaches caused by mental stress. The tension headache is due to increased tone of muscles of the neck and the scalp. However, stress can cause many other physical symptoms such as tiredness, dizziness, back pain, diarrhoea and, in women, dysmenorrhoea. The somatic symptoms due to anxiety result from enhanced activity of the autonomic nervous system. Psychogenic factors may produce muscle tension and pain. This autonomic nervous overactivity may manifest itself in several bodily systems, including, as illustrated below, the gastrointestinal system.

Anxiety attacks

As previously noted, a certain amount of anxiety and stress is a vital and healthy adaptation mechanism. In a moderate and appropriate degree, stress arouses and alerts us, improving mental and physical activity and helping us to perform better, for example in interviews, or enabling us to avoid dangerous situations.

Anxiety or panic attacks are characterised by severe sympathetic arousal, often in the absence of any obvious or immediate stressor. Panic attacks are a common presenting problem in those visiting their general practitioner (GP) with feelings of stress. During an attack, the person often experiences intense fear, accompanied by physiological signs such as palpitations, sweating, trembling, rapid respiration and pallor. The fear may be associated with a fear of collapse, death or a need to escape. Sufferers often explain they feel that their heart might burst.

By explaining the nature of these attacks, the nurse can sometimes bring an element of relief to the sufferer. It is true that the circularity of being afraid of the fear often intensifies the symptoms. Practical advice on the management of attacks is also helpful (see Case History 17.5).

Anxiety attacks are symptomatic of underlying distress. They can be acute and of rapid onset, occurring perhaps only once or twice, or can develop into a chronic symptom. Attacks may occur at any time, causing intense feelings of fear where there is no obvious cause, such as fear or discomfort in a centre seat at the cinema or on a bus. The stressor causing the attack may only become apparent, if at all, upon later introspection or therapy.

There is increasing evidence that complementary and alternative therapies can be helpful for stress-related symptoms and anxiety and depression. They can be used either alongside conventional medication-based treatment, i.e. complementary therapy, or instead of it, i.e. alternative therapy. Many of these therapies arguably have fewer side-effects than medication (Kessler et al 2001).

Post-traumatic stress disorder

This condition, which has been recognised for many years, can affect people who have experienced any serious

CASE HISTORY 17.5

Midwifery Sister B

Midwifery Sister B had been working very hard in her new post in the labour suite and she discussed with her colleagues her feeling of apprehension that she might make a mistake or be unable to deal with the management responsibility that her new post entailed. The suite was often understaffed, and although she realised that this was not her responsibility, she felt guilty about the demands it placed upon her colleagues. On her night off she went with one or two friends to a pub and, although she had not drunk a great deal, she knew that she had exceeded her usual limit.

The following morning she awoke with a feeling of unease that she found difficult to describe. She experienced something like a feeling of agitation but her skin also felt as if it were 'crawling'. She had planned to go for a walk with her friends but, when she reached the park where she was to meet them, the feeling she had experienced throughout the morning became much more intense. She became sweaty, had great difficulty in breathing and felt very afraid. Feeling her pulse, she realised that her heart was beating very fast. Sister B later described her fear that she might collapse and die during this attack. This feeling lasted for 10 min. Her friends took her home, and later she contacted her family doctor.

This episode was described by the doctor, following some routine investigations, as an anxiety attack. He explained what had happened physiologically and was able to offer reassurance. He suggested that she either attend a stress reduction workshop or talk to a counsellor, and reduce her coffee and alcohol consumption. After Sister B had taken the opportunity to talk about her fears and problems with a counsellor, she felt more able to deal with her new job. She noticed, however, that when she began to feel tired and worried, the physical signs of sweating and palpitation would re-emerge. She used this as an indication that she needed a rest. Sister B also noticed that alcohol exacerbated the problem, as it had during her first attack.

Box 17.4

Migraine phases

Migraine attacks follow a pattern consisting of the five phases described below (Blau 1987). The third and fourth phases are prerequisites of a diagnosis of classical migraine.

1. **Prodrome**
   - Subtle symptoms; may not be noticed
   - Craving to eat sweet food
   - Mood variations
   - Tiredness
   - Mild photophobia
   - Heightened visual perception
2. **Aura**
   - Multicoloured visual disturbances
   - Scotoma with flickering, scintillating edge
   - Tingling of face, sometimes one sided
   - Numbness of face
3. **Headache**
   - Slowly developing throbbing pain
   - Lasts 2–72 h
4. **Resolution**
   - Sleep is major resolving mechanism
   - Vomiting
5. **Postdromal phase**
   - 'Washed-out' or drained feeling
   - Euphoria
   - Impaired concentration
   - Irritability
   - Cerebral flow observations indicate that anomalies can outlast headache by 24 h

accident or trauma outside the range of their normal experience, such as a severe road traffic accident, rape, physical attack, 'plane crash, bomb blast, war or terrorist attack. The disorder can follow one or more of such events and can occur not only in those directly involved but also in those called to assist, such as emergency workers or onlookers. The greater the scale of the incident, the more likely it is for post-traumatic stress disorder to arise.

The person, having escaped adversity and perhaps having a sense of relief at having escaped relatively unharmed, can be very perplexed at the occurrence of distressing symptoms, sometimes a considerable time after the event. There may be a loss of memory and total amnesia and sufferers often report feeling mentally numbed (Mckinley & Brooks 1991, Fagan & Freme 2004). Symptoms may include:

- mood swings and feelings of aggression
- feelings of alarm, anxiety and irritability
- feeling jumpy
- flashbacks to the original trauma that leave the person feeling as though they were back in the traumatic situation
- loss of interest in pleasurable events
- phobic and depressed feelings, panic
- sleep disturbances, e.g.
  - — waking in alarm and unable to return to sleep
  - — difficulty in getting to sleep
  - — early morning waking
  - — distressing nightmares
  - — night sweats.

Migraine/headache

Migraine headaches have been known about for well over 2000 years and it is estimated that they are experienced by 10% of the population. Changes in the size of blood vessels and the levels of neurotransmitter substances are thought to be responsible for migraine headaches. It is recognised that they are not caused solely by stress but have a number of precipitating factors such as menstrual cycle, diet, dehydration and certain sounds and smells which, in conjunction with a feeling of stress, may trigger an attack. Many people report that the attack, paradoxically, occurs after the cessation of the stressful event.

For many people, migraine is a very debilitating and distressing condition. An analogy is of a storm building up and causing, instead of lightning, wind and rain, intense pain, nausea and vomiting, often lasting for several hours. The person is often prevented from continuing with normal activities. The phases of an attack are outlined in Box 17.4.

Physiologically, the hypothesis put forward to explain migraine (Blau 1987) is that stress causes cerebral hypoxia through increased activity in catecholamine pathways. This suggestion is supported by the observation that cerebral

Box 17.5

Symptoms associated with chronic fatigue syndrome

- Substantial impairment in short-term memory or concentration
- Sore throat
- Tender lymph nodes
- Muscle pain
- Multi-joint pain without swelling or redness
- Headaches of a new type, pattern or severity
- Poor sleep
- Post-exertional malaise lasting more than 24 h

Based on data from Sharpe & Wilks (2002) and Aylett & Fawcett (2003).

oxygen consumption rises when the individual is stressed. The role of the catecholamines — adrenaline, noradrenaline and dopamine — is to activate the cerebral metabolism. If the nerve fibres penetrate deeply enough into the brain, the sympathetic nervous system could release noradrenaline and increase neuronal metabolism in the surrounding tissue. In this hypothesis, stress increases cerebral metabolism, thereby increasing the risk of migraine.

Interventions

The person should, if possible, identify any trigger factors of their migraine attacks and avoid them. The pain can be treated with analgesics in conjunction with metoclopramide for the nausea; the latter will also improve the uptake of the analgesic from the intestine. Complementary therapies commonly used for the management of migraine/headache include acupuncture, osteopathy, relaxation therapy and homeopathy.

For further information, see Cunningham (1999).

Chronic fatigue syndrome (myalgic encephalomyelitis)

Chronic fatigue syndrome (CFS) is characterised by protracted periods of fatigue associated with a wide range of accompanying symptoms (see Box 17.5).

The symptoms of this puzzling illness, which is also referred to as myalgic encephalomyelitis, include extreme muscle fatigue, poor memory and concentration and slips of the tongue (Aylett & Fawcett 2003). This condition can cause considerable distress and disability over a period of months and sometimes years. The individual may, with devastating consequences, be unable to continue full- or even part-time work or may be forced to take frequent periods of sick leave. This and other implications of the illness can cause stress to loved ones and adversely affect the well-being of the family as a whole.

Fatigue and depression as sequelae to infection have long been recognised, particularly in relation to Epstein–Barr, Coxsackie and other enteroviruses. It is important, however, that postviral fatigue syndrome is not mistaken for psychiatric illness (Sharpe & Wilks 2002). Even today, not all GPs recognise postviral fatigue as a medical condition (CFS/ME Working Group 2002).

Some health professionals advise rest, while others, recognising the adverse effects of long-term inactivity, advise exercise. Good emotional support is vital, and it is most important that depression, where present, is treated. Other treatments are aimed at the detection of possible allergies and/or candidiasis and at maintaining a good diet.

Many patients who are able to undertake a modest amount of exercise report some improvement in symptoms. Conventional treatment approaches to CSF/ME include the prescription of antidepressant medication to promote sleep, and anti-inflammatory medication, i.e. aspirin and ibuprofen, may be prescribed to reduce muscular aches and pains. Complementary therapies are sought by many patients who do not find improvement or look to enhance the improvement from conventional medicines. Despite limited scientific evidence, herbal remedies, acupuncture, osteopathy and aromatherapy are widely used for the management of chronic fatigue syndrome.

Irritable bowel syndrome (IBS)

Stressful life events have long been associated with the development of IBS. IBS is a common functional disorder characterised by abdominal pain and altered bowel function. Although IBS is not life threatening, for many patients it can have a serious impact upon their daily activities and health-related quality of life. There are several factors which can trigger attacks of IBS in some people, e.g. work stress and examinations.

People with anxious (neurotic) personality traits may find symptoms difficult to control. The relationship between the mind, brain, nervous impulses and overactivity of internal organs such as the gut is complex (Lea & Whorwell 2003). Some patients have reported relaxation techniques, stress counselling, cognitive therapy and psychotherapy useful in controlling symptoms. Complementary therapies are also commonly employed in the management of IBS, for example gut-directed hypnotherapy, acupuncture and homeopathy are all used with good effect (see Case History 17.6). Reducing chronic stress is an appropriate and highly achievable therapeutic goal in the management of IBS (Smith 2003).

CASE HISTORY 17.6

K

K is a 24-year-old primary school teacher who was diagnosed with irritable bowel syndrome (IBS) 3 years ago. On attending a gastrointestinal clinic she reports that important life-changing events, e.g. the recent breakdown of a relationship, have made her symptoms much worse. The anxiety over IBS symptoms causes stress, which worsens the symptoms and creates a vicious circle. K states, 'Because I have IBS, I spend a lot of my time worrying about whether or not the symptoms will affect me each day' and 'I am sure the stress of my boyfriend leaving me has made my IBS much worse!'. K is encouraged by the nurse to practise stress management techniques and has been referred for gut-directed hypnotherapy.

Depression

Depression is a psychological state of melancholy and dejection that can have physical symptoms. It is not the case that everyone who feels stressed also has depression or anxiety, but the illness can be the outcome of feelings of stress; conversely, people experiencing depression can also become stressed (Herbert 1997).

It is difficult to formulate an exact definition of depression and its relationship to stress. The experience of depression seems to range from unpleasant but normal feelings of being 'fed up' to severe states of mental ill-health requiring psychiatric intervention. It is important to recognise that clinical depression, which is a serious mental illness, can be life threatening, as suicide and self-harm are frequent outcomes in severe depression. It is vital for health professionals to be alert to this possibility.

Houston et al (2003) argue that the GP, in particular, can play a major role in the detection and treatment of depression and in the after-care of patients who deliberately self-harm, as can the community psychiatric nurse (CPN).

Symptoms of depression

The presence of depression is often not obvious to the nurse, as observable signs do not always indicate the unpleasantness of the feelings that the individual is experiencing. Some symptoms, however, particularly when they occur in combination, strongly indicate the presence of depression, for example early morning wakening, a feeling of grinding tiredness, loss of energy, loss of interest in sexual relationships, loss of appetite, feeling 'down' and a feeling of bad temper. The link between anxiety and depression is debatable, but if this division is dispensed with, the list of potential symptoms of depression might, arguably, be expanded to include panic or anxiety attacks.

Feelings associated with depression

The relationship between stress and depression is an extremely close one. Some people experiencing depression feel stressed by, amongst other things, their inability to continue with day-to-day activities. Others, who are burdened by overwhelming demands, respond by becoming depressed. What is not understood is why some people respond to stress by becoming depressed whilst others show other emotions such as anger.

People experiencing depression often describe their circumstances in terms that denote an ongoing feeling of oppression, as of being under a cloud, of everything looking black or grey, or of being in a tunnel without an end. Feelings of hope diminish, to be replaced by feelings of hopelessness. They often feel uncared for and alone even when this is not the case. Undertaking tasks or projects often becomes impossible as inertia takes the place of activity. Depressed individuals often blame themselves for problems in their relationships or daily lives, where others who are not depressed might show anger. This leads to the hypothesis that depression is anger turned in on itself when for some reason it cannot be expressed openly (Freud 1917, Worden 2002).

Causes of depression

Depression can occur at any time in life and may follow on from any painful event or loss, such as the death of a loved one or the loss of a job. Depression which, when it occurs in adulthood, does not have an obvious cause, may be the result of early childhood loss or distress. Individuals who have been the victims of sexual, physical or emotional abuse as children may suffer depression as adults in a delayed response to the loss associated with abuse, which is triggered by a more recent experience of distress. Early unresolved loss has been suggested as a possible explanation for the distressing symptoms of depression following childbirth. Depression may also be triggered by the lack of light and sunlight exposure during the winter months, known as seasonal affective disorder (SAD). Conventional medical approaches for moderate to severe depression often require anti-depressant medication. In milder cases of depression, counselling and psychotherapy may be helpful, in conjunction with lifestyle, exercise and dietary advice. Complementary therapies can be used in the treatment and prevention of depression (see Box 17.6).

COPING

The concept of coping

Used in a neutral sense, the term 'coping' refers to the way in which the individual responds to a stressful situation or to the perception of threat, by attempting consciously and unconsciously to maintain an equilibrium. It is revealing, however, to reflect upon everyday usage of the word, as it can be a value-laden term, used in intrinsically judgemental descriptions of an individual's degree of mastery over a situation or environment. Consider the degree of approval or disapproval that might be implied in the following statements:

- 'She coped well in her first managerial position.'
- 'She cannot cope.'

Box 17.6

Complementary therapies used in the treatment of depression

- *Psychological therapies* — cognitive behavioural therapy and relaxation training.
- *Acupuncture* — traditional acupuncture treatment or electroacupuncture can ease depression. Some studies found this to be superior to antidepressant medication and with fewer side-effects.
- *Homeopathy* — various remedies may help. The remedy ignatia is often used to ease grief, pulsatilla may relieve tearfulness, sulphur is often indicated for despair and aurum metallicum, a natural mineral derived from gold, is used for suicidal feelings.
- *Herbal medicine* — the herb St John's wort (*Hypericum perforatum*) has been clinically proven to relieve mild or moderate depression.
- *Reflexology, meditation and yoga* — these have also been used in the treatment of depression but have not yet been tested by research.
- *Light therapy* — exposure to bright light and the use of light boxes can help people suffering from seasonal affective disorder (SAD).

- 'He finds it difficult to cope with exams.'
- 'He couldn't cope with the patient's relatives.'

The association of 'coping' with mastery and of 'failure to cope' with weakness should not be automatic. It may be the case that the individual who succumbs to feelings of stress is more able to sense tension in a situation than the person who gives the appearance of coping well. The person who effects their removal from a situation may in fact be 'coping' with it, by acknowledging that distancing or disengagement is the best way, in the circumstances, to preserve emotional health or physical safety. In some situations, the determination to persevere or to achieve mastery may be a damaging choice, ending in disease.

Different situations demand different strategies for coping. In some cases the individual may need to confront a difficulty or overcome an obstacle. In other circumstances, the person must learn how to carry on with their life in the face of an ongoing situation such as bereavement, disability or unemployment. What 'coping' entails will depend upon the individual's unique circumstances and needs, and various models such as resilience and hardiness have been put forward in an attempt to identify the factors that contribute to an individual's style of coping.

Models of coping

An understanding of the models of coping can enhance the ability of the nurse to care compassionately for patients who are experiencing stress.

One of the well-known approaches to the concept of coping focuses on the role of personality in the individual's response to stressful events and identifies 'Type A' behaviour (see below) which characterises the individual as being particularly susceptible to the health risks associated with stress. An alternative and influential approach which discusses coping within the context of stress, burnout, support and hardiness, is found in Kobasa's (1979) seminal attempts to identify those who are particularly resilient, i.e. who exhibit hardiness under stress (Duquette et al 1995). Those with hardiness have a sense of personal achievement and are less likely to have physical or psychological symptoms, and are less likely to become emotionally exhausted (Dillard 1990). This concept has many similarities to that of resilience.

Some models describe coping in terms of palliation strategies. For example, strategies that may be sought by those experiencing the early stages of burnout are exercise, relaxation, prescribed medication, drug abuse, smoking and alcohol consumption. Other models describe coping in terms of problem solving, or, as in Lazarus' (1966) approach, in terms of a dynamic process by which the individual engages with the source of the stress. It is also possible to discuss coping in terms of defence mechanisms that individuals employ to preserve themselves from a perceived threat.

Coping and personality

Some people appear to be relatively unaffected by traumatic events, while others seem to be quite unable to withstand what might appear to the onlooker to be minor upheavals. Researchers have attempted to identify individuals who are more likely than others to cope effectively with stress, by isolating relatively stable and highly consistent inborn dispositions or traits which enable the individual to function well in difficult situations. Such traits may be related to, for example, conformity or non-conformity, conscientiousness, compulsive behaviour, or the ability to suppress, repress or sublimate feelings.

Type A behaviour patterns. Extensive research into the question of whether there are certain people who experience stress more acutely than others, and who are more likely to succumb to cardiac or circulatory disease as a result, has identified a 'Type A' individual who is at particular risk from the effects of stress. Type A behaviour is not, strictly speaking, a trait; traits are by definition inborn, whereas Type A behaviour appears to be learned by social modelling. Those with Type A behaviour both wish to achieve and are high achievers (Westra & Kuiper 1997) and are more likely to have a job-centred lifestyle than one based upon interpersonal contacts with others (Fukunishi & Hattori 1997). Type A behaviour seems to have very positive short-term consequences; for example, in business or other organisations, people who show involvement, drive and initiative are often highly valued. However, O'Connor et al (1995) and Miller et al (1996) consider that this behaviour may be linked to suppressed feelings of hostility and anger, which confer different cardiovascular disease risks. The long-term consequences of Type A behaviour, however, are often negative. The Type A person is typically observed engaged in polyphasic activity, concurrently undertaking a number of tasks. Other characteristics associated with Type A individuals include time urgency, impatience, desire for control and aggression. The following interrelated elements are present in Type A behaviour patterns:

- a set of beliefs about oneself in relation to the world
- a set of values which merge with motivation and commitment
- a set of beliefs about lifestyle that are focused upon achievement and control.

Type A individuals invest a great deal of themselves in their lifestyle and expend a great deal of energy in maintaining control. When challenged, their response is often highly emotional and this is likely to stimulate frequent surges of catecholamine secretion, which can induce, in the physically unhealthy person, coronary heart disease. They often show signs of raised serum cholesterol levels, raised serum fats and diabetic-like traits; at the same time they are frequently smokers who do not have time for regular exercise. Understandably, Type A behaviour is often destructive to relationships with family members, friends or colleagues.

It is important to bear in mind that people can change their learned behaviours and improve their ability to cope with certain experiences. In addition, there can be some degree of habituation to stressors such that they seem less stressful over time.

Personality and health Kobasa (1979) examined the mediating effects of personality, not in relation to stress and disease, but in relation to stress and health. Whilst much research effort had been directed towards understanding the role of mediators such as early childhood influences,

physiological predisposition and social resources in relation to the onset of disease, Kobasa (1979) asked why some people can be under considerable stress but not become ill. Using the social readjustment rating scale (Holmes & Rahe 1967), she tested the following hypotheses:

- People who have a greater sense of control over their own lives will remain healthier than those with a sense of powerlessness.
- People who have a sense of commitment to various areas of their lives will be healthier than those who have a sense of alienation.
- People who view change as a challenge will remain healthier than those who view change as a threat.

Kobasa (1979) postulated a state of hardiness in the personalities of those who can be stressed without becoming ill. The hardy person has certain characteristics, including:

- a clear sense of self and of personal meaning
- an understanding of values, goals and capabilities and a belief in their importance
- a vigorous involvement in and commitment to their own environment
- an internal locus of control
- active involvement in change.

Klag & Bradley (2004) critique Kobasa's findings and examine the concept of hardiness in stress and illness.

The process model of coping

Lazarus and Folkman (1984) described coping in terms of a dynamic process involving movement, force and energy within the individual and their relationship with the source of stress. An important feature of the process approach is that it reflects the fact, often observed in clinical settings, that an individual's response to their situation changes and evolves over time. This response is highly complex and unique to each individual and might be described as occurring in stages, although these stages are not sequential or predictable.

Worden (2002), for example, describes four tasks of mourning that the individual must complete in order to emerge from a state of grief:

- accepting the reality of the loss
- experiencing the pain of grief
- adjusting to an environment from which the deceased is missing
- withdrawing emotional energy and reinvesting it in another relationship.

For the individual, these tasks of mourning may not be sequential, but may be experienced instead as an 'ebb and flow' of feelings. For the nurse, Worden's definition of the tasks of grieving will give an indication of the direction that a person might take in their mourning. For the individual concerned, the stages passed through might be recognised only in hindsight.

The process approach emphasises that the individual copes with stress in a unique way that is governed by both childhood and adult experiences. The ability to cope is shaped by the developmental processes that the individual undergoes from birth to death. The individual's perspective will change continually, and situations that may be stressful at one time may be viewed differently at another stage of life.

PSYCHOLOGICAL DEFENCES

While it is possible to think of defence mechanisms as both conscious and unconscious strategies of self-protection against perceived threat, these mechanisms may seriously compromise the effective functioning of the individual. Defence mechanisms operate essentially by restricting situations which are seen as threatening, narrowing down the individual's field of action to one that is manageable. They enable the individual, often against overwhelming odds, to maintain an equilibrium of feelings, thoughts and actions in daily life.

Problems arise when they feature inappropriately, as when a defence mechanism first acquired to combat severe or terrifying feelings in one domain becomes active without cause in another, perpetuating the emotional disturbance that gave rise to the mechanism in the first place. This may occur some time after the original experience, and the content of that experience may not be accessible to the person even after therapy. While it is useful for the clinician to bear in mind that unresolved conflict may exist, the detailed and often long-term task of helping the person to understand the extent of their defences is best left to therapists and counsellors.

Defences may be compared to a sea wall, in that the magnitude of the original intense fear and distress will determine the height, breadth and depth of the defence. These defences are not always infallible, however; they can be breached during sleep, under the influence of alcohol and other medications, and in conditions of stress.

A number of defence mechanisms have been identified, the most common of which are listed in Box 17.7.

MANAGEMENT OF STRESS

Effective stress management techniques can prevent stress-related ailments, boost vitality and improve quality of life. The management of stress can be approached in a number of ways (see Box 17.8).

One stress management technique often employed is to offer the individual the opportunity to examine the sources of their stress in present or past experience and to consider ways of modifying their responses to that stress. This therapy can be provided by a psychotherapist, clinical psychologist or qualified counsellor who may also be a nurse.

Some individuals suffering from acute anxiety or depression may find it impossible to confront the source of their difficulty and to make constructive changes without first being given some relief from their distressing feelings. Here, the carefully monitored use of appropriate medication, described on pages 708–709, can facilitate recovery and change. The individual suffering from stress can also learn a number of techniques that will assist them to reduce or manage their stress in day-to-day life. The role of complementary therapies in stress management is examined in the next section.

Techniques such as relaxation, yoga, biofeedback, visualisation and meditation have all gained in credibility and

Box 17.7

Defence mechanisms

Repression
Unconsciously keeping unacceptable feelings out of awareness. Not acknowledging angry or jealous feelings towards others.

Disavowal or denial
Blocking a perception from memory. Someone whose father left the family at birth may unconsciously think of him as having died rather than confront the feelings of loss and anger.

Projection
Unconsciously attributing to others their own aggressive or angry feelings. The feeling that one is being 'got at' by a colleague may be a projection of one's own angry negative feelings towards the colleague.

Introjection
Accepting another's values and opinions as one's own. A young person living with a domineering parent may unconsciously accept the attitudes of the parent rather than risk confrontation.

Reversal
Detaching a feeling from the person or object to which it should be directed and directing it to oneself instead. A wish to physically harm another may instead become a process of self-harm.

Displacement
Directing strong feelings about another person towards someone less dangerous than the original source of the feeling, e.g. a child experiencing powerful and angry feelings towards a mother may punish a favourite doll instead.

Isolation
Detaching a feeling from a thought in order to deprive the thought of emotional significance. Nurses sometimes describe helping at the scene of an accident without being in touch with the experience of the associated feelings.

Reaction formation
Disguising feelings by repression of the real feeling and reinforcement of the opposite feeling. A husband caring for a disabled wife may feel angry at her dependence, but instead shower her with loving attention.

Rationalisation
Finding false reasons to justify unacceptable attitudes. Following the termination of an employment contract, a person might claim to be pleased to be no longer employed, rather than acknowledge painful feelings of worthlessness.

Conversion
Converting a psychological disturbance into a physical disorder. A feeling of panic or fear accompanied by physical symptoms may be regarded as physical symptoms alone by the person to unconsciously avoid confronting the cause.

Box 17.8

Stress management techniques

- *Deep breathing* — this means taking a long, slow breath in, and very slowly breathing out. If you do this a few times, and concentrate fully on breathing, you may find it quite relaxing.
- *Muscular tensing and stretching* — try twisting your neck around each way as far as is comfortable, and then relax. Try fully tensing your shoulder and back muscles for several seconds, and then relax completely.
- *Improve your diet* — reduce caffeine, nicotine, junk foods and sugar, and increase whole grains, vegetables, fruit and water.
- *Vitamins and minerals* — stress puts added strain on the liver and nervous system. To strengthen these, boost intake of B vitamins, vitamin C, zinc and magnesium.
- *List major stresses* and consider solutions or lifestyle changes for each. Prioritise, practise time management and learn to delegate and say, 'No'.
- *Make time for rest and relaxation* and time for yourself on a regular basis.
- *Take regular exercise* to relieve stress and stimulate endorphin production, which has a relaxing effect.

Adapted from the Stress Management Society.

popularity in recent years. When taught well and followed up with continuing support, courses in such techniques can help people to adopt a new approach to the problem of stress. Moreover, learning a new skill such as deep relaxation can impart to the individual a feeling of well-being which may facilitate positive change in various areas of their life. However, it is important to note that if stress lies in the interaction between the person and their environment, or in the meaning they attribute to their situation, then clearly a short workshop on relaxation, for example, cannot hope to seriously address the source of their stress. Indeed, it should be borne in mind that there is a potential for courses in stress reduction to exacerbate the problem, if the individual is made to feel that any stress that is not helped by the techniques offered is intractable or somehow abnormal.

Counselling in stress

Counselling and psychotherapy aim to assist people to overcome the emotional barriers or psychological problems caused by stress and enable them to address their problems and make the life changes needed to improve their health and well-being.

Finding and choosing therapeutic help

There are a number of ways to find therapeutic help and various professional bodies for counselling and psychotherapy will give suggestions (see 'Useful websites', p. 713), although the availability of some types of psychotherapy

will depend upon where in the UK the person seeking help lives. Whilst many people travel long distances to see a counsellor or psychotherapist, the regular nature of the consultations, which may be weekly, may cause an added burden if extensive travel is required.

If psychotherapeutic help is sought through the NHS, a referral can be made by the GP. Many departments of clinical psychology will accept self-referrals, but will ask the person if they may contact their GP. Where the therapy being sought is through the private sector, the person pays a fee for each consultation.

For therapy to be effective, it must respond to the person within their own frame of reference and be relevant to their own life from their own unique perspective. Finding an appropriate form of therapy can be very difficult for the individual, and many people are reluctant to approach a professional agency or voluntary organisation for assistance with personal problems. Many people think about it and wait for long periods before plucking up the courage to seek help, and often their first point of contact is with a member of the primary care team at their local surgery; this may be the GP, the practice nurse or another member of the primary care team, such as the health visitor or community psychiatric nurse. The practice nurse, or nurse practitioner undertaking screening programmes, is well placed to be able to listen to patients who are distressed (Cunningham 1996). Often, merely discussing the problem with a member of the practice team can provide considerable relief. However, when further help is required, the patient can be referred to the community mental health team, including, for example:

- the practice counsellor
- the community psychiatric nurse (CPN)
- a clinical psychologist
- the community psychiatrist.

The GP may also wish to discuss with the patient the possibility of prescribing antidepressants, but first will investigate whether the patient is suffering from a physical illness such as hyper- or hypothyroidism or anaemia which can cause symptoms similar to depression. Reassurance can be given that panic attacks are not life threatening and advice given on how to deal with them. The GP can also authorise official sick leave to enable the patient to rest.

The therapist–client relationship

People are highly individual in their feelings, experiences, backgrounds and personalities. A model of therapy which is helpful to one person may not suit another, and a therapist who is helpful to one person may fail to establish a good rapport with another. For this reason it is important for therapists to be clear with their clients about the way in which they work, what the work involves, its likely duration and, if private consultation is sought, its cost. It is possible for the client to change therapists if the therapy does not seem to be helpful, although there is one major proviso to this. For personal change to take place, therapist and client must work closely in a relationship of trust. This will enable the therapist to reflect back and challenge the behaviour that is causing the client distress. The fact that this can be an unsettling experience for the client may not be the right reason for them to abandon therapy. Nevertheless, the therapist should be willing to discuss any feeling on the client's part that the therapy is proving detrimental or unhelpful and, if appropriate, to give guidance on finding an alternative therapist.

The person wishing to become a therapist must undertake appropriate education, which involves the study of theory as well as undertaking supervised work with clients. Nurses working in clinical settings may undertake shortened courses which will help them to develop the necessary skills to listen in a therapeutic way to people in their daily work. An example of therapeutic listening is given in Case History 17.7.

CASE HISTORY 17.7

Mrs A

Mrs A cares for her cognitively and physically handicapped son, S, at home, with the help of the community nursing service and the local social work department. She is 68 years old and a widow; her son is 29. He is visually impaired and unable to communicate easily by speaking. He is always incontinent. Although he can walk, Mrs A always has to guide him. Getting him out of bed and dressed in the morning is very heavy work for her.

Mrs A has known her community nurse, N, for a number of years. N feels a sense of despair that Mrs A never has any freedom from S and has rarely had any time to herself in the years she has known her. N has tried repeatedly, both by herself and in conjunction with social work colleagues, to plan some respite care for S. This planning has taken the form of a provision for day care at a local day centre and periods of respite care at a local residential unit. But somehow, when the time came for S to attend, Mrs A managed to avoid sending him. The only assistance she will accept is from the local care attendant team; one helper, who has become a friend, sits with S for 2 hours while Mrs A does her shopping.

One day N was able to sit and talk with Mrs A whilst S was asleep. By listening carefully to her, N realised that Mrs A felt extremely guilty about S's handicap. She felt that she had caused S's condition by not taking sufficient rest during her pregnancy, and she relieved her feelings of guilt by caring for him all the time. She was also extremely fearful of what would happen to S after she died.

N continued to listen carefully to Mrs A as she talked about her painful feelings, and was aware that she had not been able to share these feelings with anyone before. She did not try to make Mrs A feel better by taking away her feelings of guilt, nor did she try to reassure her. Instead, she simply listened carefully and attentively.

They did not talk again about this problem, although N was ready to listen if Mrs A wished to raise the subject again. Some time later, however, Mrs A asked N if she could help her organise some day care for S, as it would help him to get used to other people. N was then able to arrange respite care for S, which Mrs A accepted and which also enabled her to get some rest.

Medication

The personal experience of stress can be so severe and overwhelming that the individual becomes unable to take any action to alleviate their feelings. Severe anxiety or depression, perhaps in combination with an overpowering feeling that a serious physical illness is lurking, can have an immobilising effect on the person so that even the prospect of action to alleviate symptoms is daunting. When

people feel as severely distressed as this, they may begin to entertain thoughts of suicide.

Medication can help to alleviate severe distress by relieving its most acute symptoms and thus enabling emotional rest to take place. Some medications are intended to help with sleeplessness, while others which do not have a tranquillising effect will permit those taking them to continue to work, to problem-solve, to drive, and so on. Medication should always be supplemented by continued monitoring and support by the medical practitioner. The following provides a brief overview of the main types of medication used in the treatment of stress-related conditions.

Tricyclic and related antidepressants

The most common antidepressant medications used in severe stress and depression are the tricyclic and related groups. These are usually prescribed to people suffering from moderate to severe depression, although it is important to realise that they work by alleviating symptoms. This can be useful; for instance, the person who is debilitated by anxiety might be able to find ways of living that are more constructive once their feelings of anxiety are lifted. These medications may not be helpful, however, when the depression is related to bereavement, an unhappy working environment, overwhelming family responsibilities or disturbing memories of abuse or neglect, for it is only when the underlying cause of depression can be understood, and appropriately treated, that the person is likely to obtain any lasting benefit.

Management The person prescribed tricyclic antidepressants must be seen frequently following prescription as they may take 2–4 weeks before having an effect; during this time the patient may feel isolated and helpless. Side-effects include the following:

- constipation
- sleepiness
- dry mouth
- blurred vision
- urinary retention
- sweating.

Tolerance seems to develop over time and some of the side-effects become less apparent.

If the individual's depression is severe, they may feel suicidal. Careful support and perhaps hospitalisation may be essential at this time. Treatment with this group of medications should be continued for at least 1 month (BMA 2005). Reduction or withdrawal should be carried out very slowly to avoid severe symptoms such as strange, fragmented dreams, headaches, recurrence of anxiety, depression or restlessness.

Selective serotonin reuptake inhibitors (SSRIs)

Serotonin, also known as 5-hydroxytryptamine, is a substance widely distributed in body tissue. Serotonin participates in the transmission of nerve impulses and has a function in controlling mood. SSRIs block the reuptake of serotonin, producing an increase in the amount of the neurotransmitter at central synapses. Examples of commonly prescribed SSRIs for stress-related conditions are fluoxetine and paroxetine. In contrast to the tricyclic antidepressants, SSRIs have few antimuscarinic and anticholinergic effects, and cause little sedation or weight gain. They may, however, cause nausea, diarrhoea, insomnia and anorexia.

Benzodiazepines

The benzodiazepines are 'anxiolytics'. They act at a specific central nervous system receptor or by potentiating the action of inhibitory neurotransmitters to help calm patients and promote rest and sleep. They are therefore used to help treat, but not cure, the symptoms of anxiety, such as tension, tremor, sweating and disturbed thought processes.

However, this class of medication fell into disrepute when individuals who were taking the medication for extended periods of time found that their original symptoms were intensified and that the medication was addictive. It is now recommended that benzodiazepines are prescribed for periods not exceeding 2 or 3 weeks and under careful supervision (BMA 2005).

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors (MAOIs) prevent the breakdown of monoamine neurotransmitters, thereby prolonging their action. Monoamines, which include noradrenaline and tyramine, play an important role in the metabolism of the brain. MAOIs are recommended for people with depression, anxiety and somatic complaints, for patients who do not respond to tricyclics and patients with agoraphobia. They are used less commonly than tricyclic antidepressants or SSRIs because of dangers of dietary and medication interactions.

Trazodone hydrochloride

This medication exhibits antiserotonin and α-receptor antagonist properties. Its sedative properties are useful in the treatment of anxiety.

Beta-adrenoceptor-blocking drugs

Beta-adrenoceptor-blocking drugs, also called beta-blockers, act by blocking the stimulation of beta-adrenergic receptors by the neurotransmitters adrenaline and noradrenaline. These are produced at the nerve endings of that part of the sympathetic nervous system which facilitates the body's reaction to anxiety, stress and exercise. Beta-blockers act to reduce anxiety and some physical symptoms, such as trembling, which are caused by a stress reaction. They are particularly useful for situational anxiety. For example, some musicians who become stressed take a beta-blocker to ease their shakiness before a concert performance.

Alcohol and stress

It is commonly believed that one way to cope with stress is to use alcohol. However, although alcohol may give short-term relief of stress, in the long run, it does not and drinking alcohol to 'calm nerves' is often a slippery slope to heavier and problem drinking. For most people who stay within the recommended drinking levels (see Ch. 36), alcohol can be an enjoyable aid to relaxation. However, the more an individual uses alcohol to relieve stress, the less effective it becomes. Eventually, more and more alcohol is required to achieve the desired effect of relaxation. The after-effects of alcohol may also increase feelings of anxiety and depression.

Other means of stress reduction

Complementary therapies

There is an increasing interest in complementary therapies in stress management. The five main complementary therapies are:

- acupuncture
- osteopathy
- chiropractice
- homeopathy
- herbal medicine.

Other well-known therapies include hypnotherapy, aromatherapy and massage, all of which are increasingly used in stress management. Complementary therapies focus on the whole person, with lifestyle, environment, diet, mental, emotional and spiritual health being considered alongside physical symptoms. Many complementary therapies are based on the belief that the body naturally strives to maintain homeostasis. Interventions aim to stimulate this natural healing ability. Taking responsibility for one's own health is regarded as an important part of healing, so clients are often actively involved in their own treatment. For example, self-hypnosis techniques are employed in hypnotherapy (Gonsalkorale et al 2002).

Exercise

Although there is strong research-based and anecdotal evidence that regular vigorous exercise has a positive effect upon the individual's ability to deal with feelings of depression and stress, the effects of exercise are not generally accepted or understood; for instance, those taking physical exercise may have considerable exposure to light and this may have a therapeutic effect upon feelings of depression (Groom & O'Connor 1996). There is, however, evidence that aerobic exercise may trigger panic attacks in those already experiencing them (Reif & Hermanutz 1996). Proponents of exercise, as a means of stress reduction, argue that exercise may be essential for psychological, physiological and social development, having a direct effect upon feelings of self-esteem (Segar et al 1998). However, in the treatment of depression, aerobic exercise in particular is efficacious (Beesley & Mutrie 1997, Moore & Blumenthal 1998). Physical fitness is seen as a positive aid towards emotional stability. Guidelines for exercise as a means towards stress reduction are given in Box 17.9.

Exercise works in a paradoxical manner in reducing stress. It is itself a physical stressor causing an acute stress response but nonetheless functions as a relaxant. The physiological effects of exercise include increased blood flow and oxygen consumption, as well as changes in blood pressure, heart rate, respiration and metabolic rate.

Physical exercise acts as a relaxant for a number of reasons:

- Most exercise involves effort and concentration and thus it can be difficult to sustain anxious thoughts whilst engaged in physical exercise.
- Meeting a physical challenge can give the individual a sense of achievement.
- During strenuous exercise the body produces noradrenaline and endorphins; these substances help to alleviate depression and arguably bring about feelings of happiness and tranquillity (Pert 1997).
- Exercise can be taken in the company of other people and so can diminish feelings of social isolation.

Box 17.9

Guidelines for exercise

- Any exercise is good
- Set aside a specific time for exercise. Treat that time as sacrosanct, but do not feel worried if it is necessary for some reason to miss a session
- Exercise at least three times a week if possible, for at least half an hour
- Exercise should be gentle but vigorous; build up slowly to a good exercise level
- If in doubt, have a health check and talk over your exercise programme with your general practitioner prior to starting

Relaxation

Relaxation has long been known to help alleviate feelings of stress and to enhance health-seeking behaviour (Vines 1994). Relaxation may take various forms, including relieving muscle tension, e.g. through exercise, taking time off, either on a daily or weekly basis or as a scheduled holiday, and meditation. Everly and Benson (1989) and Knight (1995) discussed the response elicited physiologically and psychologically by certain types of meditative relaxation. They identify two components of these meditation techniques which cause the relaxation response and a reduction in feelings of stress:

- the repetition of a word, sound, phrase, liturgical prayer
- the positive disregard of everyday thoughts when they come to mind.

There are six types of activity which specifically foster this type of meditative relaxation:

- meditation
- autogenic training
- pre-suggestion hypnosis
- prayer (repetitive or liturgical)
- yoga exercises
- t'ai chi chu'an.

For many people, these techniques produce a sense of well-being as well as an increase in concentration and energy. They also produce the following physiological changes (Everly & Benson 1989):

- decreased oxygen consumption and carbon dioxide elimination with no change in the respiratory quotient
- reduced heart and respiratory rates and lowered blood level of lactate
- reduced blood pressure.

Everly and Benson (1989) argue that, during relaxation, there are physiological alterations consistent with a decrease in central and peripheral adrenergic excitation, and that people who undertake regular meditative relaxation (see

Box 17.10) recover faster from stressful events than those who do not relax in this way.

For further information, see Fontana (2002).

CONCLUSION

Stress is not in itself a pathological or abnormal phenomenon. Indeed, it is hard to imagine how any individual might go through life without being faced with stressful situations. For some individuals, stress can, to a significant degree, be treated as a challenge and as a spur to personal growth and maturation. Why it is that certain people seem better able than others to withstand stressful conditions has been the subject of a great deal of debate as researchers have attempted to identify the physiological, psychological and social factors that mediate the experience of stress.

The fact that the word 'stress' is used freely in daily conversation without invoking the negative connotations of 'mental illness' perhaps indicates how the potentially grave effects of stress can be underestimated or obscured. As this chapter has shown, stress can be closely associated with serious physical, emotional or psychiatric illness, including heart disease and depression. Stress can also give rise to detrimental coping behaviours such as drug, alcohol and other forms of substance abuse (see Ch. 36). For this reason it is vital that stress is taken seriously by health professionals and that its mechanisms and effects are clearly understood.

From the nurse's perspective, perhaps the most important aspect of the experience of stress is its uniqueness for each individual. The experience of stress, like the experience of pain, must be assessed in each patient, and approaches to stress management must be congruent with the individual's personality, experiences and values. It is hoped that this chapter has assisted the nurse in formulating a practical understanding of stress and its effects, and will enable a positive contribution to be made to the treatment and management of stress and stress-related disorders in their patients. It is also hoped that the reader will be able to meet with greater confidence the challenge of recognising and coming to terms with the effects of stress in their own professional and personal life.

Box 17.10

Guidelines for meditative relaxation

Setting the scene

- Find a quiet, warm, comfortable room where you are unlikely to be disturbed (try to exclude children, pets, ticking clocks or telephones).
- Meditate sitting upright and well supported in a comfortable chair. Rest the feet flat on the floor and the hands loosely in your lap.
- Have a watch or clock in clear view. The session lasts 20 minutes. If you feel that you are likely to fall asleep, set an alarm.
- Loosen any tight clothing; slip off your shoes if this makes you more comfortable.
- Meditate whilst neither too hungry nor too full.
- Try to meditate twice each day for 20 minutes. Because you may feel deeply relaxed, it is better not to meditate close to bedtime, as this might interfere with your sleep patterns

The process

- During the process of meditation you will remain completely conscious.
- You may prefer to meditate with your eyes closed. Begin the process by taking one or two deep, relaxing breaths.
- Gently begin to count, either on each inhalation or exhalation, with the number one, then two, then three ... Every time you become aware of a thought, any thought, calmly return to number one. It is unlikely, though, that after a number of years of regular meditating you will go beyond the number one; indeed, the principle of this sort of meditation is not one of mastery, but of the gentle pushing aside of thoughts to enable the body and the mind to achieve complete rest.
- You may find that you have spent the whole session thinking over a problem. If so, do not worry; before you finish the session gently return to the counting, for 1 or 2 minutes.
- If you find that you have fallen asleep, do not worry about this. It may be that you are very tired and your body needs sleep. Before finishing the relaxation, gently return to the counting for 1 or 2 minutes. If you find that during the meditation, you have solved a major problem, written a poem or worked out a solution, before finishing the session, gently return to your counting.
- At the end of the session, before moving, stretch gently and sit with the eyes closed for a few moments.

INTRODUCTION

Despite advances in diagnosis, treatment and management, shock remains one of the leading causes of death in the critically ill patient. It is important that nurses from all areas of clinical practice have the knowledge required to identify patients at risk and ensure timely and appropriate intervention is carried out.

The aim of this chapter is to facilitate the understanding of the pathophysiology of shock and the nursing care required.

In any environment, awareness of the predisposing factors which may lead to shock, early detection and prompt action are vital for a good prognosis. Caring for patients who are suffering from shock requires not only an understanding of the pathophysiology of shock and the principles of its treatment and management, but also an awareness of the devastating psychological and social impact such a sudden change from health to illness can have on patients and their families.

THE PATHOPHYSIOLOGY OF SHOCK

Circulatory homeostasis exists when the circulating blood volume and the vascular tone of blood vessels are in dynamic equilibrium. Shock is a state in which tissue perfusion is inadequate to maintain the supply of oxygen and nutrients necessary for normal cellular function and disequilibrium ensues. The cells may also be unable to extract and utilise normally the reduced supply of substrates and oxygen which is delivered.

Shock is categorised according to the underlying cause (Haslett et al 2002), namely:

- Hypovolaemic — due to reduction of blood volume
- Cardiogenic — due to myocardial dysfunction
- Obstructive — due to obstruction to blood flow in the circulation
- Distributive — due to altered vascular resistance. This category includes septic shock, neurogenic shock, spinal shock and anaphylactic shock.

The stages of shock

Before considering specific types of shock it is necessary to understand the basic pathophysiological processes which produce the clinical picture typically observed in shock. These processes can be divided into four stages (Hand 2001):

1. *Initial stage* — there are no signs and symptoms but cellular changes begin to occur in response to a disturbance in cell perfusion and oxygenation. This disturbance progresses to a change from aerobic to anaerobic cellular metabolism, in which production of lactic acid and pyruvic acid leads to metabolic acidosis.

2. *Compensatory stage* — physiological adaptations occur in an attempt to overcome the original problem, e.g. hypovolaemia.
3. *Progressive stage* — compensatory mechanisms begin to fail and produce adverse effects.
4. *Refractory stage* — pathophysiological processes set in motion cannot be arrested or reversed. Death is imminent.

It is important to understand that the stages of shock comprise continuous and complex processes and that there is usually no sudden transition from one stage to the next.

The compensatory stage

When circulation becomes inadequate due to reduction of circulating fluid, pump failure or massive vasodilatation, various mechanisms are activated in response to hypotension, hypoxaemia or acidosis, or a combination of these. These mechanisms are neural, hormonal and chemical, but since the body functions as a whole system they are closely interlinked.

Neural mechanisms Hypotension leads to decreased stimulation of the aortic and carotid sinus baroreceptors, which in turn reduces impulses to the vasomotor centre and thus reduces inhibition of the vasoconstrictor centre. This stimulates the sympathetic nervous system, resulting in the activation of the stress response. This response includes the discharge of the catecholamines, namely adrenaline and noradrenaline, resulting in vasoconstriction in the skin, kidneys, gastrointestinal tract and other organs while blood supply to the heart and brain is preserved. Vasoconstriction and increased heart rate may initially restore the arterial blood pressure to normal, but peripheral resistance will be raised, making the myocardium work harder to maintain cardiac output. Urinary output and peristalsis will decrease, and the individual's skin will become pale and cool. Sympathetic nervous system stimula-tion will also result in increased respiratory rate and depth, dilated pupils and increased sweat gland activity, causing the 'clammy' skin typically found in all forms of shock, other than early septic shock.

Hormonal mechanisms Adrenaline secreted by the adrenal medulla stimulates the anterior pituitary gland to release adrenocorticotrophic hormone (ACTH), which causes the adrenal cortex to release glucocorticoids such as hydrocortisone and mineralocorticoids such as aldosterone.

Glucocorticoids raise blood sugar by increasing gluconeogenesis and thereby the availability of glucose for energy. In addition, the glucocorticoids mobilise amino acids from the tissues and decrease protein synthesis. They also reduce glucose uptake by the cells and mobilise fatty acids from the adipose tissue into the plasma. Cortisol shifts cell metabolism from glucose to fatty acids for energy, enhancing fatty acid oxidation, and also reduces tissue destruction by stabilising lysosomal membranes (Guyton & Hall 2000).

Aldosterone decreases excretion by increased reabsorption of sodium and chloride by the kidney, and increases excretion of potassium and hydrogen ions. Thus metabolic acidosis and hypokalaemia can occur. The high serum osmolality resulting from a high concentration of sodium chloride stimulates the hypothalamic osmoreceptors to release antidiuretic hormone (ADH) from the posterior pituitary gland.

ADH stimulates an increase in renal water reabsorption, in an attempt to restore normal serum osmolality and thus increase circulating fluid and blood pressure.

Noradrenaline secretion by the adrenal medulla results in renal artery vasoconstriction, which in turn stimulates secretion of renin by the kidney. In the circulation, renin reacts with angiotensinogen, producing angiotensin I. This is converted by an enzyme in the lungs to angiotensin II, which causes venous constriction and increases aldosterone release, thus leading to increased fluid and sodium retention, increased blood volume and therefore increased venous return, blood pressure and renal perfusion.

Thyroxine secreted by the thyroid gland sensitises the beta-receptors in the heart to noradrenaline and so increases heart rate, systolic pressure, stroke volume and cardiac output.

Chemical mechanisms Poor lung perfusion leads to ventilation–perfusion mismatch and decreased oxygen tension in the circulating blood. This is detected by chemoreceptors in the aorta and carotid bodies. The carbon dioxide concentration falls as the respiratory rate increases and the amount of carbon dioxide is 'blown off', thus producing a respiratory alkalosis. Cerebral blood vessels constrict in response to decreased carbon dioxide tension leading to cerebral hypoxia. Subsequently, the acid–base balance is further complicated by a metabolic acidosis resulting from the anaerobic metabolism of glucose to lactic acid.

These mechanisms may initially combine to compensate for the initial problem, but unless the latter is promptly and successfully overcome, more clinical signs will become evident. The typical clinical picture at this stage of shock is of a patient with cool, pale, clammy skin, decreased urinary output, increased heart rate and decreased bowel sounds. The patient may be anxious, restless or confused due to the cerebral effects of hypoxia, hypocapnia and sympathetic nervous system stimulation.

Anxiety will intensify the physiological responses to stress and thus it is very important for the nurse to provide much needed reassurance to both the patient and any relatives during a major life crisis.

The progressive stage

Although the compensatory mechanisms may at first appear to reverse the effects of shock, if the cause is not treated appropriately then the next stage of shock becomes evident.

With decreased perfusion, the supply of oxygen and nutrients to the cells will be inadequate to produce sufficient adenosine triphosphate (ATP) (see Fig. 18.1). The sodium pump will fail and sodium will increase inside the cells while potassium leaks out (see Fig. 18.2). This can result in hyperkalaemia, which may in turn cause cardiac arrest. The anaerobic metabolism which results from an inadequate oxygen supply will increase the production of lactic acid, resulting in a metabolic acidosis.

The consequences of the increasing acidosis and hypoxia are that the precapillary sphincters become fatigued, causing collapse of the microcirculation and increasing hydrostatic

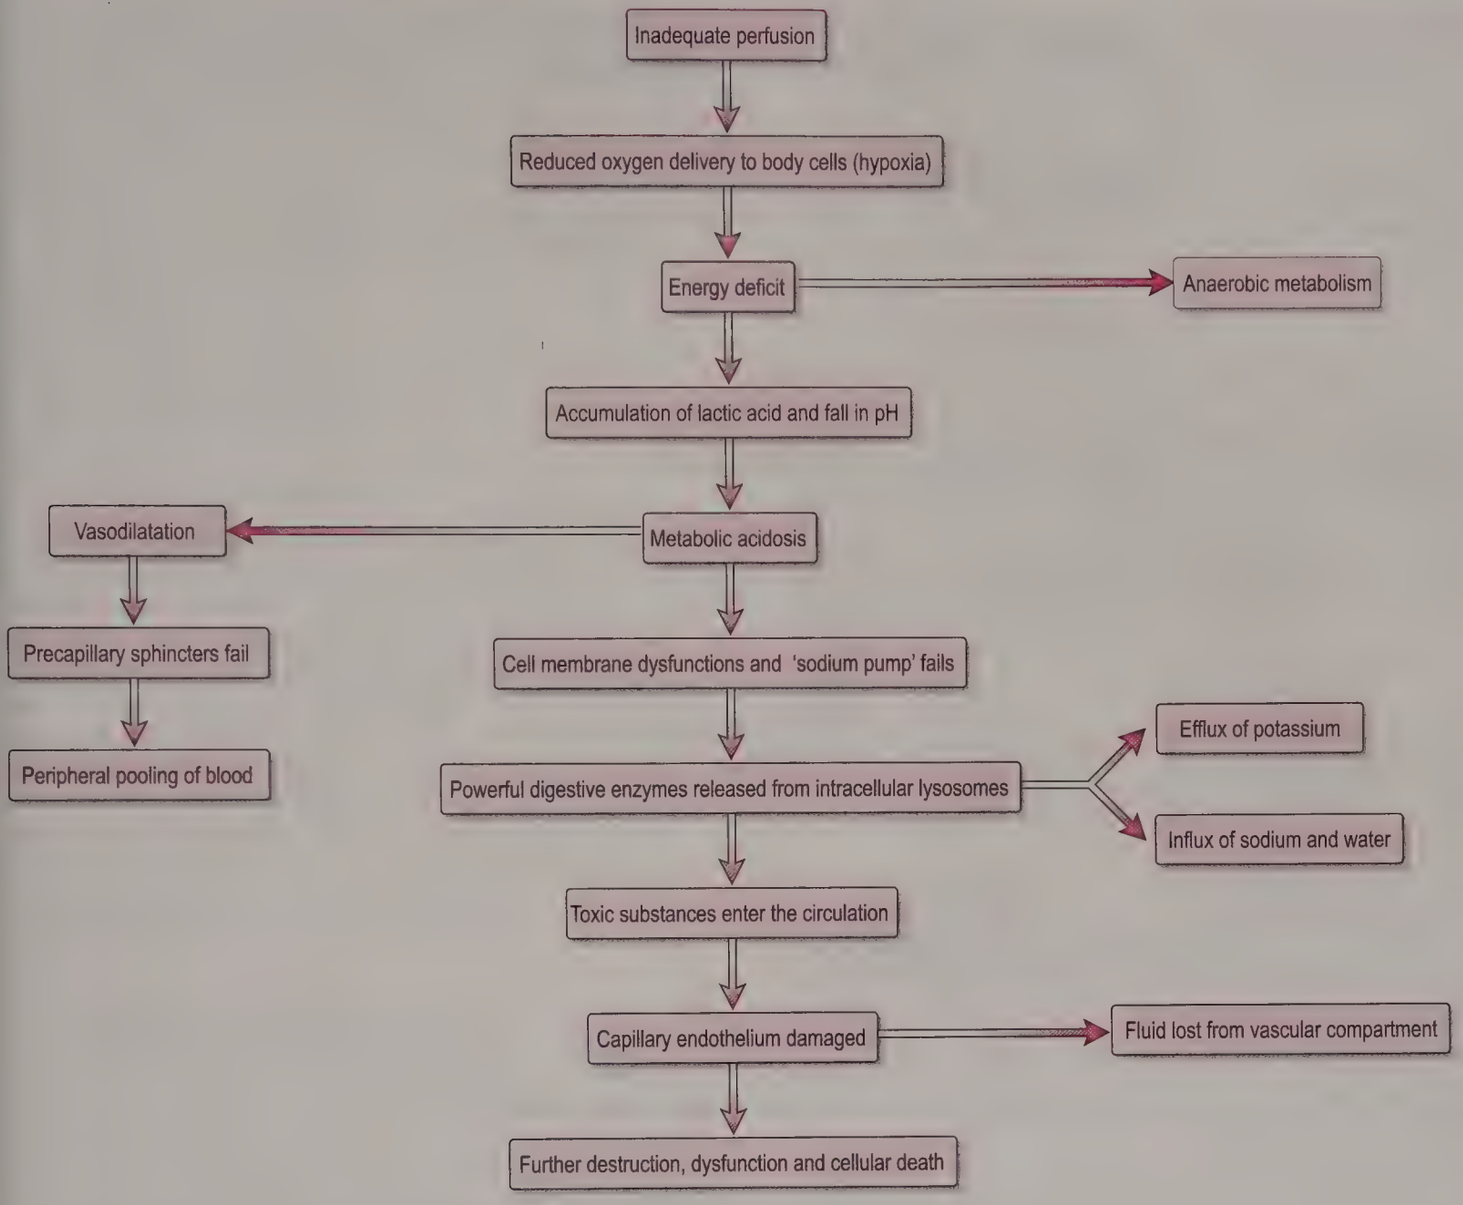

Fig. 18.1 Effects of inadequate perfusion on cell function.

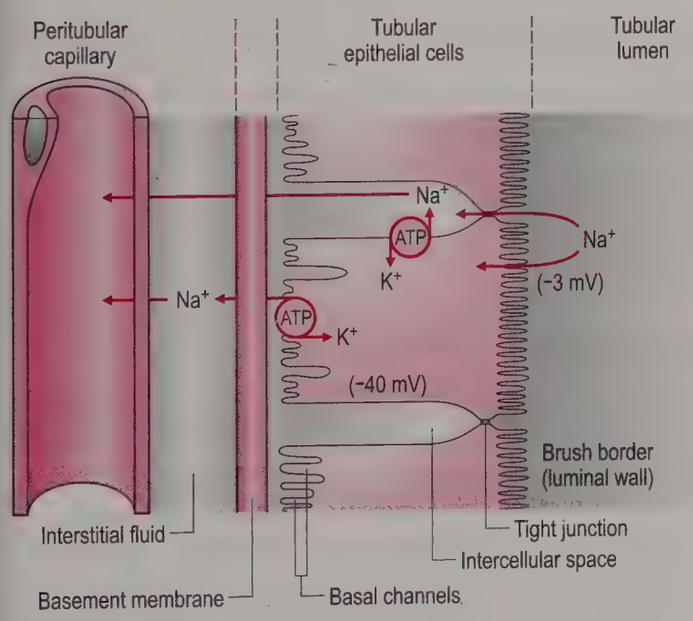

Fig. 18.2 The sodium–potassium pump. (Reproduced with permission from Guyton & Hall 2000.)

pressure and capillary leakage. Haemoconcentration and viscosity will increase. Sludging in the microcirculation may lead to disseminated intravascular coagulation (DIC; see p. 732), one of the complications of shock. Figure 18.3 illustrates the vicious cycle of shock.

Prolonged vasoconstriction and its impact on cell function will soon compromise the functioning of the vital organs, as follows:

- The kidneys will be unable to filter, reabsorb and excrete fluid normally. Urinary osmolality will fall, and output will be reduced to below 20 mL/h. Acute tubular necrosis may occur, causing a marked rise in blood urea and creatinine.
- Pancreatic cells will release the enzymes amylase and lipase into the circulation, contributing to the formation of myocardial depressant factor (MDF), which decreases myocardial contractility.
- The lungs will become less compliant as fluid and plasma proteins leak into the alveoli, altering osmotic pressure and leading to pulmonary oedema. This in turn reduces gaseous exchange and may result in adult

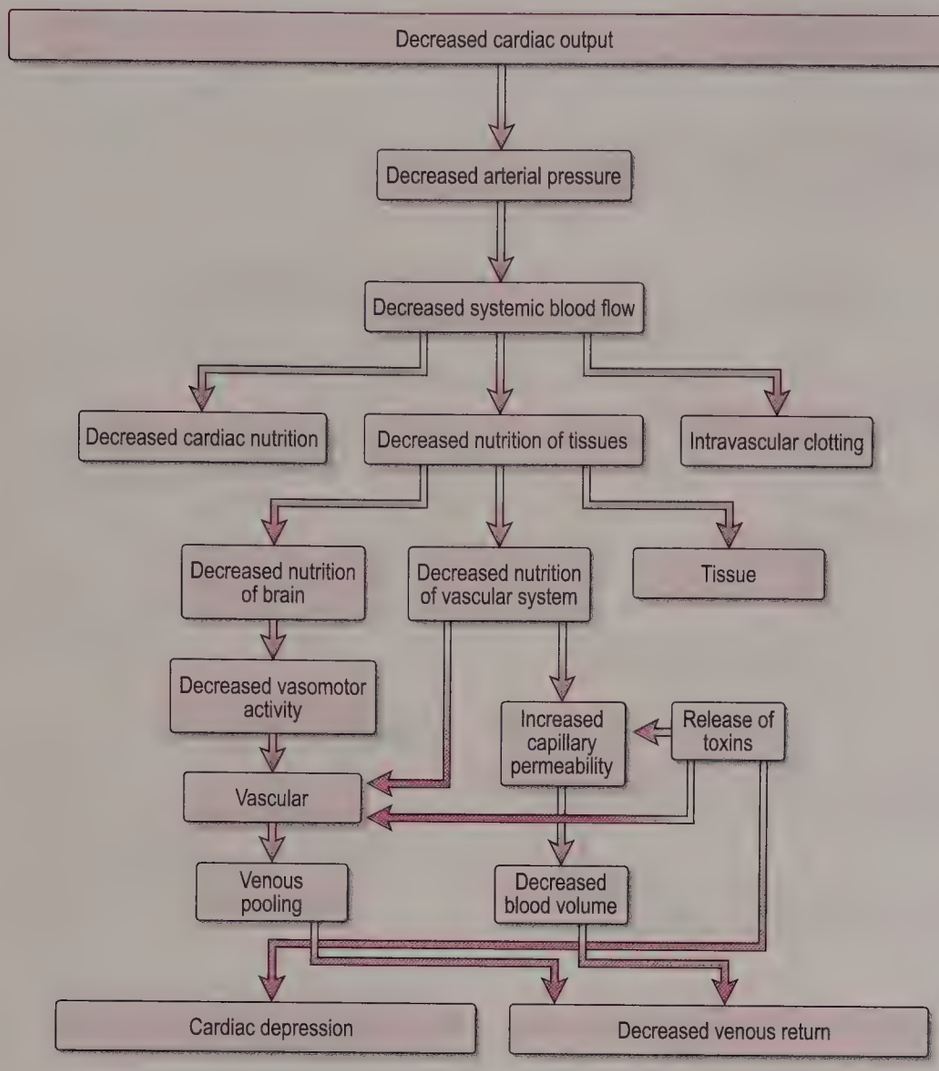

Fig. 18.3 The vicious cycle of shock. (Reproduced with permission from Guyton & Hall 2000.)

respiratory distress syndrome (ARDS; see p. 732). Hydrostatic or cardiac pulmonary oedema may occur as the heart fails. All of these changes will increase hypoxia and acidosis.

- The heart will eventually fail as coronary perfusion and oxygen supply become inadequate to meet the demands of the myocardium, which will be working hard to maintain blood flow by pumping rapidly against high resistance and disadvantaged by the effect of MDF.
- Ischaemic damage to the intestinal mucosa will result in the release of bacteria and toxins from the gut into the circulation.
- Alteration in cerebral function may have a number of effects, ranging from a dulling of responses to major behavioural changes.

The refractory stage

Continuing circulatory collapse, increasing acidosis, sludging of red cells and platelets due to decreased intravascular volume will all contribute to decreasing perfusion of tissues. Massive bleeding due to DIC may also exacerbate this effect. Inadequate ventilation will lead to increasingly inadequate oxygenation. Renal failure will contribute to increasing metabolic abnormalities, and vital centres in the brain will eventually cease to function due to ischaemia and hypoxia. If the refractory stage is reached, the shock is irreversible and death will occur.

TYPES OF SHOCK

Specific aspects of the pathophysiological processes of shock will be evident depending on the type of shock which is occurring. The following sections will describe the distinguishing features of hypovolaemic shock, cardiogenic shock, obstructive shock and the different forms of distributive shock.

Hypovolaemic shock

This is the most common type of shock. Its primary cause is loss of fluid from the circulation, which may be described as:

- *external fluid loss* — due to superficial bleeding, vomiting, diarrhoea, overuse of diuretics or burns
- *internal fluid loss* — due to internal bleeding such as haemothorax or bleeding into tissues at fracture sites after injuries, paralytic ileus, intestinal obstruction or acute dilatation of the stomach.

While internal conditions may not be an obvious cause of fluid loss, their effect can be very serious. For example, 1 L — around 20% of the blood volume of an average man — or more of fluid may be sequestered in the gastrointestinal tract during paralytic ileus and/or acute dilatation of the stomach, and the same volume or more of blood may escape into the tissues and/or thorax as a result of multiple injuries.

The physiological implications of hypovolaemia are:

- reduced blood volume
  ↓
- decreased venous return
  ↓
- decreased cardiac output
  ↓
- reduced tissue perfusion.

In early hypovolaemic shock, the compensatory mechanisms described (see p. 725) are activated when the blood pressure starts to fall. These mechanisms will compensate for up to 10% reduction of the circulating volume of a healthy person without the development of marked symptoms. However, if a greater volume of fluid is lost and is not replaced quickly, the compensatory mechanisms may fail quite suddenly, in which case the patient's condition will deteriorate rapidly. It should be recognised that, in older people, the cardiovascular system is often less able to cope with haemodynamic changes, and the heart may be less able to pump faster and harder in order to maintain cardiac output against high peripheral resistance.

Recognising hypovolaemic shock

The following signs and symptoms of hypovolaemic shock are reliable only if they are considered in relation to one another and the patient's previous, stable, condition. Nevertheless, whenever several of these indicators occur together, the possibility of shock should be considered, as a successful outcome depends upon early intervention. The nurse should therefore be alert to the following:

- rapid and deep respirations in response to sympathetic nervous system stimulation, hypoxia and acidosis
- a rapid, weak, thready pulse, due to low blood flow despite a rapid heart rate
- narrowing of the pulse pressure, i.e. a reduced difference between systolic and diastolic pressures due to decreased stroke volume and increased peripheral resistance indicating vasoconstriction of the skin and viscera, reflecting decreased blood flow (Guyton & Hall 2000)
- anxiety, restlessness and confusion, which may indicate decreased cerebral perfusion and oxygenation
- cool, clammy skin and cold peripheries due to vasoconstriction and sympathetic stimulation of sweat glands
- decreased urinary output, due to renal artery vasoconstriction and endocrine compensatory mechanisms
- lowered body temperature, which may be related to altered metabolism, perfusion and oxygenation and, possibly, heat loss from evaporation of sweat from the skin
- thirst and a dry mouth related to fluid depletion and possibly to sympathetic nervous system stimulation
- fatigue, probably related to inadequate perfusion and oxygenation of the tissues and vital organs.

As stated earlier, it is relatively easy to diagnose hypovolaemic shock when a patient is bleeding externally. Diagnosis is more difficult when hypovolaemia is developing as a consequence of an internal crisis. Nurses must be alert to recognise the above signs and context of the crisis and to ensure that prompt action is taken and/or help is sought.

Cardiogenic shock

The clinical definition of cardiogenic shock is hypotension with evidence of impaired perfusion, in the setting of acute myocardial infarction. A variety of other causes, such as myocardial contusion, myocarditis and cardiomyopathy can produce cardiogenic shock, but the majority of cases result from atherosclerosis and resulting myocardial necrosis (Tiffany & Jorden 2001).

18.1 Refresh your knowledge of cardiac function by reviewing Chapter 2.

18.2 Review the terms listed in Box 18.1 to ensure that you understand how they would be applied in the course of treatment and monitoring for cardiogenic shock.

Ischaemic muscle is deprived of adequate oxygen and substrates for effective contraction, and infarcted muscle or scar tissue is unable to contract. When more than approximately 40% of the left ventricle is infarcted the ability to maintain the systemic circulation is significantly impaired.

The compensatory mechanisms that normally act to prevent hypotension can worsen the situation. The catecholamine release produces tachycardia, vasoconstriction and increased cardiac contractility, all of which increases the workload of the left ventricle and increased myocardial oxygen demand, potentially causing extension of the infarct and further compromising left ventricle function (Jowett & Thompson 2002).

In addition, since the left ventricle is not being emptied effectively, pressure will rise in the left atrium, the pulmonary circulation and the right side of the heart. As the pressure rises, pulmonary oedema will eventually ensue, reducing oxygenation. Thus, not only will the tissues be poorly perfused, but also the blood which does reach the tissues will carry less oxygen. As shock progresses, without effective intervention the vicious circle of effects shown in Figure 18.3 will occur.

Signs of cardiogenic shock

The signs of cardiogenic shock include:

- systolic pressure <80 mmHg
- tachycardia and a weak, thready pulse
- cold, clammy skin
- oliguria — urine output <20 mL/h
- confusion
- mottling of the extremities, particularly the legs
- if measured, pulmonary artery wedge pressure is >18 mmHg, cardiac index is <1.8 L/min per m^2 (see Box 18.1).

Box 18.1

Key terms relating to cardiac status

Cardiac output
This is the product of the heart rate multiplied by the stroke volume and represents the amount of blood ejected from the heart each minute. In the adult, cardiac output is normally 5–8 L/min.

Cardiac index
This is the patient's cardiac output divided by the body surface area. It indicates how many litres per min per square metre of body surface the heart ejects. The normal range for an adult is 2.7–4.3 L/min per m^2.

Stroke volume
This is the amount of blood delivered to the aorta during a left ventricular contraction (normally 80–120 mL in an adult). Three factors influence stroke volume: preload, afterload and contractility.

Preload
Indicators are central venous pressure (CVP) and pulmonary artery wedge pressure (PAWP). By means of a CVP transducer, right atrial pressure can be measured. CVP reflects the pressure in the right atrium and systemic veins but does not reliably reflect left ventricular pressures. PAWP gives an indication of the compliance of the left ventricular myocardium during diastole and the left atrial filling pressure necessary to fill the left ventricle with blood prior to systole.

Afterload
This is the resistance to systolic ejection of blood from the ventricle and can be assessed by measuring pulmonary vascular resistance and systemic vascular resistance. The pulmonary vascular resistance is the ratio of the pressure drop across the pulmonary vascular system to the total flow passing through the pulmonary circulation. Systemic or peripheral vascular resistance is a measurement of the vascular resistance to blood flow.

Contractility
This refers to the ability of the myocardium to contract effectively and act as a pump to maintain the circulation of blood.

Tiffany and Jorden (2001) state that signs and symptoms can vary from patient to patient and can also rapidly deteriorate in any given patient. Therefore close observation and assessment are required by the health care team.

Obstructive shock

This type of shock is caused by obstruction to blood flow in the circulation (Haslett et al 2002). Examples of obstructive shock include pulmonary embolism, cardiac tamponade or tension pneumothorax. Clinical signs of shock are similar to hypovolaemic and cardiogenic shock, producing cold peripheries, weak central pulses and low cardiac output.

Distributive shock

Distributive shock can be divided into three different types: septic, neurogenic and anaphylactic. All are characterised by a loss of blood vessel tone, enlargement of the vascular component and displacement of the vascular volume away from the heart (Hand 2001). Although the blood volume remains the same, due to vasodilatation the vascular compartment has expanded, resulting in a reduction in cardiac output. This is described by Dipenbrock (1999) as the 'tank being too large'.

Septic shock

Septic shock is a medical emergency and is the most common type of shock that develops as a result of widespread infection (Smelzer & Bone 2000). Full assessment of the patient may need to wait until resuscitation and antimicrobial drugs have commenced (Green & Lynn 2000).

Sepsis and septic shock encompass a spectrum of clinical conditions caused by the systemic response to infection (see Box 18.2). Patients with sepsis usually present with a localised infection, which progresses into an uncontrolled systemic reaction. Patients can then develop acute organ failure at locations distant from the initial infective site, ultimately leading to death. The incidence of sepsis is thought to be rising (Bone et al 1997). Factors that can contribute to this include:

- an increased use of invasive surgery
- an increased incidence of bacterial resistance
- a greater number of immunocompromised patients.

Box 18.2

Working definitions for conditions related to sepsis

- *Infection* — invasion of microorganisms into a normally sterile site, often associated with an inflammatory host response
- *Bacteraemia* — viable bacteria in bloodstream
- *Septicaemia* — no uniform definition, often interpreted as bacteraemia plus severe illness
- *Sepsis* — clinical evidence of infection plus systemic response indicated by two or more of:
  - — hyper- or hypothermia: core temperature >38°C or <36°C
  - — tachycardia: heart rate >90 bpm
  - — tachypnoea: respiratory rate >20 resps/min
  - — white blood count $>12 \times 10^9$
- *Severe sepsis* — sepsis associated with organ dysfunction:
  - — hypotension
  - — oliguria
  - — hypoxia
  - — confusion
  - — metabolic acidosis
  - — disseminated intravascular coagulation
- *Septic shock* — severe sepsis with hypotension unresponsive to intravascular volume replacement
- *Refractory shock* — hypotension not responding to vasoactive agents
- *Systemic inflammatory response syndrome (SIRS)* — similar physiological response to sepsis but unrelated to infection. May be caused by a variety of acute insults, e.g. pancreatitis

Adapted from Bone et al (1992).

Septic shock is commonly seen as a complication of bacterial infection and is characterised by a wide range of metabolic and haemodynamic abnormalities (Bone et al 1992).

Bacteraemia Bacteraemia is a serious condition with potentially fatal consequences. Recognition and prompt use of empiric antibiotic therapy will reduce the risk of severe sepsis and may be life saving (Green & Lynn 2000). Septic shock may be caused by any invading microorganism. However, this condition is commonly associated with Gram-negative bacteria such as *Escherichia coli*, *Meningococcus*, *Klebsiella*, *Pseudomonas*, *Bacteroides* and *Proteus*.

For further reading, see British Infection Society (2003).

Gram-negative bacteria contain a lipopolysaccharide in their cell walls called endotoxin. When released into the bloodstream, endotoxin produces a variety of adverse biochemical changes and activates immune and other biological mediators that contribute to the development of septic shock (Hudak & Gallo 1998).

Gram-positive organisms such as *Staphylococcus*, *Streptococcus* and *Pneumococcus* are also implicated in the development of sepsis. Necrotising fasciitis is a soft tissue infection often caused by two or more bacteria, most commonly Group A streptococcus bacteria.

For further reading, see Gully (2002).

Phases of septic shock The clinical effects of septic shock occur in two distinct phases: the warm hyperdynamic stage and the cold hypodynamic stage (Hudak & Gallo 1998).

The hyperdynamic phase This first stage is characterised by:

- high cardiac output
- low systemic vascular resistance
- vasodilatation
- volume depletion and hypotension
- fever and chills
- low urine output
- tachycardia
- tachypnoea
- restlessness, agitation and confusion.

Unlike the other types of shock, which are characterised by a compensatory increase in systemic vascular resistance, septic shock often presents with a relative hypovolaemia due to massive vasodilatation and leakage of fluid into the interstitial space (Hand 2001).

The hypodynamic phase Following the hyperdynamic phase, the hypodynamic stage occurs. This is characterised by:

- high systemic vascular resistance
- vasoconstriction
- hypotension
- hypoperfusion
- cold, clammy skin
- subnormal or elevated temperature
- depressed conscious level.

At this stage, clinical findings begin to resemble more closely those typically associated with shock. Catecholamine release results in vasoconstriction and the patient's skin becomes cold, moist and possibly mottled at the peripheries. The pulse becomes rapid, thready and weak, and ECG changes suggest an inadequate coronary blood flow. Patients who reach this clinical state are particularly at risk of developing multisystem failure.

During this phase it is common for haematological problems to become evident. The released endotoxins damage the endothelium and cause adhesion of platelets and subsequent destruction of the microcirculation. These effects, together with the activation of the coagulation and fibrinolytic systems, may give rise to DIC (see p. 732). Hyperventilation persists but fails to overcome hypoxia. Lactic acid builds up and there is increasing metabolic acidosis, further compromising cell function.

All the body systems will become affected. As blood flow to the brain is reduced, conscious level falls and the patient is unable to respond to verbal stimuli. In the gastrointestinal tract, ischaemia may cause stress ulceration, leading to potential bleeding. The liver loses its ability to remove bilirubin, resulting in jaundice (Hand 2001) (see Case History 18.1 and Nursing Care Plan 18.1).

18.3 Which stage of shock do the clinical findings in Case History 18.1 represent: hyperdynamic or hypodynamic?

Neurogenic shock

This type of distributive shock is associated with the central nervous system. It can occur when a disease process, drug or traumatic injury blocks sympathetic nerve impulses from the brain's vasomotor centre and thus increases parasympathetic activity. Neurogenic shock produces a picture of vasodilatation with loss of vascular tone. Venous return is reduced, cardiac output falls and hypotension rapidly follows.

There are a number of preconditions which may, over the course of several hours, or even a few weeks or months,

CASE HISTORY 18.1

Mr R (see also Nursing Care Plan 18.1)

Mr R, a 50-year-old bank manager, was admitted to the surgical unit for a hemicolectomy for diverticular disease. The surgery went according to plan and Mr R appeared to be progressing well. On the fifth postoperative day, however, the staff nurse noticed that he looked ill, and Mr R admitted that he was 'not so well today'.

Physical findings included:

- tachycardia
- tachypnoea
- warm, pink skin
- restlessness
- pyrexia
- polyuria.

The doctor concluded that Mr R was in the early stages of septic shock. Nursing staff then implemented the interventions summarised in Nursing Care Plan 18.1.

Nursing Care Plan 18.1 Mr R — care of a patient with septic shock (see Case History 18.1)

Nursing considerations	Goal	Action	Rationale
1. Potential risk of fluid volume depletion due to peripheral vasodilatation and capillary leakage	To restore and maintain circulating blood volume	• Assess vital signs, skin colour and capillary refill time	Depending on the shock phase, Mr R may present with an increased cardiac output, which causes a flushed, pink appearance. As the hypodynamic phase develops, the cardinal signs of shock become evident (see p. 719)
		• Ensure i.v. access with a minimum of two large-bore catheters	Fluid volume loss due to redistribution requires blood, colloid and crystalloid replacement
		• Monitor and record vital signs and core body temperature	Alterations in vital signs determine stability, improvement or deterioration and indicate whether changes need to be made to therapy
		• Insert a urinary catheter	Renal function is a good indicator of overall tissue perfusion. A urine output of 0.5–1.0 mL/kg per h is desirable. In the early stages of septic shock, an inappropriately large volume of urine may be passed due to renal vasodilatation caused by bacterial toxins. In such circumstances, urine output can be more than 100 mL/h
		• Assist with the insertion of a pulmonary artery catheter	Ideally the left ventricular function should be monitored by means of a PA catheter. If this is not possible then a central line will monitor the CVP and serve as a guide to fluid replacement
		• Administer and evaluate the effectiveness of inotropic agents: – dobutamine – dopamine – dopexamine	Inotropic agents increase cardiac output and therefore improve renal, coronary, mesenteric and cerebral blood flow
2. Potential for impaired gas exchange due to interstitial fluid overload	Restore and maintain optimal pulmonary function	• Assess Mr R's respiratory status, rate and rhythm: – Is he distressed? – Does he have any bronchospasm? – Monitor arterial blood gases – Monitor O_2 saturation via pulse oximetry	Escalating demands on the cardiovascular system increase oxygen consumption. In the early hyperdynamic stage, the ABGs may be relatively normal and it is not until the hypodynamic stage that they reflect hypoxia or metabolic acidosis
		• Encourage Mr R's cooperation in optimising respiratory function by means of: – breathing exercises – chest physiotherapy – incentive spirometry (see Ch. 3) – progressive O_2 therapy	Mr R may eventually need intubation and ventilation to maintain acceptable ABGs. To try to avoid this the nurse can employ these interventions

Nursing Care Plan 18.1 Mr R — care of a patient with septic shock (see Case History 18.1) *(Continued)*

Nursing considerations	Goal	Action	Rationale
2. Potential for impaired gas exchange due to interstitial fluid overload *(Continued)*		• Administer bronchodilators as prescribed by the physician	Bronchodilators cause airway dilatation by acting directly on β_2 receptors
3. Potential for further systemic infection	Reduce or eliminate the systemic risk of further infection	• Administer appropriate antibiotic therapy via i.v. route	Antibiotics are given i.v. to ensure a high level of the drug in the blood, body cavity fluids and tissues
		• Minimise the introduction of further infection by: – careful and frequent hand washing – maintaining aseptic techniques for all invasive procedures	Shock states alter the immune response and these patients are even more susceptible to infection. The increased use of invasive monitoring techniques offers more opportunities for invading pathogens
		• Perform frequent bacteriological screening	The use of antibiotic 'cocktails' to treat one organism may allow others to proliferate

lead to the development of neurogenic shock. One of the most common causes is spinal anaesthesia, especially that which extends up the length of the spinal cord and results in a blockage of sympathetic impulses. Cerebral trauma such as contusions or concussion, particularly to the brain stem or medulla oblongata, may also produce severe neurogenic shock. Another potential cause is spinal cord trauma in which all reflex activity below the level of the lesion is lost.

Spinal shock

Trauma to the head, neck, back or shoulders resulting from an accident may cause injury to the vertebral column and/or spinal cord. Spinal injuries are most prevalent among young men who have been previously healthy and for whom the injury is a catastrophic event necessitating major changes in lifestyle.

The degree and type of force exerted on the spine at the time of injury will determine the nature and severity of the injury. The most frequently seen and, unfortunately, the most damaging type of spinal injury as a result of a road traffic accident is a sudden hyperflexion and rotation with fracture–dislocation of the vertebral column at C5 and C6, and T12 to L1. Within 30–60 min of the trauma, autonomic and motor reflexes below the level of the injury are suppressed. This state is known as spinal shock and it may last hours or even weeks.

For further reading on spinal shock, see Fahey (2001).

Anaphylactic shock

If it is not dealt with immediately, this type of shock is life threatening. It arises when the individual develops a hypersensitivity response to an antigen, drug or foreign protein in which the release of histamine causes widespread vasodilatation resulting in hypotension and increased capillary permeability with loss of fluid into the interstitium.

The main causes of systemic anaphylaxis are insect bites and stings, particularly from bees and wasps, drugs, notably penicillin, and food such as peanuts, eggs or shellfish. Occasionally, diagnostic contrast media, e.g. iodine based, may also precipitate anaphylactic reactions.

18.4 What precautions might be observed before a patient undergoes a diagnostic test involving a contrast medium?

The individual developing anaphylactic shock presents with a combination of the following symptoms:

- laryngeal stridor, dyspnoea, cough and, occasionally, cyanosis
- local oedema, particularly around the face
- a weak and rapid pulse
- skin eruptions, large weals.

Treatment will be needed urgently because of the respiratory problems caused by local tissue swelling, laryngeal oedema and/or bronchospasm in addition to circulatory insufficiency (see Ch. 16, p. 682).

Box 18.3 provides a summary of interventions used in the treatment of shock.

FIRST AID TREATMENT FOR SHOCK

Nurses may be called upon occasionally to help people on the street or in other public places who have gone into

Box 18.3

Definitive and supportive therapy in clinical shock

Definitive therapy

Hypovolaemic shock
- Maintain or increase intravascular volume
- Decrease any future fluid/blood loss via i.v. fluid regimen
- Give supplementary O_2 therapy

Cardiogenic shock
- Reduce cardiac muscle damage by O_2 supply and reduce cardiac demand by O_2 therapy and cardiac medication to dilate the coronary vessels and by decreasing pain and activity
- Increase effectiveness of heart as a pump via inotropic medication

Septic shock
- Restore adequate intravascular volume via i.v. fluids
- Give supplemental O_2 therapy
- Identify and control source of infection via bacterial screening
- Administer appropriate antibiotics
- Remove nidus of infection if possible

Anaphylactic shock
- Identify and remove causative antigen
- Reduce effects of mediator substances that have caused massive vasodilatation, e.g. give adrenaline to restore vascular tone, antihistamines to reverse histamine effects, bronchodilators to oppose bronchial constriction
- Give O_2 therapy and i.v. fluid replacement

Supportive therapy
- Give adequate ventilation and oxygenation via optimal airway maintenance, optimal breathing technique and supplemental O_2
- Maintain or restore adequate perfusion of tissues to ensure oxygen delivery, via maintenance of cardiac pump to effectively circulate the blood and medication to improve contractility and reduce cardiac workload
- Maintain or restore metabolic equilibrium
- Reverse metabolic acidosis via hyperventilation and, if severe, by i.v. sodium bicarbonate administration

Adapted from Rice (1991).

shock as the result of an accident, heart attack or severe allergic reaction, and so should be aware of the appropriate first aid to give in the absence of clinical facilities.

The main objectives of intervention in such an emergency should follow the chain of survival used in basic life support (Colquhoun et al 2003):

- Maintain an adequate supply of blood to the heart, lungs and brain
- Limit haemorrhaging and prevent further injury
- Ascertain the cause of the shock
- Arrange for transfer to hospital.

Box 18.4 lists the steps to take in the event of an emergency, especially where hypovolaemic shock is suspected or imminent.

For further reading, see Resuscitation Council (UK) (2000).

Box 18.4

Emergency interventions at the scene of an accident

1. Immediately reassure and comfort the person.
2. Check the airway for patency. If breathing is laboured or difficult, lie the individual in the recovery position if it is safe to do so. This will reduce the risk of aspiration of stomach contents. The jaw may need to be lifted, without hyperextension of the neck, to aid in the maintenance of the airway. Loosen any tight clothing, especially around the neck. NB: do not attempt to move the person if there is any likelihood of cervical or other spinal injury.
3. If haemorrhaging is obvious, try to control it by applying pressure.
4. Call 999. Give clear instructions, i.e. what kind of help is needed and the correct location of the accident. People tend to panic when a crisis occurs and someone needs to assume the position of leader and maintain an air of calm efficiency. Discourage onlookers from gathering as this only distresses the individual even further.
5. If relatives or friends are at the scene, ask them for a brief history. This may help to ascertain the cause of the shock.
6. Someone may be able to provide a blanket or coat to cover the person. However, do not accept the offer of a hot water bottle, as the application of heat would only increase peripheral vasodilatation and draw some of the blood supply away from the vital organs.
7. If the person complains of thirst, moisten the lips with water but do not allow drinking.
8. If a cardiac or respiratory arrest develops, commence artificial resuscitation immediately.
9. Transfer the person to hospital as soon as possible.
10. Try to ensure safety, considering the cause of the problem. For example, in the case of a road traffic collision, ask someone to warn and divert traffic, whilst maintaining personal safety.

GENERAL PRINCIPLES OF THE MANAGEMENT AND TREATMENT OF SHOCK

As well as being able to recognise the warning signs of shock (see p. 715), the nurse should be able to identify those patients who are most at risk of developing shock. Increasingly, hospitals are implementing early warning teams who can be called upon for advice and, if required, to treat patients in the early stages of shock. Examples of this initiative include ALERT – Acute Life Threatening Events Recognition and Treatment, and MEWS – Medical Early Warning Systems.

For further reading, see http://web.port.ac.uk/alert/intro.htm and McArthur-Rouse (2001).

In its early stages, shock demands immediate intervention. The initial treatment priority is the control of life-threatening abnormalities through assessment of airway, breathing and circulation (Sepsis Care Initiative 2002). When obtaining a patient's initial history the nurse should take note of the risk factors listed in Box 18.5. Thereafter, the

Box 18.5

Identifying patients at risk of experiencing shock

- Has the patient experienced multiple trauma?
- Has the patient had surgery recently?
- Has the patient suffered severe burns?
- Is the patient postpartum?
- Does the patient have a history of oesophageal varices or peptic ulceration?
- Is the patient taking anticoagulant therapy?

The above factors put the patient at risk of *hypovolaemic* shock.

- Has the patient experienced chest pain recently or suffered a myocardial infarction — especially in vessels supplying the anterior wall of the left ventricle?
- Does the patient have a history of cardiac failure or cardiac dysrhythmias?

The above factors put the patient at risk of *cardiogenic* shock.

- Does the patient have impaired immunity, e.g. are they suffering from AIDS or cancer, or undergoing chemotherapy?
- Does the patient have a resistant deep-seated infection?
- Is the patient seriously ill and requiring multiple invasive catheters and devices?

The above factors put the patient at risk of *septic* shock.

- Does the patient suffer from any disordered state resulting in impaired nervous stimuli to vascular smooth muscle?
- Has the patient experienced recent spinal anaesthesia?
- Has the patient experienced trauma to the brain and/or spinal cord?

The above factors put the patient at risk of experiencing *neurogenic* or *spinal* shock.

- Does the patient have significant allergies or sensitivities?
- Is the patient undergoing tests requiring contrast media?

The above factors put the patient at risk of experiencing *anaphylactic* shock.

management of shock includes treatment of the underlying cause, restoration of tissue perfusion and patient support (see Fig. 18.4). The purpose of oxygen support is to restore and help maintain adequate tissue oxygenation. The goals of haemodynamic support are to restore an effective blood pressure, to ensure tissue perfusion and to normalise cellular metabolism.

18.5

(a) Read Case History 18.2. In your opinion, is Mr A suffering from shock? If so, which type?
(b) Why might his abdomen be rigid?
(c) What initial steps should medical and nursing staff take?

Management and treatment of hypovolaemic shock

Regardless of what may have triggered the patient's hypovolaemia, the restoration of circulating fluid volume is the key to management. As soon as the patient's airway has been secured and oxygen therapy instituted, the next priority is to assess circulatory status and commence replacement i.v. fluids via two large-bore cannulae. Fluid therapy remains the cornerstone for almost every form of shock, although the original insult must also be identified and resolved where possible.

The nurse must ask:

- What kind of fluid is required?
- How much fluid does the patient need?

Fluid replacement must be accurately recorded and observations taken regularly to assess the patient's response.

Crystalloids

Normal saline solution (sodium chloride 0.9%) is often the first replacement fluid administered to the shocked patient, although its large concentration of chloride ions could be disadvantageous to the patient whose renal function is

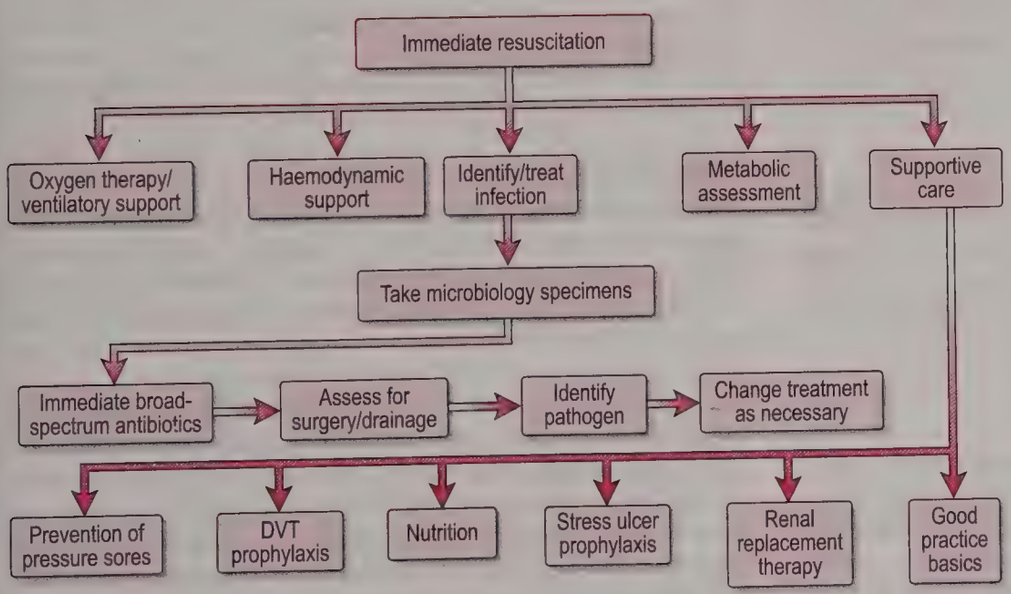

Fig. 18.4 Treatment: general approach to septic shock. (Reproduced with kind permission from Eli Lilly & Co. Ltd.)

CASE HISTORY 18.2

Mr A

Mr A, aged 35, is married and has two young children. While travelling to work one morning he was involved in an RTA. Within 30 min he was admitted to the nearest emergency department, where initial assessment showed the following:

Vital signs

- Blood pressure — systolic = 70 mmHg but diastolic difficult to hear
- Heart rate — 150/min; pulse weak, thready and rapid
- Respirations — 40/min; breathing shallow
- Temperature — 35.5°C

Neurological signs

- Little response to painful stimuli
- Poor gag and cough reflex
- Right pupil unresponsive to light
- Left pupil reacting sluggishly
- Glasgow Coma Scale score = 4

General examination

- Large swelling in right occiput
- Rigid abdomen; bowel sounds absent
- Obvious fracture to right femur with large gaping wound
- Possible fractured pelvis
- Skin moist and clammy; mouth dry

already impaired. It may also cause hypernatraemia, hypokalaemia or a hyperchloraemic metabolic acidosis.

Dextrose 5% is not considered a suitable fluid for the patient in shock, although it may maintain water balance and supply the calories necessary for cell metabolism.

Hartmann's solution, an electrolyte solution consisting of sodium chloride, potassium chloride, calcium chloride and sodium lactate in water, is one of the most common resuscitative fluids used in haemorrhagic shock. As it closely resembles blood plasma, but without the formed elements, it can be used as an emergency plasma expander until the patient's blood has been grouped and cross-matched. It rarely causes any adverse reaction, is inexpensive and readily available.

Colloids

A colloid is a solution containing large particles, such as protein, which help to restore the interstitial osmotic pressure. Examples of colloids are albumin and fresh frozen plasma. However, synthetic solutions, such as succinylated gelatin (Gelofusine) or dextran, are being used increasingly, due to the expense of human products.

Combined solutions

Mayor (2004) in a recent research study involving 7000 critically ill patients, suggested that there was no difference in outcomes for those patients resuscitated with saline or albumin. Intravenous therapy needs to replace fluid in the cells as well as the vascular compartment, therefore the use of both crystalloid and colloid is indicated.

Blood

The rapid replacement of blood and blood products is essential in the haemorrhagically shocked patient. Blood replaces volume in the intra- and extracellular spaces and, in addition, has oxygen-carrying capacity as well as clotting factors. It is often necessary to use a pressure infuser to increase the rate of delivery and a blood warmer to bring the blood up to body temperature in order to avoid excessive cooling of the patient (see Ch. 27).

Autotransfusion This procedure, normally carried out in the operating theatre, involves collecting the lost blood from the patient, filtering the blood, treating the blood with an anticoagulant and reinfusing the patient. Autotransfusion is a popular practice in large trauma centres.

For further reading, see Vanderlinde et al (2002).

Management and treatment of cardiogenic shock

The main goals of therapy in cardiogenic shock are:

- to re-establish circulation to the myocardium
- to minimise heart muscle damage
- to improve the effectiveness of the heart as a pump.

Damage to cardiac muscle can be minimised by improving the heart's oxygen supply and, at the same time, reducing its own oxygen demand. Oxygen supply can be increased by the administration of a high percentage of O_2 via a non-rebreathing face mask. Monitoring via pulse oximetry and blood gas analysis should guide administration (Hand 2001).

An essential part of management is the control of pain, including the administration of intravenous morphine. Morphine also dilates the blood vessels and reduces peripheral resistance, which in turn will further reduce oxygen demand. Tiffany and Jorden (2001) describe the challenges of maintaining an adequate blood pressure by careful fluid management and the use of vasopressor drugs.

The catecholamines, such as adrenaline and noradrenaline, are commonly used to improve contractility and correct hypotension, and since the patient with myocardial ischaemia and impaired myocardial contractility will also be at risk of arrhythmias, anti-arrhythmic agents may also be administered.

Medications commonly used

Catecholamines function by stimulating the smooth muscle receptors of the myocardium. This leads to an increase in the contractility of the myocardium and thereby increases cardiac output, raises arterial pressure and improves tissue perfusion.

Dobutamine is considered the medication of choice by many (Tiffany & Jorden 2001) as it has the advantage of increasing cardiac output and lowering left ventricular filling pressure while not increasing the pulse rate or increasing oxygen demand. If the blood pressure remains low despite adequate doses of dobutamine, dopamine is added to the regimen. Amrinone and milrinone have also been effective in improving cardiac output. Vasodilators such as intravenous nitroglycerin and nitroprusside can

be added to decrease afterload and therefore reduce left ventricular work and oxygen consumption. Extreme caution must be used when using these potent medications because of their hypotensive effects.

The intra-aortic balloon pump (IABP)

The IABP is often used in conjunction with medication to improve afterload. It assists a weakened or damaged left ventricle by aiding left ventricle ejection and thus improving coronary artery and peripheral tissue perfusion.

There are various types of IABP, all of which work on the same principle. A balloon-tipped catheter is inserted via the femoral artery and is advanced into the aorta until the balloon is just distal to the left subclavian junction. The cardiac cycle triggers the inflation and deflation of the balloon with carbon dioxide or helium. Inflation during diastole increases intra-aortic blood pressure, thereby improving coronary artery perfusion.

Ventricular assist device

For some patients, the above therapies are not sufficient and ventricular assist may be needed. This device is basically a pump which bypasses a failing ventricle and physically removes blood from the circulation, allowing the ventricle to rest and recover. A large-bore cannula is inserted from the atria to drain blood to the pump and back via another inflow cannula from the pulmonary artery or aorta. The decision to use a ventricular assist device should not be taken lightly, due to the possibility of life-threatening complications such as haemorrhage, arterial occlusion or pulmonary embolism. There is increasing interest in applying this technology to provide implantable assist devices to patients with refractory heart failure until recovery or consideration for heart transplant (Westaby 2000). Both therapies require highly skilled nursing.

Management and treatment of septic shock

Treatment of septic shock is summarised in Figure 18.4. The initial priority is assessing airway, breathing and circulation (Green & Lynn 2000).

Blood gases

Blood gases should be monitored regularly. Access can be gained by arterial cannulation and increasingly nurses are taking responsibility for arterial line sampling in the light of the *Code of Professional Conduct* (Nursing and Midwifery Council 2004). Many patients with septic shock present with a mixed acidosis due to respiratory and metabolic elements. Treating the cause is obviously vital and most patients will require artificial ventilation in a critical care unit.

Nitric oxide and nitric oxide inhibitors

The action of nitric oxide was first identified by Furchgott as early as 1980. Many studies have been carried out to determine the benefits of treatment and successful applications have been made in North America, Europe and Australia (Cuthbertson & Webster 1995).

Vasoactive substances essential in the physiological regulation of blood vessel tone are produced within the endothelial layer of the pulmonary vasculature. One of these substances is endothelium-derived relaxing factor (EDRF). Nitric oxide is the gaseous form of this potent vasodilator.

The physiological effects of nitric oxide The release of nitric oxide is responsible for many physiological effects, including control of vessel tone and tissue perfusion, platelet aggregation, white cell function and neuronal activity. Nitric oxide is produced by the enzyme nitric oxide synthase from the substrate amino acid L-arginine. The nitric oxide produced then diffuses to the vascular smooth muscle layer, stimulating the enzyme guanylate cyclase. Guanosine triphosphate is formed, which then catalyses the production of guanosine monophosphate. This chemical cascade is responsible for smooth muscle relaxation and vasodilatation.

In septic shock, endotoxin stimulates the formation of excessive amounts of endogenous nitric oxide, resulting in profound vasodilatation and hypotension.

Inhalational nitric oxide In many critical care units, nitric oxide in the form of inhalation therapy is currently being used successfully for the treatment of adult respiratory distress syndrome (ARDS; see p. 732) and pulmonary hypertension. Inhalational nitric oxide (INO) improves ventilation–perfusion matching by selectively dilating blood vessels adjacent to ventilated alveoli, without affecting systemic circulation. Although a number of studies have noted an improvement in oxygenation, a multicentre trial failed to show any demonstrable effect on outcomes (Dellinger et al 1998).

Microcirculatory changes

The patient suffering from septic shock needs particular nursing attention to the condition of their skin. The administration of inotropic agents increases peripheral vasoconstriction and the resulting decrease in tissue perfusion puts the patient at risk of pressure ulcers. Moreover, the patient may not be sufficiently haemodynamically stable to allow frequent repositioning or assessment of pressure areas. Such critically ill patients often require the expertise of a tissue viability nurse or specialist nurse to assess and implement a strategy for the prevention of pressure ulcers (see Ch. 29). A number of therapeutic beds are now available for purchase or rent which will provide appropriate therapy; in addition some beds rotate the patient, providing a useful adjunct to postural drainage and physiotherapy (James 1997).

Management and treatment of anaphylactic shock

Swift recognition of anaphylactic shock, which results from a severe allergic reaction to a specific antigen, is vital to the individual's survival. Intervention should aim first at identifying and removing the cause. If this is not possible, the effects of the reaction must be reversed.

In extreme circumstances, intubation and artificial ventilation may be needed to overcome respiratory complications. The medication of choice is i.v. adrenaline to restore vascular tone. Aminophylline may be given to counteract bronchoconstriction and antihistamines may be administered to reverse the adverse effect of the mediator histamine

involved in the reaction. As with other forms of shock, oxygen therapy and i.v. fluid replacement will usually be required (see also Ch. 16, p. 682).

Definitive and supportive therapy

From the above, it can be seen that the interventions used in the management and treatment of shock may be described as either 'definitive' or 'supportive' (Rice 1991). The goal of definitive therapy is to locate and correct the cause of the shock and to restore and maintain adequate perfusion and oxygenation of the tissues, whereas the goal of supportive therapy is to improve oxygen delivery to the tissues, to restore and maintain tissue perfusion, and to restore cellular function.

For further reading on the management of shock occurring as a result of fractures and burns, see Chapters 10 and 30, respectively.

MONITORING THE PATIENT IN SHOCK

Monitoring and observation of the patient's ever-changing condition will allow for the prompt correction of deficits. The following are the most important indicators of tissue perfusion and will be discussed in the following sections:

- cardiac status
- respiratory status
- haemodynamic status
- level of consciousness
- renal function
- body temperature
- skin condition.

Monitoring cardiac status

Electrocardiography

An electrocardiogram (ECG) is a recording of the electrical activity of the myocardium and indicates the changes which occur as a result of contraction. The contraction of any heart muscle is associated with electrical changes called depolarisation and these can be detected by electrodes attached to the surface of the body (see Ch. 2). An ECG can be obtained quickly in an emergency department or with a portable electrocardiograph at the site of an accident and can give useful information about the rate and rhythm of the heart. Thus, if arrhythmias arise, they can be detected and treated immediately. All patients who are likely to be suffering from shock should be monitored by electrocardiograph. In addition, heart sounds should be assessed, as should major arterial pulses, for rate, rhythm and pressure.

18.6 What might cause a shocked patient to experience:

(a) tachycardia — heart rate >100 beats/min
(b) bradycardia — heart rate <60 beats/min?

Monitoring respiratory status

The shocked patient's respiratory status may change rapidly and therefore should be monitored at frequent intervals, allowing for the early detection of potential deterioration. In the early stages, the nurse should be alert to hyperventilation, resulting in respiratory alkalosis followed by fatigue of the respiratory muscles. This may lead to shallow breathing and the risk of respiratory distress, necessitating mechanical ventilation.

Monitoring oxygen saturation

The level of O_2 saturation in the patient's blood (S_aO_2) will give some indication of respiratory status. Continuous monitoring will give valuable information on the individual's response to interventions and can provide early warning of hypoxaemia. Both invasive and non-invasive techniques are available for S_aO_2 measurement.

Pulse oximetry Arterial O_2 saturation along with pulse rate can be monitored continuously by means of a non-invasive electronic device called a pulse oximeter. This functions by measuring the absorption of red and infrared light passed through living tissue, usually a finger, toe or ear lobe. Since results correspond closely to arterial blood gas values, this instrument reduces the need for blood samples. Readings are not affected by skin colour but can be distorted by high blood bilirubin levels, as in jaundice, and in cases of carbon monoxide poisoning and smoke inhalation. Results for very heavy smokers may also be difficult to interpret.

For further reading, see Woodrow (1999) and Casey (2001).

The fibreoptic catheter The fibreoptic catheter can be used to measure the patient's venous oxygen saturation. This pulmonary artery catheter contains two optical fibres: one transmits light from the optical module to the catheter tip; the other collects reflected light at the catheter tip and transmits it back to the optical module. These signals are transmitted to a computer which calculates oxygen saturation percentage values. These values are continuously displayed in numerical form and recorded as a graph. Acceptable oxygen saturation levels are considered to be above 90%, although observing for changes in trends should be the nursing priority.

Monitoring haemodynamic status

In the shocked patient, blood pressure may initially be kept within normal limits by the compensatory mechanisms described earlier (see p. 716). However, as shock progresses and cardiac output decreases, blood pressure will fall. In progressive decompensating shock, the use of a sphygmomanometer to estimate blood pressure is inaccurate and inadequate, and more sophisticated investigation will be required.

Central venous pressure (CVP) monitoring

CVP is the blood pressure within the right atrium and vena cava. Its measurement can give information about blood volume or venous system capacity. It can also give an indication of vascular tone and pulmonary vascular resistance, as well as of the effectiveness of the right heart pump. However, it does not measure left ventricular function and it can be unreliable in the critically ill patient with chronic lung disease, right and left heart failure and valve disease.

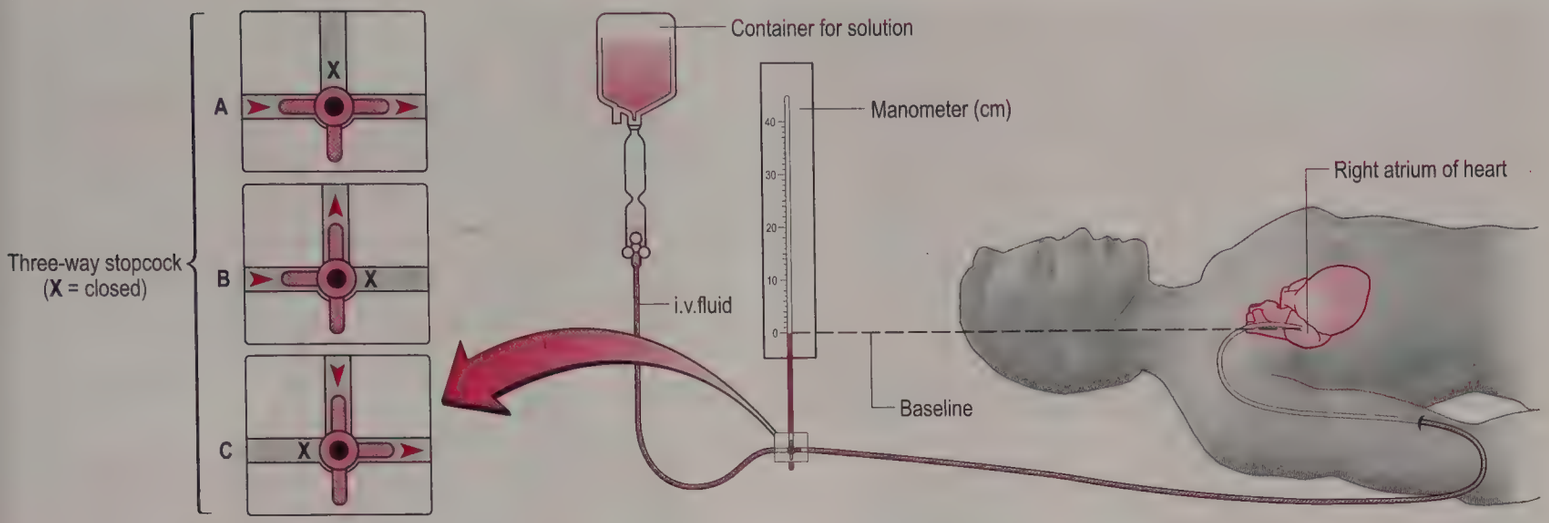

Fig. 18.5 Diagram of a CVP water manometer. A: Before measuring central venous pressure (CVP), the infusion flow is to the patient and the three-way stopcock is closed to the manometer. B: To measure CVP, the stopcock is turned so that it is closed to the patient. This allows the manometer to be refilled with fluid. C: The stopcock is turned so that it is closed to the infusion fluid. This allows a free flow of fluid from the manometer to the intravenous catheter. The fluid level will fall until the level corresponds with the pressure in the right atrium or superior vena cava. (Adapted from Jamieson et al 2003.)

CVP monitoring reflects the rate of blood return to the right side of the heart and can be an accurate guide for fluid replacement. A CVP of approximately 0.5 cm H_2O in the presence of a low arterial blood pressure usually indicates hypovolaemia, whereas a CVP above 14 cm H_2O in the presence of a low arterial blood pressure indicates cardiac failure (see Fig. 18.5).

Technique A large-bore catheter should be inserted under aseptic conditions into the internal or external jugular, subclavian or femoral vein, either using the percutaneous technique via a large-bore needle or by means of a venous cutdown by a member of the medical staff. The site of the central line is checked radiologically prior to the commencement of fluid therapy.

In the intensive therapy or high-dependency unit, a transducer can be attached to the central line in order to obtain a waveform and digital display of the CVP reading in mmHg. Continuous monitoring will indicate the effectiveness of treatment.

Central venous lines, although extremely important for a critically ill patient, present a danger of bacterial infection. Nurses can make an important contribution to care by ensuring that aseptic techniques are adhered to when the line is inserted initially and that the insertion site is kept clean and dry. Once it is no longer needed, the line should be removed as quickly as possible to reduce the risk of infection.

Arterial pressure monitoring

An accurate assessment of blood pressure can be made by measuring the arterial pressure directly. This is performed by medical staff by the insertion of a flexible catheter into an easily accessible artery. The most commonly used site is the radial artery, as the line can be readily secured and observed at this point, and the hand has a good collateral circulation. Other frequently used sites include the brachial, femoral and dorsal arteries.

Once the catheter is inserted, it is attached to a bag of normal saline, which is normally pressurised to around 300 mmHg (see Fig. 18.6). Approximately 2–3 mL/h of the solution is delivered into the artery to maintain patency. By means of a transducer the arterial waveform is displayed on a monitor along with arterial pressure readings.

Patients with an arterial catheter in place require constant nursing supervision in order to ensure that the catheter does not become disconnected — should this happen, the patient could exsanguinate in a matter of minutes. The nurse should ensure that the catheter is securely positioned and covered with a sterile dressing. In addition, the catheter should be clearly labelled to prevent the line being used as an injection port.

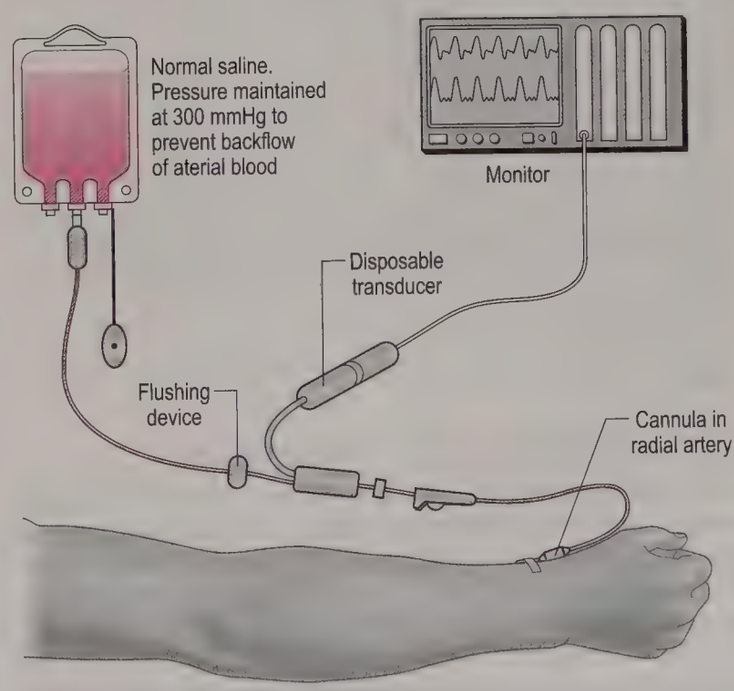

Fig. 18.6 Arterial pressure monitoring equipment.

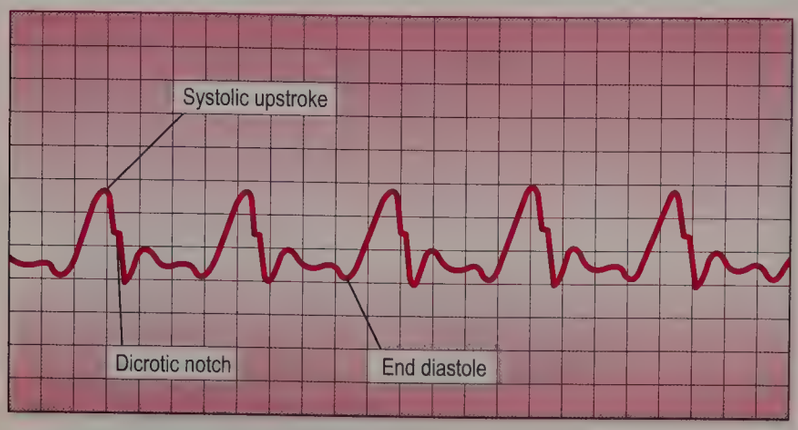

Fig. 18.7 Normal arterial waveform.

The normal waveform will indicate that the arterial catheter is functioning and that the digital blood pressure display is accurate. The nurse must be able to recognise its distinct pattern, which is composed of a systolic upstroke and a dicrotic notch on the downstroke (see Fig. 18.7). The dicrotic notch occurs as a result of the aortic valve closing and a simultaneous increase in aortic pressure. If this pattern becomes dampened, the nurse must be aware that it may indicate a clot in the catheter, air in the line or pressure from the tip of the catheter against the vessel wall itself.

18.7 If the patient has a pulmonary artery wedge pressure (PAWP) of <8 mmHg, what does that indicate?

18.8 If the PAWP is >25 mmHg, what might be the medical diagnosis?

Cardiac output monitoring

The critically ill patient (see Ch. 29) may require invasive monitoring to allow measurement of cardiac output and oxygen content of both arterial and mixed venous blood.

Cardiac output, and right and left ventricular pressures can be measured by inserting a pulmonary artery catheter into the internal jugular, subclavian, basilic or cephalic veins (see Fig. 18.8). The readings obtained allow the clinician to determine the intervention and therapies required (see Fig. 18.9).

There is much debate in the literature regarding the usefulness and safety of invasive haemodynamic monitoring (Vincent & De Backer 2002). Complications in the use of pulmonary artery catheters have led to ongoing interest in non-invasive or minimally invasive monitoring including Doppler technology, thoracic electrical bioimpedance and pulse contour devices.

For further reading, see Chaney & Derdak (2002).

Monitoring level of consciousness

In the early stages of shock, the patient may still be quite alert and anxious. They may complain of pain and may be able to give a history which will help the clinician to establish a diagnosis. However, if cerebral perfusion pressure falls, with resulting cerebral hypoxia, the patient will gradually become less coherent and may eventually become comatose. The nurse should observe the patient carefully at this stage and ensure the airway is maintained. It may be

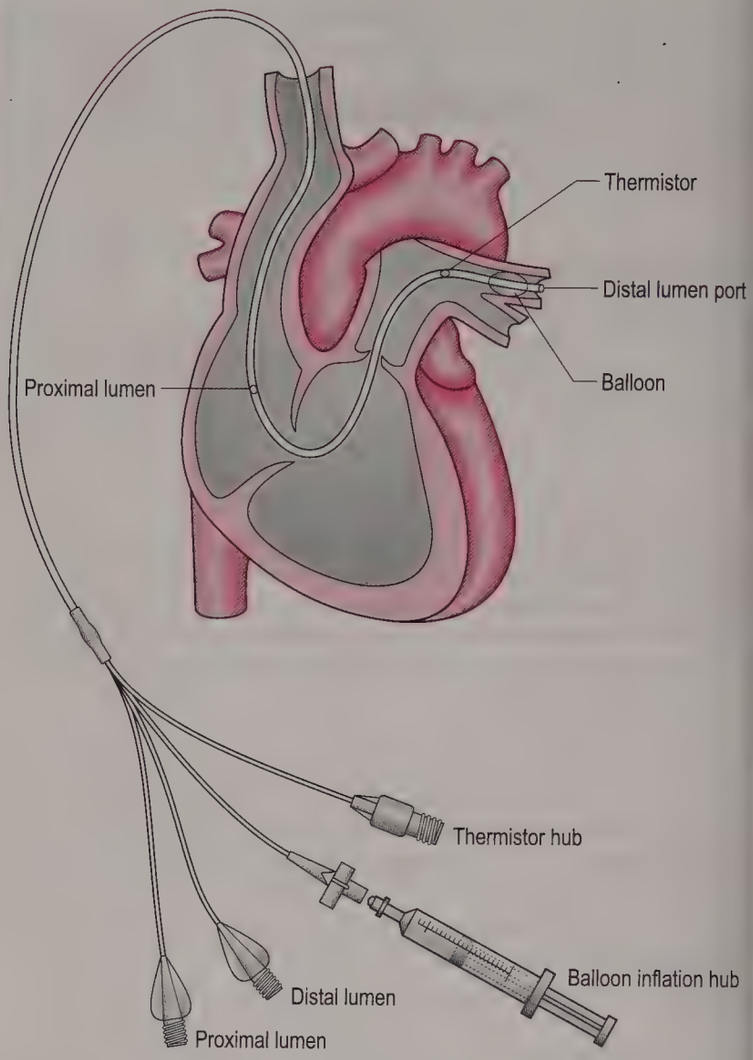

Fig. 18.8 A pulmonary artery catheter. *Distal lumen*: located at the tip of the catheter in the pulmonary artery. Pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP) and mixed venous gas pressures are obtained at this port. *Proximal lumen*: used for central venous pressure (CVP) monitoring or main fluid infusion lumen. It is situated in the right atrium and can also be utilised to measure the right atrial pressure. *Balloon inflation valve*: the balloon situated at the end of the catheter may be inflated to read the PAWP. *Thermistor hub*: situated 4 cm from the tip of the catheter and used to measure cardiac output by thermodilution methods (see Fig. 18.10).

advisable to place the patient in the lateral position. In a clinical setting, medical staff may elect to intubate and artificially ventilate the patient. The Glasgow Coma Scale (see Fig. 28.4, p. 971) is a useful tool with which to assess the patient's cerebral function.

For a detailed discussion of consciousness levels, see Chapter 28, page 967.

Monitoring renal function

Renal function is a very good indicator of tissue perfusion and should therefore be monitored carefully in patients suffering from shock. Since the kidneys are dependent on adequate tissue perfusion, a drop in urinary output will indicate poor perfusion. Unless the patient is dehydrated, urinary output should be 0.5–1.0 mL/kg per h.

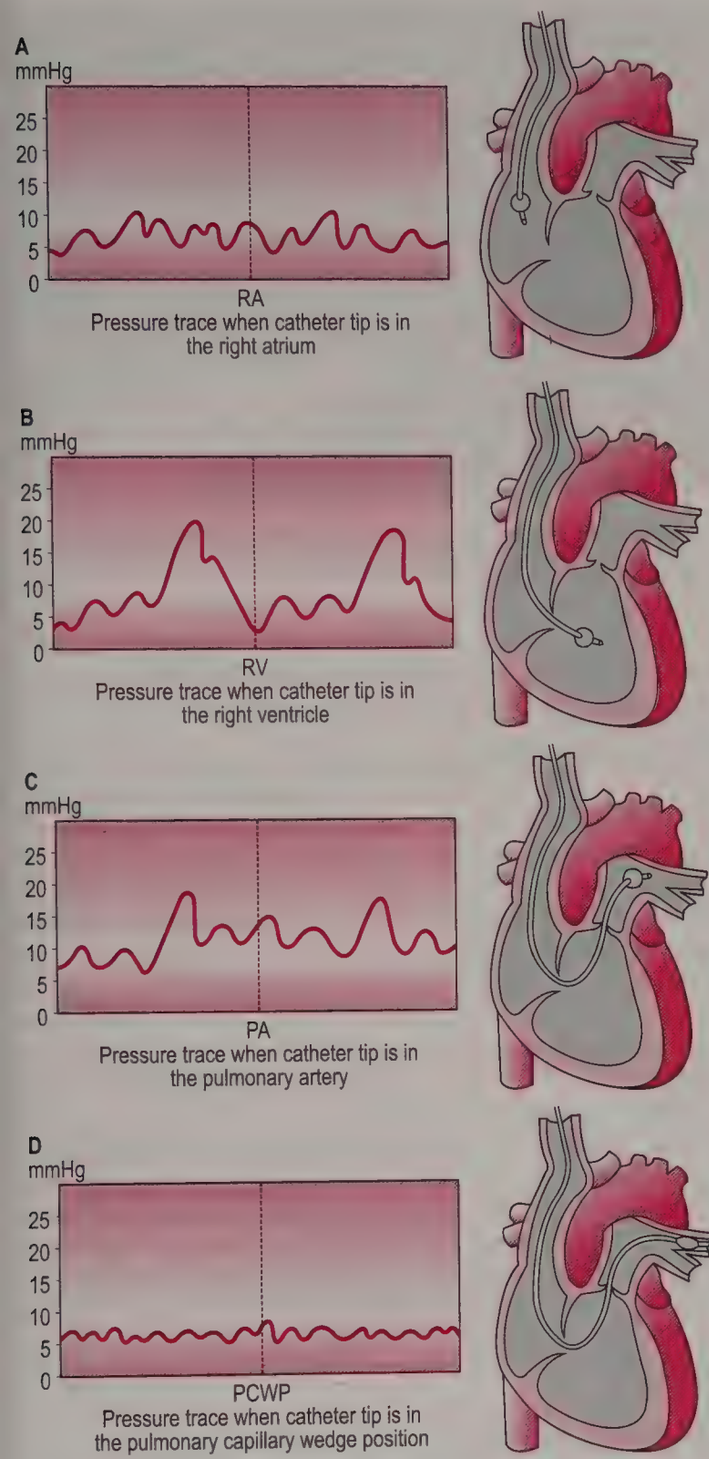

Fig. 18.9 Waveform changes during monitoring by pulmonary artery catheter. A: The catheter is advanced by the doctor until it is in the right atrium. The balloon is then inflated. B: The balloon carries the catheter through the tricuspid valve and into the right ventricle. C: The pressure of blood flow carries the catheter through the pulmonary valve into the pulmonary artery. D: When the catheter has become wedged in a branch of the pulmonary artery, the balloon is deflated and falls back into the pulmonary artery, where it can be used to monitor continuously the pulmonary artery pressure.

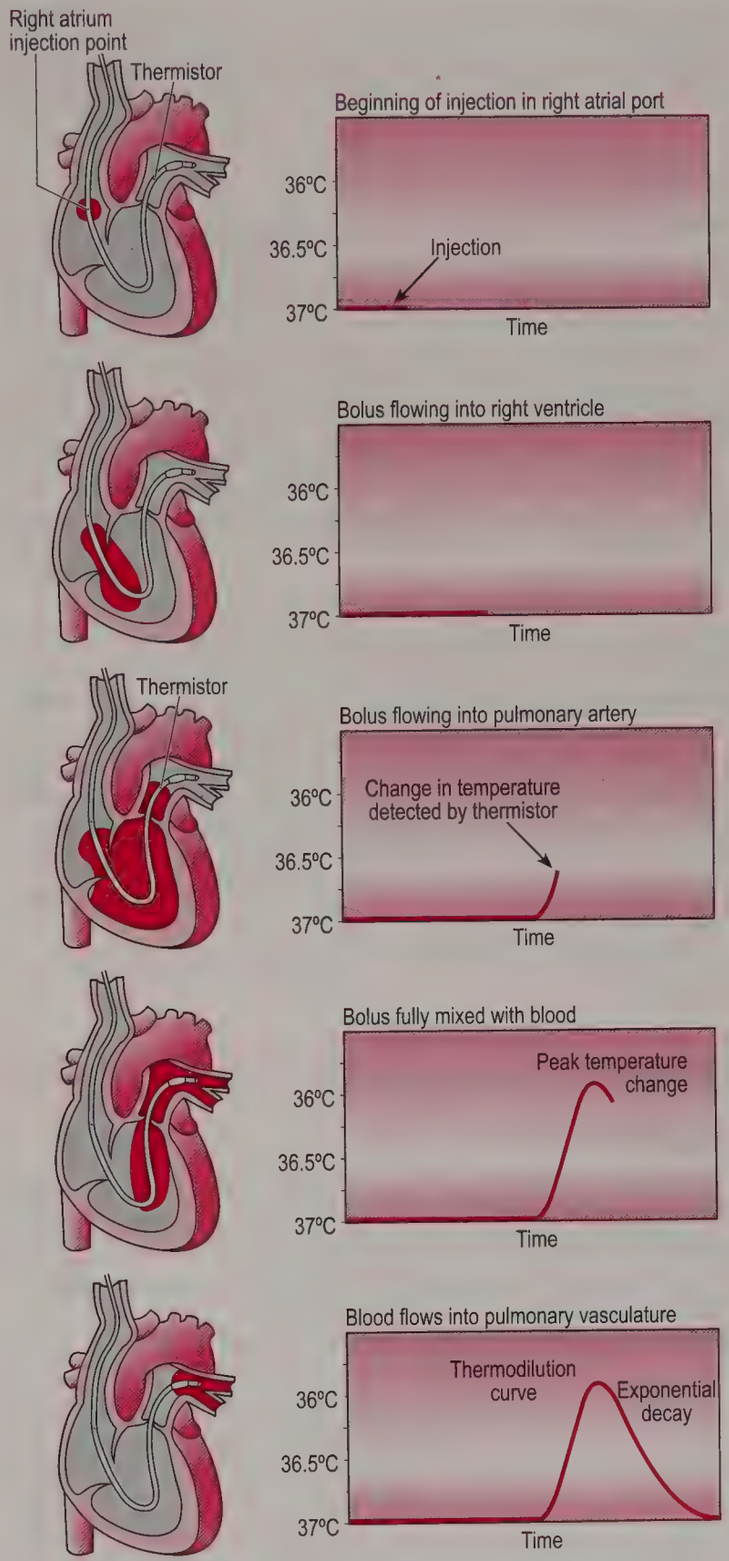

Fig. 18.10 The thermodilution technique for assessing cardiac output.

Urinary catheterisation and hourly urine volumes can assist in early detection of decreasing renal perfusion.

Measurement of specific gravity and osmolality will reflect the concentration of the urine. In the early stages of shock, when urine volume falls, the concentration of excreted waste products rises. However, if the shocked state progresses, urine volumes remain low but the ability to concentrate the urine and blood and the osmolality are fixed or low (Hand 2001).

Monitoring body temperature

The importance of obtaining accurate body temperature measurements should not be underestimated, as many

clinical interventions are based on these readings. These factors, as well as procedures for obtaining accurate core temperature readings, are described in detail in Chapter 22.

Observing skin condition

Direct observation of the skin colour, temperature and condition will reflect the stage of shock that the patient is in. Intense activation of the sympathetic nervous system will result in pale, clammy skin and a dry mouth. Failure of capillary refill will indicate sustained and prolonged vasoconstriction. If oxygen delivery is severely impaired, the skin will become cold, mottled and cyanosed. However, it should be noted that the clinical picture in septic shock is different. In the early stages of this type of shock, the skin becomes warm, dry and flushed as bacterial toxins cause vasodilatation.

Laboratory and diagnostic tests

Arterial blood gas (ABG) analysis can give some indication of circulatory efficiency. In the early stages of shock, it is not uncommon to find a fall in the partial pressure of oxygen (PO_2) and a rise in the partial pressure of carbon dioxide (PCO_2). However, PCO_2 may fall due to hyperventilation. With an increase in anaerobic metabolism and in the production of lactic acid, metabolic acidosis is frequently seen in the severely shocked patient.

Information on a range of diagnostic tests is given in Appendix 1.

COMPLICATIONS OF SHOCK

Renal failure

When the crisis of shock occurs, blood flow to the kidneys is reduced both by the original hypovolaemic or other circulatory problem and by the vasoconstriction which occurs as part of the body's compensatory mechanisms (see p. 716).

18.9 What are the functions of noradrenaline?

In addition to the reduction of blood flow to the kidneys, there is also a change in the flow within the kidneys. Blood flow is directed away from the renal cortex to the renal medulla to preserve the function of the juxtamedullary nephrons. This is essential if the countercurrent system of concentrating the urine is to function (see Ch. 8). If, however, the shock persists without prompt treatment, then the countercurrent mechanism will fail and the urine will become dilute, leading to the early stages of acute renal failure.

Haemofiltration

Many patients with acute renal failure will require renal replacement therapy as part of their treatment. Haemofiltration is the removal of excess fluid and waste products from the blood by a filter in conjunction with fluid replacement. Increasingly, haemofiltration is being used in the critical care area and offers a number of advantages to dialysis (see Fig. 18.11).

Fig. 18.11 Patient on haemofiltration therapy. (Reproduced with kind permission from NHS Lothian.)

Adult respiratory distress syndrome (ARDS) or acute lung injury

ARDS, now referred to more commonly as acute lung injury (ALI), is characterised by acute, severe and progressive respiratory distress, increased stiffness of the lungs and diffuse lung opacification. At cellular level, a number of substances are activated, including macrophages, platelets, proteases, lysosomes, endotoxins, polymorphonuclear lysosomes and free oxygen radicals, which cause damage to the alveolar capillary membrane and lead to the classic signs of pulmonary oedema. In addition, surfactant production is decreased, secondary to atelectasis, resulting in dyspnoea.

Although treatment has become sophisticated, there is still no medication or procedure which will cure ARDS/ALI. The mortality rate remains approximately 60% and has shown little reduction despite increased technology and intervention (Brower et al 2001). Standard supportive care for patients with ARDS/ALI will involve therapeutic intervention in an intensive care unit. Increasingly, novel modes of mechanical ventilation are being used to treat this group of patients.

Positioning of patients

The body position of critically ill patients may have a profound effect on arterial oxygenation. The prone position is used primarily for the treatment of ARDS/ALI and can significantly improve oxygenation in this group of patients (Marion 2001).

For further reading, see MacDonald & Armstrong (2000).

Disseminated intravascular coagulation (DIC)

DIC is a serious disorder of coagulation that may cause severe organ damage or failure. Some of the pathophysiological processes leading to DIC have already been described in relation to septic shock (see p. 720). In DIC the patient's normal clotting mechanisms do not function correctly. Clots may be produced in capillaries where they are not

Table 18.1 Signs of disseminated intravascular coagulation (DIC)

System	Haemorrhagic signs	Microemboli signs
Integumentary	Oozing/bleeding from i.v. sites, arterial lines, previous surgical sites and mucous membranes	Patchy cyanosis, gangrene
Neurological	Altered level of consciousness, subarachnoid bleeding	Altered level of consciousness, cerebral vascular accident
Pulmonary	Haemoptysis	Pulmonary embolus, adult respiratory distress syndrome
Gastrointestinal	Gastrointestinal bleed, abdominal distension	Bowel infarction, constipation, diarrhoea
Renal	Haematuria	Haematuria, oliguria, renal insufficiency/failure

required, and sites where clotting factors could be utilised are deprived of them. Fibrinolytic (clot-dissolving) factors then go into action where they are not needed, and the end result is uncontrolled haemorrhage. The nurse plays an essential role in early recognition of DIC and Table 18.1 lists the signs of DIC (Geiter 2003). Treatment is aimed at replacing the clotting factors by administering blood and blood components, platelets, fresh frozen plasma and possibly cryoprecipitates.

CONCLUSION

Although there have been important advances in the resuscitation and treatment of patients in shock, survival can be further improved by early recognition and supportive therapy.

Assisting individuals suffering from shock, whether in a hospital or a community setting, presents the nurse with a major challenge. Intervention will require not only a sound understanding of the pathophysiological processes of shock, but also the ability to act swiftly on the basis of that understanding and to assist with a range of resuscitative and investigative procedures. Above all, the nurse is in a unique position to ensure that patients and their loved ones are supported and informed throughout this life-threatening experience.

INTRODUCTION

Although pain is a common experience, it is a complex one, unique for each individual every time it is experienced. The experience of pain is influenced by an interaction between physiological, psychological and sociocultural factors and encompasses sensory, emotional, cognitive and behavioural components (Melzack & Wall 1996). This means that it is difficult to understand what pain is like for another person. Much is known about the pathophysiology of pain and treatment modalities but less about the lived experience of pain. Research is beginning to address this deficit, through studies that vividly portray the individual's personal description of their pain experience, and also those which focus on clinical decision making about pain management. This chapter will commence with two such personal descriptions, followed by a discussion of various definitions of pain. The many and complex factors which influence the experience of pain will then precede discussion of the mechanisms of pain and the implications for nursing care.

THE EXPERIENCE OF PAIN AND THE ADEQUACY OF DEFINITIONS OF PAIN

19.1 Think about a time when you were in pain. Write down your description of this experience. Compare your description with the discussion below.

Here is how one person described the pain she experienced: 'Bodily feelings were shrieking agony at the top of their voices, mental feelings were fury and total frustration' (Seers & Friedli 1996).

Another quotation from the same study describes the overwhelming nature of pain:

> *Pain is now beyond coping with … it has stopped me leading my whole life. I'm petrified they'll say I have to learn to live with this level of pain … I would rather die. I'd like to be unconscious. Deep inside I feel suicidal … Can't see through the pain when there is so much and I know I do not want to live with it.*

These quotations give vivid insight into the impact that pain has on an individual's life. In contrast, many definitions

of pain emphasise the physiological sensation of pain. For example, the International Association for the Study of Pain (1994) defined pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage'. This definition has been criticised for not accounting for other peripheral stimuli, for central nervous system (CNS) activity and the variable way in which the nervous system responds to stimuli, especially after injury (Melzack & Wall 1996).

The concept of pain as a sensation is criticised by Bendelow and Williams (1995) from a sociological perspective. They argued that this emphasis elevates sensation over emotion and ignores social and cultural perspectives. They draw on Morris (1991) who suggested that pain emerges at the intersection of bodies, minds and cultures. Some definitions have tried to encompass this interaction, e.g. National Institutes of Health (1987):

> *Pain is a subjective experience that can be perceived directly only by the sufferer. It is a multidimensional phenomenon that can be described by pain location, intensity, temporal aspects, quality, impact and meaning. Pain does not occur in isolation but in a specific human being in psychosocial, economic, and cultural contexts that influence the meaning, experience and verbal and non-verbal expression of pain.*

Some definitions emphasise the invisibility of pain and its inexplicability, qualities that Scarry (1985) first proposed as being intrinsic to the experience of pain. These qualities make it possible to be physically near someone in pain yet to be unaware of their pain (Whelan 2003). McCaffery (1972) referred to the invisibility of pain in her seminal definition: 'Pain is whatever the experiencing person says it is, existing whenever he says it does'. This definition has encouraged nurses to value a patient's self-report of pain, although in clinical practice this is often balanced against other information, such as the nurse's expectations of how much pain a patient should be in (Carr & Mann 2000). As Scarry (1985) argued, health professionals can 'perceive the voice of the patient as an "unreliable narrator" of bodily events and discount patient report in favour of what the body reveals'. On the other hand, if nurses believe the patient's self-report of pain at face value, they may not take into account personal and contextual issues that can influence an individual's self-report (Price & Cheek 1996). For example, surgical patients have been reported to underplay their pain if they see nurses are busy (Carr & Mann 2000), older people may minimise their pain for fear of being 'taken over' by medicine (Frampton 2003), and Thomas (2000) stated that people with persistent pain do not talk about their pain for fear of adverse reactions from others. Thus, accepting the patient's report at face value may not enable the practitioner to explore the person's experience of pain in order that it can be understood in terms of the impact of pain on their self-concept and their quality of life. To achieve this, a patient's report of pain must be framed within the context of their experience and the depth of interaction between practitioner and patient (Price & Cheek 1996).

McCaffery's (1972) definition depends on an individual being able to say that they are in pain and to describe this experience. As Whelan (2003) states: 'Pain is ineffable and elusive: it confounds the grasp of language'. This perhaps explains why, as yet, no definition adequately describes the all-encompassing experience of pain.

Despite the lack of an adequate definition of pain, research over the last decade or more has expanded understanding of the experience of pain. Using the philosophical concept of embodiment, Bendelow and Williams (1995) presented a sociological response to their criticism of the dominance of the sensation of pain over the emotional experience.

- *Embodiment* describes the usual state in which the body is experienced in health. On the whole, people are unaware of their body. In illness or pain the body can become the focus of experience; it is monitored for changes and life is lived in relation to this. People in persistent pain describe the body as an obstacle to daily living (Thomas 2000, Paulson et al 2002) and wait to feel 'themselves' again — paradoxically meaning that they will no longer be aware of their body.
- In severe or persistent pain, people begin to define themselves in terms of pain. This is called *disembodiment*. The participants in Paulson et al's (2002) study described how pain altered their perception of themselves, so that each became a different person to the one before they had pain. Madjar (1998) and Thomas (2000) described how pain blocked all other sensations and thoughts. Participants in Thomas's (2000) study felt continually tied to their internal pain, which was described as 'tormentor', 'opponent' or 'monster'.

Pain also took over lived space and time. Space became reduced to the immediate environment and people felt isolated as a consequence (Paulson et al 2002). Time became defined in terms of the 'moment' (Thomas 2000), the moment in which pain is experienced and the thought of future suffering. When pain was at its worst, people experienced a stopping of time, as if the moment would never end. Madjar (1998) quoted one participant who said:

> *... everything just slowed down because that was hurting so much and relief was not coming soon enough. So I think a second turns into a minute and a minute into an hour.*

Madjar (1998) and Paulson et al (2002) also pointed to the exhaustion that accompanies being in, and enduring pain. They described how participants were exhausted by the intensity of pain, the tension and vigilance needed to face and endure it, and, in Madjar's study, by the energy expended to cope with nursing procedures that accompanied their condition. One participant explained:

> *I've got no choice but to sit in here and face this pain. All my energy is going in [to] this pain and that's getting it away from me.*

FACTORS INFLUENCING THE EXPERIENCE OF PAIN

19.2 Think back to the experience of pain that you described in stop-think 19.1 and to your experiences of caring for people in pain. From these experiences, make a list of factors that might influence someone's pain. Organise your thoughts under the following headings: factors related to individual differences; factors related to small systems such as families and care teams; factors related to organisations, society and cultures. Compare your thoughts with the following discussion.

How pain is experienced is influenced by a number of factors.

Individual influences

Past learning

Learning about pain takes place throughout life, through the process of socialisation. If a child falls over and hurts their knee, they learn that this feeling is called pain. They also learn how they are expected to react by the response that they elicit, e.g. sympathy and a cuddle may reinforce crying when in pain, whereas ignoring the complaint and subsequent praise may reinforce the minimisation of pain.

Gender

It has been suggested that men are better able to tolerate pain than women, but the evidence for this is inconclusive and mostly taken from data reporting the incidence of pain. A population prevalence study (n = 10 000) in Sweden, found women reported significantly more incidence of pain than men (Müllersdorf & Söderback 2000). Similar findings were reported from an epidemiological study of pain in the Grampian region of Scotland (n = 3605) (Elliott et al 1999) and from a population-based telephone survey by Portenoy et al (2004). These findings may be explained by the different ways in which men and women are socialised (Bendelow 1993). In some societies men are expected to be 'brave', and tend not to report pain, whereas women are expected to be expressive or 'emotional', and tend to report pain. Another possibility is that gender differences can be explained in terms of coping style. Rollnik et al (2003) found that women were more likely to adopt passive coping strategies, whereas men were more likely to adopt active coping strategies. Passive coping strategies are more likely to result in disability as a consequence of pain.

Coping is also influenced by socioeconomic factors. Portenoy et al (2004) argue that women are more likely to have poorer socioeconomic conditions than men, which may provide an alternative explanation for gender differences in the pain experience and behavioural response.

Age

The evidence with respect to the influence of age on the experience of pain is conflicting. It has been suggested that age diminishes the experience of pain. In a study examining the influence of age on women with fibromyalgia, Burckhardt et al (2001) found that younger women perceived pain severity to be higher than older women. This is in contrast to evidence that pain is more common and more severe in older people (Elliott et al 1999) and that older people do not seek help because they feel their pain is to be expected and tolerated (Yates et al 1995, Lansbury 2000). In Yates et al's (1995) study, one participant stated:

> *Well, I just realised that I've got to live with it you know ... it's always there ... it's no good. I've just got to learn to live with it, I know fully well that nothing will help me now.*

The underplaying of pain in older people is likely to be reinforced by a lack of recognition and assessment of pain in this group by health and social care professionals (Blomqvist & Edberg 2002, Blomqvist 2003, Frampton 2003), and by a desire to remain independent on the part of the older person (Frampton 2003):

> *I'm concerned of others' reactions. I don't like to tell others about my pain for fear of worrying them. I am concerned that they will try and take me over and I will lose control.*

Personality

An individual's personality will influence the way in which they express and cope with pain. For example, drawing on Eysenck's theory of the personality, several studies have demonstrated that an internal locus of control, in combination with active coping strategies leads, to less depression and pain compared with an external locus of control and passive coping strategies (Arraras et al 2002, Smith et al 2002, Bishop & Warr 2003).

The ability to cope

Several studies suggest that a person's ability to cope with pain influences perceptions of disability and quality of life (Walker et al 1990, Melanson & Downe-Wamboldt 2003, Tsai et al 2003). These studies adopt the definition of coping given by Lazarus (1993):

> *What a person does to cope depends on the context in which the disease occurs, and this will change over time because of what is attended to, and the threats themselves also change.*

Walker et al (1990) found that older people were less likely to cope if they were lonely, or coping with other problems such as financial difficulties or the illness or death of a friend. From a descriptive longitudinal study (n = 39; 75 years+), Melanson and Downe-Wamboldt (2003) suggested that the ability of older people to cope with the pain resulting from rheumatoid arthritis influenced their ability to be independent and have a sense of control in their lives. The majority of participants perceived pain as signifying harm and coped through problem-solving strategies.

From a study examining the relationship between pain and other influences on daily stresses and between stress and depression in a group of older people with arthritis (n = 71; mean age 71.6, range not given), Tsai et al (2003) suggested that people's ability to cope was influenced by the degree to which they felt supported by others. Their results demonstrated that pain, disability and social support were predictors for daily stress and that daily stress *per se* was predictive of depression.

The meaning of pain

Pain will have different meanings for different people. Some patients may view pain as a punishment, while others may see it as having some value for self-testing or personal growth; yet others may see it as something that must be eradicated. Pain from a recurrence of cancer, for example, is likely to have a different significance for the patient compared to pain following elective surgery. People with cancer often fear that pain means that their disease is progressing, or that pain will increase as death approaches (Oldham & Kristjanson 2004). Pain following surgery is expected, although people often underestimate the intensity of the pain to be experienced (Carr & Thomas 1997), causing them to fear that the pain signifies complications. Persistent pain may also have implications for the individual's self-image

by necessitating a change in or loss of role. The meaning of pain will also be influenced by individual pain beliefs (Williams & Thorn 1989). In an influential analysis, Williams and Thorn (1989) described three beliefs that negatively influence the experience and severity of pain — whether the individual blames themselves for the pain, sees the pain as mysterious and/or sees pain as something that has to be endured. They argued that any of these beliefs could negatively affect self-esteem, and predispose to psychological distress and a feeling of loss of control.

Body part affected

The part of the body involved may influence the expression of pain (McCaffery & Pasero 1999). Some areas of the body, such as the rectum or genitals, may be difficult for some people to talk about, and thus pain in these areas may go unreported and potentially have a negative effect on an individual's sexuality and self-concept. The assessment and relief of pain in these areas therefore needs skilled management and the patient may benefit from referral to a nurse specialist in pain management.

Factors related to families and the care teams

Interaction between the person in pain and their partner

Pain rarely has an isolated influence. The influence of pain in relationships has been long recognised. Witnessing pain is distressing (Coyle 2004) and can affect the physical and psychological health of a partner (Turk et al 1987, Taylor et al 1990). In Ferrell et al's (1991a) study, family carers described their feelings of fear, suffering, helplessness, heartbreak and denial. They quote one spouse who said: 'It is the saddest thing in the world. I share her pain. If she hurts, I hurt. What else can I say?'. Sometimes, such feelings can influence the way in which couples communicate and cope with the experience of pain. In a phenomenological study describing seven people's experience of cancer pain, Coyle (2004) reported that severe pain can influence an individual's desire for death and this can cause conflict with family members' wish for that person to live.

The impact of pain on styles of interaction between couples has been studied more comprehensively in persistent pain, some research suggesting that particular styles of communication can reinforce an individual's disability. Romano et al (1995) and Schwartz et al (1996) found that physical and psychosocial disabilities were more likely in spouses responding in a concerned way, who were solicitous, and less likely in those whose spouses responded in a negative way. A review of 27 studies examining patient–spouse interactions confirmed these findings (Newton-John 2002) but warned that interactions are more complex than suggested by the research on which these findings are based.

Some of the complexity of spousal experience of pain is elicited in a narrative study of five men married to women with fibromyalgia, undertaken by Söderberg et al (2003). The analysis highlighted how pain influenced many aspects of the spouses' lives, in addition to their relationship with their wife. This included changing relationships with friends and relatives, i.e. less frequent contact, and deepening relationship with their children, as well as taking responsibility for work within the home and acting as an advocate for their wife.

Family dynamics

Families play an important role in the health of individuals and in their care (Oldham & Kristjanson 2004). Thus the experience of pain will be influenced by how family members cope. Families who have effective coping strategies can positively influence an individual's experience of pain through support. On the other hand, families who have ineffective coping responses may aggravate an individual's pain and, in turn, the family dynamics (Schwartz et al 1996). Dura and Beck (1988) observed that families with ineffective coping strategies are typically characterised by:

- enmeshed relationships where interactions are polarised — either overprotective or detached
- lack of cohesion within the family group
- controlling and manipulative behaviour
- conflict and a lack of expression of their feelings.

Team dynamics

A patient's experience of pain can be influenced by the response of health care professionals (Carr & Mann 2000). If a nurse can be with someone in pain without becoming unduly distressed or without judging that person's response, then nurse and patient are likely to interact in a way that encourages discussion and optimal pain management. Conversely, a nurse who feels overwhelmed by such situations is likely to use distancing strategies such as depersonalising the pain and playing down its severity (Madjar 1998). Such strategies result in poor assessment of pain and the exacerbation of patient and nurse distress. An individual's experience of pain will also be influenced by the way in which the health care team functions. Nursing is predominantly a team endeavour, irrespective of where it is taking place. For example, effective pain relief postoperatively is dependent on a congruent plan between anaesthetists, ward-based nursing and medical personnel, general practitioners and district nurses. Where there is disagreement about a care plan, tension may arise and this can negatively affect the patient's experience of pain (Carr & Mann 2000).

Social and environmental factors

Cultural influences on the experience of pain

The relationship between culture and pain has been researched by what Lasch (2002) describes as two genres of studies. The first — culture *of* pain — refers to research investigating the way in which society shapes the meaning and treatment of pain. The second — culture *in* pain — refers to research addressing the ways in which pain is moulded by an individual's perception and expression of pain. Few studies have been undertaken to understand the way in which society shapes the meaning and treatment of pain (Lasch 2002), although Carr and Mann (2000) and Portenoy et al (2004) suggest that people from minority cultural groups are more likely to experience poor pain management. However, more research has been undertaken about cultural perception and expression of pain. Each cultural group has its own behaviours, beliefs, values and

meaning 'scripts' that shape responses to pain, as well as help-seeking activities and receptivity to health care interventions. For example, most British people traditionally value control over the display of emotions — maintaining a 'stiff upper lip' — which has the effect of discouraging people from reporting pain.

A classic study by Zborowski (1952) illustrates the link between culture and pain. Men from three groups were compared: 'old Americans', i.e. their grandparents or earlier forebears were born in America and they did not identify with a particular cultural group, Italian Americans and Jewish Americans. The 'old Americans' attempted to avoid showing any pain, tended to withdraw and preferred to be alone when in severe pain. The Italian and Jewish Americans, however, openly expressed their pain and did not want to be alone. The Italian Americans were concerned with relief of their pain, while the Jewish Americans were concerned about the implications of their pain for the future. This study has been criticised for selecting people whose culture, and consequently their responses, may have been 'diluted' by their residence in America; nevertheless, the study points to the influence of culture on expression and experience.

The influence of culture on the experience and expression of pain has more recently been explored through narrative research. This approach to understanding the influence of culture on the experience of pain enables the beliefs and values that shape this experience to be understood. Lasch (2002) gives an overview of this work on the International Association for the Study of Pain website (see 'Useful websites and addresses').

Socioeconomic factors

Several studies have demonstrated that socioeconomic factors influence pain experience. In their epidemiological study of pain, Elliott et al (1999) found that persistent pain was associated with living in rented council accommodation, being retired and being unable to work. Portenoy et al (2004) found a similar relationship between persistent pain and low income. Richards et al (2002) found that people from a socioeconomically deprived area were less likely to report chest pain than people from more affluent areas. In a qualitative study examining variations in perception and behavioural response to pain, they found that people from deprived areas were less likely to present to medical services following chest pain because they were concerned that they would be chastised for their risk behaviours, e.g. smoking. The authors suggested that this affects their access to health services.

Organisational factors

Organisational culture can influence pain experience; for example, patients may respond to their pain in hospital according to how they feel they should respond, rather than according to the pain experienced. Davidson (1988) suggested that organisations utilise a variety of strategies to manage difficult situations such as pain. He describes these strategies as the 'institutional denial of pain'. The most powerful of these strategies is to render the patient a passive receiver of care. Carr and Thomas (1997) described how patients may be reluctant to tell nurses that they are in pain because they feel dehumanised and helpless while in hospital. In an extensive phenomenological study, Madjar (1998) illustrates how the clinical environment encourages patients to behave with composure and cooperation, despite being in considerable pain. In this study, patients with severe burns described how they controlled their expression of pain during dressing changes, in order not to impede the work of nurses, so as to have the best possible chance of recovery.

Organisational issues also influence how nurses respond to pain. Madjar (1998) described several instances where nurses expect patients to cope with pain through their ability to endure pain rather than through having adequate analgesics, as the following excerpt from the study illustrates:

> *His requests for pain relief, his obvious distress, obvious physical distress, and just his communication, his whole attitude ... I think he is at the stage now where we have to be firm with him, talk to him, try and talk him through [painful procedures without the use of opioids], to make him more comfortable in other ways.*

In addition to environmental influences, several structural organisational issues influence pain, such as the availability of medications. In some countries, common analgesics such as morphine are unavailable and, in the UK, these medications may be unavailable or restricted out of hours and at weekends. Similarly, prescription practices may influence the availability of medications (Schafheutle et al 2001).

MECHANISMS OF PAIN

In addition to individual, group and contextual influences on pain, physiological mechanisms mediate how individuals experience pain. Emotional, cognitive and behavioural influences interact with sensory mechanisms of pain, sometimes exacerbating the sensory perception of pain and sometimes modulating it (Frischenschlarger & Pucher 2002). Understanding this interaction is key to understanding how to manage pain from a pharmacological, a medical and a nursing perspective.

ANATOMY AND PHYSIOLOGY

19.3 Before reading the next section, try to describe the physiological 'pathway' of pain from an injury to your leg to your cognitive awareness of pain.

Nociceptors

As in all sensations, pain is recognised by specific receptors. These are nociceptors — free sensory nerve endings that detect physical and chemical damage to the tissues and form a widespread and overlapping network in almost all tissues of the body. Like other neurones, nociceptors are classified according to their speed of conduction and their diameter. Most nociceptors fall into the A and C groups of sensory neurones. Nociceptors are structurally similar to other sensory neurones but differ in respect of their thresholds, i.e. the minimum stimulus that activates them, and their specificity (Carpenter 2003). Some nociceptors, such as the fast conducting myelinated A-delta (A-δ) neurones, are unimodal and respond to high threshold mechanical stimulus. Other A-δ neurones are bimodal,

responding to both chemical and mechanical or thermal stimuli. Most of the slower conducting non-myelinated C fibres are polymodal and respond to chemical, thermal, mechanical and touch stimuli. The differentiation between A and C nociceptors is a fundamental principle of the gate control theory of pain, discussed below. However, it is important to appreciate that this differentiation is simplistic, since there is a dynamic interaction between all nociceptors.

Chemical stimulation is usually a result of tissue damage and the subsequent release of chemicals around the free nerve endings. These chemicals are released by damaged cells and by the action of neurotransmitters released by nociceptors. For example, damaged cells synthesise prostaglandins and leukotrienes from membrane phospholipids. The neurotransmitter, substance P, and other peptides are released from C fibres, causing sensitisation, vasodilatation and leakage from blood vessels. In addition, substance P induces histamine release from mast cells and 5-hydroxytryptamine — 5-HT, serotonin — from platelets. Chemicals are also released from the sympathetic fibres and contribute to pain and aspects of the inflammatory process (Stannard & Booth 2004; see also Ch. 23, p. 835). Such chemicals either directly initiate a response in the nociceptor or sensitise it to further stimulation, i.e. lower the threshold.

Peripheral nerve pathways

Once a nociceptor has been activated, an electrical impulse is conducted along afferent, i.e. sensory, neurones to the CNS. This is achieved through the exchange of sodium and potassium across the neurone membrane through the sodium pump, a specialised membrane-bound protein.

Spinal cord pathways

Nociceptors communicate with the CNS at the dorsal horn of the spinal cord (see Fig. 19.1). The dorsal horn is the posterior part of the grey, butterfly-shaped area seen on cross-section of the spinal cord. This is surrounded by white matter — myelinated axons stretching the length of the spinal cord. These fibres are either ascending or descending pathways connecting the brain with the dorsal horn.

The grey matter comprises the cell bodies of interneurones, small neurones that link the peripheral nervous system with the CNS via specialised nerve pathways. A cross-section of the spinal cord shows a loose structural organisation of these cells in 10 layers called lamina. Six of these laminae are in the dorsal horn and roughly correspond to the cells responsible for nociception. The outer two, laminae I and II, comprise the substantia gelatinosa, identified by Melzack and Wall (1996) as a key area in nociception, central to the gate control theory. However, research has shown that most noxious stimuli are assessed by nociceptive-specific (NS) cells in lamina I (Lima 1997). Other stimuli, such as those caused by heat, pressure and touch, are assessed by wide dynamic range (WDR) neurones predominately found in laminae IV, V and VI (Lima 1997). Thus peripheral fibres interact with NS and WDR fibres depending on the stimulus they are conveying. The role of the NS and WDR neurones in assessing impulses from the peripheral nervous system is an important one and determines whether the impulse will be transmitted to the brain (Carpenter 2003). For example,

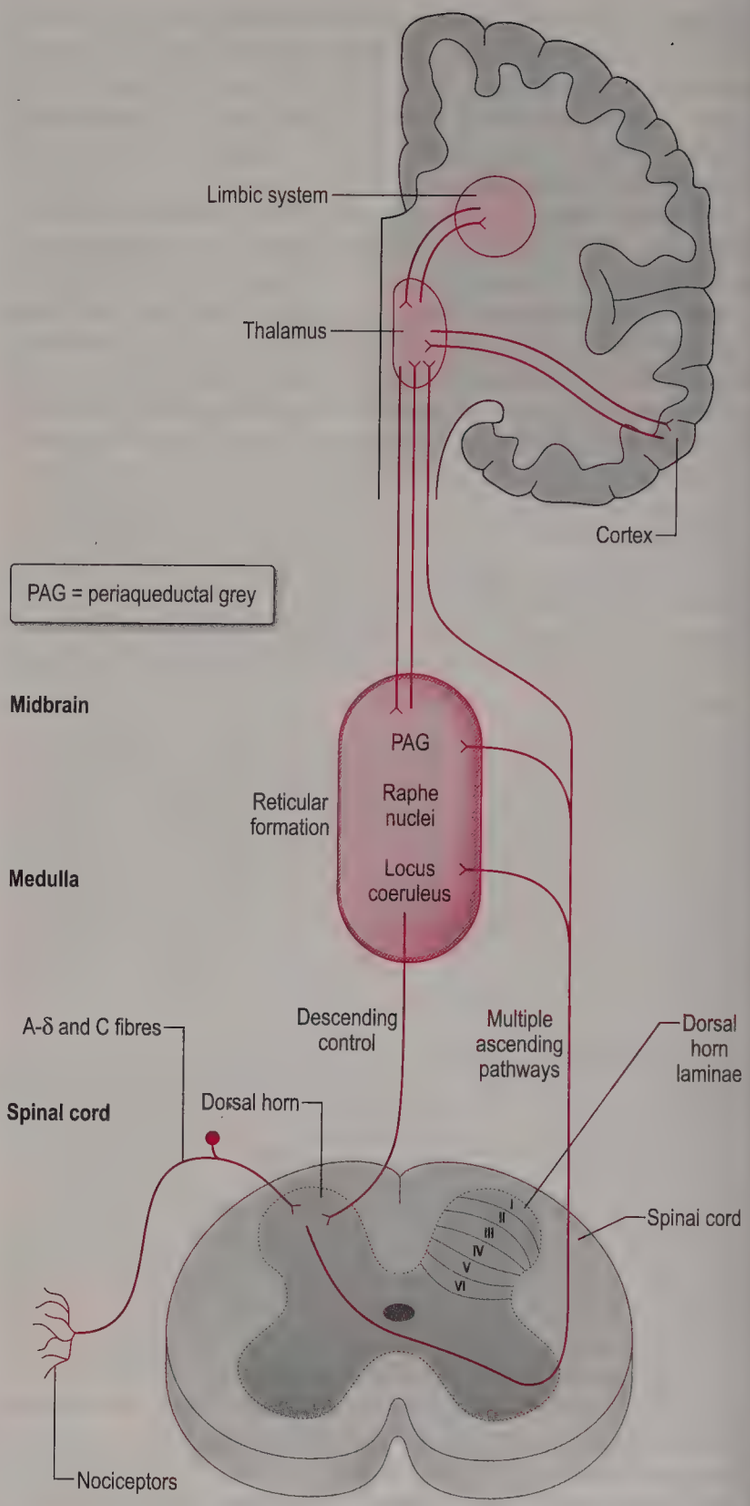

Fig. 19.1 Diagrammatic representation of some neural pathways involved in pain transmission.

research has shown that brief stimuli are sufficient to activate NS neurones, whereas prolonged stimulation is required to activate WDR neurones (Lima 1997). Carpenter (2003) suggests that the evidence now available points to NS and WDR neurones being part of two distinct but complementary nociceptive systems.

Ascending pathways

Ascending pathways consist of neurones that link the dorsal horn with centres in the brain. There has been significant

growth in knowledge about these pathways. Perhaps the most important information to come to light is the number of pathways identified in nociception and their role in a compound processing system activated by any kind of sensory input (Lima 1997).

From a review of research using chemical and electrophysiological tracing techniques, Lima (1997) has identified the following ascending tracts as nociceptive pathways: lateral spinothalamic, medial spinothalamic, spinomesencephalic, spinoreticular medial, spinocaudal ventrolateral medullary reticular, spinodorsomedullary reticular, spinosolitary, spinohypothalamic, spinoamygdalian and spinoorbital cortex. However, although all of these pathways are capable of transmitting pain, they are not, in most cases, pain specific. Each of these tracts connects a particular area of the dorsal horn with a specific area in the brain. While much remains to be discovered about the operation of these tracts, their apparently overlapping functions may include (Carpenter 2003):

- signalling the 'sensory–discriminative' aspects of pain, e.g. location, identification
- signalling its 'motivational–affective' aspects, e.g. unpleasantness of the sensation, desire to escape, anxiety
- triggering motor and autonomic responses
- activating descending analgesia systems.

Brain mechanisms

From the number of ascending tracts described above, it can be seen that many areas of the brain are involved in pain transmission. Each of these centres receives and integrates sensory inputs, relates them to past experiences and thus brings about behaviour to promote survival. Central to these centres is the reticular formation in the central core of the medulla, pons and midbrain (see Ch. 9). The reticular formation contains the periaqueductal grey (PAG), the locus coeruleus and the raphe nuclei. Of these, the PAG has particular importance for receiving inputs from the frontal cortex, the limbic system, particularly the thalamus and hypothalamus, as well as some ascending tracts. In turn, the PAG relays information to the nuclei of the rostral ventral medulla (RVM), such as the nucleus raphe magnus (NRM), the nucleus reticularis magnocellularis (Rmc), the reticularis paragigantocellularis (Rpgl) and the medullary adrenergic cellular groups (MA). The neurotransmitters involved in this relaying of information appear primarily to be serotonin and neurotensin (NT). Through these connections the PAG has a monitoring as well as a response role in pain sensation and perception, coordinating a negative feedback loop between the ascending tracts and the cortex, and the descending tracts and the dorsal horn. It is proposed that this feedback loop modulates the responses of convergent, i.e. multireceptive neurones (Carpenter 2003).

Descending pathways

Descending pathways connect the brain centres described above with the dorsal horn. They have a key role in the modulation of pain, primarily through the release of specialised neurotransmitters at the dorsal horn. The principal neurotransmitters associated with these pathways are noradrenaline (NA) and serotonin (5-HT). They coexist with other neuropeptides such as the endogenous opiates, endorphins and encephalins.

Throughout the central nervous system pain is further influenced by excitatory and inhibitory receptor mechanisms. These can be broadly divided into two groups: excitatory mechanisms are managed by glutamate synapses, particularly N-methyl-D-aspartate (NMDA) receptors; inhibitory mechanisms are managed by gamma-aminobutyric acid (GABA)-ergic synapses.

The primary excitatory mechanism in the CNS is glutamate synapses, in which the key neurotransmitters are L-glutamate acid and L-aspartic acid. These amino acids open sodium channels and so increase sodium concentration. This leads to depolarisation and increased neuronal firing (Carpenter 2003). These neurotransmitters bind with two main types of receptor that have been distinguished pharmacologically: AMPA receptors and NMDA receptors. Both receptors are elements of a complex protein molecule that forms part of a postsynaptic ionic channel.

The NMDA channel has several critical properties:

- it is voltage dependent, due to the ability of magnesium to block the channel
- it has several binding sites, including a phencyclidine site that binds with some opioids and dissociate anaesthetics such as ketamine that then prevent ion transfer
- it has a high permeability for calcium.

These properties are thought to be key to the mechanisms involved in persistent pain.

The primary inhibitory mechanisms in the CNS are GABA-ergic. The key neurotransmitters in these synapses are amino acids such as gamma-aminobutyric acid (GABA), glycine, aurine and proline. These inhibitory amino acids open chloride channels and so increase conductance of postsynaptic membranes, leading to hyperpolarisation and decreased neuronal firing (Carpenter 2003). These amino acids bind with GABA receptors.

The GABA receptor is found in neuronal membranes throughout the CNS, particularly in the thalamus, hypothalamus, hippocampus and basal ganglia of the brain and the substantia gelatinosa of the dorsal horn of the spinal cord. This receptor is a complex protein that can be classified into two types – $GABA_A$, selective for chloride as described above, and $GABA_B$, selective for potassium.

$GABA_A$ receptors are complex proteins consisting of five different subunits arranged around a central core. Each subunit has an affinity for different neurotransmitters and thus the binding of different substances to different subunits brings about a large number of possible actions.

RELATING THE PHYSIOLOGY OF PAIN TO ANALGESICS

Peripheral mechanisms and non-steroidal anti-inflammatory drugs

Pain is stimulated by the release of noxious substances such as prostaglandins, histamines and kinins within the tissues, 'released' in response to tissue damage such as that

caused by injury, tumour infiltration or inflammation. Of these chemicals, the synthesis of prostaglandins is of interest, since preventing its synthesis, and therefore preventing pain stimulation, is possible through administration of glucocorticoids and non-steroidal anti-inflammatory drugs (NSAIDs).

Prostaglandins

Prostaglandins are synthesised in response to tissue damage from arachidonic acid (AA). AA is an important constituent of the lipid component of phospholipids that constitute cell membranes. AA is obtained from dietary animal fats or converted from dietary linoleic acid found in animal and plant fats, especially seed oils. The amount of AA that is 'free' and not incorporated within cells is very small and this is one of the main factors limiting the production of prostaglandins. AA is freed from cell membranes by the enzyme phospholipase A_2 (PLA_2). This enzyme is found in cell lysosomes. PLA_2 separates the phosphate from the lipid element of the phospholipid. The AA liberated may be synthesised by two pathways to form potent biological mediators that include prostaglandins. Collectively these mediators are called eicosanoids. Two different enzymes initiate the two pathways of AA metabolism: cyclo-oxygenase (Cox), an enzyme bound to the reticulum of the cell, and lipo-oxygenase (Lox), an enzyme found in cytosol. Cox synthesises AA into endoperoxides, short-living intermediates. These are further synthesised into prostaglandins and thromboxanes (collectively called prostanoids) by the enzyme synthetase. Two types of Cox are now recognised: Cox I is involved in gastric cytoprotection and renal function; Cox II is involved in inflamed tissue (Pace 1995). Lox converts AA into non-cyclised hydroxy acids. These are further synthesised into leukotrienes.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are a group of compounds that share common pharmacological properties but are not necessarily chemically related. NSAIDs all possess anti-inflammatory, analgesic and antipyretic actions. With respect to pain, NSAIDs have an analgesic effect by:

- inhibiting prostaglandin (PG) synthesis through inhibiting the enzyme Cox and thereby reducing peripheral nociceptor stimulation. Cox also inhibits the role of PG in sensitising the CNS to noxious stimulus
- inhibiting superoxide anion formation — superoxide anion is formed by polymorphonuclear cells in response to inflammation and is one of the chemicals that can stimulate nociceptors peripherally. NSAIDs block the action of the enzyme produced by polymorphonuclear cells to initiate the production of superoxide anion and thereby reduce peripheral nociceptor stimulation. Diclofenac is an example of a NSAID that has been found to have this effect
- increasing beta-endorphins and therefore inhibiting the action of nociceptive neurotransmitters
- stimulating serotonin (5-HT) synthesis in the CNS and so inhibiting nociceptor transmission by blocking the action of neuromodulators.

The way in which these effects are brought about varies with different groups of NSAIDs because the chemical effects and potency of NSAIDs vary. NSAIDs have a range of side-effects, the most serious being adverse gastrointestinal events such as ulceration, bleeding and perforation. Patients at high risk of these side-effects include those who are 65 years or older, those with a previous history of such events, concomitant use of medications, e.g. steroids or anticoagulants, the presence of co-morbidity such as cardiovascular disease, renal or hepatic impairment, diabetes and hypertension (National Institute for Clinical Excellence 2001). Some of these side-effects, it is argued, are minimised by a new group of NSAIDs – the Cox II selective inhibitors. The enzyme Cox II is thought to be specific to prostaglandins synthesised as a result of inflammation. The NSAIDs such as celecoxib have been developed to act specifically to prevent the synthesis of this form of the Cox enzyme. They are more expensive than other NSAIDs and evidence about the claims that they minimise side-effects is limited. However, the National Institute for Clinical Excellence (2001) stated that there is 'pragmatic evidence of a reduced incidence of serious gastrointestinal events compared to standard NSAIDs'. The complete version of the evidence and guidance is available on the NICE website (see 'Useful websites and addresses'). This evidence is under review following withdrawal of the Cox II drug, rofecoxib, by the manufacturers because of recent controlled trial evidence suggesting similar side-effect dangers to a Cox I comparative NSAID (naproxen). An overview of the pharmacology, effectiveness and clinical use of NSAIDs is given on the Bandolier website (see 'Useful websites and addresses').

Central mechanisms and opioids

Analgesic opioids, e.g. morphine, mimic the effect of endogenous opiates and bind to opioid receptors found throughout the CNS. Naturally occurring endogenous opiates are neuropeptides, neurotransmitters synthesised and released by descending fibres in the CNS. When bound with an opioid receptor they have a modulating effect on pain. Their effect is determined by a complex multiple messenger system, sometimes referred to as co-transmission, meaning that other substances, e.g. serotonin and substance P, are involved in the effect that endogenous opiates have when bound to a receptor. Co-transmission enables an increased level of control at the synapse, compared with simple synapse mechanisms.

Neuropeptides are found in the gut, hypothalamus, anterior pituitary and posterior pituitary gland.

At least 10 opioid neuropeptides have been identified. They arise from three major groups of endogenous opiates: encephalins, endorphins and dynorphins.

The release of neuropeptides from a descending fibre is dependent on calcium activation. Termination of the activity of neuropeptides is believed to be initiated by enzymes, which release the neuropeptide from the receptor binding site.

Opioid receptors

A number of key opioid receptors have been identified:

- Mu (μ) receptors preferentially bind with opioids such as morphine and fentanyl, i.e. as an agonist to these

drugs. When an opioid binds with a mu receptor it activates the cyclic adenosine monophosphate (AMP) secondary messenger system within the nerve cell, and this causes the opening of potassium channels. This reduces the excitability of the cell and consequently reduces the firing rate of the nerve. Mu receptors are distributed in the peripheral and central nervous system, with high densities in the brain stem, trigeminal nuclei, spinal cord, periaqueductal grey region, amygdala and cerebral cortex. Naloxone, an antagonist to morphine, also binds to mu receptors, so preventing morphine from binding at this site.

- Delta (δ) receptors are located throughout the peripheral and central nervous system and preferentially bind with the neuropeptide, leucine–encephalin. When bound with an opioid, delta receptors mediate hyperpolarisation and inhibit the release of noradrenaline. This reduces nociception by decreasing firing and reducing neurotransmission at the dorsal horn synapse. Delta receptors are partially agonistic to naloxone whereby there is a small attraction between naloxone and these receptors.
- Kappa (κ) receptors have a different spectrum of action to mu and delta receptors. They are agonistic to pentazocine and endogenous dynorphin and are predominant at spinal sites. Binding with an opioid causes less respiratory depressive effect but more hallucinogenic effects.

Therapeutic use of opioids

Morphine is the standard, first choice, 'strong' opioid for nociceptive pain. When titrated against an individual's pain, it provides effective and safe analgesia. Other opioids in clinical use include diamorphine, tramadol, fentanyl, oxycodone, buprenorphine and methadone.

The side-effect profile for each of these opioids varies in the degree to which they are experienced. In persistent and cancer pain, rotation between opioids may be necessary to find the opioid that gives the best therapeutic effect with the minimum side-effects. Typical opioid side-effects include the following (Stannard & Booth 2004):

- Respiratory depression and sedation due to binding with mu receptors in the pons and medulla. Respiratory rate, depth and rhythm can be altered, leading to carbon dioxide retention. Respiratory depression is rarely a problem in long-term opioid therapy but is more common postoperatively because of the compounding influence of anaesthetic agents. Sedation usually declines within a few days.
- Nausea and vomiting due to stimulation of the chemoreceptor trigger zone in the CNS and gastric stasis due to binding with mu receptors in the gut. This tends to be a transient side-effect that will pass within a few days.
- Constipation due to direct effect on the smooth muscle of the gut. This is a persistent side-effect that is likely to require treatment with laxatives.
- Hallucinations and agitation, thought to be due to the action at kappa and sigma (σ) receptors.
- Myoclonus, i.e. jerking or twitching of muscle groups.
- Itching, due to histamine release in the skin.
- Urinary retention, due to increased smooth muscle tone in the urinary tract.

Morphine is contraindicated in patients with raised intracranial pressure because the respiratory depressant effect may cause an increase in arterial PCO_2, resulting in a further rise in intracranial pressure. Care also needs to be taken in patients with renal impairment since the excretion of morphine and its metabolites will be impaired and the likelihood of side-effects therefore increased. Careful titration and increasing the time interval between doses is often necessary for these patients.

THEORIES OF PAIN

19.4 Before reading the following section, make a note about how theories might help you to understand pain. As you read the section, judge the contribution of each theory to your understanding of pain.

Several theories have been developed to explain pain. The philosopher Aristotle drew on Plato's theory about extremes and opposites, arguing that pain was the opposite of pleasure and that both pain and pleasure were 'quales' — emotional qualities of the soul. An important part of Aristotle's differentiation between pleasure and pain was the belief that pleasure is good whereas pain is bad. Thus Aristotle viewed both pain and pleasure as having moral value and, indeed, he argued that these quales were fundamental moral drives directing human action. Furthermore, he suggested that pain could be overcome by reason.

The specificity theory

Descartes (1596–1650) proposed a direct channel for pain from the periphery of the body to the brain, proposing that when the body was exposed to a painful stimulus, this was relayed to the brain by a specific pain pathway. This is known as the specificity theory and is challenged by Melzack and Wall (1996), who point to clinical evidence such as phantom limb pain that contradicts the existence of specific pain pathways.

The pattern theory

This theory develops the concept that any stimulus is capable of producing pain if it reaches sufficient intensity. Pattern theory differs from the specificity theory in that it proposes that all fibre endings are alike (except innervate hair cells) and that the pattern for pain is produced by intense stimulation of non-specific receptors (Melzack & Wall 1996). The pattern theory also introduced the concept of summation – that successive impulses collectively 'summate' to reach a critical firing level. Pattern theory suggests that summation can be prevented by specialised rapidly conducting fibres. Melzack and Wall (1996) later developed the concept of summation in the gate control theory.

The gate control theory

The gate control theory of pain, developed by Melzack and Wall (1965), combines pertinent aspects of older theories

with an account of what happens in clinical practice. According to this theory, the transmission of information from a potentially painful stimulus can be modified by a gating mechanism situated in the substantia gelatinosa in the dorsal horn of the spinal cord. This mechanism can increase or decrease the flow of nerve impulses from the periphery to the CNS. If the gate is open, impulses pass through; if it is partially open some pass through; and if shut, no impulses get through and pain is not experienced.

Melzack and Wall (1965), in their seminal text, argued that whether the gate is open or closed is determined by:

- activity in small diameter fibres (A-δ and C fibres, which transmit pain)
- activity in large diameter fibres (A-β fibres, which transmit touch)
- descending influences from higher centres, including those concerned with motivational and cognitive processes.

Melzack and Wall (1965) proposed that the substantia gelatinosa is activated by large A-β fibres that shut the gate and inhibited by small A-δ and C fibres that open the gate. This activity then influences the information sent to the brain, which in turn initiates descending inhibitory controls depending on the information from other areas such as the cortex.

Implications of the gate control theory

The physiology of pain has developed since the gate control theory was first proposed. However, the inherent fundamental principles have stood the test of time and influenced pain management. Clinically, the gate control theory has been applied to nursing care (Carr & Mann 2000) through measures such as massage and the application of heat. The use of touch and massage can stimulate the skin, increasing large fibre (A-β) activity and thereby closing the gate at the spinal cord level and relieving pain. This rationale also explains the benefit of the advice: 'rub it better'.

Closing the gate at the brain stem level can sometimes be achieved by ensuring sufficient sensory input, e.g. by using distraction and imagery (see p. 754). Similarly, at the level of the cortex/thalamus, the gate can be closed by reducing anxiety, e.g. by providing accurate information about the cause, likely course and relief of pain and thereby increasing the patient's confidence and sense of control.

Developments since the gate control theory

The pain control system described by the gate control theory is one that acts rapidly. Research has demonstrated the existence of 'plasticity' or adaptability in the nervous system, which allows for both rapidly transmitted impulses and slow-onset, long-duration changes. It is thought that C fibres, especially those originating in deep tissues, trigger these slower messages (Price 2002). This prolonged mechanism, referred to as 'wind up', results in a sustained experience of pain, which may account for some cases of neuropathic pain (Price 2002). In addition, there is some evidence that this kind of pain can be explained by changes in central neural function (Coderre et al 1993).

More recently, spinal cord glial cells have been implicated in persistent pain. Glia regulate extracellular ions and neurotransmitters, and clear debris such as dead cells. It has been suggested that these cells are responsible for amplifying pain by releasing proinflammatory cytokines, which stimulate the CNS pain response (DeLeo & Yezierski 2001, Watkins & Maier 2003, Wiesler-Frank et al 2003).

KEY CONCEPTS IN PAIN

19.5 When reading the following section, think about the meaning of the words acute and chronic. How might this influence someone's pain experience and management?

Pain threshold

Pain threshold is 'the least experience of pain which a subject can recognise' (International Association for the Study of Pain 1994). Laboratory studies of pain have demonstrated that pain thresholds are fairly constant across the population. In other words, the vast majority of people agree on the point at which a sensation becomes painful.

Pain tolerance

Pain tolerance is 'the greatest level of pain which a subject is prepared to tolerate' (International Association for the Study of Pain 1994). Pain tolerance needs to be distinguished from drug tolerance.

Acute and chronic pain

Pain was traditionally classified as either acute or chronic. Acute pain distinguished pain that was short lived and related to injury, e.g. following surgery or trauma. Chronic pain described pain that was long lived, most definitions suggesting 3 months or more (Royal College of Anaesthetists and The Pain Society 2003), and that was typically harder to control. Chronic pain was further divided into chronic malignant pain, due to cancer or other similar progressive illnesses, and chronic non-malignant pain, due to injury, such as prolapsed intervertebral disc, but persisting beyond the healing of the injury. The physiological mechanisms present in pain due to trauma reinforce this view — there is usually an associated sympathetic nervous system response which results in observable changes: nausea and vomiting, increased oxygen consumption, raised blood pressure and pulse rate and vasoconstriction or, less commonly, a parasympathetic stimulation resulting in decreased pulse rate and blood pressure. In chronic pain these signs are not present and can lead to assumptions that someone is not in pain.

More detailed knowledge of the physiology of conditions that were associated with chronic pain makes the classification of chronic pain by time frame redundant (International Association for the Study of Pain 1994). There is therefore a growing use of the term persistent pain to describe chronic pain and to classify pain by its physiological mechanism, 'nociceptive' describing pain caused by tissue damage and 'neuropathic' describing pain that persists beyond the original cause as a result of disruption to the normal transmission of pain, e.g. through nerve injury, nerve infection and nerve compression. Classifying pain by the physiological mechanism in this way has the advantage of

informing decision making about how best to manage the pain (Arnér 2000, Dann et al 2000, Caraceni 2001).

Nociceptive and neuropathic pain

Nociceptive pain is typically experienced as sharp or aching and it may be intermittent or continuous. Neuropathic pain is characterised by continual severe unremitting pain, often associated with burning or shooting or stabbing sensations and with allodynia – where light touch normally not painful is excruciating. In practice, people use phrases such as: 'It feels as though a knife is digging into me'; 'I can't bear to put my pyjamas on because they hurt so much'. One patient said: 'It feels as though my knee cap is going to explode'.

The cause of neuropathic pain will determine some of the symptoms that people experience as a consequence. For example, nerve root compression can cause pain along the distribution of the nerve being compressed, the compression preventing the action potential moving smoothly along the neuronal membrane. The notion of a 'short circuit' in the nerve is helpful to explain this. The resultant excessive firing exacerbates the strength of the sensation being interpreted at the dorsal horn and is responsible for the sensation of severe pain. Where pain is persistent, such as in nerve damage, the CNS can undergo particular changes that make it very responsive to any received sensory information, causing it to fire in circumstances when the strength of this sensation would not normally cause this reaction. This is called 'wind up', a term used to describe the enhanced responsiveness of the CNS to sensory stimuli.

Referred pain

Normally, if one stubs a toe or cuts a finger, it is apparent exactly where the injury has occurred. However, this localisation of pain is limited to the skin. Pain from the viscera and from deep somatic tissue can be felt in apparently unrelated but predictable locations. For example, the pain of a heart attack is often referred to the left arm, and pain in the early stages of appendicitis may appear to originate from above the umbilicus. Pain is usually referred to a structure developed from the same embryonic structure or sclerotome.

Another type of referred pain is associated with trigger points. These are small hypersensitive regions in muscle or connective tissue that may be located in the area of pain or at some distance from it. This referred pain does not follow any known dermatomes, but stimulation produces pain in a relatively constant and predictable location (Stannard & Booth 2004).

PAIN MANAGEMENT

Nursing assessment

19.6 Think back to the last time that you assessed a person in pain. How did you go about this? What influenced this process?

Assessment is fundamental to pain management. It is a crucial nursing activity that must be carried out as part of the initial nursing assessment and at regular intervals thereafter in order to obtain a complete and evolving picture of the patient's pain. Sjöström et al (2000) emphasise the importance of this individual assessment rather than relying on typologies of patients (such as 'major' or 'minor' surgery) as this leads to underestimation of pain.

Pain assessment is complex and dependent upon the interaction between patient, nurse and clinical context (Manias 2003). It includes observing the patient's behaviours, taking account of relevant physiological measurements, interviewing the patient, understanding their concerns and responding to cues appropriately. Assessment may incorporate a framework such as a pain assessment tool, but it should be remembered that a pain tool is only one facet of an adequate assessment.

Observation

Observation of pain is difficult and unreliable, but is usually based on verbal clues such as direct statements, as well as moaning, crying, sighing and grimacing, and non-verbal clues such as guarding, bracing and lying perfectly still. However, these clues do not have to be present for someone to be in pain. Indeed, such clues are frequently absent. Thus, caution should be exercised in the interpretation of non-verbal signals. However, they remain an important source of assessment for people who cannot respond verbally, such as those who are unconscious or disorientated and confused. Where this is the case, observational assessment needs to be systematic and may be enhanced by the use of an observational tool such as that reported by Simons and Malabar (1995).

Asking the patient

Observation must be combined with discussion with the patient wherever possible, in order to assess whether someone is in pain and, if so, to understand the nature of the pain and the degree to which it is influencing that individual's experience of life. On the whole, this aspect of pain assessment is undervalued, with some studies demonstrating that few patients are asked about their pain (Carr & Thomas 1997) and as a consequence experience pain unnecessarily. Results of studies in which patients and carers were asked how nurses could help to relieve pain reinforce the importance of nurses listening and being sensitive to their concerns and experience in order to understand and anticipate these, and guide the patient and carer to information that may be helpful (Walker et al 1990, Ferrell et al 1991a,b, Madjar 1998, Manias et al 2002, White 2003). Box 19.1 gives an example of how assessment can be shaped to gain an understanding of a person's experience of pain.

Pain assessment tools

Assessment is often complemented by a pain assessment tool, and there are many different tools available for this purpose. The characteristic of a tool is shaped by the underpinning interpretation of pain (Coll et al 2004a). Pain scales, such as the visual analogue scale or numerical rating scale, assess pain sensation and intensity (see Figs 19.2–19.4). Tools such as the McGill Pain Questionnaire (MPQ) assess multidimensional aspects of pain such as sensation, intensity, quality, physical function and the effectiveness of pain-relieving strategies. Tools such as pain diaries are designed to assess the impact of pain on the quality of a person's life.

Box 19.1

One nurse's process of pain assessment

Setting the scene
I explain who I am and what I am doing. I might say something like: 'I am one of the nurses in the unit and have a responsibility to make sure that you are comfortable. Is it alright if I talk to you for a few minutes about this?'. If this is acceptable, then I proceed with a question such as: 'Can you tell me if you have any pain or discomfort?'. If it is not acceptable, then I negotiate another time when it is convenient. The question about pain is quite a closed one and has the disadvantage that it focuses attention on one facet of the patient's illness but I find that this means we have a place to start. If I feel someone will be comfortable with an open question I will say something like: 'Tell me what's been happening to you'. Within the conversation that follows I will include the following pain themes: location, severity, quality, pattern and effect on other aspects of life.

The location of pain
I ask where the pain is and check the location, and also ask whether the patient has more than one pain. A question such as 'Can you tell me where you get the pain' will often prompt people to point to the pain. If this is easily reachable, important information can be gained by watching how the affected part is touched. For example, if someone has nerve pain they often show the location along the sensory distribution of a nerve and this can give a clue as to which nerve is affected. If the place is difficult to reach, I ask the patient just to describe where the pain is so that their discomfort is not increased.

The severity of pain
In assessing the degree to which pain is affecting a person's ability to be independent and what coping strategies are used, a question I often ask is: 'Can you divert your attention away from the pain?'. If pain is all-embracing, in the way that Bendelow and Williams (1995) suggest, then it is difficult for someone to forget the pain because 'they become the pain'. If a patient tells me that this is really difficult to do, I suggest that their pain is really severe; this is typically followed with relief that someone has recognised how awful their experience is.

The quality of pain
How pain is described provides information about the mechanisms of the pain. Common words include throbbing, shooting, stabbing, sharp, cramping, gnawing, hot/burning, aching, heavy, tender, splitting, tiring/exhausting, sickening, fearful and punishing/cruel. It is important to be aware that some people may not actually use the word 'pain' when asked about their discomfort and may even deny having pain. In these cases it can be helpful to incorporate words such as 'ache', 'hurt', 'sore' and 'discomfort' into an assessment.

The pattern of pain
Pain often follows a pattern that gives a clue about its nature and what can be done to relieve it. For example, pain in arthritis is often worse in the morning and knowing this can influence the medication that is given at night in an attempt to alleviate it. Similarly, persistent pain is sometimes worse when the individual is tired; knowing this can help the individual to plan their day. Questions that enable such patterns to be identified include:

- When did the pain start?
- How long does it last?
- Does it come and go or is it there all the time?
- Does anything relieve it?
- Does anything make it worse?

The effect of pain on other aspects of life
Pain often influences whether someone can sleep or socialise and so a question about how pain is influencing the quality of life is important as there may be ways to help with this. I sometimes ask: 'How are you coping?', both to elicit this information and to find out how the person is feeling in themselves. This sort of question not only gives people an opportunity to explain how pain is influencing their life but also to raise other related concerns, such as finances or care needs, or fears about medications or their illness. This gives me an opening to ask questions about the sense that they might be making of the pain, which in turn helps me to understand the meaning they are attributing to their experience.

Anything else?
This last question makes sure that I have not missed any cues given to me earlier. I ask something like: 'What else do you think I should know?' or 'Is there anything else you would like to tell me?'.

Summary
After this assessment I summarise what I have been told by affirming that someone has pain and by explaining what is possible to help this pain. A typical comment would be: 'From what you have told me the pain in your [place of the body] has been really difficult to cope with. I think we can do something to relieve this pain'. I then go on to discuss what this might be. In the case of complex pain I explain that easing the pain might take a little time ('to get the recipe right') but that there is much that can be done ('there is a lot left in the tool kit yet'). If it is clear what can be tried straight away, I go on to discuss this. If I am not sure, I explain that I need to take some advice and will come back to explain what the possibilities might be. However, for the majority of people in pain there are simple strategies which can be implemented immediately that will make a significant and positive difference to their experience of pain.

19.7 Compare the following discussion with the pain tool that you use, or that is available, in your ward, team or organisation. What sort of tool is used? How applicable is it to the patient group that you care for?

Pain scales
Typically, intensity of pain is determined using a scale designed to enable the patient to rate the degree of pain felt. These scales can also be used to note any change in pain levels following an intervention or to indicate when the 'worst pain' or 'least pain' was felt, thus giving a profile of the pain experience over time. Scales can also be used to help the patient quantify the distress caused by the pain or to determine at what level of intensity the patient would like to be given analgesics. It should be remembered, however, that this level is not necessarily constant and that the patient's pain tolerance may fluctuate from day to day or within a 24-h period. Scales also have a place in minimising

the discrepancy between a patient's experience of pain and the nurse's judgement of it, as observed by authors such as Whelan (2003).

Three pain scales in current use that have been demonstrated to be both reliable and valid in people with cognitive function (Lundeberg et al 2001, Coll et al 2004a) are the visual analogue scale, the numerical rating scale and the verbal rating scale. Details of the research underpinning the reliability and validity of these tools is given in McCaffery and Pasero (1999). Closs et al (2004) found that the verbal rating scale provided a more reliable guide to the intensity of an individual's pain compared to the other scales, but that this was possible only in people with a small degree of cognitive impairment, the scales being inadequate to assess pain in people with severe cognitive impairment.

Visual analogue scale (VAS) This consists of a 10 cm line with the words 'no pain at all' at one end and a phrase such as 'agonising pain' or 'worst pain possible' at the other end (see Fig. 19.2). The line is usually horizontal but can be vertical. The patient is asked to mark this line at whatever point corresponds to the degree of pain being experienced at that moment. The assessor then measures in centimetres from the left-hand side of the pain scale (or the foot if a vertical line is used) to the mark in order to obtain the pain 'score'.

The advantages of this scale include the absence of numbers or words; the person in pain is not required to assign a precise numerical value to the pain or to choose a word that may not exactly represent their pain.

Numerical rating scale (NRS) This scale is like the VAS but is calibrated with the numbers 0–10 (see Fig. 19.3). The patient is asked to make a mark at a point that indicates the intensity of their pain. McCaffery and Pasero (1999) provide translation of the numerical rating scale into several languages that can be copied for clinical use.

Verbal rating scale (VRS) This scale provides graded categories, e.g. 'no pain at all', 'slight pain', 'moderate pain', 'very bad pain' and 'agonising pain' (see Fig. 19.4). The patient marks whichever category is most like their pain and this is assigned a score from 0 to 4. Many patients find this scale easy to use although it has the disadvantage of fewer assessment points compared to a 0–10 scale and therefore is not as sensitive.

Fig. 19.2 The visual analogue scale.

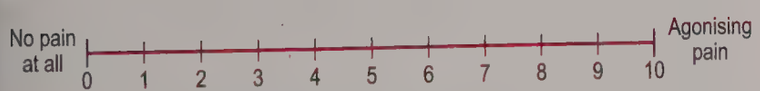

Fig. 19.3 The numerical rating scale.

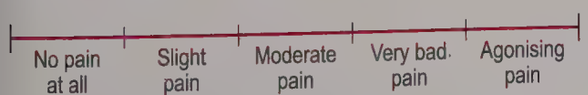

Fig. 19.4 The verbal rating scale.

The visual, numerical and verbal pain scales rate pain intensity, which is only one aspect of pain experience. These tools also encourage a linear assessment of pain intensity. Turk (1989) was one of the first authors to note that pain intensity may not be perceived in a linear fashion, and that linear scales may constrain and distort patient experience. This was borne out by a participant in Whelan's (2003) study who commented on the difficulty of expressing the meaning of the pain when using a numerical scale:

> *I wanted to put a meaning next to those numbers, so that if I said to my doctor 'I'm having pain that's about a seven' what I mean is, it's really bad, it's incapacitating enough that I'm not able to do my daily duties, but it's not so bad that I'm not able to get out of bed.*

Furthermore, the effectiveness of any of the above assessment tools may be distorted by the patient's inadvertent and deliberate denial or minimisation of pain (McCaffery & Pasero 1999).

Multidimensional pain tools

The scales described above are relatively simple forms of pain assessment tools. Many tools are more comprehensive and incorporate a body outline on which the site(s) of pain can be noted, scales to rate the intensity and quality of the pain and words that can be used to describe the pain, e.g. the McGill Pain Questionnaire (MPQ) and Brief Pain Inventory. McCaffery and Pasero (1999) provide examples of multidimensional assessment tools that can be copied for clinical use.

Pain tools to assess the impact of pain on a person's quality of life

There are several ways in which the impact of pain on an individual's life can be assessed. Pain diaries are useful assessment tools for this purpose. These are kept by the patient to record intensity of pain, effect of medication, other pain-relieving measures used and major activities, e.g. lying, sitting, walking. General impact of health questionnaires, such as the Sickness Impact Profile and the Nottingham Health Index, reviewed by Bowling (2004), are used by some pain clinics and in pain research to elicit disruption in daily activities and family relationships.

Selecting an appropriate tool

Coll et al (2004a) advocate using the framework developed by Fitzpatrick et al (1998) to select the most appropriate tool to complement pain assessment. The framework was developed from a review of 5621 abstracts and articles that focused on methodological aspects of patient-based outcome measures and consists of the following eight criteria, which state that the tool must be:

- appropriate — for the purpose intended and the setting in which it will be used
- reliable — in terms of reproducibility and internal consistency
- valid — in that it measures patients' perceptions of pain

- responsive — to changes of importance to patients
- precise — accurate and discriminating
- interpretable — in that meaningful information is produced
- acceptable — to those completing it
- feasible — in that the degree of burden and effort involved in using it is acceptable.

Nursing care

19.8 Before reading this section, consider your own feelings about pain and pain relief. If you were in pain, what sorts of things would be important to you to help you cope? Would this be different if you were at home rather than in hospital? Would different things be important for different types/causes of pain?

Nurses have a very significant role to play in pain management. Effective pain management depends upon the relationship developed between the nurse and the patient and, in part, this is why pain assessment is so important, as it sets the 'spirit' of that relationship, whether the patient's concerns will be taken seriously and how they will be responded to. The importance of this kind of nursing relationship, and of the nature of the characteristics required to achieve it, can be drawn from several studies that represent the patient view. A respondent in Carr and Thomas's (1997) study emphasised the importance of this relationship:

> *If she [the acute pain nurse] had just walked away I don't know what I would have done. Her being with me enabled her to understand what I was going through. I didn't feel alone. I felt that I had someone who was helping … you know. She was sort of experiencing it with me. Really, it was a wonderful feeling in that way … that she was with me.*

The patient respondents in Madjar's (1998) research identified particular qualities that they valued in the ways that nurses responded to their pain. These included:

- *gentleness* — a softness and tenderness in the way a nurse saw to their comfort
- *trustworthiness* — a combination of characteristics such as calmness and ability to inspire confidence
- *sensitivity* — responding through appropriate use of talk and silence and pacing nursing care according to the person's ability to tolerate it
- *technical competence* — being organised and efficient and able to perform technical tasks with skill and agility
- *knowledge and skilful communication* — being able to judge what information would be important at a particular time and the ability to communicate it in a way that fostered reassurance and encouragement.

Manias et al (2002) point to another nursing skill in pain management. This study highlighted that nurses are regularly interrupted in their work and needed skill in managing frequent interruptions and the competing demands placed on their time, since these qualities influenced pain management, e.g. how long a patient waits for analgesics.

Information and explanation are important aspects of support and therefore crucial to the nurse's role. The purpose of these activities is to ensure the patient has realistic expectations and that the nurse works towards achieving these. The aim is to achieve congruence between patients' expectations and their experience, since this has been shown by studies to reduce distress (Carr & Thomas 1997, Boström et al 2004).

Congruence between expectation and experience will also depend on the type of pain. In neuropathic pain it may take time to achieve a reduction in pain, although much can be done to help people cope. On the other hand, nociceptive pain can be relieved in nearly everyone and it is realistic to work towards considerable pain relief. However, despite advances in pain management, some doctors and nurses still believe that pain is an inevitable consequence of treatment and care (McCaffery & Pasero 1999, Carr & Mann 2000) and overestimate patients' ability to cope with pain (Madjar 1998). This is compounded by patients not realising that they can ask for pain relief (Carr & Thomas 1997, McCaffery & Pasero 1999) or waiting until they are in severe pain before requesting an analgesic (Carr & Mann 2000). Carr and Thomas (1997) suggest that this is due both to the lack of information and to the fact that patients can see that nurses are busy: 'Well, you could see the bells ringing here, there and everywhere and I wasn't that bad, so why worry them'.

The nurse's role in pain management extends to the family. Part of the nurse–family relationship is to recognise that family members have information needs of their own, particularly if they are the key carers. The carers in Oldham and Kristjanson's (2004) study of cancer pain identified the need to have the following concerns addressed: the nature of pain, concerns about medication and how to provide comfort.

The principles of the nursing management and the issues that challenge this are summarised in Table 19.1.

The role of the person in pain

The role of patients in the management of their own pain has been largely ignored. In part, this can be explained by the way in which health care professionals have encouraged a passive patient role. In addition, patients have not been given sufficient information about pain relief (Carr & Mann 2000), with the result that they have low expectations about what level of relief can be achieved.

Health care professionals can encourage patients to play a role in their pain management by adopting a partnership approach to care, involving patients in the assessment of their pain and its relief. This approach can foster a sense of control and reduce reliance on health care professionals. Control can be enhanced by giving adequate information about pain and pain relief prior to surgery (Carr & Thomas 1997) and by the self-administration of medications, e.g. by the use of patient controlled analgesia (PCA), postoperatively. In addition, with appropriate instruction and support, patients may contribute to their pain management by using complementary methods of pain relief (see p. 754).

Patients can also be helped to have a sense of control in their pain management if their coping strategies are built on, rather than ignored (Richardson & Poole 2001); finding out how people cope with pain becomes a crucial part of assessment. Richardson and Poole (2001) advocate using Turk et al's (1987) taxonomy of coping with pain to achieve

Table 19.1 Principles of pain management

Principles	Issues in practice
Base your management on a thorough assessment	Nurses often rely on their ability to judge a patient's pain rather than asking the patient about it (McCaffery & Pasero 1999). Many nurses assume that a patient who does not appear to be in pain is in no discomfort when the opposite might be true. Moreover, they assume that analgesics have been effective because the patient does not say anything to the contrary (Carr & Mann 2000)
Believe that it is possible and desirable for people to be pain free	Both nurse and patient may view pain as something to be tolerated. Research has shown that both patients and nurses often have low expectations of analgesics, and accordingly are satisfied with pain 'relief' that allows significant levels of pain to remain (Carr & Thomas 1997, Schafheutle et al 2001)
Provide analgesics until the person is pain free or experiences side-effects	PRN is sometimes wrongly interpreted as 'as little as possible' rather than 'as needed' until pain free. PRN prescriptions can be given in addition to regularly prescribed medication
Provide regular analgesics throughout the 24-h period to maintain pain-free state	Giving analgesics 'around the clock' at set times has been shown to maintain constant plasma blood levels of the drug (see Fig. 19.5) and thus prevent the peaks and troughs associated with PRN prescription (WHO 2004). This method of administration breaks the pain–anxiety cycle and decreases the patient's anticipation of pain worsening or returning
Use the analgesics prescribed to their full prescription to achieve the pain-free state	Very often nurses give the minimum dose prescribed and give analgesics less frequently than prescribed. As a consequence, many people experience pain unnecessarily. Sometimes prescribing is inadequate to provide pain relief (Schafheutle et al 2001)
Do not rely on the patient to tell you they are in pain or to remind you to provide analgesics — base your management on regular review	Few nurses accurately document their pain assessment or their evaluation of the effectiveness of any drug or comfort measure given to relieve pain (Carr & Mann 2000). Nurses may not trust the pain assessment and instead rely on their own judgement (Schafheutle et al 2001). Nurses may not ask patients if they have pain if they have recently had analgesics, if they have a PCA device or epidural in place or if they have been asleep (Schafheutle et al 2001)
Address fears of medication so that patients can make an informed choice about the analgesics you are offering	Many patients and family members have fears associated with the prescription of opioids, such as fear of becoming addicted, and fear that tolerance will prevent adequate analgesia later in their illness (McCaffery 2001). These fears are not always recognised or addressed by health professionals
Remember the importance of the environment on an individual's ability to cope and their spiritual well-being	Carr and Thomas (1997) suggest that depersonalisation, helplessness and passiveness are inherent in being a patient and influence people's ability to have a sense of control over their pain management (Arraras et al 2002, Smith et al 2002, Bishop & Warr 2003)

PCA, patient controlled analgesia; PRN, as required (*pro re nata*).

this. This taxonomy consists of three classifications of coping:

- *dysfunctional coping* — coping that does not influence the impact of pain on daily life, with the consequence that pain interferes with daily activities of living and results in psychological distress
- *interpersonally distressed* — where a perceived lack of support makes coping difficult
- *adaptive coping* — where coping is successful in managing pain.

Richardson and Poole (2001) suggested that these taxonomies can be identified from nursing assessment of activities of daily living.

The role of family members and carers

Family members have a key role in pain management. Ferrell et al (1991a) noted that family carers contribute to pain assessment by identifying the nature of pain through descriptors such as those used by patients — e.g. 'aching', 'horrendous', 'excruciating' — and by referring to anatomical locations of pain. Carers are also perceptive as to the degree to which pain is hidden by patients or minimised: 'A lot of the time I can sense what she is going through, but she doesn't want to burden others, so she minimises' (Ferrell et al 1991a). However, the degree to which family carers' assessment of pain is congruent with that of the patient is dependent on the severity of the pain. McMillan (1996) found that congruence was more likely when pain was at its least, rather than when it was at its worst, which is likely to be due to the distress experienced by family members when the patient's pain is severe.

Family members also play a very significant role in pain relief at home. With respect to people with cancer pain, Ferrell et al (1991b) found that carers often had a 24-h responsibility for deciding which analgesic to give and when. In addition, they were involved in reminding and encouraging the patient to take the analgesic and in keeping a record of what was taken and when. They were also involved in

non-pharmacological pain management such as positioning, massage, the use of heat, cold and touch, and the use of talk and other distraction techniques.

Pharmacological management

Pain can be relieved pharmacologically through the use of analgesics to provide analgesia — the 'absence of pain in response to stimulation which would normally be painful' (International Association for the Study of Pain 1994). Analgesics are commonly divided into the following groups:

- NSAIDs/non-opioids, e.g. paracetamol, ibuprofen
- weak opioids, e.g. codeine
- strong opioids, e.g. morphine.

Frameworks for the use of analgesics

Two frameworks can guide the use of analgesics: the World Health Organization pain ladder (WHO 2004) and systematic reviews of analgesic effectiveness. These frameworks have in common the principle that safe and effective analgesia can be provided by titrating the dose of analgesics to gain a balance between therapeutic effect and side-effect.

The World Health Organization pain ladder

The World Health Organization pain ladder (WHO 2004) is a three-step ladder that guides analgesic decision making. In clinical studies assessing the effectiveness of this framework, pain relief was attained in 80–90% of cases (WHO 2004). The underpinning principle of this framework is that the right drug should be given, at the right dose, at the right time. In persistent pain, titration should be done by moving from non-opioids, e.g. paracetamol, and NSAIDs through to weak opioids, e.g. codeine, and through to strong opioids, e.g. morphine, i.e. moving up the ladder. In surgical or trauma pain, titration will move in reverse order, from strong opioids to weak opioids to non-opioids and NSAIDs. In both cases analgesics should be given regularly to maintain a constant analgesic plasma concentration (see Fig. 19.5). For example, if a patient needs morphine, this will require to be given 4-hourly unless given in a sustained release preparation such as Zomorph, which enables a twice a day dose.

The right dose of analgesic is that which provides pain relief with the lowest side-effect profile. When moving from strong opioids to weak opioids, or vice versa, it is important to take into account the equipotency of the drugs involved. If a patient has been having 60 mg oral codeine 6-hourly and still has pain, the starting dose of oral morphine needs to be equivalent to more than this dose, in order to increase analgesia. For example, 60 mg oral codeine 6-hourly is approximately equivalent to 4 mg oral morphine 4-hourly. The starting dose of oral morphine therefore needs to be in the order of 7.5 mg 4-hourly rather than the typical oral starting dose of 5 mg 4-hourly.

Calculating an appropriate dose is equally important when changing routes of analgesic delivery. For example, patient controlled analgesia (PCA) and epidurals have significantly diminished people's experience of pain in the immediate postoperative period (Buggy & Smith 1999, Chang et al 2004) but, when discontinued, pain escalates

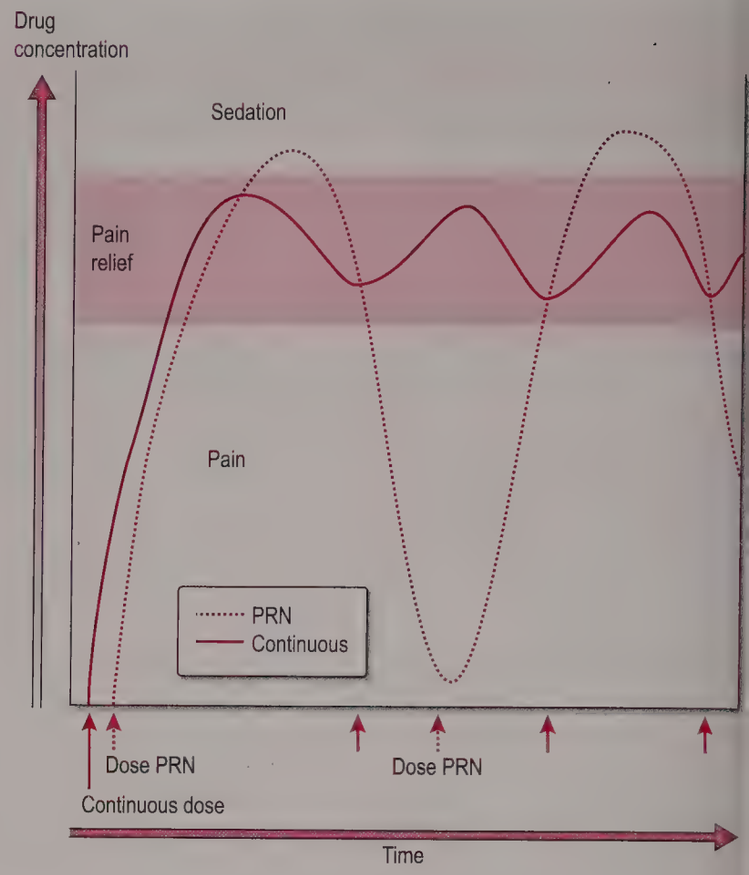

Fig. 19.5 PRN versus around-the-clock administration of analgesics.

because insufficient analgesics are given in their place (Carr & Thomas 1997). For example, if someone has had PCA and used 20 mg morphine over the course of 24 h, 5 mg oral morphine would be needed, 4-hourly, to achieve a similar level of pain control.

The principles of using the WHO framework discussed here are summarised on the WHO website (see 'Useful websites and addresses', p. 761). Equipotent doses for morphine are given in Table 19.2 for commonly prescribed weak and strong opioids.

Number needed to treat (NNT)

In systematic reviews, the effectiveness of analgesics is expressed as 'number-needed-to-treat' (NNT). NNT means the number of people needed to receive the medication to achieve at least a 50% reduction of pain compared with a placebo over a 6-h treatment period. The most effective drugs have a low NNT of around 2 (McQuay & Moore 1998). Systematic reviews of surgical pain suggest that oral diclofenac 25–50 mg, oral ibuprofen 400 mg (both NSAIDs) and morphine 10 mg i.m. have low NNTs of between 2.3 and 2.9 over the 6-h test period, and tramadol 100 mg has a NNT of 4.8.

Comparisons between opioids show 'no compelling evidence' that any opioid is better than another, although pethidine 'has a specific disadvantage and no specific advantage' (McQuay & Moore 1998). The disadvantage referred to is the irritation caused to the CNS by one of the drug's metabolites, norpethidine, which can cause convulsions, especially in patients who have renal dysfunction

Table 19.2 Equipotent doses of commonly used analgesics

Analgesic	Equipotent dose	Example
Oral morphine: subcutaneous morphine	Two-thirds of the oral dose = s.c. dose	Morphine 10 mg orally is roughly equivalent to 6.5 mg s.c./i.m.
Oral morphine to subcutaneous diamorphine	One-third to one-half of oral dose	Morphine 10 mg orally is roughly equivalent to diamorphine 3–5 mg s.c.
Oral codeine to oral morphine	One-tenth of the dose	Codeine 60 mg orally is roughly equivalent to 6 mg oral morphine
Oral tramadol to oral morphine	One-fifth of the dose	Tramadol 100 mg is roughly equivalent to 20 mg oral morphine
Oral morphine to oral oxycodone	One-half of the dose	Morphine 10 mg orally is roughly equivalent to oxycodone 5 mg orally

where the metabolites are likely to accumulate in the blood, rather than be excreted. NNTs for commonly prescribed analgesics are given on the Bandolier website (see 'Useful websites and addresses').

Neuropathic pain and adjuvant drugs

Most neuropathic pain can be relieved using the principles discussed above. Until the late 1990s it was believed that neuropathic pain was not responsive, or only partially responsive, to opioids. However, reviews by Arnér (2000) and on the Bandolier website (see 'Useful websites and addresses') have shown that many people with neuropathic pain gain effective pain relief from opioids, provided the principle of balancing therapeutic effect with side-effects is followed, i.e. it is important to give a dose large enough to gain maximum analgesic benefit with minimal side-effects. Nevertheless, for a small number of people with neuropathic pain it is likely that adjuvant drugs will also be needed. These include the following:

Anticonvulsants, e.g. sodium valproate, are membrane stabilisers and work by blocking the channels through which sodium and potassium are exchanged across the membrane. As a consequence, an action potential is not produced and thus the pain is prevented. Local anaesthetics work in a similar way (Colvin & McClure 1997). Anticonvulsants also enhance the activity of GABA-ergic synapses (Stannard & Booth 2004). As described above, this receptor complex inhibits pain transmission, so an enhancement of its function will reduce pain transmission.

Gabapentin is a new anticonvulsant, licensed for the treatment of neuropathic pain, that has a slightly different action from other drugs in this group. The precise mode of action of gabapentin is unknown but it is thought that it binds with a specific protein in the CNS, involved in the amino acid cell transport system and in this way influences a cell's responsiveness (Stannard & Booth 2004). A Cochrane Review of pain relief using anticonvulsant drugs concluded that, although gabapentin was increasingly being used to treat neuropathic pain, there is no evidence that it is superior to other anticonvulsants (Wiffen et al 2004).

Antidepressants, e.g. amitriptyline, work by preventing the reuptake of noradrenaline from the synaptic cleft after it has been released by the neurone to transfer chemically an action potential. This depletes the available neurotransmitter and therefore diminishes pain (McQuay et al 1996).

Glucocorticoids, e.g. dexamethasone, are helpful in reducing nerve compression, e.g. as a consequence of tumour. Swelling often occurs around a tumour and these drugs reduce the swelling, so relieving the degree of pain experienced.

Routes of administration

Analgesics are administered via a number of routes — oral, intramuscular, intravenous, rectal, sublingual, buccal, transdermal, subcutaneous, by inhalation, intrapleural, respiratory and spinal — depending on such factors as efficacy, convenience, desired onset of analgesia, acceptability to the patient, side-effects and cost. The choice of route should be made after careful consideration of the comparative risks and benefits of the various routes possible for a given drug. The following discussion provides only a brief introduction to the routes of analgesic administration in common use.

Oral Tablets or liquids are usually easy to administer and place no restrictions on patient mobility. However, their effectiveness is dependent on patient adherence. Sustained-release preparations can enhance adherence by limiting the number of tablets needed each day and have the advantage of attaining consistent blood plasma levels. However, absorption of drugs given by the oral route will be compromised if the patient has nausea and vomiting. In addition, this route has the disadvantage that it is susceptible to the 'first-pass effect' in the liver and intestine, by which some of the drug is metabolised and thus inactivated before it enters the circulation. The oral route is often thought to be appropriate only for mild to moderate pain, but there is much research to show that oral opioids such as morphine and oxycodone can be effective against severe pain if they are given regularly and the dose is titrated to the pain (Hanks 2001).

Intramuscular This route is often used in the treatment of postoperative pain. It has the advantage that it enables

the rapid absorption of drugs, although morphine, because of its particular molecular structure, may be more slowly and erratically absorbed than water-based drugs, such as diamorphine. Intramuscular injections can be painful as the needle passes through subcutaneous tissue densely packed with pain receptors. In addition, the injection of the solution can be painful at the site of injection, particularly if the volume of drug exceeds 4 mL. Patients may have to move to expose an injection site and this may cause additional pain. This route also has the disadvantage that it takes time to prepare the injection and have it checked, which can delay analgesia for the patient.

Intravenous The action of analgesics administered by this route is rapid in onset but of short duration, and therefore a continuous infusion rather than bolus injection may be more effective in maintaining the level of analgesic in the bloodstream.

Rectal Medications given by the rectal route are absorbed across the mucous membrane and generally the bio-availability of opioids given via this route is similar to that obtained via the oral route (Hanks et al 1996). Indeed, there is some indication that this route may be better, because the first-pass effect might be avoided as a result of venous drainage (McQuay 1990). However, absorption can be incomplete or erratic, particularly if the patient is constipated. This is a useful route for people unable to take drugs by the oral route, e.g. if they have nausea and vomiting or difficulty in swallowing. Rectal preparations may not be suitable for people who are neutropenic or in danger of being so. Minor trauma on inserting the drug may allow entry of gastric intestinal tract commensals into the systemic circulation and result in septicaemia. Examples of analgesic drugs given rectally include the NSAID diclofenac (Voltarol) and paracetamol suppositories. Most drugs come as a suppository preparation. These preparations have the advantage that they can be given at home and are useful in the management of terminally ill people. However, some people find drug administration by this route unacceptable (Stannard & Booth 2004).

Sublingual and buccal In sublingual administration, the medication is placed under the tongue; in buccal administration it is placed between the upper lip and gum or between the cheek and gum. These routes may avoid the first-pass effect and are rapid in onset of action. However, there is the disadvantage that the patient may inadvertently swallow the drug, and buccal administration may be difficult if the patient has upper dentures. The Expert Working Group of the European Association of Palliative Care (EAPC) (Hanks 2001) has recommended that this route be avoided in cancer pain therapy as it has no clinical advantage over other routes and drug absorption is unpredictable. An example of an analgesic drug available for administration via this route is the opioid buprenorphine.

Transdermal This method of pain relief involves placing a drug-containing patch directly onto the skin, where absorption occurs. The opioid fentanyl has been shown to give effective pain relief by this route and is currently licensed for people with cancer pain and non-cancer pain. Patches need to be changed, usually every 3 days, and have the advantage of continuous pain relief without the need to remember to take tablets throughout the day and night. Research has shown that once the correct dose to manage the pain is achieved, this route of providing analgesia is effective and improves the person's quality of life (Ahmedzai & Brooks 1997). Successful management of pain by this route is dependent on the patch being in contact with the skin and on the availability of oral morphine to control 'breakthrough' pain. Absorption can be speeded up by warmth, so care is needed when bathing or sunbathing.

Subcutaneous infusion is the recommended preferred route for administration of opioids and NSAIDs for people with chronic illness who are unable to take oral medications (Hanks 2001). This route offers a simple, safe and effective alternative to i.v. or i.m. injections and can be used safely in the patient's home.

Inhalation This route enables rapid absorption of gaseous, volatile and atomised substances. For example, nitrous oxide (Entonox) administered with a mask or inhaler can help the patient to deal with bursts of pain, as in childbirth, or during dressing changes or other painful minor procedures. However, this route has the disadvantage that it can be difficult to administer an exact dose and the drug may cause airway irritation.

Spinal This route enables medications to be given directly into the epidural or subarachnoid space of the spinal column. This has a rapid onset of effect and can offer effective pain relief for a wide variety of pain (Stannard & Booth 2004). Medications typically given by this route are opioids and anaesthetic agents which, if given together, can have a synergistic effect. Because of the direct access to the CNS afforded by this route, much smaller doses are required. Whilst this route has many advantages — including a reduction in postoperative complications (Buggy & Smith 1999) and neuromodulation of persistent pain, using opioids to reduce wind-up in neuropathic pain — it has important and potentially serious complications such as respiratory depression and sudden dramatic lowering of blood pressure. Giving analgesics by this route is an extended role for the nurse and subject to the same requirements as discussed under the i.v. route. Despite the need for caution, many people with persistent pain are managed at home for long periods of time, with spinal analgesics administered via a small portable syringe pump or through a medication pump implanted under the skin. Although this treatment has high initial costs, it significantly reduces long-term costs (Winkelmüller 1999).

Patient controlled analgesia (PCA)

PCA refers to the administration of analgesics by any appropriate and safe route over which the patient has control. It usually refers to the self-administration of i.v. boluses of an opioid analgesic, usually morphine, via a specifically designed pump. The pump is set with 'lock-out' intervals and doses to regulate the dose of medication received. This method is typically used postoperatively, but can be used for people with incident-related pain. PCA is dependent on the patient being able and willing to use it and therefore

attention to patient information needs is important. From focus group discussions with patients who had experience of using PCA, Chumbley et al (2002) identified that information should include detail about side-effects, but give reassurance that it was safe, and that overdose and addiction was not possible. Information was also sought on how to use PCA and the support available from staff. Despite these concerns, satisfaction with PCA is generally high (Shiloh et al 2003, Chang et al 2004).

PCA has been found to be a safe method of analgesic administration although, depending on the opioids used, side-effects such as nausea and sedation have been reported (Sidebotham et al 1997, Chang et al 2004). There is evidence that PCA offers improved pain relief and quicker recovery following surgery, resulting in earlier discharge (Chang et al 2004). However, results from randomised controlled trials comparing PCA and i.m. injection of morphine are mixed. Snell et al (1997) found no significant difference, whereas Chang et al (2004) found significantly lower levels of pain in the PCA group compared to the i.m. injection group. Thomas and Rose (1993) pointed out that the efficacy of PCA is influenced by the opioid chosen, the demand dose and the lock-out interval set on the PCA pump, as well as by patient psychological variables.

The most frequently purported psychological benefit of PCA is the patient's specific control over pain, PCA eliminating the need for a patient to wait for a nurse to administer pain relief. To test the influence of this on pain experience, Shiloh et al (2003) undertook a randomised quasi-experimental design trial in which postoperative patients (n = 120) were assigned to one of three groups, each receiving different pain management regimens. These were PCA; perceived PCA (PPCA), i.e. a continuous intravenous infusion of analgesics, but without actual control; and continuous intravenous infusion of analgesics (CII). The PPCA and the CII groups received the same dose of morphine over a 24-h period. The PCA group received a background dose equivalent to 50% of the dose received by the other two groups and they could demand bolus doses of morphine up to a total of one and a half times the total dose of morphine received by the other two groups. The groups were compared on reported pain, morphine consumption and satisfaction with pain relief, and individual differences in preferences for control and in state trait anxiety were measured. The study found that the PCA group consumed less morphine than the PPCA and CII groups, reported more pain, but had slightly higher satisfaction with pain relief. The PPCA group were intermediate in relation to both other groups in their reports of pain and morphine consumption, but had the lowest satisfaction with pain relief. Individual differences did not alter the effects of PCA. The authors suggest that the main effect of PCA is increased pain tolerance and that this may be due to the patient's control over their pain and thus a decrease in uncertainty about the availability and effectiveness of pain relief. This may in turn lead to an increase in the use of strategies such as diversion to help the pain.

In a cost-effective analysis, Chang et al (2004) found PCA to be more costly, but this might be explained by the amount of opioid used — being sufficient to control pain in the PCA group but insufficient to control pain in the i.m. injection group.

Other medical interventions

Local anaesthesia and regional nerve blocks These interventions work by injecting local anaesthetic, sometimes together with a steroid, near to or in a peripheral nerve or major nerve plexus or into the spine. Although there can be adverse reactions and complications, the pain-relieving effects often outlast the duration of the local anaesthetic. A review of the efficacy of nerve blocks by Raj and Schwiers (1999) concluded that they are important in the management of pain, particularly for intractable cancer pain and for some people with persistent pain. McCaffery and Pasero (1999) provide an overview of this method and the nursing implications.

Surgery Nerves can be transected in an attempt to reduce or eliminate intractable pain. Examples of surgical methods of pain relief include sympathectomy and cordotomy. Although this measure may work initially, pain often returns and may be worse than it was pre-surgery (Stannard & Booth 2004). For this reason, other techniques, such as spinal cord stimulation, are more common.

Spinal cord stimulation involves the implanting of epidural electrodes, which are controlled either via an external radio frequency transmitter or an implanted pulse generator. Spinal cord stimulation is used for the management of neuropathic pain which has not been relieved by less invasive techniques. Evidence for this technique is limited and predominantly retrospective in design but suggests lasting pain relief in about 50% of patients (Winkelmüller 1999).

Radiotherapy, chemotherapy and hormone therapy may relieve pain by reducing invasive tumours (Stannard & Booth 2004). The effectiveness of radiotherapy in pain relief has been subjected to Cochrane systematic reviews (McQuay et al 2004, Sze et al 2004). These concluded that radiotherapy provided pain relief for three-quarters of patients treated at 1 month after treatment, although the degree to which pain was relieved varied. A single fraction of radiotherapy was found to be as effective as a course of radiotherapy. Radiopharmaceuticals such as strontium chloride-89 have also been shown to be effective in pain due to bone metastases (Robinson et al 1995). There is also growing evidence that bisphosphonates such as pamidronate are effective in relieving bone pain (Wong & Wiffen 2004) (see also Ch. 31).

Specialised pain services

Acute pain services

In response to continuing documentation of inadequate postoperative pain relief, adoption of multiprofessional acute pain services in hospitals is recommended by the Royal College of Anaesthetists and The Pain Society (2003). They recommend that the objectives of a service should include:

- establishment of a system for regular assessment and individual treatment of acute pain
- provision of specialist care and advice for difficult acute pain problems such as occur in patients already taking strong analgesics for persistent pain, and who are drug users

- seamless liaison with other health care teams responsible for the shared care of patients with acute pain
- provision of back-up arrangements, education programmes and appropriate guidelines or protocols to ensure that there is continuous cover for acute pain management around the clock, 7 days a week
- information, education and reassurance for patients, presented in a way that they can understand
- education for nurses, medical staff and allied health care professionals leading to increased awareness of the consequences of unrelieved acute pain and of the techniques available to relieve pain
- continuing audit and evaluation of the service and the needs of patients.

Evidence of the effectiveness of such services is sparse. A systematic review and meta-analysis undertaken by McDonnell et al (2003) concluded that there is insufficient robust research to assess the impact of acute pain teams on adult patients or on the process of postoperative pain relief. There is a little evidence of the cost utility and cost-effectiveness of acute pain services. An analysis by Stadler et al (2004) showed minor reductions in postoperative complication rates in some surgery but no change in duration of hospital stay and postoperative mortality.

Although these studies show a modest influence of acute pain services on patient care, there is emerging evidence of the impact of specialist acute pain teams on nurses' knowledge and attitudes towards pain management. Mackintosh et al (2000) found a consistent positive trend in improved knowledge and attitudes in pain management following the development of a pain service. Similar findings were demonstrated from a survey study (n = 286) by Barton et al (2004), who found that nurses who were unaware of an acute pain service in their organisation had less knowledge about pain than nurses who were aware of the service.

Hospice/palliative care teams have a wealth of expertise in pain and symptom control and can be a valuable resource (see Ch. 33). Such teams are usually multidisciplinary and situated in a variety of care settings. The key functions of such teams are to provide support to other professionals in caring for people with life-threatening illness. Pain is a typical reason for referral to these services, accounting for approximately 64% of referrals (Potter et al 2003). To meet this level of need, palliative care services provide pain control for 2800 patients per million population (Franks et al 2000). A large and thorough review of the research, *Improving Supportive and Palliative Care for Adults with Cancer* (Gysels & Higginson 2004), demonstrated that palliative care teams positively influence patients' experience of pain (see Ch. 33).

Chronic or 'persistent' pain services

These offer a service to people with persistent pain. Clinics are usually multidisciplinary and may be staffed by anaesthetists, nurses, psychologists, physiotherapists, occupational therapists and pharmacists with the aim of increasing the person's ability to function and lead a more fulfilled life. This aim incorporates the belief that persistent pain is the result of multiple interrelating physical, psychological and social or occupational factors.

For detailed objectives of such a service, see the Royal College of Anaesthetists and The Pain Society (2003); for a systematic review of the effectiveness of these services in the care of people with back pain, see Guzmán et al (2001).

Complementary methods of pain relief

'Complementary' methods of pain relief have gained in popularity and include distraction, relaxation, imagery, transcutaneous electrical nerve stimulation (TENS), massage, the application of heat or cold, hypnosis, biofeedback and acupuncture. There is some overlap between certain of these techniques; for example, imagery contains elements of distraction and relaxation.

As with all aspects of pain management, the success of the therapy is dependent on the quality of the relationship between the therapist and the patient. Many nurses have incorporated complementary therapies into nursing practice in order to develop their caring relationship with patients (Royal College of Nursing 2003). Integration of such complementary therapies into nursing practice must be undertaken within the context of the Nursing and Midwifery Council's *Code of Professional Conduct* (2004) and the principles of clinical governance, with the aim to enhance safe, effective and appropriate patient care (Royal College of Nursing 2003).

For guidance on issues which must be taken into account when introducing complementary therapies, see Royal College of Nursing (2003).

Many nurses may use such complementary techniques without realising that they are using them, or explicitly recognising their value. For example, a nurse may distract a patient during a dressing change by asking about holidays or their family. Equally, many patients incorporate complementary techniques into their lives without realising it — they might, for example, use distraction such as watching television, listening to music, or thinking about pleasant times and memories to help them relieve their pain.

Nevertheless, whilst many people find specific complementary therapies helpful, some are sceptical. In part, this is due to the lack of sound research demonstrating their effectiveness, but it may be that pharmacological methods are seen as the only legitimate treatment for pain. In addition, some people, when offered complementary therapies, might feel there is a suggestion that their pain is 'all in the mind'. Some people may refuse complementary therapies because they believe that their pain is too bad. If complementary therapies are offered, explanation about them is best given when pain is either not present, i.e. before surgery, or not at its worst.

Distraction

Distraction involves diverting attention away from the distressing stimulus so that it is no longer the main focus. This can be achieved, as noted above, by encouraging patients to participate in activities that they find absorbing, e.g. conversation, listening to music or focusing on everyday stimuli in the immediate environment. Distraction can give patients a sense of control over their pain and can improve

mood (McCaffery & Pasero 1999). However, it also has the following potential disadvantages:

- the validity of the individual's pain may be doubted if distraction is successful
- distraction may not reduce the need for analgesics
- no lasting effect follows a period of distraction; indeed, an individual may be more aware of the pain afterwards
- distraction needs energy and therefore a person might feel fatigued and irritable afterwards.

Relaxation

McCaffery and Pasero (1999) define relaxation as 'a state of relative freedom from both anxiety and skeletal muscle tension'. Relaxation may help to reduce the distress associated with having pain. Relaxation needs to be taught; face-to-face teaching has been found to be more effective than using taped instructions (Seers & Friedli 1996), although once the patient has been given personal instruction, a tape could be given to refresh their memory.

Various methods may be used to promote relaxation; some of these highlight breathing techniques and others attempt to focus the attention sequentially on various parts of the body and then 'letting go' of the tension in those areas. Relaxation can be used to help people cope with specific painful procedures or events or to help people live with persistent pain. Systematic reviews of relaxation in acute and persistent pain are inconclusive overall (Carroll & Seers 1998, Seers & Carroll 1998).

Guided imagery

This technique involves using the imagination to help control pain. Typically, it involves a variety of senses in conjuring up an image. For example, an image about the seaside might include 'seeing' the sand and waves at a beach, 'hearing' the waves and the wind, 'feeling' the sand and the warmth of the sun, 'smelling' the sea air and 'tasting' the salty sea spray.

Evidence for the effectiveness of imagery is weak. In a review, Wallace (1997) found few controlled studies, lack of control groups, small sample sizes, weak theoretical frameworks and few complete descriptions of the nature of the pain being treated. However, notwithstanding methodological problems, some studies suggest benefit, particularly when a person chooses their own image and controls when to use it. Imagery is not advised for people who are psychotic because of the risk that it might exacerbate their psychosis by making it more difficult for them to differentiate between what is real and what is imagined.

Cutaneous stimulation

Transcutaneous electrical nerve stimulation (TENS) In this intervention, low-voltage electrical stimulation is delivered via electrodes placed on the skin near to or on the site of pain. This usually causes a sensation of vibration or tingling and can be used in an intermittent or continuous mode. The device is powered by a battery pack and can be operated by the patient. Care needs to be taken to discriminate the standard TENS device from a variety of commercial devices being marketed, such as microcurrent electrical therapy devices, TENS-pens. In a thorough review of the available devices and the effectiveness of TENS, Johnson (2001) concluded that TENS is not effective for labour pain and postoperative pain and that evidence is inconclusive for persistent pain. However, the studies on which these conclusions are based have methodological problems, therefore health professionals are advised not to dismiss the use of TENS until the methodological issues have been resolved. TENS is not suitable for people with cardiac pacemakers or people suffering from cognitive impairment and should not be placed over a pregnant uterus or the carotid sinus (McCaffery & Pasero 1999).

Massage Throughout history, massage has been used to alleviate pain and suffering (Ernst 2003). Evidence for the effectiveness of massage in relieving pain is sparse. The exception is a Cochrane Review of massage treatment for back pain. This concluded that massage was superior to placebo, relaxation treatment, acupuncture or self-care education; inferior to manipulation, shiatsu or TENS; and no different from treatment with corsets or exercise. The benefit lasted 1 year (Furlan et al 2000). There are several reasons for the scarcity of research, including methodological difficulties, such as the variety of massage techniques practised and the difficulty of designing a placebo with which to compare massage intervention, and a lack of research culture amongst massage therapists (Ernst 2003). Massage should not be confused with therapeutic touch, a technique designed to realign energy fields through the transfer of energy from a healer or therapist.

Heat and cold The application of heat or cold may relieve pain through a 'counter-irritant' effect as well as by direct effects on peripheral and free nerve endings (McCaffery & Pasero 1999). Care should be taken when using this method with patients who have impaired sensation or a reduced level of consciousness as their skin could be inadvertently damaged.

Hypnosis

The nature of hypnosis and the mechanism of its effects are unclear. However, it seems to be an altered state of consciousness in which concentration is focused and distractions are minimised. Success appears to be determined by the individual's ability to respond to suggestion (McCaffery & Pasero 1999), although the person may choose to inhibit this responsiveness. In addition, it seems to be dependent on the type of pain being treated, the context and goals of treatment, the skill of the therapist and the expectations and motivations of the patient. A systematic review of hypnosis concluded that it increased pain relief (Hawkins 2001). However, this technique is not one that should be attempted without special education and training.

Biofeedback

Biofeedback is a method used to encourage and develop relaxation skills. An individual is encouraged to use relaxation to alter specific body functions, such as muscle tension, blood pressure, pulse and/or temperature. Information about these functions is fed back to the individual as they relax, enabling them to learn how to influence positively tension and anxiety.

Acupuncture

Acupuncture originated in China thousands of years ago. It involves inserting needles into the skin at specific acupuncture or Hoku points that are located in a series of channels or meridians. These needles may be manipulated to maximise the effect. The mechanism of action has been the subject of many debates, and activation of endorphins has been implicated.

Studies examining the effectiveness of acupuncture show varying results. A randomised trial comparing acupuncture for the treatment of headache with the accepted management in primary health care (n = 401) found that acupuncture led to significant lasting benefits for patients, including a reduction in pain, medication and sick leave (Vickers et al 2004). Reduction in pain and improvement of movement was demonstrated by Irnich et al (2001) in a randomised trial of acupuncture compared with conventional massage and 'sham' laser acupuncture for neck pain (n = 177). In this trial, benefits were significantly greater for people who had had pain for more than 5 years and in patients with myofascial pain syndrome. Little detail is given about differences between assessment time points in this study so it is difficult to comment on the lasting effects of acupuncture. A Cochrane Review examining the effectiveness of acupuncture for the relief of low back pain found little evidence for its effectiveness and commented on the poor quality of the majority of the studies reviewed (van Tulder et al 2004).

In acupressure, the acupuncture points are stimulated by pressing and/or rubbing rather than by the insertion of needles.

Behaviour therapy

The development of behaviour therapy programmes for pain management owes much to Fordyce (1978), who first drew attention to the rewards a person in persistent pain may receive for 'pain behaviour', such as sympathy, attention and exemption from certain tasks. Since behavioural psychologists believe that all behaviour is governed by its consequences, it is felt that discouraging pain behaviours, such as moaning or grimacing, and encouraging 'well behaviours', the person may adopt a more normal pattern of behaviour. This has been described as operant conditioning. A cognitive–behavioural approach includes the modification of the patient's thoughts and feelings as well as behaviours; it also includes a commitment on the patient's part to behaviour therapy procedures in promoting change, such as graded practice and homework assignments. A systematic review and meta-analysis of cognitive and behavioural therapy for chronic pain found evidence that these therapies were effective in reducing pain experience, and in improving appraisal and coping (Morley et al 1999). Pain clinic programmes usually contain some element of behaviour therapy.

Chiropractic and osteopathy

There is much overlap between the methods and techniques of chiropractic and osteopathy, with what Tanner (1987) describes as 'subtle' differences. He argues that chiropractors are more likely to emphasise the structure of the spine, whereas osteopaths emphasise abnormal movement of the spine. Research supporting these practices is sparse.

Other therapies

Discussion of other therapies such as faith healing, herbal remedies, music therapy, art therapy, aromatherapy and reflexology are not addressed here. However, much of what has already been said above is equally applicable to these therapies, in that they promote well-being and relaxation and may decrease anxiety and thus pain. Art and music therapy may also enable active expression of feelings, which can contribute towards pain relief.

Support and self-help groups

People suffering from pain often seek help from relatives and friends before approaching a professional, such as their GP, within the health care system. Examining the 'trigger' that converts a 'person' into a 'patient' can help to determine how best to help those who do seek help. Examining this in people with persistent pain, Reitsma and Meijler (1997) found that those employing effective coping strategies were less likely to be consumers of health care. In contrast, those people without effective coping strategies were more likely to see themselves as patients and have a greater degree of disability. This suggests that if individual coping skills are developed then disability and distress might be reduced. Emotional coping skills may be developed through self-help groups and organisations such as the National Back Pain Association and the Migraine Action Association (formerly the British Migraine Association) (see 'Useful websites and addresses').

BARRIERS TO PAIN MANAGEMENT

The theory–practice gap

19.9 Why do you think that the gap between theory and practice exists in respect of pain management? What would influence your ability to provide adequate pain relief for someone you were looking after?

There is arguably a gap between theory and practice in current pain management. Despite significant developments in research-based knowledge, people still experience pain that could be adequately relieved. Surveys of the incidence of postoperative pain demonstrate that moderate to severe pain is common (Royal College of Anaesthetists and The Pain Society 2003). In a critical literature review of pain after day surgery, Coll et al (2004b) found that pain management strategies had been overlooked, resulting in people experiencing pain unnecessarily. These results suggest very little improvement in pain management in the past 10–15 years since the results are very similar to those reported by Seers (1989), Carr and Thomas (1997) and McQuay et al (1997).

The picture is no better with respect to persistent pain. In a large (n = 3605) epidemiological study in the Grampian region of Scotland, 50% of the sample reported having persistent pain (Elliott et al 1999). One-quarter of the people reporting pain had pain that was disabling and limited their daily activities. There are indications from the study that much of the reported pain was poorly treated (for a review and commentary of this paper, see www.jr2.ox.ac.uk bandolier/band70/b70-3.html).

The World Health Organization (WHO) guidelines for analgesia are frequently not utilised in practice (Kuuppelomäki 2002) despite evidence that they are effective (WHO 2004).

Fears associated with opioids

Pain management is influenced by fears about opioids (Carr & Mann 2000) and these fears tend to be common to nurses, patients and their family members/carers. They include fear of addiction and dependence, fear of tolerance and fear of side-effects. Most of these fears are propagated by reports of addiction in people using opioids for recreational use, the dangers to which this use exposes them and the difficult symptoms that they experience when trying to withdraw from this use. In order to examine these fears, it is important to clarify the terms 'addiction', 'tolerance' and 'dependence' (see Ch. 36 for a discussion of these terms).

Addiction to opioids when used specifically in pain management is rare. Two seminal studies found the following incidence of addiction in patients receiving opioid analgesics was virtually non-existent:

- Porter and Jick (1980), n = 12 000; four cases of addiction reported, only one of which required treatment
- Perry and Heidrich (1982), n = 10 000; no cases of addiction reported.

Dependence on opioids occurs in prolonged use and therefore care is needed when reducing the dose. If the dose is reduced gradually, withdrawal symptoms will not occur.

Tolerance to opioids is varied. It is not usually necessary to increase the dose of an opioid to maintain a similar therapeutic effect. In other words, more of the drug is not needed as someone 'gets used to it'; in cancer pain, an increase in dose is normally only needed with disease progression. Therefore, concerns that if morphine is started too soon it will not be possible to control the pain later are unfounded. On the other hand, tolerance does develop to some of the side-effects of opioids. For example, it is common for people to experience nausea and vomiting and drowsiness in the first few days of taking an opioid, but this then passes and is rarely a continuing problem. It is important to note that constipation is a continuing side-effect of opioid use.

Issues in professional education and training

A number of researchers have demonstrated that there is insufficient education in pain management throughout the world (Brunier et al 1995, McCaffery & Ferrell 1995, Clarke et al 1996, Kubecka et al 1996). This can lead to attitudinal barriers and inappropriate behaviours in pain management (McCaffery & Pasero 1999). For example, most nurses in these studies did not understand the fundamental principles of pain relief or take responsibility for pain assessment, and they misunderstood the extent to which opioids induce respiratory depression and addiction. However, such attitudes have been shown to respond positively to education when this is provided (Brunier et al 1995, Dalton et al 1996, McCaffery & Ferrell 1997).

Professional and cultural biases in inferences of pain

At the beginning of this chapter, it was argued that it is very difficult to know what anyone's experience of pain is like. However, many studies have shown that nurses make assumptions and judgements about the amount or type of pain their patients are suffering, which significantly influence the quality of care provided (McCaffery & Pasero 1999).

There is a significant body of evidence that supports the view that nurses and other health care professionals view pain as 'normal' or to be expected and thus underestimate the severity of the patient's experience (Carr & Mann 2000). Underestimation of pain may also be due to nurses adopting a detached, rather than an involved, stance towards someone in pain. For example, Madjar (1998) noted that some nurses distanced themselves from the pain that patients were experiencing as a way of protecting themselves from the emotional experience of caring for someone in pain. In this way, these nurses became desensitised to patients' distress.

Evidence suggests that factors influencing the patient's experience of pain also influence a nurse's judgement of pain. For example, McCaffery and Pasero (1999) draw attention to societal prejudices that can influence nurses' inferences of pain and psychological distress, such as patients' socioeconomic, religious or ethnic backgrounds.

Furthermore, there is evidence that nurses make judgements about pain based on whether or not they believe it has a cause. In a study examining nurses' discourse of pain, Wakefield (1995) found that nurses believe that pain can, and should, only be manifest in the presence of an identifiable cause and that, if no cause was identified, nurses were likely to believe that patients were trying to get analgesics by immoral means. This 'acute pain model' is noted by McCaffery and Pasero (1999) as being a major obstacle to effective pain management and has a profound effect on patients, as illustrated by another example from the study by Seers and Friedli (1996):

> *I had something that was medically unacceptable. The GPs labelled me as neurotic because they couldn't find anything wrong. Their dismissive 'unlistening' attitude to my mysterious pain almost amounts, in my opinion, to mental cruelty.*

Madjar (1998) found that nurses were more likely to label patients as complainers if they felt that they were exaggerating their report of pain or that they were not coping adequately with their pain. McCaffery and Pasero (1999) also suggest that unpopular or difficult patients are often labelled as not having 'real' pain.

The research referred to in this chapter has begun to explain why it is so difficult to put knowledge about pain management into practice. The complexity of practice cannot be underestimated. Competing demands and resource limitations challenge the ability to care for people in pain but the distress of pain makes it imperative that these challenges are conquered.

CONCLUSION

19.10 Now that you have read this chapter, make an action plan of how you are going to improve the

care that you provide to people in pain. Share this action plan with your mentor or a colleague to help you implement it.

Pain and its relief form a central part of nursing in almost all care settings. Ongoing education for health professionals and an understanding of the complexities of pain and its management are crucial in forming a sound basis for practice (Royal College of Anaesthetists and The Pain Society 2003). The person in pain should be believed, their pain should be systematically assessed, treated and reassessed, and they should be involved in pain management whenever possible. Pain and its relief must be given a high priority in care, and health professionals should be accountable for the pain relief of people in their care. Indeed, failure to do so contravenes the Nursing and Midwifery Council *Code of Professional Conduct* (2004). Nurses are in the fortunate position of being able to make an important contribution towards the comfort and well-being of people in pain and to rise to the challenges of influencing the contextual factors that shape this care.

INTRODUCTION

Monitoring and manipulating body fluid and electrolytes form a crucial aspect of nursing care. For the average male, only about 18% of the body weight is protein with 15% fat and 7% minerals; 60% is water. For health, body water and electrolytes must be maintained within a limited range of tolerances. Homeostatic mechanisms regulate parameters such as body fluid volume, acid–base balance (pH) and electrolyte concentrations, maintaining a delicate, dynamic balance which can be destabilised during illness. In extreme cases, the fluid or electrolyte deficit can lead to death. Consequently, nurses must have a clear understanding of fluid and electrolyte homeostasis so that they can assess fluid and electrolyte status, anticipate/recognise deterioration and implement corrective interventions.

Nursing interventions in relation to fluid therapy may range from encouraging the patient to drink an afternoon cup of tea to managing a complicated intravenous fluid regimen. Ill-defined terms, such as 'restrict fluids' or 'push fluids', and instructions to record fluid intake/output or daily weight, are commonly encountered. However, without a knowledgeable appreciation of the physiology and pathophysiology of fluid and electrolyte balance there is a real risk that these tasks will be performed in a somewhat mechanistic fashion, without sufficient thought or understanding.

This chapter reviews the normal mechanisms which regulate body fluid and outlines some of the basic adaptive responses to stress. The regulation of acid–base balance is also considered, along with basic principles in the management of fluid and electrolyte disorders. Throughout the chapter, typical clinical situations where fluid and electrolyte control may be compromised are reviewed. Reference is made to the ethical dilemmas which may be associated with the administration/withdrawal of hydration measures.

Students who are unfamiliar with the physiology of fluid, electrolyte and acid–base balance are advised to read this chapter in conjunction with their physiology and pathophysiology textbooks. It is important for the reader to be familiar with units and terms such as 'moles', 'molality', 'equivalents', 'diffusion', 'osmosis', 'osmoles', 'osmolality', 'tonicity' and 'filtration'.

For more detailed information, see Smith & Kinsey (1991), Porth (2002) and Marieb (2004).

Nursing goals in the care of patients with existing or potential fluid and electrolyte problems include:

- the promotion and maintenance of a healthy pattern of fluid intake/output appropriate to the patient's lifestyle and wishes

- the detection of existing or potential fluid and electrolyte imbalances
- the re-establishment of fluid and electrolyte balance when homeostasis is disturbed
- the development of educational programmes on the maintenance of fluid and electrolyte balance.

It is hoped that this chapter will provide some of the essential background knowledge necessary to achieving these aims.

BODY WATER

Water has a range of functions within the body which are essential to sustaining life and maintaining health. These include:

- giving form to body structures and cushioning the body from shock
- acting as a transport medium for nutrients, electrolytes, blood gases, metabolic wastes, heat and electrical currents
- providing insulation
- aiding in the hydrolysis of food
- acting as a medium and reactant in chemical processes
- acting as a lubricant.

Body tissues contain varying proportions of water, ranging from 10% for fat to 83% for blood. A young 70 kg man of average build has a total body water (TBW) of about 60% of body weight, or 40 L. The percentage of body weight represented by the TBW varies from one individual to another, depending on factors such as age, gender and build. Fat contributes little towards TBW and is the main source of this variation. A 70 kg woman of average build would have a TBW of about 52% (36 L) due to the greater proportion of adipose tissue. In both genders, the percentage of body water tends to decrease with age. Lean tissue has a fairly constant water content of 71–72 mL/100 g, and if adipose tissue is disregarded as a non-functional storage tissue, then the TBW of the lean body mass is about 73%. As water makes up nearly three-quarters of the body's active tissues, homeostatic regulation of body fluids is essential to normal function and health.

Fluid compartments

Body water is distributed between two major compartments: the intracellular fluid (ICF) and the extracellular fluid (ECF). The distinction between the two compartments is maintained by the selective permeability of cell membranes. The intracellular environment is not homogeneous but varies greatly between cell types. However, all cells can tolerate only a limited variation in the volume and composition of their ICF before function is disrupted.

Large proteins which are synthesised by the cell remain inside as they are too big to pass through the membrane. However, the membrane is freely permeable to water. Selective membrane transport processes regulate the distribution of electrolytes, and hence water, across the cell membrane. The ICF has been estimated to be approximately 40% of TBW, or about 28 L in a 70 kg male.

The ECF bathes and surrounds the cells, forming a relatively constant environment. It has a smaller volume than the ICF, accounting for about 20% of TBW (or 14 L), and can be divided into four subcompartments:

- the extravascular fluid (interstitial or tissue fluid)
- inaccessible bone water (skeletal water)
- the intravascular fluid compartment (blood plasma)
- transcellular fluids.

Interstitial fluid includes lymph and accounts for about 15% (10.5 L) of TBW. Interstitial fluid is defined by two membranes: the cell membrane which separates the lymph from the ICF, and the capillary endothelium which separates it from plasma. Interstitial fluid forms the interface and exchange route between the ICF and plasma. Plasma represents about 4% of body weight (3 L).

Transcellular fluids are specialised fluids which are separated from the ECF by an additional epithelial cell layer. They include:

- cerebrospinal fluid (CSF)
- aqueous and vitreous humor of the eye
- glandular secretions
- synovial fluid
- pleural fluid
- peritoneal fluid
- glandular secretions
- saliva and other gastrointestinal secretions
- respiratory tract fluid
- fluid within the urinary system.

Transcellular fluid volume is highly variable, and some transcellular fluids have a very high turnover; in the gastrointestinal tract alone it can be greater than 20 L/day. Some water is trapped in the deeper layers of bone; this is inaccessible and, because it does not readily exchange with the rest of the ECF, is difficult to measure. The relative contribution of each compartment is summarised in Box 20.1. In infants and children, although the actual ECF volume is much smaller than in adults, the ECF:ICF ratio is larger, i.e. the ECF represents a greater percentage of the TBW, and fluid loss can rapidly lead to dehydration. The consequences of ECF losses from, for example, vomiting, sweating or diarrhoea are potentially more serious in the infant than in the adult.

For further details, see Porth (2002) and Marieb (2004).

Box 20.1

The major fluid compartments of the body in the average young male weighing 70 kg and containing 40 L of body water

- Intracellular fluid: 40% body weight and 25 L
- Extracellular fluid: 20% body weight and 15 L, of which:
  - 80% (12 L) is interstitial/tissue fluid
  - 20% (3 L) is plasma

These figures include water found in serous fluid, cerebrospinal fluid and bones.

Solutes and electrolytes

Body fluids cannot be equated simply with water, as they also contain dissolved substances or solutes as well as larger particles in suspension (colloids). Solutes may be complete molecules (non-electrolytes) or parts of molecules (electrolytes). Measures of body fluid volume, such as the litre, refer to the volume of water and its dissolved solutes. Glucose is a good example of a non-electrolyte. It dissolves in body water but does not dissociate into component parts. An electrolyte, however, will dissociate in solution into its constituent ions. Sodium chloride (Na^+Cl^-) is the most important example of this. In solution, a molecule of sodium chloride dissociates into a positively charged sodium ion (cation) and a negatively charged chloride ion (anion). Sodium is the dominant cation in the ECF but smaller concentrations of potassium (K^+), magnesium and calcium ions are present. Chloride and bicarbonate are the major extracellular anions.

Inside the cell, potassium is the dominant cation. Lower concentrations of magnesium, calcium and sodium are also present. Intracellular anions include phosphate, sulphate and intracellular proteins which also behave as anions. The cell regulates the movement of ions across its membrane, and maintenance of an appropriate distribution of ions between the ECF and ICF is essential for cell function, particularly in excitable tissues such as nerve and muscle.

Fluid exchange

Fluid exchange between ICF and ECF

The movement of body fluids and their constituents between the different compartments involves both active and passive transport processes (Porth 2002). The main mechanisms which enable body fluids to enter the cell membrane are:

- diffusion
- facilitated diffusion
- voltage-gated channels
- ligand-gated channels
- mechanically gated channels
- active and co-transport.

For further reading, see Marieb (2004).

Lipid-soluble substances diffuse directly through the cell membrane, while water and electrolytes utilise channels formed by membrane proteins. The membrane is freely permeable to water but is only selectively permeable to electrolytes. Permeability is affected by the size and charge of the hydrated ion; for example, the membrane is 50–100 times more permeable to K^+ than to Na^+. Movement into the cell via membrane proteins may be by simple diffusion, facilitated diffusion (carrier-mediated transport) and active transport. Glucose, for example, enters the muscle cell by facilitated diffusion under the influence of insulin. The most important example of active transport is the sodium–potassium pump. This pump is a membrane protein that couples the active transport of Na^+ out of the cell with the active transport of K^+ inwards. It requires energy derived from the hydrolysis of adenosine 5-triphosphate (ATP) to function.

Tissue–capillary fluid exchange

Just as the cell membrane separates the ICF from the ECF, the capillary wall represents the boundary between the intravascular and interstitial compartments of the ECF. The capillary wall is selectively permeable to substances of a molecular weight less than 69 000 Daltons (67.0 kDa) and to lipid-soluble molecules. The exchange of water, electrolytes, metabolites and waste products between the plasma and interstitial fluid occurs in the capillary bed. Fluid movement is determined by three forces: diffusion, osmosis and filtration. The capillary endothelium is freely permeable to water and solutes but the larger plasma proteins are retained. At the arterial end, fluid is forced out of the capillary by hydrostatic pressure. As water is lost from the capillary, the plasma proteins become more concentrated and the colloid osmotic or oncotic pressure exerted by the plasma proteins increases. Oncotic pressure reflects osmotic pressure caused by the presence of colloids, i.e. colloid osmotic pressure. At the venous end, the hydrostatic pressure, lower than the osmotic pressure, draws fluid back into the capillary.

Because the capillary endothelium is a very imperfect barrier, plasma proteins may leak into the interstitial fluid, complicating the situation described above. If these proteins were not removed, the oncotic pressure of the interstitial fluid would rise, disrupting capillary fluid exchange and favouring retention of water in the interstitial spaces. The lymphatic system is central to maintaining interstitial fluid volume. Blind-ended lymphatic capillaries in the interstitium are more permeable than the capillaries and easily take up and remove plasma proteins and fluid from the interstitial space. The fluid formed in these vessels — lymph — is carried through the lymphatic system, eventually returning to the circulation via the central lymphatic and the thoracic duct.

As approximately 20% of body fluid is found in the interstitial or tissue spaces, the maintenance of fluid volume in this compartment plays a key role in homeostasis. Normally, a dynamic equilibrium exists which maintains the extracellular fluid content of both the plasma and the tissue spaces. However, this delicate balance can easily be disturbed by the following factors:

- *Alterations in capillary pressure* — changes in pressure at either end of the capillary bed will alter net movement of fluid. Increased arterial pressure or venous congestion both tend to favour the loss of fluid to the interstitial space. Examples include hypertension, hypotension, heart failure, and arterial or venous obstruction.
- *Alterations in the plasma proteins* — a reduction in plasma proteins due to malnutrition, liver or renal disease, loss of circulating plasma or leakage of proteins into the tissue fluids will alter the osmotic pressure gradient and prevent fluid being reclaimed from the tissue spaces. Failure of the lymphatics to remove this fluid will increase the osmotic pressure of the interstitial fluid and favour fluid retention.
- *Changes in the integrity of the capillary membranes* — factors which alter the normal mechanisms regulating the permeability/pore size of the capillary membranes also change the osmotic or hydrostatic pressures. These

effects may be local or systemic. Examples include membrane damage from burns, anoxia, pressure, septicaemia and the presence of inflammatory mediators such as bradykinin or histamine.

- *Accumulation of metabolites* — an accumulation of metabolites within the tissue fluid can alter the hydrostatic and colloidal osmotic pressures with consequent changes in fluid movement. For example, in some states of shock or tissue hypoxia, the cumulative effects of lactic acid and carbon dioxide when combined with vasoactive substances may result in oedema.

Oedema

Oedema is an accumulation of fluid in the interstitial spaces or other sites, such as the pericardial sac, between the pleura, in the peritoneal cavity or within the joint capsule. Oedema alters the natural turgor of the tissue spaces and may be noticed by swelling or distension. If the swollen tissue is indented by slight pressure, it is called pitting oedema. In the case of blocked lymphatics for example, protein leakage from the capillaries is not reclaimed from the tissue fluid and the oedema so caused is firm due to the presence of the proteins and does not tend to pit — a characteristic sign of lymphoedema. Oedema may be localised, as in the case of inflammation and tissue damage, or generalised, as seen in heart failure.

General features

Oedema presents several problems to the patient. Its characteristic features may be described as follows:

- it accumulates in dependent areas, especially soft tissues
- it presents as swelling and distension which sometimes 'pits' under pressure
- it hinders the diffusion of gases and transport of nutrients and waste products
- the oedematous tissues lose integrity and are easily traumatised
- tissues adjacent to the oedema may be damaged by the pressure.

20.1 Oedema can occur for the following reasons:

(a) cardiac failure
(b) protein loss
(c) renal dysfunction
(d) soft tissue injury
(e) deep vein thrombosis
(f) arterial insufficiency and the accumulation of metabolites liberated from hypoxic cells.

20.2 Why should one try to avoid giving injections in oedematous areas?

Management

It is important to ascertain the cause(s) of the oedema before initiating any nursing actions.

Consideration of the points listed below may enable a safe, effective plan of care to be initiated which is specific to the person concerned.

- Identify the cause of the oedema and ascertain the appropriate management by liaising with medical staff and other health professionals, e.g. physiotherapists or podiatrists may advise in the case of sports or orthopaedic problems and dietitians where there is protein loss.
- Consider the use and effects of gravity, which may alter fluid drainage or blood flow.
- Monitor and record the extent and nature of the oedema. Communication between day and night staff may identify oedema due to the effects of gravity/position. For example, oedematous feet in the evening may appear to be resolved by a night in bed, only to be replaced in the morning by sacral or orbital oedema, the latter recognised by puffy eyes.
- Assess the effects of the oedema on local tissues and take appropriate action. For example, sacral oedema increases the risk of a pressure ulcer, and severe oedema of the fascia may restrict blood flow and lead to tissue hypoxia.
- Implement medical therapies with appropriate interventions, e.g. administration of diuretics.
- Consider the potential implications and complications of specific types of oedema, e.g. pulmonary or cerebral, and initiate appropriate nursing assessment.
- Consider how oedema may restrict movement, alter a person's self-image and cause practical difficulties in daily life. Ankle oedema may be exacerbated by tight-fitting shoes, whilst ascites may cause respiratory embarrassment and affect the body image. Attention to small details may greatly enhance the comfort of a person with oedema.

20.3 What advice would you give to an older person who suffers from persistent ankle oedema and who wishes to buy a new pair of shoes?

WATER AND ELECTROLYTE HOMEOSTASIS

Constancy of the internal environment is essential for efficient cell function. In health, the volume and composition of the different fluid compartments is finely regulated, with daily fluctuations in TBW of less than 0.2%. Water and electrolytes are ingested and absorbed through the gastrointestinal (GI) tract, although a small volume of water is produced through the oxidation of hydrogen in food. Excess water, electrolytes and waste products are excreted via the kidneys and in faeces. Additional water and salt loss occurs via the skin and respiratory tract.

Since losses from the GI and respiratory tracts are not subject to fine regulation, the kidney is the main regulator of fluid and electrolyte balance. Plasma represents about 4% of the body weight, or only 3 L, but the glomerular filtration rate is 125 mL/min, or about 180 L/day (Marieb 2004). This means that the 3 L of plasma contained within the body is filtered and reabsorbed about 60 times a day! With such a large turnover, the kidney can exert a major influence on plasma composition and, through plasma, on the composition of interstitial and, ultimately, intracellular fluid. Basal urine production in the absence of fluid ingestion is about 300 mL/day. The maximum rate seen in some disease states is 23 L/day, and a normal volume is approximately 2–2.5 L/day. The kidney regulates not only fluid volume, but also electrolyte composition, pH and osmolality. (Osmolality is the concentration of a solution defined in

terms of the number of osmoles per kg of solvent; this is a measure of a solution's osmotic property.) Central to the renal regulation of body fluid, osmolality and volume is the kidney's role in the handling of sodium and water.

20.4 How much daily water is required by a 26-year-old woman who weighs 62 kg? How much extra water might she need if she had a pyrexia of 39°C?

Regulation of ECF volume, osmolality and sodium

Volume and osmolality regulation involves a series of homeostatic mechanisms which regulate the constancy of the ECF. Although the plasma compartment is small, it is dynamic, with shifts in volume and pressure occurring in response to internal and external stimuli. The rapid turnover of the plasma makes it the ideal target for regulatory mechanisms. Although plasma volume and osmolality are monitored, sodium is also a major factor in the regulation of ECF. Changes will also occur in the interstitial and intracellular fluid volumes, but these are usually slower than changes in plasma volume and the body can adapt to them with less functional disruption. The kidney regulates sodium and water ingestion/excretion under the influence of two hormones, aldosterone and vasopressin, also known as antidiuretic hormone, ADH, with additional input from the renin–angiotensin system.

Osmolality and ADH

Within the hypothalamus are specialised cells called osmoreceptors which monitor and respond to changes in plasma osmolality. They are very sensitive and respond to changes of as little as ±3 milliosmoles (mOsml). Plasma osmolality is normally in the range of 280–290 mOsml/kg water. The osmoreceptors respond to variations in plasma osmolality by stimulating two mechanisms: ADH release and thirst.

ADH acts on the epithelial cells of the nephron collecting ducts to increase tubular permeability to water and therefore water reabsorption. If a large volume of water is ingested, the plasma sodium is diluted, causing a fall in the plasma osmolality. This fall is registered by the osmoreceptors, with a resultant decrease in ADH release. Lowered plasma ADH then results in decreased tubular permeability, less water is reabsorbed and water is excreted in the form of a more dilute urine. Conversely, if plasma osmolality is increased, e.g. after fluid loss or after the ingestion of excess salt, a higher plasma ADH results, with an increased permeability of the collecting ducts, and water is absorbed to dilute the hypertonic plasma.

The presence of a non-absorbable solute in the tubular lumen will increase water loss. For example, when plasma glucose levels are raised, as in diabetes mellitus, and filtered glucose exceeds the ability of the nephrons to reabsorb it, urine production is increased. The glucose exerts an osmotic force, keeping water in the tubule. Osmotic diuresis can also be induced therapeutically by the i.v. administration of a non-absorbable molecule such as mannitol.

Other factors affecting ADH regulation of osmolality

ADH release may be altered by some drugs, including nicotine and alcohol. Alcohol inhibits the release of ADH, with a resulting diuresis. Nicotine, morphine and barbiturates are drugs which increase ADH release. Adrenal insufficiency alters the renal response to water loading. Deficiency in adrenal glucocorticoids causes an increase in distal tubular permeability to water. Water reabsorption is increased and dilute urine cannot be produced. Tubular response to ADH is decreased and, even in the absence of ADH, permeability to water remains high.

Regulation of ECF volume and sodium

ECF volume is principally determined by sodium, and body sodium is regulated by the kidney, mainly under the influence of aldosterone. Aldosterone is a mineralocorticoid essential for sodium (with associated water) reabsorption. It has a complex effect: it stimulates Na^+ reabsorption but is not the main regulator of this process, i.e. excess aldosterone production does not usually lead to excess sodium retention. When aldosterone is lacking, Na^+ reabsorption does not occur; this can rapidly lead to death from sodium and water depletion. Aldosterone is also important in hydrogen/potassium ion exchange in the kidney, and in the reabsorption of sodium in the gut and from sweat and the salivary glands. Aldosterone release is stimulated by plasma potassium concentration, plasma sodium concentration and changes in ECF volume. Increases in serum potassium levels of as little as 0.1 mmol can cause a marked increase in aldosterone release.

However, hypovolaemia, which reflects a fall in sodium content (as opposed to concentration), will increase aldosterone secretion via the renin–angiotensin system. Changes in the effective circulating volume, i.e. the blood volume actually perfusing the tissues, which may be less than the total blood volume, stimulate renin release.

Renin is a proteolytic enzyme released from the juxtaglomerular apparatus when sodium loss causes a drop in the effective circulating volume. Renin acts on a plasma protein called angiotensinogen, causing it to release angiotensin I. Angiotensin I is in turn split by a converting enzyme into angiotensin II. Angiotensin II has several actions:

- it is a potent vasoconstrictor
- it stimulates the release of aldosterone
- it increases the reabsorption of sodium by the proximal convoluted tubule
- it acts on the hypothalamus, which then stimulates the thirst centre and increases ADH secretion.

For further information, see Marieb (2004).

DISORDERS OF WATER AND SODIUM BALANCE

Water volume and sodium imbalances frequently occur in combination with other electrolyte problems, although occasionally they occur alone. Principal causes of disturbance can be related to:

- insufficient or excessive intake or output
- problems in the regulation of intake and output which may be associated with disease states, e.g. heart failure or renal failure
- problems related to fluid shifts within the body.

It merits beginning by considering the effects of water deprivation (dehydration) and excessive intake (water overload).

Fluid volume deficit (see Boxes 20.2 and 20.3)

An ECF volume deficit will arise when water loss exceeds water intake. Insufficiency of intake may be related to a number of factors. For example, a patient may be reluctant to swallow because of oral or pharyngeal pain and so may take in less fluid and food. Depressed, anorexic, nauseated or fatigued patients may also fail to take in adequate fluid. Patients suffering from neuromuscular impairment or who are unconscious will have an impaired ability to swallow and thus will also be prone to fluid volume deficit.

Dehydration

Strictly speaking, dehydration refers only to water losses from the body which exceed intake, leaving the person with a corresponding accumulation of sodium (hypernatraemic dehydration). However, 'free water' losses are unusual and it is more common for water to be lost in conjunction with sodium and/or in its role as the biological solvent. Dehydration may thus be isotonic, hypernatraemic or hyponatraemic with respect to the ECF. Isotonic dehydration occurs when the fluid lost is isotonic with the ECF in relation to water and sodium content, whereas in hyponatraemic dehydration the sodium losses exceed the water losses.

Water-only depletion causes a volume deficit in the ECF. Sodium concentration is increased, hypernatraemic dehydration, with a consequent rise in osmolality and haematocrit (packed cell volume, PCV; see Appendix 2). If the dehydration is not resolved, the cells will ultimately become dehydrated. Compensatory mechanisms initially maintain blood pressure, heart rate and haematocrit, but as the dehydration continues, blood pressure falls, pulse volume weakens, and heart rate and haematocrit rise. Haemoconcentration also causes apparent rises in haemoglobin and albumin levels. Eventually the person will be unable to meet the obligatory volume necessary to excrete waste products in the urine. The sequelae of this — metabolite accumulation, acidosis, renal failure and toxaemia — may lead to death.

Dehydration can be assessed according to the approximate percentage of body water that is lost; in the adult this may be defined as follows:

- mild: 4% (3 L)
- moderate: 5–8% (4–6 L)
- severe: 8–10% (7 L).

The management of dehydration is often complex, especially in severe states where there is gross derangement of body chemistry. In mild to moderate dehydration, fluid losses should be replaced slowly to prevent sudden shifts of water and/or electrolytes between fluid compartments, which would aggravate ionic balance. However, as severe dehydration, as seen in diabetes insipidus, heat illness or

Box 20.2

Causes of fluid volume deficit and excess

Fluid deficit

Reasons for inadequate fluid intake: give at least seven reasons

—

Reasons for excessive fluid losses

- Gastrointestinal losses: give at least six reasons

—

- Urine losses: give at least five reasons

—

- Skin losses: give at least three reasons

—

Third space losses (Na^+ and H_2O): give at least four reasons

—

Fluid excess

Reasons for excessive sodium and water intake: give at least three reasons

—

Reasons for inadequate renal losses: give at least three reasons

—

Reasons for increased corticosteroid levels: give at least two reasons

—

For further information, see Porth (2002) and Marieb (2004).

Box 20.3

Signs and symptoms of fluid volume deficit and excess

Complete this box with reference to your textbooks and discussion with your practice mentors.

Fluid deficit

- Thirst
- Acute weight loss: how might this be noticed?

—

- Alteration in renal function: how might this be noticed?

—

- Alteration in cardiovascular function: how might this be noticed?

—

- List six other signs or symptoms of fluid deficit

—

Fluid excess

- Acute weight gain (in excess of 5% body weight)
- Alteration in cardiovascular function: list five signs or symptoms and give a reason why this has occurred, e.g. — pitting oedema (cardiac failure)
- Alteration in respiratory function: list five signs and symptoms and give a reason why this has occurred, e.g. — frothy white sputum (pulmonary oedema)

For further information, see Porth (2002) and Marieb (2004).

severe heat exhaustion, may lead to fatal hypovolaemia, aggressive therapy is required (see Ch. 22). The effects of hyponatraemia and hypernatraemia which may accompany dehydration will be discussed later (see p. 770).

Gastrointestinal losses

Within the GI tract there is a continuous exchange of fluids, with most of the fluid produced being absorbed. Illnesses which present with diarrhoea or vomiting, or conditions in which fistulae, drainage tubes or GI suction are involved, can result in excessive fluid volume losses, potentially up to about 8–9 L/day. Continuous GI or fistula drainage will have the same consequences for a patient as severe diarrhoea and vomiting.

Urinary loss

Patients who have incurred head injury, have undergone hypophysectomy, or who have a primary diagnosis of diabetes insipidus, may excrete excessive volumes of water and electrolytes due to a disruption in the hypothalamo-pituitary release of ADH. Diabetes insipidus occurs when there is either a deficiency in the manufacture and release of ADH, or an inability of the kidney to respond to ADH. ADH deficiency and its consequences are discussed in Chapter 5.

Osmotic diuresis

In osmotic diuresis, polyuria results from the presence of large quantities of solutes in the blood which enter the glomerular filtrate and are not reabsorbed. The high osmolality produced in the renal tubules inhibits the action of ADH and prevents reabsorption of water. This principle can be used to produce an osmotic diuresis therapeutically, e.g. mannitol can be administered to reduce intracranial pressure.

Osmotic diuresis will occur in the following circumstances:

- when the production of large particles exceeds the body's ability to reabsorb or excrete them — classic examples are glucose excess in diabetes mellitus and urea excess in renal failure
- when solutes which can be filtered by the kidney are not reabsorbed, e.g. when mannitol and polysaccharides are administered
- when substances are infused beyond the capacity of the nephron to reabsorb them, e.g. sodium chloride and urea.

Skin losses

The loss of sodium and water from the skin increases dramatically during excessive sweating or if large areas of the skin have been damaged. For example, in extreme hot weather as much as 1.5–2.0 L/h can be lost through sweat. In the patient with fever, water loss may be up to 3 L/24 h. Burns patients suffer excessive fluid losses; evaporation losses can increase ten times with severe burns (Porth 2002; see also Ch. 30). Total loss from burns can be as much as 6–8 L/24 h.

Third space losses

The concept of the 'third space' is used to describe the presence of fluids in areas of the body where they are usually absent, or present only in small quantities, e.g. the peritoneal cavity. Although not lost from the body, the fluid is physiologically unavailable and thus many of the effects of fluid loss may be produced. Whilst the total body weight may remain constant with no net change in body water, the distribution of fluid within the body may be altered. The difficulty in ascertaining the actual problem experienced by a patient is illustrated in 'Stop-think' 20.5.

20.5 Mrs Jones, aged 26, is receiving a continuous infusion of opiates to relieve postoperative pain, and she has a urinary catheter in situ. Mrs Jones's urinary output has been measured at <25 mL/h for the past 3 h.

(a) Identify at least five potential causes of this reduced urinary output.
(b) How might you ascertain which was the most likely cause?

While diagnosis may be the physician's role, astute nursing assessment and implementation of a sound plan of care for such a patient may prevent or anticipate likely problems in relation to the patient's fluid and electrolyte balance.

20.6 What might be the significance of a patient complaining of being very thirsty?

Fluid volume excess (see Boxes 20.2 and 20.3)

The retention of fluid results in a fluid volume excess. Such an imbalance can be caused by overloading with fluids or by reduced functioning of the body's homeostatic mechanisms responsible for maintaining fluid and electrolyte balance. Circulatory overload is a condition associated with an increase in the intravascular blood volume. It is most often observed during the administration of i.v. fluids or in blood transfusion, especially if the amount or rate of the administration is excessive. Isotonic fluids such as 0.9% sodium chloride (normal saline) or Ringer's lactate contain large amounts of sodium. With some patients, e.g. older people or those who have a history of heart disease, careful attention must be given to i.v. fluid therapy. Other sources of sodium gain include some proprietary drugs, e.g. Alka-Seltzer.

Effects of drinking large amounts of hypotonic fluid, e.g. water When a large volume of water is ingested, it begins to be absorbed within about 15 min, in consequence of which the osmolality of the blood decreases. This causes an inhibition of the production and secretion of ADH. Absence of ADH makes the distal convoluted tubule and collecting duct impermeable to water and so more urine is excreted by the kidney, thus producing a more dilute urine and a water diuresis. Following a single large intake of oral fluid, the maximum effect upon diuresis will be noticed about 40 min later. A similar effect is achieved if a bolus or fluid challenge of i.v. fluid is administered.

Water intoxication The kidney has a maximum rate at which it can excrete fluid. If water ingestion, or a hypotonic i.v. fluid administration, exceeds this capacity, then the ECF remains hypotonic. The hypotonic ECF results in fluid moving into the ICF, with a subsequent swelling and bursting of cells. This is most serious in the brain, causing raised intracranial pressure, convulsions and death. Another

significant cause of death from water intoxication occurs as a consequence of the use of recreational drugs like ecstasy. Ecstasy reduces or suppresses the thirst sensation with a resultant risk of dehydration. To prevent the likelihood of dehydration, ecstasy users are advised to drink approximately a litre of water an hour if they become hot and/or expend energy, e.g. while dancing. The particular danger is that the user misjudges how they should compensate their fluid intake while taking ecstasy (see Ch. 36).

Fluid volume adjustments

Chapter 2 describes how the circulatory system comprises the arterial system of high pressure and low volume and the venous system which operates with a lower pressure and higher volume. Approximately 55% of the plasma volume is in the venous system, 10% in the arterial system and the remaining 35% distributed in the heart, lungs and capillaries. Thus changes in volume are usually accommodated by the venous system. The effect of gravity upon fluid in the circulatory system is marked, causing pooling of blood in the venous system with a consequent reduction in the arterial blood volume. If an individual stands for a prolonged period, particularly in a warm environment, there is a reduction in arterial flow to the cells; inadequate venous return then leads to a fall in end-diastolic volume and hence cardiac output. Inadequate perfusion of the brain can then lead to fainting.

The tissue spaces can accommodate large volumes of fluid, but the process is slow and causes fewer disturbances to the ICF or plasma. Adults can usually tolerate changes of about 2 L in the tissue spaces before there are noticeable signs of a volume shift. This 'hidden' accumulation of fluid may, however, be noticed by changes in body weight, 1 L of water being equivalent to 1 kg.

THE ELECTROLYTES

Sodium

Sodium is a major cation found in the ECF, and its concentration is maintained within the range 135–145 mmol/L. Its importance for a number of body functions is related to its role in maintaining the osmolality of extracellular fluids, normal muscular functioning, acid–base balance and a number of other chemical reactions. While hyper- or hyponatraemia usually indicates changes in body water content rather than in the intake of sodium, it is not unknown for individuals to have bizarre eating habits and thus become hypernatraemic, e.g. eating excessive amounts of peanuts or crisps. Furthermore, as sodium is the main extracellular cation, addition of substances to the plasma may cause a dilution effect rather than an actual loss of sodium. For example, serum sodium may appear to have fallen when glucose levels suddenly rise, either due to parenteral nutrition or in diabetes mellitus. Sodium losses may occur from the GI tract, kidney, skin or traumatised limbs.

Normally, the kidneys are extremely efficient in controlling sodium when the intake is reduced. Hyponatraemia, i.e. sodium depletion in the extracellular fluids, is defined as a sodium concentration in the blood of less than 135 mmol/L. The loss of sodium from the ECF is usually a result of excessive fluid loss and not a deficit in intake (see Boxes 20.4 and 20.5).

Box 20.4

Key signs, symptoms and reasons for hyponatraemia (serum sodium <135 mmol/L)

Reasons	Clinical examples
Excess sodium loss	Gastrointestinal loss
	Exercise
Sodium dilution	Excessive fluid intake
Hormone-induced water gains	Renal tubule dysfunction
	Increased ADH

Typical signs and symptoms of hyponatraemia

- Muscle cramps
- Weakness
- Headache
- Hypotension
- Oedema
- Mood changes
- Depression
- Lethargy
- Coma

Box 20.5

Key signs, symptoms and reasons for hypernatraemia (serum sodium >148 mmol/L)

Reasons	Clinical examples
Excess sodium intake	Diet
	Near drowning
	Excessive i.v. administration of Na^+-containing solutions
Decreased extracellular water	Dehydration
Water deprivation and decreased water intake	Confusion
	Impaired thirst sensation
	Communication difficulties
Hormone related	Diabetes insipidus

Typical signs and symptoms of hypernatraemia

- Confusion
- Lethargy
- Twitching
- Convulsions
- Polydipsia (diabetes insipidus)

Chloride

Chloride is ingested either with sodium or as potassium chloride. Normal daily intake is approximately 70–120 mmol, and the minimum requirement is 75 mmol. Chloride output is via sweat (15 mmol/L), gastric juice (90–150 mmol/L) and other intestinal secretions (50–100 mmol/L). Renal excretion is in conjunction with ammonia (NH_4Cl) and occurs mainly in the proximal tubule. Reabsorption occurs in the ascending limb of the tubule and is passively linked with Na^+ reabsorption. Cl^- reabsorption is inversely linked to bicarbonate. As Cl^- is linked to Na^+ reabsorption, aldosterone is an indirect regulator.

Potassium

Potassium (K) is the major intracellular cation. The body contains 2900–3500 mmol of potassium, of which 98% is intracellular and 2% is in the ECF. The intracellular potassium level is approximately 150 mmol/L, as compared with a plasma concentration of 3.5–4.8 mmol/L. Of the body's potassium, 90% is exchangeable while the remaining 10% is bound, mainly in the red blood cells. Men have approximately 45 mmol/kg body weight and women 37 mmol/kg body weight of exchangeable K. The total body K declines significantly with increasing age in both genders. Potassium continually leaks out of the cells, but a high intracellular level is maintained by the sodium–potassium pump. Although extracellular K is low, both intracellular and extracellular K^+ are essential for normal physiological function.

As the muscle cell membrane potential is largely a function of the ratio of intracellular K^+ to extracellular K^+, any alteration of this ratio can adversely affect neuromuscular function. The low ECF potassium means that large changes can occur in total body potassium without a significant effect on plasma K^+.

Potassium is acquired through the diet. Although the potassium content of food varies widely, any diet providing sufficient energy will invariably supply more than enough K, and a normal intake would be 40–200 mmol/day. Potassium is not as well conserved by the kidney as sodium and the minimum daily K loss is approximately 40 mmol: obligatory losses are approximately 15–20 mmol from the gastrointestinal tract and skin, and 10–20 mmol in urine. As noted above, dietary K is usually sufficient to cover the individual's needs, but additional potassium may be required during trauma and stress. Potassium excretion is regulated mainly by the kidney, and plasma K^+ levels are regulated by both renal mechanisms and shifts between the intracellular and extracellular compartments. Although only small amounts are normally lost through the GI tract, diarrhoea and vomiting can quickly lead to potassium imbalances (see Boxes 20.6 and 20.7).

Potassium cannot be conserved by the body, and so a daily intake is required. In the proximal tubule, 80–90% of filtered potassium is reabsorbed; this is essentially an obligatory process little influenced by regulatory factors. Renal regulation of potassium excretion occurs in the distal tubule and collecting duct. Aldosterone is the regulatory hormone for potassium ions. A rise in plasma K^+ concentration increases aldosterone secretion, resulting in increased potassium excretion; a fall in plasma K^+ decreases aldosterone secretion. It is important to recognise that some medications may influence potassium levels, particularly the use of diuretics and angiotensin-converting enzyme (ACE) inhibitors.

Box 20.6

Key signs, symptoms and reasons for hypokalaemia (serum potassium <3.5 mmol/L)

Reasons	Clinical examples
Inadequate intake	Starvation Anorexia
Excessive gastrointestinal losses	Diarrhoea Vomiting Excessive nasogastric tube aspirate
Excessive renal losses	Diuretic therapy Hyperaldosteronism
Intercellular movement	Side-effect of some beta-blockers Insulin therapy, e.g. diabetic ketoacidosis

Typical signs and symptoms of hypokalaemia

- Muscular weakness
- Cardiac dysrhythmias
- Cardiac arrest
- Hypoventilation
- Alkalosis
- Mental confusion

Box 20.7

Typical signs, symptoms and reasons for hyperkalaemia (serum potassium >5.5 mmol/L)

Reasons	Clinical examples
Excessive intake or gain	Oral or i.v. potassium
Inadequate renal losses	Renal failure Renal tubule dysfunction Side-effects of ACE inhibitors
Release from intracellular compartment	Tissue trauma Burns Crush injuries

Typical signs and symptoms of hyperkalaemia

- Cardiac dysrhythmias
- Cardiac arrest
- Twitching
- Skeletal muscle weakness
- Nausea, vomiting and gastrointestinal disturbances

Hyperkalaemia

Body regulation of potassium is geared mainly towards management of hyperkalaemic states, with general excretion occurring via the colon and kidney, whilst serum levels are also influenced by the catecholamines, the pancreatic hormones (insulin and glucagon) and by acid–base states. Due to the cation exchange mechanism which operates in the regulation of acid–base balance, potassium secretion is increased by the nephron in alkalotic states and decreased in acidosis. For example, in metabolic alkalosis the potassium levels rise in the ICF to compensate for hydrogen ion loss. Potassium levels are thus high in the nephron and so excretion takes place with a resultant total body loss of potassium. Hyperkalaemia may be associated with acidosis when there are shifts in the potassium and hydrogen ion concentrations. This may be aggravated by medications such as ACE inhibitors, and require dietary restriction of potassium.

Changes in serum potassium levels tend to reflect either total body changes of potassium or movement of potassium from one fluid compartment to another. Potassium levels

are interrelated with sodium and body water levels. This relationship is disturbed by illness, especially if cell membrane function is disrupted. Cell membrane function is itself very susceptible to changes in potassium concentrations; even small alterations affect membrane excitation, with potentially dire consequences for cardiac tissue. In diabetes mellitus, the administration of insulin causes potassium to enter the cells with glucose in a co-transporter system, leading to a fall in serum potassium. Thus potassium depletion decreases insulin secretion, with the cells having a lower tolerance to glucose. This action of insulin can be utilised in the management of patients with hyperkalaemia: insulin and glucose can be administered to reduce serum potassium.

Hyperkalaemia may also be managed by creating GI losses through the induction of diarrhoea or by using an ion exchange, i.e. a sodium or calcium resin which exchanges with the potassium (Porth 2002). Intravenous calcium gluconate or chloride may temporarily reverse the toxic effect of potassium upon cardiac tissue.

Hypokalaemia

Management of hypokalaemia involves the treatment of any accompanying alkalosis or potassium losses. Potassium supplements may be given orally or intravenously. However, i.v. potassium can cause peripheral vein phlebitis and overly rapid infusion may cause cardiac dysrhythmias and death. Intravenous potassium should not be added to blood products, where it may cause erythrocyte lysis, nor should it be added to solutions of mannitol, amino acids or lipids, as precipitation may occur. Nursing considerations in the administration of potassium are summarised in Boxes 20.8 and 20.9.

Calcium

Calcium is the fifth most abundant element in the body, constituting 2% of body weight. Of the total body calcium, 99% is found in bone, 0.5% in teeth and the remaining 0.5% in soft tissues. Total plasma content is low (8 mmol) and over half of this is bound to albumin. Binding to plasma proteins is pH sensitive, so that acidosis can cause an increase in plasma Ca^{2+} without changes in the total Ca^{2+}. Spuriously high Ca^{2+} levels will be measured if a tourniquet is used to obtain blood for calcium levels. This is due to venous constriction increasing fluid loss with an apparent concentration of the Ca-binding plasma proteins. Normal plasma levels are 2.2–2.6 mmol/L and urinary excretion is 2.5–7.5 mmol/day.

Calcium is required for a range of physiological functions, including:

- calcification of bones and teeth
- regulation of cell metabolism

Box 20.8

Critical factors to observe when administering i.v. potassium

- Never give a rapid bolus of potassium, as this may cause cardiac arrest
- 10 mmol/h via a peripheral line and 20 mmol/h via a central line are maximum recommended infusion rates
- Maximum adult dose is 100–200 mmol/24 h
- Avoid giving higher concentrations of i.v. potassium via a peripheral vein, as this causes venous pain and sclerosis
- Use an infusion pump to control rate when giving higher concentrations intravenously. Observe closely for signs of extravasation
- Observe for signs of thrombophlebitis
- Use ready-prepared solutions when possible
- Ensure thorough mixing of the infusate when potassium is added to infusion solutions. Never add potassium to an infusion bag which is hanging in the upright position because the patient may receive a bolus of undiluted potassium due to inadequate mixing
- Avoid i.v. potassium if the patient is dehydrated or has seriously impaired renal function. Adequate urine flow is required before i.v. potassium can be administered
- Always dilute potassium ampoules before administration. Usual concentration is 40 mmol/L (range 40–60 mmol/L); do not exceed 80 mmol/L
- Monitor the patient carefully, noting excretion of urine, cardiovascular parameters, infusion rate and infusion site. Potassium is highly irritating if it leaks into subcutaneous tissues and may lead to serious tissue damage

Adapted from Metheny (2000).

Box 20.9

Oral potassium supplements: nursing implications

Common side-effects of the administration of oral potassium are nausea, vomiting, gastrointestinal discomfort and diarrhoea. These are due to gastrointestinal irritation and can be reduced by the steps listed below. Because of these side-effects, oral potassium supplements are used with caution in patients who have gastrointestinal problems and patient adherence may be poor, limiting the effectiveness of the supplements. Liquid preparations are preferred to slow-release tablets. Potassium-sparing diuretics are used where possible as they do not require potassium to be supplemented, unlike other diuretics. Potassium supplements can be a cause of hyperkalaemia.

Prevention of gastrointestinal irritation/ulceration

- Always dilute potassium preparations according to the manufacturer's instructions
- Advise patients to sip the diluted solution slowly, over a 5–10 min period
- Effervescent products must be fully dissolved and should not be swallowed until they have stopped fizzing
- Advise the patient to drink a full glass of water with slow-release tablets to help them dissolve in the gastrointestinal tract
- Give potassium supplements after meals
- Observe patients on slow-release potassium tablets for signs of gastrointestinal bleeding
- Check manufacturer's information before crushing potassium tablets — some types must not be crushed

Adapted from Metheny (2000).

- excitability of nerve and muscle, synaptic neurotransmitter release, muscle contraction
- cardiac conduction
- haemostasis
- complement activation.

Calcium is an important intracellular cation, with free calcium ion levels of 10^{-7} mol/L. Within the cell, calcium may be contained within organelles or bound to proteins. A calcium/magnesium ATPase may maintain the concentration gradient of calcium across the cell membrane.

Bone calcium, found in the hydroxyapatite form, provides a large reserve of calcium. The continual formation and destruction of bone, together with soft tissue calcium and calcium in the ECF, provides a small, exchangeable pool which can compensate for decreases in plasma Ca.

Calcium is ingested through the diet. Its absorption from the gut varies according to the presence of vitamin D, parathyroid hormone, growth hormone, corticosteroids and lactose (see Ch. 5). Calcium exists in two major forms within the ECF: as plasma, namely as freely ionised calcium ions, and as a complex bound to proteins (usually albumin). It is the freely ionised calcium which is important for nerve and muscle function. In the plasma, the ratio of the two forms of calcium is usually 50:50, although in the tissue fluid there is only freely ionised calcium.

The location of plasma calcium varies according to pH. The more acidic the plasma, the less protein is available for binding with calcium, and thus the free calcium ion level rises. In a patient with alkalosis there may be signs of hypocalcaemia because the free ions are reduced, yet total plasma levels remain unchanged. Any sudden change in pH will change the free calcium levels and cause clinical effects. This is one reason why, in the treatment of metabolic acidosis, e.g. after a cardiac arrest, any infused sodium bicarbonate should be given slowly and with caution. Where there is a low serum albumin, the free calcium ion level will be normal, although the total plasma calcium will be low. A total serum calcium that is corrected for albumin is the result routinely used in clinical practice. It should be noted that calcium should not be added to blood, lipid, bicarbonate or amino acid preparations, as precipitation may occur.

It is known that cardiac muscle contraction is dependent not only upon the concentration of calcium ions, but also upon the acidity of the extracellular environment. Myocardial depression may occur when there is a rapid drop in calcium levels, as for example following massive blood transfusion when the calcium may have been chelated by the citrates and the bone reservoir cannot release calcium quickly enough to compensate.

The myocardial depression will be aggravated in states of shock where there is poor coronary perfusion. The normal ionic regulation of the cardiac cells is disturbed when there is myocardial necrosis; in this circumstance calcium ions can pour into the cells and overactivate the ATPases, which in turn aggravate and worsen the cardiac necrosis. Thus, where the cell becomes overloaded with calcium ions, uncoordinated and disturbed waves of contraction spread through the muscle, inhibiting effective contraction. Unfortunately, following myocardial ischaemia, immediate reperfusion of the cells with oxygen and nutrients does not necessarily reverse the problem.

Box 20.10

Key signs, symptoms and reasons for hypocalcaemia (serum calcium <2.12 mmol/L)

Reasons	Clinical examples
Impaired ability to mobilise calcium from bone	Hypothyroidism
Abnormal calcium binding	Raised pH Rapid transfusion of citrated blood
Abnormal losses	Pancreatitis
Renal failure, liver disease	Reduced absorption or intake

Typical signs and symptoms of hypocalcaemia

- Paraesthesia
- Spasms
- Cramps
- Tetany
- Hypotension
- Cardiac dysrhythmias
- Bone pain
- Osteomalacia
- Deformity
- Fracture

Calcium-blocking drugs such as verapamil, nifedipine and beta-blockers can slow the entry of calcium into the cells, thus reducing the effects of the necrosis. Calcium blockers may be used for their two major effects, namely to relax muscle and cause vasodilatation, and to alter cardiac rhythm.

Digoxin is known to ultimately change intracellular calcium levels through its action on the sodium–potassium pump. It is this action which enables digoxin to improve the contractility of cardiac muscle.

Signs, symptoms and reasons for calcium deficit and excess are listed in Boxes 20.10 and 20.11.

Box 20.11

Key signs, symptoms and reasons for hypercalcaemia (serum calcium >2.62 mmol/L)

Reasons	Clinical examples
Excessive gains	Increased vitamin D or calcium in diet
Increased bone resorption	Malignant neoplasms
Increased levels of parathyroid hormone	Hyperparathyroidism
Inadequate losses	Thiazide diuretics Lithium therapy
Renal insufficiency	Altered calcium and phosphate absorption or binding

Typical signs and symptoms of hypercalcaemia

- Polyuria
- Polydipsia
- Anorexia
- Nausea and vomiting
- Constipation
- Muscle weakness
- Lethargy
- Cardiac disturbances

Tetany

If there is a decrease in extracellular freely ionised calcium ions, then a condition known as hypocalcaemic tetany may be observed. In the absence of sufficient calcium ions in the ECF, neurotransmission is inhibited, but the deficit of calcium ions in the cell leads to an excitatory effect on nerve and muscle cells, giving rise to increased motor activity. The outcome of this neuromuscular activity is marked spasms of skeletal muscle, particularly affecting the larynx and extremities. If laryngospasm becomes severe, then the person may suffer respiratory obstruction and arrest.

ACID–BASE BALANCE

Body fluids are normally slightly alkaline, within a pH range of 7.36–7.44 (hydrogen ion concentration ($[H^+]$) 35–45 nmol/L). Blood has a H^+ concentration of 40 nmol/L, or a pH of 7.4. Acidaemia occurs when the arterial blood pH is less than 7.36 (greater than 44 nmol/L H^+). An arterial pH greater than 7.44 (or less than 36 nmol/L H+) is alkalaemia. The body enzymes which control most physiological processes are optimally active within the normal pH range, and variations from this range can rapidly result in severe disability or death. It is therefore essential to understand the basis of acid–base balance in health and the effects of disease on this balance. A pH outside the range 6.9–7.7 is incompatible with life and variations outside 7.36–7.44 are serious and may be difficult to rectify. Whilst the blood pH is maintained at a slightly alkaline level, the pH of urine is frequently acidic as the body seeks to excrete surplus acids which have been produced by both metabolic and respiratory processes.

The long-term regulation of pH occurs through the lungs and kidneys, whilst buffers in the blood provide an immediate response to changes in pH. With adjustments in respiratory rate, carbon dioxide levels, and hence pH, can also change. The response, involving the kidney, is slower and sometimes referred to as the 'renal lag'. The kidney's ability to regenerate bicarbonate ions whilst excreting hydrogen ions enables it to aid the regulation of pH. Crucial to the management of these problems is the reversal or removal of the causative factor (Porth 2002, Marieb 2004).

Acidosis and alkalosis

The terms acidosis and alkalosis refer to abnormal situations which lead to acidaemia and alkalaemia, respectively, if there are no secondary compensatory mechanisms to reverse the situation. Both situations can be equally disruptive.

Acidosis occurs when there is a high hydrogen ion concentration and thus a low pH of <7.36. It can arise through:

- metabolism of proteins producing sulphuric and phosphoric acids
- anaerobic metabolism producing lactic acid
- metabolism of fats producing acetoacetic acid and ketone bodies
- excessive intake of acidic products orally or intravenously
- excessive loss of bicarbonate from the body
- hypoventilation with resulting retention of carbon dioxide.

Alkalosis occurs when there is a loss of hydrogen ions or a gain in bicarbonate ions and hence a correspondingly high pH >7.44. Alkalosis can occur through:

- excessive loss of gastric juices, e.g. vomiting, gastric aspiration
- excessive intake of alkaline products, e.g. overdose of antacids
- hyperventilation with resulting removal of carbon dioxide.

Changes in carbon dioxide tension which have a respiratory origin result in respiratory acidosis or alkalosis. Changes in bicarbonate levels reflect metabolic causes: metabolic acidosis or alkalosis. Whilst the primary causes may be metabolic or respiratory, the adaptive responses involve both systems and lead to compensatory states. Occasionally both metabolic and respiratory problems occur simultaneously and a confused picture presents, as in respiratory failure in a patient with renal failure.

Buffers

20.7 Refer to your physiology textbook to review the Henderson–Hasselbalch equation.

Regulation of blood pH involves complex chemical reactions in which buffers play a critical role. Buffers are substances which prevent major changes in the pH of a solution by removing or releasing hydrogen ions. In humans there are three main buffer systems:

- carbonic acid bicarbonate
- phosphate and sulphate compounds
- proteins and haemoglobin (main ICF system) (see Porth 2002).

Buffers are found in both the ICF and the ECF and enable products to be safely transported to the site of excretion.

For further reading on buffers and pH regulation, see Porth (2002) or Marieb (2004).

Carbonic acid bicarbonate

This is the main buffer in humans and will serve as an illustration of the role of buffers in the body. This mechanism operates through the following reversible reaction:

$$H_2O + CO_2 \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \text{ (bicarbonate ion)}$$

In situations where hydrogen ions are added to body fluids, they combine with the bicarbonate ion:

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3$$

In situations where the hydrogen ion levels become low or there is an excess of hydroxyl ions, carbonic acid dissociates, releasing hydrogen ions into solution:

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

In alkalotic states, the level of bicarbonate ions rises (metabolic alkalosis) or the amount of carbon dioxide in solution falls (respiratory alkalosis). In acidic states, the level of bicarbonate decreases (metabolic acidosis) or the amount of carbon dioxide in solution rises (respiratory acidosis). There is thus a reciprocal relationship between the levels of carbon dioxide and the bicarbonate ions. This dynamic

relationship, which enables pH to be regulated, is utilised in several ways within the respiratory system and the renal tubule. The enzyme carbonic anhydrase catalyses the formation of carbonic acid from water and carbon dioxide. Acetazolamide is an example of a drug which blocks carbonic anhydrase and thus inhibits both the regeneration of bicarbonate ions and the production of hydrogen ions in the renal tubule.

Alterations in the pH of the body may be indicated by clinical signs and laboratory results. The acidity of plasma is determined using arterial blood gas samples, but changes in other body fluids may be detected by testing urine, intestinal fluids, CSF and other exudates.

Handling blood gases

Obtaining a sample for the analysis of blood gases can be effected by direct arterial puncture or the withdrawal of blood from an arterial line. The nurse responsible for the patient will need to ensure that several precautions are taken to prevent a false result. The specimen form should include such details as:

- the patient's temperature
- respiratory pattern
- concentration of oxygen in the inspired gases
- any relevant recent therapies, e.g. physiotherapy, administration of bicarbonate or blood
- time the sample was taken.

The sample is collected in a small prepared heparinised syringe (1 or 2 mL). Should this be unavailable, add a small quantity of dilute heparin (100 units/mL) to a syringe to prevent coagulation. The amount of heparinised saline added should be just enough to fill the dead space of the syringe. In the case of collecting a blood sample from an arterial line, it will be necessary first to withdraw and discard the heparinised saline in the arterial line tubing (excess heparin itself reduces the measured pH). A second syringe may then be used to withdraw the arterial blood itself. As soon as the sample has been collected, a bung or stopper is attached to the end to prevent air contamination. The syringe should be labelled and sent to the laboratory as soon as possible. If the ambient temperature is warm then the sample can be transported in ice. The arterial line will need to be flushed and reset in order to remove the blood which has been drawn back into the line. With direct puncture, firm digital pressure will be required over the puncture site for at least 5 min to prevent arterial haemorrhage or subsequent aneurysm formation. The circulation of the limb distal to the puncture should be checked later. Normal blood gas results are listed in Box 20.12.

Box 20.12

Normal blood gas results (slight variations according to local laboratory)

pH	7.36–7.44
$[H^+]$	35–45 nmol/L
P_aCO_2	4.6–5.6 kPa (35–42 mmHg)
P_aO_2	11.3–14 kPa (90–105 mmHg)
HCO_3	23–31 mmol/L
Standard HCO_3^-	22–26 mmol/L
Base excess	–2 to 2 mmol/L
Saturation O_2	97%

The acidotic/alkalotic states

20.8 Disorders of acid–base balance are primarily respiratory or metabolic in origin. From the information given so far, draw up a chart to indicate how the respective acid/base states may influence the pH, the bicarbonate ion levels (HCO_3^-) and the partial pressure of carbon dioxide in the plasma (PCO_2) in:

(a) metabolic acidosis
(b) respiratory acidosis
(c) metabolic alkalosis
(d) respiratory alkalosis.

Recognition and management of metabolic alkalosis

Metabolic alkalosis is caused by a loss of hydrogen ions, e.g. through vomiting, or a gain of alkali, as seen in the excess intake of sodium bicarbonate. It is characterised by high pH and a high concentration of bicarbonate ions. This rise in pH decreases the ionisation of calcium, thus giving signs of hypocalcaemia. Indicators of hypokalaemia may also arise. The respiratory response seeks to compensate for the alkalosis by raising the PCO_2 through a decreased respiratory effort: thus a respiratory acidosis may accompany the metabolic alkalosis. The increasing numbers of bicarbonate ions utilise free sodium ions, thus decreasing the ratio of free sodium ions to chloride ions. There is a slight renal compensation which attempts to conserve hydrogen ions. Usually, a metabolic alkalosis is successfully treated by management of the cause with appropriate monitoring of any hypokalaemia and/or by restoration of fluid volume. Occasionally, acidification of the plasma may be required, or the administration of acetazolamide to inhibit carbonic anhydrase.

Antacid use Antacids are bases used to neutralise the acidity of gastric juices. Injudicious use can lead to metabolic alkalosis and problems associated with other side-effects of the substances used. Most antacids comprise a combination of aluminium or magnesium hydroxides, or derivatives of carbonates. It is important that patients who take antacids are aware of the necessity to keep within the prescribed doses and to report side-effects or failure of the therapy to their physician or community pharmacist; some antacids, for example, are contraindicated in patients with peptic ulcers (see *British National Formulary*, www.bnf.org).

Recognition and management of metabolic acidosis

Metabolic acidosis is characterised by a low pH and low levels of bicarbonate ions. The lowered pH leads to a compensatory respiratory drive to hyperventilate, thus causing a transitory fall in the PCO_2. If this is successful, the pH will return towards normal. However, if the acidosis is severe, cardiac output may drop with accompanying bradycardia,

because acidosis impairs cardiac contractility. Renal compensation is made through the excretion of extra hydrogen ions. Hyperkalaemia may also be present, depending upon the cause of the acidosis. The features of the underlying acidotic state, e.g. peripheral vasodilatation, will also be present. The main aim of treatment is to reverse the cause. This may involve the administration of bicarbonates, but it is important to recall that each mmol of sodium bicarbonate given contains 1 mmol of sodium ions. The three most common causes of metabolic acidosis are renal failure, diabetic ketoacidosis and hypoxia.

Recognition and management of respiratory alkalosis

The most common cause of respiratory alkalosis is an anxiety attack which has led to the person noticeably hyperventilating. The subsequent removal of carbon dioxide leads to a raised pH and eventually a fall in the bicarbonate level when renal compensation has occurred. The aim in managing the anxiety attack is to enable the person to breathe more slowly, to calm them, with a sedative if necessary, and, if it is safe, to enable them to rebreathe expired air, thus raising the carbon dioxide level. This can be achieved by having the person breathe in and out of a paper bag. While this technique is effective, it must be supervised to ensure that the person does not suffocate or do it to excess. Other instances of alkalosis will require management of their specific causes.

Recognition and management of respiratory acidosis

Respiratory acidosis is caused by an excess of carbon dioxide. It is most frequently caused by primary disorders of the respiratory tract, or by conditions which affect the respiratory centre, e.g. drug overdose and central nervous system problems. Faults in the management of mechanical ventilation may also lead to respiratory acidosis.

Respiratory acidosis may be detected when the underlying respiratory problem is recognised, e.g. asthma or bronchitis, and/or when the signs of acidosis become apparent. People with chronic respiratory problems may already have well-established compensatory mechanisms; for example, in chronic obstructive pulmonary disease (COPD) there may be a renal compensation which retains bicarbonate ions to counter the respiratory acidosis generated by a chronic high level of PCO_2 (see Ch. 3). In these situations, biochemical results may have a different significance from those associated with acute respiratory acidosis.

NURSING CONSIDERATIONS IN MAINTAINING FLUID AND ELECTROLYTE BALANCE

Assessment

Assessing fluid and electrolyte status

The effects of a fluid/electrolyte loss or gain depend to a large extent on the volume of the loss or gain and the rate at which it occurs. Effects are more acute when they develop rapidly, when the person is older and when the person is debilitated. Signs and symptoms observed by the nurse will depend upon the effects of the fluid loss or gain on the serum osmolality. A major problem in the assessment of fluid and electrolyte imbalance is that significant changes occur before they can be detected by clinical measurements such as blood pressure or central venous pressure. The nurse therefore needs to be able to use a wide range of skills to detect early changes. These include the following:

- *Knowing what to look for* — using a sound knowledge of physiology, the nurse will know what early and late clinical signs may be present, including signs of compensation by the body in its attempt to maintain homeostasis.
- *Knowing how often to look* — the nurse will be able to assess the severity of the situation and assess/monitor the patient accordingly.
- *Knowing what the anticipated effects of a variety of medical interventions are* — in order to assess effectiveness of treatment and plan further care.

Changes in tissue fluid volume are noticed mainly through observation of mucous membranes and skin elasticity, the latter being more easily observed over bony prominences. With an infant, the anterior fontanelle provides a good indication of hydration status.

The nurse's frequent contact with the patient should enable detection of any disturbances of features which may be related to fluid and electrolyte status. Unfortunately, nursing management of patients' needs for food and fluid is often neglected and notoriously full of errors and confusion (see Research Abstract 20.1). In illness, certain groups of patients, such as older people, children and pregnant women, are particularly susceptible to fluid and electrolyte problems. Others are at risk by virtue of an underlying pathological problem and/or as a result of nursing or medical interventions.

RESEARCH ABSTRACT 20.1

Nutritional care of the unconscious patient

Jones (1975) published the results of a study into the nutritional care of unconscious patients being fed by a nasogastric tube. Amongst the many findings of this study were several points pertinent to the fluid status of the patient. We suggest that you consult this seminal study which discusses some of the errors commonly made in fluid measurement and administration, problems which are still valid today. Metheny (2000) identifies other potential sources of error when recording fluid input and output.

Jones D C 1975 Food for thought. Royal College of Nursing, London
Metheny N 2000 Fluid and electrolyte balance: nursing considerations, 4th edn. Lippincott, Philadelphia

20.9 Carry out the activities listed below. What are the implications of your findings with regard to a patient's hydration status?

(a) Measure out 100 mL quantities of liquid using a syringe or i.v. burette and inject them into the following utensils, observing the water levels:
- urinal
- catheter bag

- measuring jugs
- standard hospital glass, cup and cereal bowl.

(b) Determine how much liquid is contained in the standard hospital glass, cup and bowl when:
- full to the brim
- half full
- filled to the level usually served by the catering staff.

20.10 Select a suitable person on your next clinical allocation and make an assessment.

(a) What is the state of the person's hydration?
(b) What is the person's ability to regulate fluid and electrolyte intake and to excrete necessary fluids?
(c) Give reasons for your conclusions.

A number of parameters may indicate changes in fluid or electrolyte status, but minor changes are often recognised only by those familiar with the person. Thus effective communication is crucial between nurses, e.g. at handover reports, and with relatives and carers who may notice changes. The rapid detection of patterns and trends can be important in identifying deterioration or improvement in the patient's condition.

A structured approach to nursing assessment should facilitate the identification of actual and potential patient problems. Indeed, the initial assessment may not be completed until a 24-h observation of the patient has been undertaken. Assessment of the patient's fluid and electrolyte status involves a four-stage process, some of which may run concurrently.

Stage 1: Consider observable and reported parameters
Stage 2: Consider measurable parameters
Stage 3: Consider the underlying pathophysiology
Stage 4: Consider the effects of medications.

Observable and reported information

Many changes in tissue volume can be noticed through sensory observation or by the patient reporting symptoms. When this information is combined with the measurable data, it can give a reliable indicator of the patient's fluid status.

For further details of the physiological processes which influence fluid and electrolyte status, see Porth (2002), Marieb (2004) and Tables 20.1 and 20.2.

Effects of underlying pathophysiology and/or medications

Underlying pathological processes and the effect of medications frequently distort clinical signs. The examples in Table 20.1 indicate their possible effect when assessing a patient's fluid and electrolyte status.

Monitoring fluid balance

The two most important components of monitoring a patient's fluid balance are measurements or estimations of fluid intake/output and weight. Insensible fluid losses are estimated according to standard norms and often account for a much larger volume than is usually estimated in clinical practice (Marieb 2004). It is therefore important to make adjustments for the following factors:

- body temperature
- ambient temperature
- basal metabolic rate
- respiratory rate
- respiratory assistance, e.g. use of oxygen, humidification
- other pathologies
- fluid content in stools
- internal losses due to fluid movement
- losses through skin trauma.

Whilst some losses and gains have to be estimated, in appropriate circumstances others can be measured, for example:

- volume of oral fluid intake and fluid in foods
- i.v. fluids
- GI gains through enteral sources
- GI losses
- losses from fistulae and drains
- urine: volume and concentration, i.e. an output <0.5 ml/kg body weight per h
- fluid pressures through observing the jugular venous pressure or measuring central venous pressure.

Unfortunately, the volume of oral fluid intake or fluid in food is usually estimated rather than measured. Indeed, some 'fluid foods' such as soups and custards are not necessarily included in fluid recording. This is particularly important in patients who are restricted to a liquefied diet or whose fluid intake is restricted, as in renal failure.

Fluid balance charting: possible sources of error

Nurses should be aware of the many ways in which the accuracy of fluid intake/output calculations may be compromised. Examples include:

- duplication or omission of items
- use of estimations rather than measurements
- arithmetical errors
- i.v. fluids administered in theatre and not correctly accounted for
- shift change errors, i.e. in carrying forward from the previous shift
- not specifying whether fluid is colloid or crystalloid in calculations
- recording wrong i.v. bag — confusion between treatment chart and fluid chart
- failure to observe patterns in consecutive daily balance
- the patient is unable to accurately recall events and forgets their fluid or food intake.

Measurement errors also arise when inappropriate utensils are used. To reduce the margin of error, low volumes of urine should be measured in containers with graduations designed for low volumes. Large volumes measured from catheter bags may prove to be different if the bag is emptied and then measured from a rigid jug. Similarly, i.v. fluid bags may contain more than the actual amount specified. Understanding the relative acceptable margins of error is an essential but neglected aspect of fluid monitoring. In a fit, healthy person, small errors may not be significant, but in a vulnerable person they can lead to inappropriate treatment

Table 20.1 Observable/reportable signs of fluid and electrolyte disturbance and their possible significance

Clinical signs/symptoms	Clinical significance	Cautions in interpretation
Mucous membranes will appear dry and the patient will complain of thirst	Decreased saliva production will result in a dry mouth and sensation of thirst Osmoreceptors detecting hypovolaemia will also trigger a feeling of thirst. This acts as a useful backup, as good mouth care often disguises the decreased saliva production	Mouth breathing Oxygen administration Anticholinergic drugs
Tongue furrows	A normal tongue has one long longitudinal furrow, but in dehydration additional furrows will be present and the tongue will appear smaller due to fluid loss (Lapides et al 1965)	—
Sunken eyes	As a result of decreased intraocular pressure	—
Increased jugular venous pressure (JVP) With a patient at 45°, venous distension should not exceed 2 cm above the sternal angle	Distended veins indicate fluid overload; flat veins indicate decreased plasma volume	Assessing the right internal jugular vein gives a more reliable reading than on the left as it is the most anatomically direct route to the right atrium
Reduced capillary refill time	Capillary refill taking 2–3 s indicates a mild fluid deficit Refill times in excess of 3 s signify severe fluid deficits	Peripheral shutdown due to cold will slow capillary refill irrespective of fluid status
Reduced skin turgor	Reduction in interstitial and intracellular fluid will reduce skin elasticity	In an older person it is difficult to detect changes in skin turgor due to the gradual loss of skin elasticity with age
Cool peripheral temperature and pale skin colour	As a result of the renin–angiotensin cycle, hypovolaemia will result in peripheral vasoconstriction and therefore reduced temperature and colour	Patients with poor circulation, e.g. peripheral vascular disease/Raynaud's disease, will normally have cool peripheries Certain antihypertensives including vasodilators and ACE inhibitors will disguise the body's normal compensatory mechanism
Dark urine	Hypovolaemia will trigger release of ADH, leading to more concentrated urine	Patients with liver disease may have bilirubin present in their urine giving it a very dark colour Administration of diuretics will override the body's production of ADH
Peripheral oedema	Oedema occurs as a result of movement of fluid into interstitial spaces as a result of fluid excess and/or reduced levels of plasma proteins A consequent decrease in intravascular fluid may lead to a drop in blood pressure	—
Pulmonary oedema, observable through frothy sputum and/or shortness of breath	Pulmonary oedema will result in decreased gaseous exchange, with a reduction in oxygen saturations and arterial oxygen levels	—

regimens with consequent problems. Due to the problems associated with estimating and measuring fluid intake and output volumes, many view the use of daily weight recordings as a more reliable indicator of fluid status. However, for these measurements to be accurate and meaningful, the weight should be taken at the same time each day and with the patient wearing the same clothes and shoes. Lean body mass changes do not occur quickly and the measurement of daily weight is particularly useful when assessing the older person and those with renal or cardiac impairment. Finally, measurement of bioimpedance may be a way forward in the assessment of fluid volumes within the body. Bioimpedance measures the extent to which the body conducts electricity. However, interpretation of measurements is complex and it is unlikely that this will become a widely used technique.

Table 20.2 Measurable parameters and their possible significance in fluid and electrolyte imbalance

Clinical measurements	Clinical significance	Cautions in interpretation
Pulse	If there is a reduction in circulating volume and therefore stroke volume, the heart rate will increase to compensate and maintain cardiac output Initial assessment of rhythm, based on the regularity of the pulse, may be useful and indicate a need for an ECG recording	Cardiac drugs, e.g. beta-blockers, will inhibit the body's compensatory mechanism and therefore block an increase in heart rate
Blood pressure	Measurement of blood pressure will give an indication of circulating volume Pulse pressure, the difference between systolic and diastolic pressure, will give an indication of vasoconstriction, i.e. compensation by the body	As a result of numerous compensatory mechanisms, blood pressure is maintained by the body for as long as possible. A 'normal' blood pressure in the presence of compensation must be acted upon immediately
Central venous pressure (CVP)	Will be reduced as a result of hypovolaemia and/or vasodilatation An increase in CVP does not necessarily indicate fluid overload as CVP is influenced by numerous other factors including cardiac competence, systemic vascular resistance, intrathoracic and intra-abdominal pressure. For further information, see Chapter 18	—
Urine volume	In health, the body produces 1 mL urine/kg of body weight per h Acceptable urine output in the critically ill patient is equal to 0.5 mL urine/kg per h	A knowledge of the patient's weight and calculation of desired urine output based upon that is essential Administration of diuretics will override normal physiological processes. Their use must be noted when assessing volume of urine produced
Specific gravity of urine	Demonstrates the body's ability to concentrate urine as an indicator of kidney function and/or response to ADH production	Administration of diuretics will override normal physiological processes. Their use must be noted when assessing urinary specific gravity

Managing fluid and electrolyte therapy

Aims

The aims of all fluid and electrolyte therapy are:

- to regulate, where possible, the patient's fluid and electrolyte balance by controlling the content and volume of the oral/enteral route; when oral/enteral routes are inadequate, venous access is used
- to control excessive losses and gains, e.g. by means of surgical intervention to prevent blood loss or by the use of diuretics to regulate fluid balance.

Both the medical and nursing management of the patient's fluid and electrolyte status will be derived from the initial assessment. The patient may require one or more of the following interventions:

- Assistance with the maintenance of normal fluid and electrolyte requirements; this usually occurs for a short period of time in a previously well-nourished person, e.g. following surgery or during a brief period of coma
- Correction of fluid/electrolyte imbalances
- Parenteral nutrition (PN) (see Chs 4 and 21).

Occasionally, a person will require all three measures simultaneously; for example, someone with a major injury to the abdomen may need immediate correction of blood losses and electrolyte disturbances. There would then be a need to ensure that normal fluid and electrolyte requirements are met, with consideration being given to changes in demand due to the injury.

If oral/enteral feeding is unlikely to be resumed within 2–3 days, then immediate plans should be made to commence parenteral feeding.

In deciding on the most appropriate plan for a patient, consideration is given not only to the content of the therapy, but also to the resources available, the patient's coexisting problems, e.g. cardiac failure or diabetes mellitus, and the particular hazards associated with the respective methods of administration. The timing, rate and duration of the therapy can also determine which route will be most effective.

Determining the volume and content of the therapy

The regimen prescribed for the patient will be based on the following essential considerations:

- What needs to be replaced — measured and insensible or hidden losses from the body
- What needs to be removed — where there is excess production or excretory failure

- What needs to be adjusted — where there is translocation of fluids or electrolytes
- What needs to be resolved — the cause of the problem, e.g. vomiting, haemorrhage.

The identification of these requirements will be based on nursing observation, medical assessment and laboratory analysis of specimens. However, the method of administration will influence the nature of the fluid regimen.

Routes for fluid and electrolyte therapy

The oral route

Replacing fluids via the oral route is without doubt the safest method. In a healthy adult who has no circulatory or renal insufficiency, the need for fluid is 1500–3000 mL/24 h. Replacing fluids orally will involve identifying the person's preferred drinks and then making these available, where reasonable, in the desirable quantity.

In some situations the patient may be prescribed 'restricted fluids', the amount usually being stated. For example, a person with renal failure may have a restricted fluid intake of 1000 mL/24 h. In other circumstances the nurse may be instructed to 'encourage fluids', especially when the goal is to prevent urinary stasis in the catheterised patient.

Two key points for the nurse to bear in mind when caring for patients requiring replacement of fluid and electrolytes by the oral route are as follows:

- Always ascertain the exact meaning of any rather vague verbal or written orders concerning fluid replacement, e.g. 'push fluids', 'encourage fluids', 'taking sips'. Remember that fluid and electrolyte balance is important and that the nurse has a key role to play in preventing further problems.
- If at all possible, know exactly how much fluid a person is required to have over a 24-h period. Medical orders can easily be written to identify appropriate daily fluid intake targets, e.g. 2000–2500 mL/24 h.

Sometimes patients on fluid replacement therapy still complain of thirst. Whilst the thirst reflex will be permanently relieved if the thirst sensors in the hypothalamus are no longer stimulated, a temporary depression of the thirst mechanism has been associated with interventions related to the oropharyngeal region (Anderson & Rundgren 1982). The patient troubled by thirst may be comforted by the following nursing actions:

- Carrying out frequent oral hygiene
- Applying lubricant to lips
- Giving mouth rinses with fresh water
- Choosing carefully the type and temperature of fluids
- Offering ice chips for the patient to suck.

The parenteral route

For a number of patients, fluid and electrolyte therapy must be administered via the parenteral (i.v.) route. Parenteral fluid administration enables solutions to enter into the extracellular compartment directly, enabling a rapid and controlled method of delivery. Managing an i.v. therapy regimen has become a common nursing responsibility, with some practitioners being qualified to initiate specified therapies under specified authority. Before commencing an i.v. therapy regimen, assessment should consider the adequacy of the patient's renal/cardiac function and current fluid/electrolyte status, referring to such objective measures as laboratory results, body surface area and intake/output.

The subcutaneous route

In older patients who have impaired venous access, in those who are confused or find it difficult to tolerate an alternative route, or in the terminally ill patient, the use of subcutaneous fluid administration (SFA) can be both appropriate and preferred (Mansfield & Monaghan Hall 1998). The sites of choice include the anterior or lateral aspects of the chest wall, the abdominal wall, the anterolateral aspects of the thigh and the scapula. The site of the subcutaneous administration should be regularly inspected and changed every 24 h.

Other routes

Fluids can be administered through the rectum and through ostomies, although these routes are not always effective. A feeding tube may be inserted into the stomach, e.g. via a percutaneous endoscopic gastrostomy (PEG), or into the jejunum and used to administer fluids (see Ch. 4). When the oral route is inadequate, arteriovenous (AV) access may be used for i.v. therapy. In renal failure, fluid and electrolyte regulation may also involve the use of human or artificial membranes in the case of peritoneal dialysis or haemodialysis.

Major complications of i.v. therapy

Due to advances in technology, i.v. therapy is now relatively safe; however, it is still possible for serious complications to arise. Unfortunately, as noted by Speechley and Toovey (1987), complications are sometimes regarded as routine occurrences or a mere 'nuisance', but to overlook or underestimate the potential risks of i.v. therapy is to lose sight of the aim of therapy, which is to effectively replace fluid and electrolytes without causing the patient discomfort or further injury. The most common complications are:

- occlusion
- infiltration, i.e. leakage of non-irritant or vesicant fluid into the tissues surrounding the vein
- extravasation, i.e. infiltration of irritants or vesicants that cause tissue damage
- phlebitis.

Factors associated with an increased incidence of phlebitis include:

- cannula location — insertion in the lower extremities or movable joints presents an increased risk
- duration of therapy — increasing length of time raises the incidence, especially over 24 h
- blood flow problems in the region of the cannula site
- inadequate sterilisation of the cannula site
- pre-existent infection
- pH and osmolality of the fluid — acidic infusates in particular

- particulate matter which may contaminate the delivery system.

Selecting the site

Patients who are particularly vulnerable to complications are those with existing infections or immune suppression and those whose restlessness or mental state may lead them to traumatise the cannula site. In their seminal work, Maki et al (1973) pointed out that the cannula site is similar to an open surgical wound containing a foreign body and should be treated as such.

For a summary of the potential complications associated with i.v. devices, see Dougherty & Lamb (1999) or Finlay (2004).

Some practical considerations are involved in site selection, namely:

- the nature and anticipated duration of the therapy
- situational and environmental factors
- patient and safety factors
- availability of products
- staff expertise.

Insertion of the i.v. cannula, although often considered to be an expanded role of the nurse, is usually undertaken by medical staff or specially trained nurses. Some suggested competencies for i.v. drug administration are outlined by Finlay (2004) and are the subject of ongoing development by the Royal College of Nursing IV Therapy Forum. Effective communication between patient, nurse and doctor may enable a more effective and safe selection of site, materials and insertion technique. In life-threatening circumstances, the selection of the i.v. site is largely dependent upon the expertise of the staff available, the products to hand and the purpose of the line. Whilst infection control measures are important, at the scene of a disaster or accident, environmental contaminants may be inevitable and speed may take priority. The more invasive the procedure, the greater is the importance of environmental control. Where possible, central vein devices, especially those involving a cutdown procedure, should be inserted in an operating theatre environment. Local factors which may be controlled during the time of insertion include the elimination of airborne contaminants and the avoidance of debris or bacteria entering via the insertion site.

Patient factors Patient mobility and comfort may be enhanced or hindered by site selection. It is wiser, and causes less discomfort, to site the i.v. cannula away from movable joints or sites where clothes may rub. Skin areas which are vulnerable to breakdown should also be avoided, including areas which are burned, oedematous, traumatised, inflamed or affected by dermatological conditions such as eczema or psoriasis. The integrity and state of the veins themselves should also influence selection.

The safety of lines in patients who are restless often poses a practical problem for nursing staff. Stability of the line may be enhanced by the method of attachment to the patient, and applying principles of countertraction, through the use of loops, may prevent unnecessary trauma. Personal and environmental hygiene factors may necessitate that the insertion site be covered.

Central lines

Chapter 18 discusses the management of central lines used for the measurement of central venous pressure (CVP) and summarises the potential problems associated with the insertion, maintenance and removal of CVP lines. Similar principles apply when the central line is used for the long-term administration of infusates, e.g. patients requiring PN, cytotoxic and antibiotic therapy. However, the greatly increased incidence of complications associated with the use of central lines necessitates a very cautious and competent approach to their management. Finlay (2004) reminds us of the dangers associated with central line insertion and maintenance, namely pneumo- or haemothorax, arterial puncture, atrial fibrillation, venous embolism on insertion, during maintenance or upon withdrawal, infection and thrombosis.

20.11 This résumé of the numerous issues involved in the safe management of a person with an i.v. device illustrates the complexity and importance of skilful and knowledgeable nursing practice. The professional accountability of the nurse practitioner is outlined by the Nursing and Midwifery Council in their standards and guidance regarding *Professional Conduct, the Administration of Medicines, Records and Record Keeping* (NMC 2004). In the light of these standards, review your local Trust or Unit protocols and evaluate the 'customs and practices' in your own clinical areas. It would be a useful management exercise to attempt to devise some criteria/standards and actions which could be employed to evaluate the effectiveness of local policies.

20.12 Identify the observations you should make when a patient has (a) a peripheral device and (b) a central device. How might you recognise signs of a problem associated with the maintenance of these i.v. devices?

20.13 What specific problems may be encountered in a person with an infusion device who is being cared for at home?

Types of parenteral fluids

The nature of the products to be infused determines both the number and location of the lines. Some infusates cannot be mixed, and if concurrent administration is required, two or more lines may be needed. Infusates which increase the likelihood of microbial contamination include those used in PN, especially those containing high concentrations of glucose. Each infusate carries with it particular risks, and nurses should familiarise themselves with the specific potential side-effects associated with different infusates.

Broadly speaking, the infusates commonly used in i.v. therapy, as opposed to PN, may be categorised as follows:

- colloidal solutions:
  - — blood and blood products
  - — plasma and plasma substitutes
- crystalloids — water, electrolytes and isotonic solutions.

There is ongoing clinical debate as to which type of i.v. fluid is preferable. Research has provided mixed evidence, and several Cochrane Reviews have added to the debate but have not drawn firm conclusions (Alderson et al 2003, Bunn et al 2003).

Infusates can also be categorised with respect to their tonicity.

Isotonic solutions have the same osmolarity (tonicity) as serum or other body fluids and expand the intravascular compartment without affecting the intracellular and interstitial compartments; 0.9% saline is an isotonic fluid with respect to plasma.

Hypotonic solutions have a lower serum osmolarity and cause body fluids to shift away from the blood vessels and into the intracellular and interstitial spaces to areas of higher osmolarity. Hypotonic solutions may be used in the case of cellular dehydration due to diabetic ketoacidosis.

Hypertonic solutions cause fluid to move from the interstitial and intracellular compartments towards the intravascular compartments. For example, hypertonic saline will increase plasma and interstitial fluid osmolality.

For further information, see Finlay (2004).

Dehydration and hydration in the terminally ill individual The ethical and clinical debates continue as to whether, and when, to withhold or withdraw intravenous, subcutaneous or nasogastric hydration in the terminally ill patient (see Ch. 33). Nurses may well be presented with situations where a decision regarding hydration of their patients must be made. Nurses need to be knowledgeable of the benefits and disadvantages of both terminal dehydration and the rationale for hydration (Jackonen 1997). Decisions made must be individualised and based on careful assessment that considers the clinical and ethical problems related to dehydration, the potential risks and benefits of fluid replacement and the patient's and family's wishes. Guidance is forthcoming associated with the outcomes of the current Draft Mental Capacity Bill and the Glass family case in the European Courts. There is also ongoing guidance from the General Medical Council (www.gmc-uk.org).

PROBLEMS ASSOCIATED WITH DISORDERS OF FLUID AND ELECTROLYTE BALANCE

This section outlines some areas in which patients commonly experience difficulties with fluid and electrolyte control. Nurses in many areas of practice will encounter patients whose fluid and electrolyte balance has been challenged, with potentially dire consequences, e.g. patients with burns, cardiac failure or respiratory problems. The reader is referred to the relevant chapter of this book for information on fluid and electrolyte management in these more specialised contexts.

Gastrointestinal disorders

Disorders of the GI system are very likely to lead to derangements in the normal balance of fluid and electrolytes, with subsequent problems in acid–base control (British National Formulary 2005). Fundamental problems can arise in circumstances such as the following:

- fluids are lost from the body by vomiting, diarrhoea or from a stoma
- the body is unable to absorb ingested fluids and foods
- the usual GI fluids are produced either normally or in excess but the body is unable to reabsorb them; thus the gut acts as a third space, as seen in paralytic ileus
- body fluids leak into the gut or GI fluids leak into adjacent organs or cavities (which again act as a third space) — examples include GI bleeding from oesophageal varices or GI ulcers, fistulae and peritonitis.

It is possible for several of these conditions to occur simultaneously, e.g. in a person with intestinal obstruction who is vomiting, has abdominal distension from the obstruction and may develop paralytic ileus. Two common problems of the GI tract which can be fatal if left untreated are vomiting and diarrhoea.

Vomiting

Loss of fluid through vomiting can rapidly cause dehydration and, if prolonged or severe, may lead to metabolic alkalosis and malnutrition. Following surgery to the thoracic and abdominal regions, vomiting can exacerbate the pain experience and delay healing, due to the strain imposed upon the abdominal muscles. In the case of a person's inability to protect their airway, e.g. through coma, inhalation of vomitus may lead to inhalation pneumonia and possibly death.

Vomiting causes fluid loss through the ejection of recently ingested foods and fluids, the loss of gastric or upper intestinal juices, the loss of blood from GI lesions and the prevention of oral fluid and nutritional replacement. Thus prolonged or severe vomiting requires not only the prevention and/or control of the vomiting itself, but also adequate fluid replacement.

The loss of gastric juices, which contain hydrochloric acid and potassium ions, initially leads to metabolic alkalosis due to a surplus of bicarbonate ions. In severe, prolonged vomiting without adequate nutritional replacement, the body begins to metabolise fats as an energy source, producing ketone bodies and further exacerbating the metabolic acidosis.

Thus fluid and electrolyte losses caused by vomiting may be summarised as follows:

- depletion of the ECF volume
- hypochloraemia (Cl^- loss)
- alkalosis
- hypokalaemia
- possible acidosis
- anaemia due to any blood losses.

Nursing management The actual control and the prevention of further episodes of vomiting will depend upon the cause of the vomiting and on available resources. However, whilst the patient is vomiting, some practical measures can help to alleviate some of the distress. These include providing a receptacle to vomit into, ensuring privacy if possible, and providing something to wipe away the vomit and mucus. The controlled use of breathing and swallowing techniques can sometimes enable the patient to regain control of the waves of contraction that accompany the vomiting episode.

The ability to enable a patient to adopt such techniques often rests on the nurse's interpersonal skills and confidence.

The use of touch can also help the patient to relax and thus avoid unnecessary muscular contractions which may aggravate any wound pains. In the presence of a wound, it is important for the patient or nurse to support the wound. When the immediate episode is over, a method of refreshing the mouth is essential. Judicious use of pharmacological agents, e.g. antiemetics, may prevent vomiting episodes, especially if their timing is sequenced for maximum benefit, e.g. taken before anticipated vomiting triggers. With very severe vomiting episodes there is a risk that inhalation may occur; in such cases observation of the patient's breathing pattern is essential. Indeed, occasionally gastric contents may be emitted via the nose. If a patient vomits whilst a nasogastric tube is in place, the nurse should investigate the following possibilities:

- Is the tube blocked, kinked, in the wrong place or spigoted?
- Is the tube too fine for the aspirate?
- Does the frequency of gastric aspiration need to be altered?
- Is there a deterioration in the patient's condition, e.g. haemorrhage?
- Should the tube be removed?

The best action is to leave the tube on free drainage and aspirate intermittently, unless this is contraindicated. At a suitable point, the effectiveness of the tube should be re-evaluated.

20.14 What actions could be taken when the following patients seem likely to vomit?

(a) A patient with a spinal injury.
(b) A patient with a wired jaw.

20.15 What is the significance of the information that may be obtained through observation of vomitus and the accompanying episodes of vomiting?

Diarrhoea

Worldwide, diarrhoea is a serious problem and the most important indication for fluid and electrolyte replacement. It occurs when the body is unable to reclaim/absorb the fluids in the intestinal tract and the peristaltic contractions of the gut expel the intestinal contents. Generally, intestinal fluids are isotonic with the ECF until the colon is reached, at which point the contents gradually become hypotonic due to the colon's role in water reabsorption. Severe and prolonged diarrhoea, as seen in cholera or in some forms of infant enteritis, can lead to severe electrolyte imbalance, dehydration and, ultimately, death if treatment is unsuccessful or delayed. The fluid losses may cause:

- depletion of ECF volume
- hyponatraemia
- hypokalaemia
- metabolic acidosis due to loss of bicarbonates in the digestive juices
- severe water dehydration (if the problem is located in the colon).

The causes of diarrhoea are identified and its nursing and medical management discussed in Chapter 4. Fluid and electrolyte replacement is an essential component in the management of the effects of diarrhoea, with accompanying management of the causative agent. Oral rehydration therapy is frequently employed in cases of enteritis and dehydration, providing the gut is able to absorb ingested fluids (see Box 20.13).

Box 20.13

Contents of a solution to use in oral rehydration therapy (to be reconstituted with water to make a total volume of 1 L)

Substance	WHO formulation
Sodium chloride	3.5 g
Potassium chloride	1.5 g
Sodium citrate	2.9 g
Anhydrous glucose	20.0 g

This combination gives (mmol/L):

- sodium: 90
- potassium: 20
- chloride: 80
- citrate: 10
- glucose: 111.

In UK practice, where less severe forms of dehydration are found than in developing countries, the sodium content is slightly less and the glucose higher. It is important to ensure that the water additive is safe and free from contaminants.

Adapted from British National Formulary (2005).

20.16 Why do oral preparations to rehydrate a person suffering from diarrhoea/dehydration contain salts and glucose? (See British National Formulary 2005, section 9.2.)

Special needs of the person undergoing surgery

The person undergoing surgery, whether elective or emergency, is particularly vulnerable to several disturbances of fluid and electrolyte balance. Disturbances in the composition and placement of the body fluids and electrolytes accompany many procedures and include blood loss, dehydration from preoperative fasting, bowel preparation and surgical exposure (see Ch. 26). Problems due to the underlying pathology and the patient's general health status can exacerbate the situation. Surgery/trauma causes a defensive metabolic response which conserves water and sodium and changes the plasma levels of sodium, potassium, nitrogen and albumin. The basis of the response is vasoconstriction of the renal artery, stimulation of osmoreceptors and the release of antidiuretic hormone (ADH), whilst any changes in blood pressure which affect the juxtaglomerular apparatus will stimulate the renin/aldosterone systems. This response enables conservation of plasma volume and the retention of sodium, whilst an increase in catecholamines raises the cardiac output and heart rate.

The renal response to trauma usually takes 24–72 h to recover and during this time the patient is unable to cope normally with electrolyte control and cannot produce hypotonic urine. The risks of fluid overload and water

intoxication are thus high; yet, conversely, inadequate replacement therapy may lead to dehydration and shock. Thus, in a vulnerable patient, it is important not only to measure daily fluid balance but also to keep a record of the consecutive daily balances over the first 72 h. Oedema may occur due to changes in vascular permeability, with translocation of fluids into the third space. The fundamental nursing activities of patient assessment and effective implementation of treatment regimens are often critical to the patient's recovery.

By convention, it is normally assumed that intraoperative fluid losses are replaced in theatre and that fluid balance recording commences postoperatively from a state of 'zero' balance. It is important to note the losses during surgery in order to anticipate any potential problems, which should be indicated in the theatre notes and postoperative guidelines from the anaesthetist. However, the picture is occasionally confused by poor record keeping and inadequate communication between staff in theatre and the ward. This may cause the postoperative fluid balance data to be misleading. Insensible losses may also pass unnoticed, e.g. loss from sweating, as in shock or pyrexia.

20.17 Select a person who is to undergo surgery and you can follow up postoperatively. Assess your chosen patient and identify actual and potential needs with particular reference to:

(a) comfort needs in respect of hydration and elimination
(b) potential fluid and electrolyte losses or gains
(c) other factors influencing fluid and electrolyte balance
(d) the changing needs of the patient from the preoperative assessment through surgery to the postoperative phase.

Critically evaluate the planned and implemented nursing care of your selected patient in respect of the identified problems derived from items (a)–(d).

CONCLUSION

This chapter has demonstrated the key skills required by the nurse when assisting patients with their fluid and electrolyte needs. These essential skills include:

- effective observation and assessment
- good communication
- detailed attention to the accuracy and frequency of taking measurements and recording
- proficient use of interventions
- a sound knowledge base of the patient as a unique individual coping with particular health and social problems
- ethical and professional commitment.

INTRODUCTION

Eating and drinking are integral parts of human existence. An adequate intake of nutrients and water is required to maintain physiological function, to allow for growth and maintenance of tissues, and to provide energy to meet the demands of daily living. Although a biological necessity, eating and drinking have significance beyond the merely physiological, forming an important part of social and psychological well-being. In any society, food production and preparation are central activities; the preparation and consumption of food may take up several hours a day. Meals are used as a time for people to come together, food or drink may be offered to make a guest feel welcome, and formal meals may be a feature of family, religious or national ceremonies.

The importance of the role of the nurse in ensuring nutritional needs are met is well recognised. Indeed, food and nutrition is one of the eight aspects of fundamental and essential care highlighted in *Essence of Care* (DH 2003a). The responsibilities of the nurse concerning nutritional care are extremely varied and range from preventing malnutrition to caring for the malnourished. For example, nurses may be involved in aspects of nutritional care relating to health education, particularly activities related to the rise in the incidence of obesity and type 2 diabetes mellitus. Nurses may also be involved with the care of the individual receiving enteral or parenteral nutrition. Nurses now play a more minor role in the preparation and serving of food to individuals in their care than in previous years. Changes in food delivery and serving methods have acted to reduce the nursing input required at mealtimes. In many areas there is a necessary delegation of responsibility concerning mealtime care to qualified health care assistants or unqualified staff. However, it must be remembered it is the qualified nurse who is responsible for ensuring food is provided, as appropriate, to the patient in their care; 'Nurses have a clear responsibility for ensuring that the nutritional needs of patients are met' (United Kingdom Central Council for Nursing, Midwifery and Health Visiting 1997).

21.1 One of the factors considered to be an *Essence of Care* (DH 2003a) is Food and Nutrition. Access the document outlining the Essence of Care Programme on the website of the Clinical Governance Support Team of the NHS Modernisation Agency (www.cgsupport.nhs.uk/Programmes/Essence_of_Care_Programme/default.asp).

Consider the 10 factors identified under Food and Nutrition. To what extent are the benchmarks being achieved in your current practice area?

This chapter will consider the principles of nutritional science, public health nutrition and the nutritional care of individuals by nurses.

PRINCIPLES OF NUTRITIONAL SCIENCE

To maintain health, an adequate supply of nutrients is required. The foods that make up the diet can vary considerably but the basic nutritive constituents of the diet fall into two main groups: macronutrients and micronutrients. The macronutrients are carbohydrate, protein and fat and the micronutrients are vitamins and minerals. Alcohol, usually in the form of ethanol, may also be considered a form of macronutrient in that it does provide the body with energy. Water is an essential component of the diet but is not usually classed as a nutrient. Water intake is discussed in Chapter 20. Some compounds present in the diet, such as food colourings and preservatives, are also important components of food.

Nutrients have a complex role in physiological function and most nutrients are involved in several processes. Nutrients are required to form the structural components of the body; for example, protein is the major constituent of muscles. Nutrients are also important in metabolic pathways and enzyme systems that enable the body to function appropriately. They can either form a part of the pathway or assist in the enzymatic reactions in that pathway (a co-factor). For example, vitamin C is required in the pathway that forms collagen; inadequate intake of vitamin C will result in collagen not forming properly.

Nutrients also provide energy for metabolism. Metabolic demand for energy comes from three essential physiological tasks: transport, turnover and work:

- Transport of nutrients and electrolytes across cell membranes can be an active process, which requires energy.
- Turnover of substrates includes activities such as converting amino acids into body protein and fatty acids into triglycerides, and vice versa.
- Mechanical work, such as maintaining cardiac output or respiration.

Metabolic demand needs to be met by an effective supply of nutrients. These come primarily from two sources: the food we eat and the breakdown of tissues in the body. There is a dynamic process between food eaten, body tissues and metabolism. Carbohydrate and fat are the body's predominant energy sources but protein may be used if these are not readily available. If the supply of nutrients from food intake is inadequate, body tissues such as adipose or muscle will be used to supply the energy needed for metabolic demand. Whilst only the macronutrients and not the micronutrients can act as sources of energy, both can form the structural components of the body and participate in metabolic pathways and enzymatic processes. Non-nutrients, such as non-starch polysaccharides, may be important for physiological function, and others such as caffeine may fulfil other lifestyle functions. Alcohol is energy rich and has a complex role in many societies but taken in excess can be damaging to health. The macro- and micronutrients are described briefly below although their digestion and metabolism are not considered.

For a more comprehensive description, refer to a physiology or nutrition textbook such as Garrow et al (2000) or Barasi (2003).

Macronutrients

Carbohydrate

Carbohydrates are classified into three major groups according to the number of 'saccharides' that make up their structure: monosaccharides, oligosaccharides, which include disaccharides, and polysaccharides.

- The monosaccharides — also known as simple sugars — include glucose and fructose. The body absorbs carbohydrate across the intestine wall in the form of monosaccharides.
- Disaccharides include sucrose (table sugar), lactose (milk sugar) and maltose.
- The polysaccharides — also known as complex carbohydrates — include starch and non-starch polysaccharides ('fibre').

Carbohydrate is the main energy source for the body and, as glucose, it is the preferred fuel for the brain. Each gram of carbohydrate yields about 17 kJ/g (4 kcal/g) (see Box 21.1). Carbohydrate is stored in the body in the form of glycogen in the liver and muscles.

Foods which are rich in complex carbohydrates, such as bread, cereal, rice and pasta, are recommended as the main energy source of a healthy diet. Generally speaking, the more refined the food the less non-starch polysaccharide ('fibre') it contains; for example white rice contains less 'fibre' than brown rice and white bread less than brown bread. Vegetables such as potatoes, peas and corn are also rich sources of polysaccharides. Fruit contains carbohydrates in the form of monosaccharides and disaccharides as well as polysaccharides. Foods such as cakes, biscuits and chocolates contain high levels of carbohydrate, particularly in the form of monosaccharides and disaccharides.

Non-starch polysaccharides ('fibre')

Non-starch polysaccharides are a very important component of the diet. They give bulk to food passing through the gastrointestinal (GI) tract, thus reducing the amount of time it takes for food to pass through the gut (bowel transit time) and increasing feelings of satiety. Non-starch polysaccharides may be classed as soluble or insoluble fibre. Soluble fibre forms a gel when mixed with water and is

Box 21.1

Energy value of macronutrients

Carbohydrate	17 kJ/g (4 kcal/g)
Protein	17 kJ/g (4 kcal/g)
Fat	38 kJ/g (9 kcal/g)
Alcohol	29 kJ/g (7 kcal/g)

found in oats, fruit and vegetables. Insoluble fibre does not mix well with water and is found in the bran layers of cereal grains and some vegetables. Soluble fibre can slow the absorption of monosaccharides into the bloodstream, enabling a slower and more sustained rise in blood glucose levels. It may also lower blood cholesterol levels by reducing absorption of dietary cholesterol and bile acids in the large intestine (Webb 2002). Some types of non-starch polysaccharide, in particular unprocessed bran, may reduce the absorption of some micronutrients, such as calcium, in the intestine (Sullivan 2000).

Protein

The smallest component of protein is an amino acid; amino acids bond together to form a protein. Some amino acids are synthesised by the body; others, the essential amino acids, cannot be synthesised by the body and must be obtained from food. There are approximately 20 different types of amino acid, of which about eight are considered to be essential. Protein is required to build new tissue as a result of growth, to replace tissue lost through injury or as a result of normal body function. Nearly all cells need to be replaced on a regular basis and, in addition, cell proteins are regularly replaced and renewed. Many enzymes and hormones are proteins. If there is no other nutrient available, the body will use protein as an energy supply. Each gram of protein yields about 17 kJ/g (4 kcal/g) (see Box 21.1). Proteins are present in most foods, including meat, fish, cereals, legumes and vegetables, but the amount and quality varies. Foods that contain all the essential amino acids required by the body are often termed 'high-quality protein foods'. Meat, milk, cheese, egg and soy are usually considered to be high-quality protein foods. If plant foods are to provide the major source of protein, a wider mix of food types is required to ensure all the essential amino acids are consumed. Foods that are traditionally eaten together often contain most if not all of the essential amino acids when combined, e.g. rice and beans. Vegetarians and vegans need to plan their dietary intake to ensure the foods they eat complement each other in that the essential amino acids absent in one food are present in another, e.g. baked beans on toast.

Fat

There are three main types of fat: triglycerides, phospholipids and sterols. Most of the fat in foods is in the form of triglycerides. Triglycerides are made up of fatty acids and glycerol. Fatty acids are classified according to their chemical structure, more specifically the number of hydrogen atoms bonded to carbon atoms in the fatty acid. Fatty acids can therefore be saturated, i.e. all the carbon atoms are fully saturated with hydrogen atoms, or unsaturated, i.e. some of the hydrogen atoms are absent and the usual single bond between carbon atoms has been replaced by a double bond. Unsaturated fatty acids may be monounsaturated, i.e. one double bond between carbon atoms, or polyunsaturated, i.e. more than one double bond between carbon atoms. Polyunsaturated fatty acids are often termed 'essential fatty acids' as the body is unable to make this type of fatty acid. These include alpha-linolenic and linoleic fatty acids, often called omega 3 and omega 6 fatty acids. *Trans* fatty acids are a type of polyunsaturated fatty acid which may occur naturally, but most that we consume are produced as a result of food processing. A high intake of saturated and *trans* fatty acids is associated with the development of some diseases, particularly cardiovascular disease.

Fat is a good energy source as it is easily stored by the body and provides a large energy store. Each gram of fat yields approximately 38 kJ/g (9 kcal/g) (see Box 21.1). Fat also provides an important insulating layer beneath the skin and surrounds some body organs, giving support and cushioning the organs from mechanical trauma. In addition, fat is a structural element forming the major component of the cell membrane. Fat is used in the formation of substances such as lipoproteins, cholesterol and phospholipids and the steroid hormones. Adequate dietary fat is important, as the essential fatty acids (polyunsaturated fats) and fat-soluble vitamins are found mainly in high fat foods. Fat also enhances the palatability of food.

Most foods contain a proportion of each of these basic types of fatty acid but are usually described according to which type predominates. It is generally quite easy to identify a saturated fat because it is usually solid at room temperature. Saturated fats originate from animals with the exception of fish and shellfish. Unsaturated fats derive from plant and seafood oils. *Trans* fats are contained in significant amounts in commercially prepared foods such as biscuits and hard margarine.

Micronutrients

Vitamins

Apart from vitamin D, which can be synthesised through the action of sunlight on the skin, and vitamin K, which can be synthesised by intestinal bacteria, all the vitamins must be obtained from the diet. Only small amounts are needed and a varied diet will normally supply all the vitamins required. Vitamins are important in many metabolic pathways in the body and also act as antioxidants. The two main groupings are the fat-soluble and the water-soluble vitamins.

- The fat-soluble vitamins (A, D, E and K) are absorbed from the small intestine along with dietary fat. They are found in foods such as fish, meat, butter, milk and plant oils. Fat-soluble vitamins can be stored in the body and excessive intake may lead to toxic levels.
- The water-soluble vitamins include B_2 (thiamine), B_1 (niacin), B_3 (riboflavin), B_6 (pyridoxine), B_{12} (cobalamin), C (ascorbic acid), folic acid, pantothenic acid and biotin. Water-soluble vitamins are easily lost from foods and from the body and little storage occurs within the body.

Vitamin deficiency is a common feature in some countries but is generally rare in the UK unless it is associated with protein-energy malnutrition. Table 21.1 outlines the vitamins required by the body, and gives details of rich food sources, at-risk groups and symptoms of deficiency.

Minerals

Some minerals play an essential role in human nutrition. Minerals are important in metabolic pathways and also form structural components of the body. A balanced diet

Table 21.1 Vitamins: rich food sources, at risk groups and symptoms of deficiency*

Nutrient	Rich food sources	Groups at risk of deficiency or excessive intake affecting health	Symptoms of deficiency
Vitamin A (retinol)	Liver, fish oils, dairy products, fortified margarine, some green, yellow and orange fruits and vegetables	*Deficiency associated with*: fat malabsorption *Excessive intake affecting health*: pregnant women should avoid supplements containing vitamin A (unless advised otherwise at antenatal clinic) and liver and liver products	Dryness of the conjunctiva and cornea, impaired adaptation to dim light (night blindness), skin changes, impaired immune function, growth retardation
Vitamin B_1 (thiamine)	Found in most foods, particularly unrefined cereal grains, fortified flour, some breakfast cereals, meat, dairy products and legumes	*Deficiency associated with*: alcoholism	Headaches, tiredness, anorexia, muscle wasting. Deficiency disease (beriberi) affects the cardiovascular and nervous systems. Wernicke–Korsakoff syndrome can develop in alcoholism
Vitamin B_2 (riboflavin)	Found in many foods, particularly dairy products, eggs, fortified cereals, ice cream, liver	*Deficiency associated with*: intestinal malabsorption, biliary atresia, older people with poor dietary intake, regular use of fibre-based laxatives, women who exercise excessively, alcoholism	Lesions of the mucocutaneous surfaces of the mouth, seborrhoeic skin lesions, vascularisation of the cornea, anaemia, retarded growth in childhood
Vitamin B_3 Niacin (nicotinic acid and nicotinamide)	Red meat, wheat flour, maize, eggs, milk	*Deficiency associated with*: alcoholism, long-term use of isoniazid medication	Changes in skin, mucosa of the mouth, GI tract and nervous system Deficiency disease (pellagra) is characterized by skin lesions in areas exposed to sun and pressure, and by diarrhoea and dementia
Vitamin B_6 (pyridoxine)	Meat, fish, eggs, milk, wheatgerm, brewers' yeast, brown rice, soybeans, unrefined wheat grains, some nuts	*Deficiency associated with*: use of drugs which cause depletion (e.g. isoniazid), intestinal malabsorption, renal dialysis, alcoholism *Excessive intake affecting health*: women may take large amounts (without medical advice) to relieve premenstrual syndrome symptoms. The Food Standards Agency (2003) advises against taking more than 10 mg/day to avoid the development of neuropathy. Supplements may reduce therapeutic effects of levodopa. Pyridoxine interacts with some drugs, e.g. phenytoin, theophylline and phenobarbital	Severe deficiency rare Inflammation and skin changes around the mouth, weakness, irritability
Vitamin B_{12} (cobalamin)	Made by microorganisms and incorporated into the food chain by animals Appears in meats or foods of animal origin	*Deficiency associated with*: lack of intrinsic factor, strict vegetarians and vegans, malabsoprtion syndrome, older people in institutional environments	Neuropathy (subacute combined degeneration), megaloblastic anaemia
Folate (folic acid)	Widely distributed in foods, particularly liver, yeast extract, leafy green vegetables, fortified grains and breakfast cereals	*Deficiency associated with*: malabsorption, alcoholism, some anticonvulsant drugs, older people on restricted diets Women in the first trimester of pregnancy or those thinking of becoming pregnant should take a daily supplement of 400 mcg (Food Standards Agency 2003). A higher dose may be recommended by the doctor or midwife if there is a history of neural tube defect	Effect on cell division leading to megaloblastic and macrocytic anaemia, elevation of plasma homocysteine, association with neural tube defect in pregnancy
Pantothenic acid	Widely distributed in foods, particularly animal products, whole grains, potatoes and tomato products	—	Rare and only demonstrated in those eating a very restricted diet

Table 21.1 Vitamins: rich food sources, at risk groups and symptoms of deficiency* *(Continued)*

Nutrient	Rich food sources	Groups at risk of deficiency or excessive intake affecting health	Symptoms of deficiency
Biotin	Widely distributed in foods, particularly liver, egg yolk, soy flour, cereals and yeast	—	Rare and only demonstrated in those receiving parenteral nutrition or eating a very restricted diet
Vitamin C	Fresh vegetables and fruit, particularly spinach, tomatoes, broccoli, strawberries and citrus fruits	*Deficiency associated with*: smokers, an absence of fruit and vegetables in the diet	Hair follicle eruption, petechial haemorrhage on limbs, bleeding gums, impairment of connective tissue formation in wound repair, joint pains, fatigue Symptoms of deficiency disease (scurvy) result from the failure of the body to synthesise collagen
Vitamin D (calciferols)	Major source is exposure to sunlight Found in fatty fish, liver, milk, eggs, fortified food such as margarine, breakfast cereals	*Deficiency associated with*: inadequate exposure to sunlight (e.g. nursing home residents, dark skinned people who habitually cover their skin), malabsorption *Excessive intake affecting health*: people with sarcoidosis should not take vitamin D supplements	Rickets in children, osteomalacia, muscle weakness, bone tenderness
Vitamin E (tocopherols)	Synthesised by plants Plant oils, nuts and seeds are a rich source	—	Deficiency only demonstrated in premature infants and those unable to absorb or utilise vitamin E Deficiency results in cell membrane dysfunction
Vitamin K (phylloquinone and menaquinones)	Green leafy vegetables and vegetable oils Also produced by bacteria in intestine	*Deficiency associated with*: malabsorption or impaired gut synthesis Vitamin K supplement given prophylactically to prevent haemorrhagic disease of the newborn in many countries due to vitamin K deficiency in the newborn	Deficiency very rare in adults and results in bleeding disorder

*For further details, see Garrow et al (2000) and Food Standards Agency (2003).

featuring a range of different foods is likely to meet daily requirements but deficiency of some minerals is very common, e.g. iron and iodine. Iron deficiency affects many people in the developed as well as the developing world. One of the major functions of iron in the body is as a component of haemoglobin. It is also important in some metabolic pathways and in the immune response. Women are particularly at risk of iron-deficiency anaemia due to loss from menstruation.

Iron is found in the haem form in meats, and in the non-haem form in plants (see Ch. 11). Non-haem iron is not absorbed by the body as well as haem iron. Other factors may also affect the absorption of iron in the digestive system, e.g. the presence of vitamin C.

Iodine deficiency is a devastating problem in some regions of the world. People living in areas where the soil, and consequently food grown in the soil, is deficient in iodine can develop signs and symptoms of iodine deficiency. These include an enlarged thyroid gland (goitre), lethargy, mental impairment and congenital abnormalities. Programmes which provide iodine supplementation by iodising salt have proved very successful in reducing the incidence of iodine deficiency (WHO 2003a). Table 21.2 shows some of the minerals required by the body, and gives details of rich food sources, at-risk groups and symptoms of deficiency.

Some nutrients are termed essential nutrients because they cannot be made by the human body and have to be obtained from the diet. If an essential nutrient, or enough of a non-essential nutrient, is unavailable to the body, then the body will be unable to function as it should. The physiological processes in which the nutrient takes part will be affected. For example, growth will be stunted if protein intake is below that which is required for the normal growth of body tissues, and if iron intake is less than required, the formation of haemoglobin will be reduced.

If intake of a particular nutrient or range of nutrients affects physiological function adversely, then the person can be said to be malnourished. Malnutrition can refer to both overnutrition, i.e. intake of energy and nutrients in excess of requirements, and undernutrition, i.e. intake of insufficient energy and nutrients to meet requirements. Malnutrition may jeopardise health status in general and can affect morbidity and mortality. The body can adapt to a low intake of some nutrients but this will affect body composition and function (see p. 800).

The amount of nutrient a person requires is influenced by their basal metabolic rate (BMR), activity level and

Table 21.2 Minerals: rich food sources, at risk groups and symptoms of deficiency*

Nutrient	Rich food sources	Groups at risk of deficiency or excessive intake affecting health	Symptoms of deficiency
Calcium	Milk, cheese, small fish, e.g. sardines, some green leafy vegetables, soybean products, fortified wheat flour and breakfast cereals, some nuts	*Deficiency associated with*: fat malabsorption, consumption of large amounts of phytates *Excessive intake affecting health*: excessive intake of calcium (e.g. antacids) and those with renal failure may be susceptible	Widespread effects of deficiency. Stunted growth and bone malformation in children, skeletal and tooth changes in adults
Magnesium	Found widely in foods, particularly green leafy vegetables, grains, nuts	*Deficiency associated with*: malabsorption, excessive renal loss (e.g. diuretic use) *Excessive intake affecting health*: those with renal glomerular failure susceptible	Widespread effects including cardiovascular and skeletal system disorders, hypocalcaemia
Phosphorous	Found widely in foods, particularly fish, poultry, red meat, dairy products, cereal grains	*Deficiency associated with*: some forms of rickets, excessive intakes of aluminium-containing antacids, vitamin D deficiency, alcoholism, diabetic ketoacidosis *Excessive intake affecting health*: those with renal glomerular failure susceptible	Widespread effects including osteomalacia, myopathy, growth failure
Sodium chloride	Salt and salty foods	*Excessive intake affecting health*: young infants should not have salt added to food as renal excretion is limited. In adults intake of no more than 6 g/day recommended to promote health	Rare except following excessive loss of body fluids, e.g. sweating Low blood pressure, dehydration and muscle cramps
Potassium	Milk, fruit, e.g. bananas, and vegetables, shellfish, red meat, white meat, liver	*Deficiency associated with*: use of some diuretics, very low energy diets *Excessive intake affecting health*: those taking potassium-sparing diuretics and some other types of drug Those with renal disease, adrenal insufficiency and insulin deficiency susceptible	Rare except following excessive loss of body fluids, e.g. diarrhoea Muscle weakness, arrhythmias, irritability, cardiac arrest
Iron (haem and non-haem form)	Liver, meat, beans, nuts, dried fruit, fish, enriched cereals, soybean flour, dark leafy green vegetables Dietary factors influencing uptake include: form of iron ingested; presence of vitamin C, phytates, calcium, soy protein	*Deficiency associated with*: infants over 6 months, toddlers, adolescents, pregnant women, menstruating women, older people, people with parasitic infestations, high intake of inhibitors of absorption, e.g. tea *Excessive intake affecting health*: frequent blood transfusion recipients susceptible	Normocytic anaemia, microcytic anaemia, reduced work capacity, reduced intellectual performance, impaired resistance to infection, impaired thermoregulation
Zinc	Meat, unrefined cereals, fortified cereal products	—	Growth retardation, defects of rapidly dividing tissues, e.g. skin, intestinal mucosa, immune system
Selenium	Fish, offal, brazil nuts, cereals	Dietary deficiency endemic in some areas of the world, e.g. China	Deficiency associated with Keshan disease, a form of cardiomyopathy; inflammatory joint disease
Iodine	Marine fish, shellfish, sea salt, supplemented salt	Dietary deficiency endemic in some areas of the world	Goitre, hypothyroidism, cretinism if fetal growth affected
Fluoride	Generally obtained from drinking water and dental products Rich food sources include tea and fish	—	Fluoride is implicated in the development of tooth health

Molybdenum, manganese, copper, chromium also required but these are widespread in foods and deficiency is only demonstrated in very restricted diets or certain medical conditions.

*For further details, see Garrow et al (2000) and Food Standards Agency (2003).

response to certain factors such as cold exposure and ingestion of food. BMR is the metabolic rate at rest and is influenced by several factors, including genetic makeup and body mass. The amount of energy required by a person can be worked out using an equation which considers BMR and activity level (DH 1991). Illness can increase BMR, but the consequent rise in energy required by the body may be counteracted by a reduction in physical activity level. If an individual has an inadequate intake of energy for a period of time, the body can adapt by reducing BMR.

Although foods containing all known nutrients can be formulated, no single naturally occurring food can meet all the daily nutritional demands. Different types of food contain different proportions of macro- and micronutrients and therefore a range of foods is necessary to provide the daily requirement of individual nutrients. In general, plant products are richer in carbohydrate but lower in protein and fats than animal products. Plants are the major source of fibre. Some foods are particularly rich in a single nutrient, although they may contain other nutrients; thus, meat should be classed as protein-rich rather than as a protein, as it also contains fat and other nutrients. Cereals are rich in carbohydrate; for example, of 100 g of wheat flour, over 70% is carbohydrate, but approximately 10% is protein and 1% is fat. Very few foods, such as sugar, almost pure carbohydrate, or cooking oils, almost pure fat, fall predominantly into one macronutrient group. Some nutrients are better absorbed by the body, i.e. they are more 'bioavailable', in certain forms and under certain conditions, e.g. iron (see above). The bioavailability of some medications can also be changed by particular foods (see p. 795).

PUBLIC HEALTH NUTRITION

The diet consists of the foods we eat from day to day. The diet we eat must supply the essential nutrients, i.e. those which are necessary for survival but cannot be synthesised by the body from other sources. It should supply all the necessary components in the correct quantities and proportions, whilst avoiding excessive intake. For optimal health, nutrient intake must balance nutrient usage; an excess intake may be damaging. There is considerable debate about the safety of some vitamin and mineral supplements that are not medically prescribed, as a result of which the UK Food Standards Agency has published a comprehensive review of the safety of vitamin and mineral supplements (Food Standards Agency 2003).

Nutritional requirements will vary depending on a person's size, gender, activity level and state of health. Nutritional requirements also vary across the life span. Infants and children require sufficient nutrients to grow and develop. Requirements for some nutrients are increased pre-conception, during pregnancy and whilst breast feeding, and also change with ageing (Barasi 2003). In the UK, estimated nutritional requirements for different groups of people within the population have been established and are published by the Department of Health (1991). These are termed dietary reference values. It is important to recognise that these are not recommendations for intake by individuals but are estimates for healthy populations only; within a clinical setting the advice of a dietitian must be sought.

21.2 Apart from pregnancy and lactation, when else during their life span may a person have sudden changes in their nutrient demand?

The diet in the UK has changed quite drastically in the last 50 years. Access to an extensive range of foods has never been greater. Nutrient intake has changed as a result of the changes in the type and amount of food eaten and few people now suffer from undernutrition. Current government guidelines on dietary intake recommend an intake thought to promote maximum health for the population. These recommendations include a fat intake of less than 35% of dietary energy intake, of which no more than one-third should be in the form of saturated fats, and a carbohydrate intake of approximately 50% of dietary energy intake (DH 1994). A salt intake of less than 6 g/day is also recommended (Scientific Advisory Committee on Nutrition 2003). How this relates to food is discussed below. The amount of fat consumed in the UK is less than in recent years but saturated fat intake is still higher than recommended (Henderson et al 2003).

The type of diet an individual eats is determined by many factors. At a global level, government policies influence food supply and legislation. Fortification of foods or water with particular nutrients is a feature in many countries and is usually managed at a central government level, e.g. the fluoridation of water supplies. The policy for food labelling is also determined centrally.

Within a country, there are regional and socioeconomic differences in dietary intake; for example, intake of fruit and vegetables in Scotland is lower than in the rest of UK and lower income households tend to eat less fresh fruit and vegetables but more canned and frozen vegetables (Buttriss 2002).

At an individual level, a person chooses to eat a particular type of diet for a variety of reasons which include sociological, psychological, economic and behavioural issues. Some of these factors are shown in Figure 21.1.

- Sociological issues include age, culture, religion, income, food availability and cooking facilities.
- Psychological issues encompass a variety of factors ranging from aversions to particular foods, to a fear of food in general.
- Economic factors are important and influence both the quality and quantity of dietary intake. If a type of food, such as fruit, is not available to buy or if there is insufficient money to buy a range of foods in appropriate amounts, dietary intake will be reduced in quality and quantity.
- Behavioural elements of food choice can also influence dietary intake. For example, toddlers can be very particular about the type of food that they will eat.

When food is available, the amount eaten is determined by appetite. Appetite is controlled by many factors, including the presence of nutrients in the GI tract, levels of GI hormones, levels of nutrients in the blood and the response of the central nervous system to hunger signals from the rest of the body. Emotional factors may also influence what is eaten; for example, some people eat particular foods to 'cheer themselves up' or a celebratory meal may be eaten. The environment to which we are exposed also affects

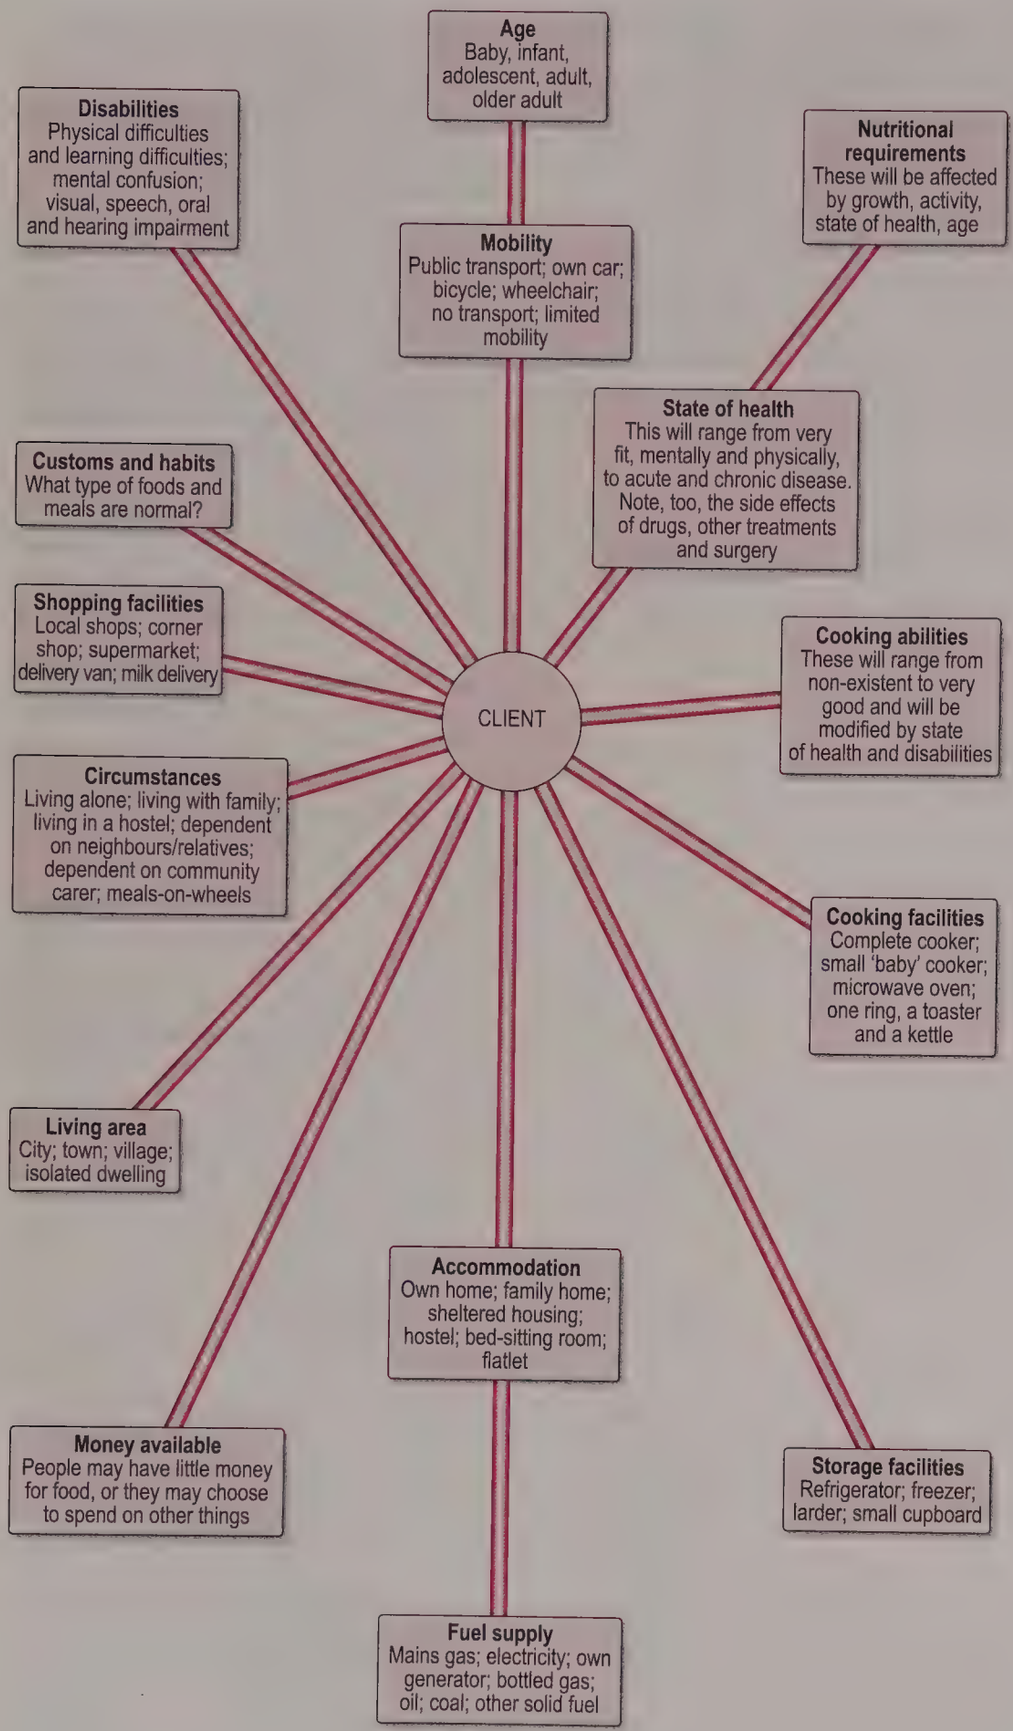

Fig. 21.1 Factors to consider when screening, assessing and planning nutritional needs. (Reproduced with permission from Sandy 1997.)

appetite; for example, the smell of freshly baked bread when passing a bakery may instigate feelings of hunger. Conversely, smelling a very unpleasant odour when eating tends to diminish appetite. People tend to eat more when eating with other people in a social setting, although this is not always the case (see p. 802).

Nurses should ascertain the dietary intake of individuals on admission to care and it is important not only to think of dietary intake in terms of nutritional content but also to consider the reasons why a particular type of diet is consumed. It is the role of the nurse to ensure that patients are provided with a diet that is acceptable to them, unless

Table 21.3 Common food-borne infections

Microorganism	Common source	Symptoms
Bacillus spp.	Cereals, dried foods, dairy products	Vomiting, 1–5 h after ingestion; diarrhoea few hours after ingestion
Campylobacter spp.	Raw or undercooked meat, poultry, untreated water, unpasteurised milk	Profuse diarrhoea, severe abdominal pain; incubation 2–5 days; prodromal phase of headache and photophobia
Clostridium perfringens	Cooked meats, gravy, fish, dried foods, vegetables	Diarrhoea, abdominal pain 8–12 h after ingestion
Escherichia coli (toxogenic strains)	Raw or undercooked beef, milk, vegetables, infected animals	Diarrhoea (can progress to haemolytic uraemic syndrome). Incubation period 1–6 days
Salmonella typhi/paratyphi Other salmonellas	Food in contact with an infected human carrier or contaminated by sewage Meat, especially poultry, eggs, milk, dairy products	Fever, malaise, constipation followed by diarrhoea. Incubation 1–3 weeks Diarrhoea, vomiting, fever, 12–72 h after ingestion
Shigella spp.	Faecally contaminated water and food, e.g. salads	Diarrhoea, fever, abdominal pain, 1–7 days after ingestion
Staphylococcus aureus	Cold food handled during preparation, dairy products	Vomiting, abdominal pain 1–7 h after ingestion
Gastrointestinal viruses, e.g. SRSV, Norwalk agent, rotavirus	Contaminated water, shellfish, cold foods handled during preparation	Vomiting, diarrhoea, fever, abdominal pain 24–48 h after ingestion

Source: PHLS Salmonella Committee (1995).

contraindicated by their medical condition. The quality of foods consumed in the diet is also an important factor and issues of food safety need to be considered.

Food safety

Food safety is a topic encompassing a wide range of factors which influence the quality of the foods that we eat. These include the use of aluminium foil and plastic to wrap food, pesticide residues in foods, natural toxins in foods and food-borne illness. Food-borne illnesses are a particular topic of nursing concern due to their impact on the health of individuals. Food-borne illnesses can be caused by improperly prepared or stored food. Older people and children are particularly susceptible as they are less able to withstand the consequences of food-borne illness, such as prolonged nausea and vomiting. Table 21.3 lists some common food-borne infections. Nurses must ensure that Food Safety Regulations are adhered to in clinical practice areas (see Ch. 16).

21.3 What regulations are in place to help to prevent food poisoning in the hospital environment?

Functional foods

In recent years the concept of consuming a food with the aim of promoting health has developed. Foods which promote health can be termed functional foods. A functional food is defined as one which has health-promoting benefits and/or disease-preventing properties, in addition to the usual nutritional value (Barasi 2003). Included in this category are fortified foods, foods containing components that do not occur generally in the normal diet and foods containing bacteria thought to promote GI function, e.g. omega-enriched eggs and probiotic-enriched yoghurts. This is a rapidly expanding area of nutrition and one about which nurses need to be informed, as patients may seek advice on the use of functional foods.

Drug–nutrient interactions

Some medications may influence food intake, absorption and metabolism. In addition, some nutrients may influence medication absorption and metabolism. The interaction may potentiate or inhibit the activity of the medication or result in side-effects. The type of interaction will vary depending on the medication and the nutrient. This is an important issue in the administration of medications and the nurse should be aware of the potential of commonly prescribed medications to interact with food. The hospital or community pharmacist can provide advice on this issue in a clinical setting.

For further reading on this topic, see Barasi (2003) and Jordan et al (2003).

NUTRITIONAL CARE

Nutritional care by nurses involves screening, assessment, planning, intervention and evaluation. This process is illustrated in Figure 21.2 (McLaren & Green 1998).

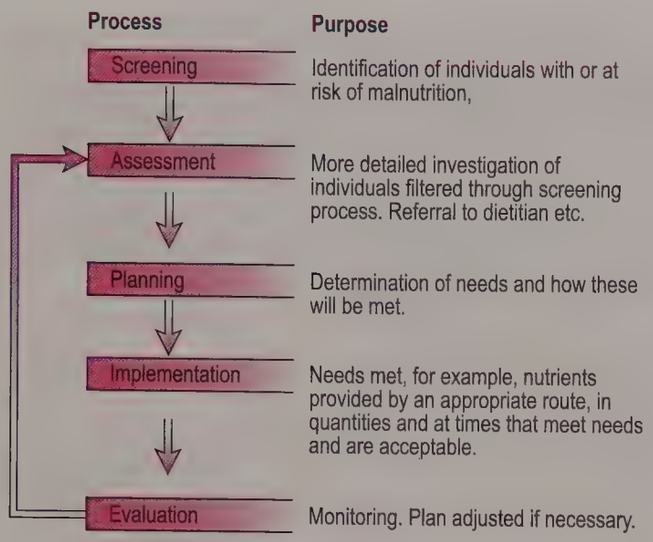

Fig. 21.2 Process of nutritional care of individuals by nurses. (Adapted from McLaren & Green 1998, with permission.)

NUTRITIONAL SCREENING AND ASSESSMENT

Nutritional screening aims to identify those with, or at risk of, malnutrition and can highlight potential causes. If an individual is considered to be at risk of or to have malnutrition, then a more detailed assessment must be undertaken. A variety of health care professionals may undertake this assessment depending on the type of problem identified at screening. The majority of patients will be referred to the dietitian if malnutrition is suspected. However, referral to another health care professional may also be appropriate; for example, referral to the speech and language therapist (SALT) if a swallowing deficit is identified, or to the occupational therapist if difficulty with manipulation of cutlery is an issue. Screening and assessment will allow identification of needs, planning of interventions and setting of goals (McLaren & Green 1998). Following this, interventions can be implemented. As always, interventions should be recorded and regularly evaluated and modified by assessment. Screening and assessment can also establish a baseline from which to monitor changes in status.

There are five principal methods of screening or assessing for nutritional status:

- Dietary history and intake
- Clinical examination
- Functional tests
- Anthropometric measures
- Biochemical tests.

Dietary history and intake

Elementary assessment by nurses of dietary history and intake is essential to determine the risk of malnutrition as well as to examine other factors, such as dietary habits, food preferences and economic factors affecting food intake. Changes in appetite, reduced food intake and absorption, the use of supplements and other issues, e.g. dietary adherence, can also be considered. The type of diet a person consumes is influenced by many factors, particularly in a home environment (see Fig. 21.1). In care environments, food charts can be used to record food intake over a period of time to assess whether dietary needs are being met. Asking a person to recall what they have eaten over the previous day, or to describe what they generally eat, are also useful ways of assessing dietary intake. These methods can also be used to identify food that may have caused a reaction. Assessment of food intake over a longer period of time, e.g. 7 days, by the use of a food diary can be useful in some circumstances, for example when working to promote dietary change in a person with obesity. Assessment of habitual intake will increase a person's awareness of their dietary intake and can highlight aspects that can be modified to help achieve an intake that follows the 'healthy eating guidelines'. The nurse is able to carry out an elementary assessment of food intake but more comprehensive dietary analyses should be undertaken by a dietitian; assessment of any individual's specific intake is a complex process.

21.4 What provision is there in your current clinical practice to meet the nutritional needs of people who eat the following:

(a) Halal food
(b) A vegan diet
(c) A gluten free diet?

Clinical examination

A clinical examination can identify medical conditions and treatment that may influence intake, digestion and absorption of nutrients. Drug and alcohol use can adversely affect nutritional status and should be considered in assessment. Changes in appetite, taste or smell, dental problems or ill-fitting dentures should be investigated. The person's usual activity level should also be considered, as well as general appearance and fit of clothes, condition of the hair, skin, eyes and mouth, and neurological and musculoskeletal systems. It is also important to assess a person's functional ability to eat; for example, are there physical or mental factors that might impair the process of eating? In addition, assessment of whether a person is able to read the language in which any dietary advice is written is essential. Issues such as literacy and visual impairment need to be considered if written dietary advice is to be given.

Functional tests

Functional tests of nutritional status are usually performed by the doctor or dietitian and include tests such as handgrip strength, using a dynamometer, and respiratory muscle strength.

Anthropometric measures

Simple anthropometric measures can be used by nurses to screen and assess nutritional status. Anthropometry refers to the measurement of the human body. It is important to weigh individuals on admission to care and periodically thereafter to identify any subsequent losses or gains. To ensure accuracy, the person should, if possible, be weighed on the same scales at the same time each day, preferably in the same clothes, and after emptying their bladder and bowel. Single measurements of weight are of limited value, but serial measurements permit trends in weight loss or gain to be identified.

Percentage weight change can be calculated using the equation:

$$\%\ \text{weight loss/gain} = \frac{\text{usual weight} - \text{current weight (kg)} \times 100}{\text{usual weight (kg)}}$$

A loss of 10% in the previous 3 months is suggestive of malnutrition. However, caution is required when interpreting weight changes as factors such as dehydration, oedema or tumour growth can complicate the picture.

Weight considered in relation to height gives a more accurate assessment of the degree to which a person is under- or overweight. Body mass index (BMI) is commonly used to assess weight in relation to height. This is simply the body weight in kilograms (kg) divided by the height in metres squared (m^2). For example, someone with a body weight of 57 kg and a height of 1.62 m has a BMI of $57/1.62^2 = 21.7\ kg/m^2$. Height can be difficult to determine, due to factors such as spine curvature and inability to stand. An estimation of height can be made using demi-span, i.e. distance from web between middle and ring finger along outstretched arm to sternal notch (Webb & Copeman 1996) or ulna length (Elia 2003). In the clinical setting, further information on these measures can be obtained from the dietitian.

The International Obesity Task Force (2000) has outlined the following categories associated with BMI: <18.5 as underweight, 18.5–24.9 as normal range, 25.0–29.9 as overweight, 30.0–34.9 obese (class 1), 35.0–39.9 obese (class 2) and >40.0 obese (class 3). When using BMI with older people the resulting plan and intervention need to be carefully considered as the usefulness of BMI as a predictor of risk of morbidity and mortality in the very old has been questioned (British Dietetic Association 2003).

Waist circumference can be used to assess the amount of fat carried in the abdominal region. This measure is increasingly being used to screen for cardiovascular risk in primary care. Men with a waist circumference >102 cm and women with a waist circumference >88 cm should be advised that weight reduction would be beneficial (Lean 2000).

Anthropometric measures that assess fat levels or muscle mass of the body can be used by dietitians or doctors in clinical environments. Nurses may use these measures in specialist units following education in their use. These measures include skinfold measures to estimate body fat, and mid-arm muscle circumference to estimate skeletal muscle mass. Electrical bioimpedance is a method of assessing the fat mass of the body, which is being used increasingly in some environments such as health clubs.

Regular checks of accuracy and, if necessary, recalibration are essential for all equipment used to measure individuals, including weighing scales.

Biochemical tests

Biochemical measures to assess nutritional status include a number of parameters, obtained from investigation of plasma, urine and tissues.

Measurement of proteins present in the blood, such as albumin and retinol-binding protein, can be useful in some clinical situations but the interpretation of what the level means needs to be considered carefully. Serum protein levels are usually more an indicator of clinical state than nutritional status in the acutely ill, as protein levels in the blood change in response to the trauma the body is experiencing. In addition, treatments such as administration of blood products will change serum protein levels. The clinical biochemist, doctor and dietitian are key members of the multidisciplinary team when considering the relationship between a patient's nutritional status and serum protein level.

Biochemical investigations can also assess circulating lipoprotein levels to give an indication of cardiovascular risk. In addition, specific vitamin, e.g. vitamin C, or mineral, e.g. iron and selenium, levels can be evaluated.

Nitrogen balance studies provide an index of protein status. Nitrogen balance is determined by estimating protein intake and subtracting urinary nitrogen excretion with an allowance for nitrogen loss via hair, skin and faeces. Additionally, losses from wound drainage or GI fistulae must be considered. A positive nitrogen balance indicates that the patient is in an anabolic state, whereas a negative balance indicates catabolism.

Accurate nutritional assessment relies on utilisation of data from a number of sources. Data from only one source can be open to misinterpretation due to the many factors, such as disease processes, that can influence individual parameters. A combination of two or more measures obtained from dietary history and intake, clinical examination, functional tests, anthropometric measures and biochemical tests is required to gain an accurate picture of an individual's nutritional status. The methods described above may be used by nurses in the context of a busy clinical environment. Other methods can be employed by dietitians and other health care professionals in the clinical environment and research settings (Garrow et al 2000).

Nutritional screening tools

Recently there has been an increase in the number of nutritional screening tools which are for use by nurses. These tools use risk factors that may lead to or be associated with malnourishment and are similar in format to a pressure ulcer risk assessment tool (see Ch. 23). They are typically in questionnaire format and are useful as an aide-mémoire for screening and as a record of information. An appropriate plan of action is identified by some. Of the many screening tools published, only a few have undergone rigorous testing of reliability and validity (Jones 2002, Green & Watson 2005). The British Association of Parenteral and Enteral Nutrition has introduced a screening tool for malnutrition for use by nurses in all areas of clinical practice (Elia 2003). This tool has undergone testing to ensure it is a valid and reliable tool with which to screen for malnutrition (Elia 2003).

A number of recent national publications (Nursing and Midwifery Practice Development Unit 2002, DH 2003a) have highlighted the need for nutritional screening and assessment, and local guidelines for nursing practice have been developed from these.

NUTRITIONAL INTERVENTION

Following screening and assessment of an individual, the nurse will plan appropriate interventions. The following sections outline interventions that may be planned by the

nurse, usually in association with other health care professionals such as the dietitian. These include advising on a 'healthy diet', promoting oral intake and enteral and parenteral nutrition. Obesity and undernutrition are also discussed. In many situations referral to the dietitian is a necessary part of the nutritional plan of care. However, in some circumstances — for example, giving advice concerning healthy eating to an individual who is overweight — this can be given by the nurse. Local guidelines should outline when referral to a dietitian is appropriate. Individuals who require therapeutic diets, e.g. those with diabetes mellitus, renal disease, coeliac disease, hyperlipidaemia and food allergy, should always be referred to the dietitian. Nurses may then follow through a plan of care prescribed by the dietitian. The dietitian is the expert on nutritional care in the health care environment.

A healthy diet

The diet which is currently recommended to promote the health of the general population in the UK is shown in Figure 21.3. This pictorial representation is termed the 'Plate model'. It illustrates five food groups and the proportion in which each group should be consumed. The model is based on guidelines for a healthy diet approved by the Department of Health (British Nutrition Foundation 2004) (Box 21.2) and is a useful health promotion tool. Such a diet is sometimes termed a 'balanced diet', i.e. it provides the appropriate amounts of all nutrients in the correct proportions to meet the requirements of the body. This diet consists of 33% vegetables and fruit, 33% complex carbohydrate, 12% protein-containing foods, 15% dairy products or similar foods and 8% fat- and sugar-containing foods. Current recommendations from the Department of Health suggest that each individual should eat five or more portions of a variety of fruit and vegetables a day (DH 2003b). The type of diet outlined above is not suitable for those under 5 years of age or those following a diet prescribed by the dietitian.

Box 21.2

Guidelines for a healthy diet

- Enjoy your food
- Eat a variety of different foods
- Eat the right amount to be a healthy weight
- Eat plenty of foods rich in starch and fibre
- Eat plenty of fruit and vegetables
- Don't eat too many foods that contain a lot of fat
- Don't have sugary foods and drinks too often
- If you drink alcohol, drink sensibly

Reproduced with kind permission from the Food Standards Agency (2003).

Obesity

Obesity is the condition of excessive accumulation of fat in the body, leading to an increase in weight beyond that considered desirable. Obesity quite simply results when intake of energy is greater than energy usage. However, the reasons why this happens are complex. Many people have the genetic propensity to develop obesity. However, the propensity does not mean the person will become obese; customary diet and lifestyle play a major role (British Nutrition Foundation Task Force 1999). A high dietary fat intake (Golay & Bobbioni 1997) and low levels of activity are strongly implicated (Prentice & Jebb 1995). Emotional factors may trigger overeating in some but it is generally thought that personality and emotional factors play only a minor role in the development of obesity, although they may be important in terms of response to treatment (British Nutrition Foundation Task Force 1999). Rarely, obesity may result from a medical condition, such as hypothyroidism.

Obesity is considered a major world health problem as the number of people who are obese is rapidly escalating (WHO 2003b). Obesity is associated with many common disorders such as cardiovascular disease, hypertension, stroke, type 2 diabetes mellitus and certain forms of cancer (WHO 2003c). The extra strain placed on the musculoskeletal system may contribute to arthritic disease, particularly of the hips and knees, and excess fat in the thoracic cavity may lead to sleep apnoea (British Nutrition Foundation Task Force 1999) (see Ch. 25). Individuals with obesity, particularly morbid obesity, may also be subject to psychological distress and social penalties. The economic costs of obesity may also be high. The National Audit Office (2001) estimated that obesity accounted for 18 million days of sickness absence and 30 000 premature deaths in 1998, and costs the NHS at least £0.5 billion a year.

Treatment of obesity

There are a number of approaches to the treatment of obesity. Currently few specialist obesity clinics exist and most people with obesity who seek help from health care professionals are assessed and managed by the primary care team. Interventions to reduce weight instigated or maintained by nurses include strategies to promote 'healthy eating' and lifestyle change. Treatment programmes within the primary care setting should be individualised and involve assessment and goal setting.

As outlined by Green and O'Kane (2002), advice given by nurses on weight management can be considered within four identified stages of health promotion:

1. Eliciting the person's views, beliefs and readiness to change
2. Explaining the nature of and reasons for advice
3. Negotiating and agreeing goals
4. Supporting the achievement of goals and maintenance of change.

Readiness to change, and the aspects of behaviour the person is willing and able to change, must be assessed. The 'stages of change' model may be used to facilitate this process (Hunt & Hillsdon 1996) (see Ch. 36). Nurses must have an understanding of the causes and effects of obesity in order to explain why weight loss is desirable. With most people the first goal should be to stabilise weight and therefore prevent further weight gain. If this is successful, moderate weight loss can then be attempted; a weight loss of just 10% can reduce the health risks associated with obesity (British Nutrition Foundation Task Force 1999). Weight loss beyond this may be attempted if the individual wishes.

Dietary change Dietary advice given by nurses to obese or overweight individuals should follow the guidelines for a healthy diet shown above. Adhering to healthy eating guidelines should lead to the consumption of a low-fat diet. The concept of healthy eating, rather than a prescriptive short-term reducing diet, is useful as it may encourage long-term or permanent changes to the individual's diet. Restriction of energy intake may be considered appropriate for some individuals, e.g. those with reduced mobility. Whilst some research has suggested weight loss has been more strongly associated with a change in the percentage of energy derived from fat, rather than with change in total energy intake (Toubro & Astrup 1997), a recent systematic review has suggested energy-restricted diets are as effective as fat-restricted diets in achieving long-term weight loss (Pirozzo et al 2003). A further review, however, suggests that whilst both low-fat diets, i.e. with 30% or less of total daily energy derived from fat, and low-fat, energy-restricted diets can promote weight loss (Mulvihill & Quigley 2003), their relative effectiveness is not clear.

There are many types of diet published, advocating various types and combinations of foods. The long-term efficacy of many of these has not been ascertained and some may be very low in energy and result in a deficiency of some nutrients. Many of these diets encourage a short-term drastic change in dietary habit, which is difficult to maintain, and most people find themselves reverting to their old eating habits.

Physical activity Increased physical activity can facilitate weight management (Mulvihill & Quigley 2003) and maintenance of a new eating pattern (Hunt & Hillsdon 1996). Some individuals may be unable to increase their physical activity levels due to their medical condition, and the advice of the doctor should be sought. The British Nutrition Foundation Task Force (1999) recommends building up slowly to walking at a pace that achieves mild breathlessness for 30 min/day at least 5 days per week. Eventually the person may consider extending some sessions to 40 min or more to encourage fat burning. Activity within the daily routine, e.g. walking rather than driving, should be encouraged. Resistance training can also help, as it will conserve muscle mass and maintain resting metabolic rate as weight is lost. Exercise on prescription may also be a useful way of promoting activity level (British Nutrition Foundation Task Force 1999).

Behaviour Strategies to promote behavioural change and modification may help individuals to avoid or cope with situations that promote overeating, and encourage the adoption of a healthier lifestyle (Hunt & Hillsdon 1996). Some individuals may find that they benefit from the support they gain from attending a reputable 'slimming club'.

Medication Drug therapy may be indicated when an obese or overweight individual with co-morbidities has been unable to lose weight by dietary change (National Institute for Clinical Excellence 2001a). In the UK there are currently two main types of medication that may be prescribed by the doctor for the treatment of obesity: one type inhibits the actions of lipases in the GI tract, thus limiting the absorption of fat, which is consequently excreted in the stools; the other type is a re-uptake inhibitor of noradrenaline and serotonin that works to reduce energy intake by increasing satiety and reducing hunger (National Institute for Clinical Excellence 2001b). Both these types of medication have been shown to be useful in promoting weight loss but there are side-effects associated with their use.

Surgery Obesity can be treated by surgical means if other methods of obesity management have failed (National Institute for Clinical Excellence 2002), although currently in the UK only a few hospitals offer this kind of surgery. The decision to undertake surgical treatment is not taken lightly as there are risks involved and eating patterns following surgery are vastly different from those before. Surgical treatments involve reducing the size of the stomach ('stomach stapling' or gastric banding) or bypassing sections of the upper GI tract. Reducing the size of the stomach restricts the amount of food a person can eat; bypassing sections of the GI tract results in less food being absorbed by the body. Care of the patient pre- and post-surgery is discussed in Chapter 26. It is important that anyone undergoing surgical treatment for obesity is referred to the dietitian. Surgical treatment for obesity will not automatically result in the consumption of a healthier diet, and may actually lead to a poorer quality of diet being consumed. The nurse must be aware that, following surgery, whilst the patient may be pleased with a very fast weight loss, a poor diet may be the cause, which can lead to a risk of malnutrition. As with any method of weight loss, weight loss maintenance is important and diet and lifestyle changes are essential factors in this.

Prevention of obesity is an important issue, as obesity levels, particularly in children, continue to escalate. Where appropriate, health promotion and education strategies by nurses should promote adherence to healthy eating guidelines and increased activity levels, not only for individuals but also for their families.

Undernutrition

Undernutrition is an endemic problem; protein-energy malnutrition (PEM) affects large numbers of the world's population and contributes significantly to human mortality and morbidity. However, in developed countries, while outright starvation might be thought to be unlikely, levels of undernutrition do exist and can result in significant morbidity and mortality. Certain groups may be at particular risk, including older adults, homeless people, substance abusers, those with eating disorders such as anorexia nervosa, those suffering from dementia and those who are hospitalised (Holmes 1999a). Undernutrition can occur as a result of:

- reduced food intake
- increased nutritional requirements
- impaired ability to digest, absorb or metabolise nutrients.

Metabolically active disease can alter or increase the need for nutrients. Disease processes may cause a reduction in food intake or absorption of nutrients; pyrexia and infection may increase metabolic rate and nutritional demands; surgery and trauma have a profound impact on metabolism, initiating a complex neuroendocrine response, resulting in an increased metabolic demand. The effects are cumulative, so that two or more of these factors occurring together will result in an even higher metabolic demand. However, the level of physical activity may be reduced, so the overall energy demand may not be raised.

Undernutrition is often associated with chronic disease and is a risk whether the person is nursed at home or in hospital, but there is also evidence of significant undernutrition in acute hospital wards. Holmes (1999a) has reviewed the literature on malnutrition in hospital patients. Surveys suggest that up to 50% of patients hospitalised for 2 weeks or longer could suffer from malnutrition. McWhirter and Pennington (1994) found that PEM was common in both surgical and medical patients. On admission, 38% of patients were undernourished and 66% suffered further weight loss whilst in hospital. A review of case notes of the 200 undernourished patients in this study revealed that only 96 had any nutritional information documented. Elmstahl et al (1997) found that, of 61 older patients in a Swedish long-stay unit, those with a low energy intake were at increased risk of morbidity or mortality.

In people undergoing surgery, undernutrition is associated with increased postoperative morbidity and mortality and studies have demonstrated that preoperative nutritional support can reduce these rates (Delmi et al 1990). Postoperative infection is particularly linked to undernutrition. Infection can induce a stress-related, catabolic response similar to that seen in surgical trauma and it is also often associated with anorexia. The links between nutrition and depression of the immune system are complex, but it is clear that a wide range of immunological functions may be affected.

Hospitalisation may predispose to undernutrition due to a number of factors:

- The patient or client may find that the anxiety and unfamiliarity of the environment reduce appetite.
- Food may not be to their taste and the presentation of meals and environment for eating may be less than ideal.
- Pain, fatigue, respiratory distress or other symptoms may affect appetite or ability to eat.
- Treatment, such as chemotherapy, may alter taste sensation (Holmes 1999b).

In addition, investigations may require periods of fasting and missed meals may not be replaced. Recommended practice is to fast patients from food for 4 h and fluids for 2–4 h prior to surgery (Maltby 1993) in order to empty the stomach and avoid perioperative or postoperative vomiting and the risk of aspiration into the lungs. However, actual fasting times for elective surgery ranging from 5 to 22 h have been reported and, in one study cited in Chapman (1996), only 16% of patients on an afternoon list were fasted for 6 h or less (Hamilton-Smith 1972, Chapman 1996); 33% had been deprived of food for more than 13 h. The theoretical 4–6 h preoperative fast appears to result, in practice, in periods of abstinence that might be better termed preoperative starvation, which could lead to a state of catabolism possibly detrimental to a patient undergoing major surgery. Smith et al (1997) found that shortening the preoperative fast time actually reduced postoperative nausea and vomiting.

For a discussion of strategies to reduce unnecessary preoperative fasting, see Jester & Williams (1999).

ENCOURAGING DIETARY INTAKE

Nurses are ideally placed to help individuals, whether at home or in hospital, to manage their nutritional needs. It is important to acknowledge that food has a number of non-nutritional roles, fulfilling a range of psychosocial and cultural needs. Eating will have very different expectations and associations for different people. Loss of menu choice, unfamiliar foods, food presentation, ethnic or cultural preferences, eating alone, eating in company, timing of meals, and even the eating utensils can all influence the motivation to eat. In addition, the patient's psychological state, e.g. stress due to the hospital environment, illness or bereavement, may modify eating behaviour. Physical factors such as ability to manipulate cutlery, ability to keep the lips together, chew and swallow, to taste food and even to reach food independently are all important. Box 21.3 outlines ways in which appetite can be promoted.

Oral intake

Individual physical and psychological factors, together with environmental or organisational factors, will influence a person's ability or willingness to eat an adequate diet. For an individual to successfully ingest an adequate oral diet at home, a number of activities are required and have to be assessed:

- Is the person able to go shopping and to choose and purchase appropriate foods?
- Is the person's nutritional knowledge adequate for informed choice and have they the financial resources to purchase the required foods?

Box 21.3

Promoting appetite

- *Presentation of food* — is the portion size appropriate? Does the food look attractive? Is it served at the correct temperature? Are mealtimes convenient?
- *Variety and choice of food* — are familiar foods served? Are they an appropriate type and consistency? Have individual food preferences and the needs of minority groups been acknowledged?
- *Frequency* — is there an option to have smaller, more regular meals? Are mealtimes spaced evenly through the day?
- *Duration* — are meals rushed?
- *Assistance* — is help with eating available, if required? Are there feeding aids to assist independence?
- *Oral hygiene* — are mouthwashes/mouth care offered after a meal? Are dentures well fitting? Is the mouth clean, fresh and without infection?
- *Toileting* — are individuals offered toilet and hand washing facilities prior to meals?
- *Positioning* — are individuals positioned comfortably and supported, if necessary, to allow them to manage their meal as independently as possible?
- *Exercise* — is activity or exercise encouraged during the day, to help improve appetite?
- *Social event* — do individuals eat alone or do they have company during meals?
- *Distractions* — are there other activities taking place at mealtimes? Are there unwanted smells/sounds/sights that may be off-putting?

Adapted from Jackson (2003).

- Once purchased, can food be transported home or is a delivery service available?
- Are there adequate facilities for storing food at home, e.g. refrigerator/freezer?
- Are adequate cooking facilities available and can the person use them safely?
- Can the person eat independently or do they need help?

If a deficit occurs in any of these areas, the nurse may need to look at alternative strategies and the occupational therapist may have a major role in assessing the home environment.

Shopping for food can be difficult for people with disabilities, the ill older adult and some people with behavioural disturbances. Ordering shopping over the internet, mobile shops and delivery services may help overcome these problems, if they are available and the individual can cope with ordering the food. However, these services may not be available or appropriate, and then the person will require outside assistance. The family or informal carers may be involved, as can social services, e.g. home helps, or voluntary agencies.

Food preparation can also be a problem. The home environment should be assessed for access to the kitchen, and access to worktops, cupboards, fridge and cooker. For example, a person who is dependent on a wheelchair may need substantial alteration to the kitchen to enable independent food preparation. People with chronic illness such as multiple sclerosis or rheumatoid arthritis may have limited mobility or may find food preparation tiring and need adapted equipment and lightweight cooking utensils. Perceptual problems and confusion may also interfere with independent food preparation. Again, if the person cannot cope, or can cope only with assistance, family or community services may need to be involved.

Physical factors influencing eating

To eat and drink normally requires the ability to transfer food to the mouth, the ability to retain food in the mouth, to chew and to swallow. Sensory function is also important; appetite is improved and eating is easier if the individual can see, smell and taste the food. Digestion and the absorption of nutrients are dependent on effective GI function, and utilisation is dependent on metabolism. The state of the teeth and mouth is important. Cleft lip and cleft palate are examples of congenital abnormalities that can reduce a baby's ability to suck. Teeth are needed for effective chewing; edentulous people may require food of a softer texture or food cut into smaller pieces, but seldom a diet of only mashed or minced foods. Such people are likely to eat fewer vegetables, less dietary fibre and be deficient in vitamins such as D (Finch et al 1998).

If the oral tissues are dry, inflamed or painful, a person may be reluctant to eat (see Ch. 15). In xerostomia, artificial saliva can be used to help lubricate food. Oral health may also contribute to improving the taste and enjoyment of a meal; poor oral hygiene can mask taste and reduce appetite. The number of taste buds per papilla of the tongue decreases with age and taste changes can occur in some conditions such as cancer. In the older adult, the perception of sweetness and saltiness may change and more highly seasoned food may be preferred.

21.5 What are the particular nutritional needs of older people? Discuss this with your mentor and lecturer.

Odour, visual appearance and texture of food

The odour of food is an important aspect of taste and enjoyment. Conditions such as upper respiratory tract infections can cause a temporary reduction in the sense of smell. Ageing may also be associated with alterations in the sensation of smell. Reduced oral sensitivity or confusion may cause the temperature of food to be misjudged, resulting in a greater risk of scalds and burns.

The visual appearance of food is also important; meals that look unappetising or are poorly presented may reduce interest in eating. The visually impaired will appreciate knowing where different foods are positioned on the plate, and some individuals who have experienced a stroke may only perceive half the plate and therefore need to be reminded about the remainder (see Chs 2 and 13).

The texture of food and the person's perception of their ability to chew it are also important. Problems with mastication appear to increase with age and may often be related to poorly fitting dentures. In some conditions there may be difficulty in coordinating chewing, and the movements

of the mouth may be uneven, with a tendency for food to dribble out of one side.

Difficulty in swallowing

Difficulty in swallowing — dysphagia – has a number of causes. It may be due to neurological injury, as in stroke, mechanical or motor obstruction of the oesophagus, oesophagitis and oesophageal cancer. The degree of dysphagia must be assessed by the SALT and local guidelines for the management of patients with swallowing difficulties should be followed. It may be that no oral intake or only soft foods or thickened fluids can be tolerated. If oral intake is problematic or impossible, then enteral feeding must be considered. McLaren (1996), in a study of nutrition in patients with a stroke, found that the responsibility for assisting patients to eat was principally devolved to student nurses and care assistants. Although attention was paid to activities related to positioning of the body, arm movement, communication and attention deficits, little interest was shown in nursing activities relating to impaired lip closure, chewing, swallowing or perception.

Food access

Reduced mobility may cause problems in access to food, choice of place for eating and attaining a comfortable eating position. Care and perhaps some dietary alterations may be required if supine or prone positions have to be adopted for eating. Any difficulty of arm or hand movement or hand–eye coordination may diminish the ability to eat. The person may need assessment for eating aids such as cutlery with special grips or shapes. If the person has to eat one-handed, stabilisation of plates, using a mat, the use of deeper plates or the provision of plate guards may help. Drinking may also be a problem and special cups and glasses are available. If the patient or client suffers from muscle weakness, special lightweight utensils can be ordered. A number of problems may result in difficulties with eating and drinking, but stroke is just one example that can markedly alter many aspects of eating and drinking behaviour (McLaren 1996).

Organising effective mealtimes

Ensuring a supply of nutritious food, at the right temperature and in an attractive and hygienic manner is the responsibility of both nursing and catering services. Although nurses remain responsible for ensuring adequate nutrition (Royal College of Nursing 1996), their role in the preparation and distribution of food has tended to be reduced. Food preparation is not usually a nursing task, but the nurse is responsible for ensuring that food is ordered and should act as advocate between the patient and the centralised catering services. Meals are often delivered to the wards pre-plated in heated trolleys at times dictated by catering service needs. However, some people may need or prefer more frequent, smaller meals. Patients may miss meals due to investigations or treatments and obtaining meals in these cases will require effective liaison with catering services. In the *Guide to the NHS* (DH 2001), the promise is given that people will be provided with good food and given any help needed to order or eat meals. The Guide also states that there should be a 24-h catering service.

Mealtimes

Mealtimes should be a planned part of nutritional care; used appropriately they can be an effective therapeutic event. Meals are often the focal point of the day, providing landmarks that break up the day and lend a familiar pattern to the ward routine. For the older person at home, the arrival of a midday meal may be an important social event; in a busy ward sharing a table may help patients to improve appetite. Mealtimes must not be considered as an inconvenience, disrupting ward activities three times a day. Rather they should be organised to be, where possible, a pleasurable social activity. Properly managed, they can provide a useful focus for social activities in continuing care environments.

To make the most of meals, they should be planned in relation to timing, environment, menu and nutritional value. Allowing individual patients to continue with their normal pattern of mealtimes is good practice; however, the necessities of catering for large numbers may preclude this.

Timing Mealtimes should, ideally, not coincide with other structured ward activities such as medication administration, shift handovers or staff breaks, since there is a risk that they will then be hurried and unsatisfactory for both nurse and patient. Some patients or clients may like to take their time over meals and others will require assistance in eating. Hovering staff, in a hurry to clear away dishes, will not encourage appetite. Even when meals are pre-plated and the trays distributed by domestic staff, it is essential for the nurse to be involved. Timing of meals may have to be a compromise, reflecting the needs of the patient, the ward and the catering service. In continuing care environments, for example, breakfast time could be flexible, especially if cold cereals or a continental style breakfast have been chosen. If the evening meal is served early, a snack and hot drink later in the evening is a useful way of increasing nutrient intake. Some flexibility over mealtimes is preferable in the acute setting but it is essential that an effort is made to meet residents' needs and norms in long-term care. It may be possible for residents to take an active role in choosing menus and deciding on mealtimes.

Environment Ideally the patient will have a choice of where to eat, particularly for individuals in long-stay units. While some may prefer to eat by their bed or in their own room, a separate dining area, distinct from the bed spaces and treatment area of the unit, is ideal. The nature of the open ward, with inevitable sights, sounds and smells of illness, is not conducive to appetite.

The dining area should be decorated to provide a social atmosphere and provided with small tables to allow people to eat in their natural groupings. Provision for those who wish to eat alone or who need assistance is also necessary. Forcing relative strangers to eat together or to have to watch a person with eating difficulties may not aid appetite. Although the eating area may also function as the day room, it can be specifically set up at mealtimes. If a person has visitors during meals, this can be helpful, as relatives can be involved in assisting with eating or enjoy a meal with them. Some Trusts have employed hostesses or volunteers at mealtimes to assist patients with eating (Hobday 1997).

Food selection and presentation

Although nurses do not always serve meals, it is important for them to make sure that each patient receives the right food in sufficient quantities. Patients need to be active in food selection where possible. In a care setting, helping a person to fill in a menu card or offering a choice from a bulk trolley is an important nursing function. Foods should be attractively served, with small inviting portions placed separately on the plate. Presenting a heaped plate of food to a patient with a poor appetite will be counterproductive. For some, large portions of food can be daunting. For those requiring a soft diet, food moulds can enhance the presentation of a meal.

The temperature of food is another factor that affects appetite; care should taken to ensure hot foods are served hot and cold foods are served cold (Ellis 2002). It is also important that food is served using a no-touch technique. Chipped or cracked crockery should not be used as it will not clean properly and can become a source of cross-infection.

Assisting people to eat

When someone has difficulty eating, it becomes the nurse's responsibility to help with this basic activity of living. Assisting a person to eat requires considerable skill. Having to be fed by someone can be a threat to the individual's integrity and self-esteem. This should be recognised and every effort made to minimise the negative aspects. Before preparing for the meal, the dependent person should be offered toilet facilities, followed by the opportunity to wash their hands. Eating is easier and more natural sitting out of bed, but the person on bed rest can be assisted to sit upright and be made comfortable, if this is not contraindicated. An appropriate table is required so that the food can be set out, allowing the person to see the food and indicate preferences. The nurse should sit level with the person and encourage a relaxed social atmosphere.

Food habits The person's food habits must be identified and the rate and manner of assistance with eating and drinking should be at the person's normal pace and pattern. The pace of eating can be controlled by the person if their hand is placed on the nurse's forearm during assistance with feeding and drinking. Plenty of time is essential to allow the person to chew, to pause between mouthfuls and to have a drink when desired. If protection for clothing is required, a normal serviette can be used. The use of plastic bibs or rolls of paper towel may damage self-esteem. Normal crockery should be used if the nurse is assisting the person to eat and drink; if the person is able to participate, then feeding aids may improve independence. Spoons have their place, but knife and fork should be used if possible. The nurse should check that plates and food are at an appropriate temperature and ensure that any bones or fruit pips are removed. The person should be offered mouth care after the meal.

Patient participation A study by ACHCEW (1997) suggested that staff shortages, combined with pressure to undertake other duties, prevented nurses from offering assistance at mealtimes to those who needed it. What the patient can do for themselves they must be given the time and encouragement to attempt. Food and drink can be positioned on the dominant side, well within reach. If a person cannot manage to pour a drink, a glass can be left ready filled. Some individuals are unable to cut up food and require assistance with this. By giving individuals your full attention and allowing them to control the process of eating and drinking as much as possible, the negative effects of having to be assisted to eat and drink can be minimised.

Food supplements People with a poor appetite or dysphagia may not be able to ingest enough food to meet nutritional needs, and supplements of liquid foods between meals may be required. These may be powdered supplements, which are added to milk, or complete formulae supplied ready packaged. Although providing a range of nutrients, these are particularly useful for providing a supplementary energy intake.

Some individuals may need some encouragement to take supplement drinks. Supplements can be presented in a range of ways: frozen to the consistency of a mousse or ice cream or warmed to resemble soup. If an individual's intake is poor, it is important to 'make every mouthful count'. This can be achieved through strategies such as the addition of butter or cheese to vegetables, ice cream to puddings and milk drinks, vanilla or neutral flavour supplements in place of milk on cereals. If a person has a poor intake or requires assistance with eating and drinking, it is important to chart daily intakes of food and fluid and to note in the nursing records which assistance strategies were effective.

For further information, see 'Small is beautiful', in *Eating Matters* (Bond 1997).

ENTERAL FEEDING

Enteral feeding in the context of this chapter refers to the delivery of nutrients directly to the patient's stomach or small intestine via a tube. If a patient is not able to eat or drink sufficiently adequately to maintain nutritional status, enteral feeding should be considered and can be used as the sole form of nutrition or as a supplement to oral intake. Indications for enteral feeding are shown in Box 21.4.

If a person has a functioning gut, enteral nutrition should always be considered before parenteral nutrition (BAPEN 1999). Enteral nutrition is less costly, safer, easier to manage and has fewer side-effects than parenteral nutrition. Compared to parenteral nutrition it is thought to preserve intestinal mucosal structure and function and allow for the absorption and utilisation of nutrients in a more physiologically normal way (BAPEN 1999).

Enteral nutrition is contraindicated in some conditions, e.g. obstruction or incompleteness of the GI tract. The decision as to whether a person is enterally or parenterally fed should be informed by the Nutrition Support Team if present in the clinical setting, or with the input of a dietitian and pharmacist if not. When deciding whether enteral nutrition is appropriate for an individual, ethical and legal issues need to be considered.

For further information on this complex and important area of clinical practice, see Lennard-Jones (1999).

Box 21.4

Indications for enteral feeding

Increased nutritional needs
- Hypercatabolic states, e.g. following extensive burns, major sepsis or severe trauma
- Major surgery. Enteral feeding may be commenced prior to surgery to improve nutritional status

Compromised access to GI tract
- Head and neck surgery
- Obstruction due to tumour, e.g. carcinoma of the mouth or oesophagus
- Oesophageal stricture
- Oesophageal fistula

Inability to eat
- Unconscious
- Confused
- Unwilling to eat, e.g. persistent anorexia due to chemotherapy
- Persistent nausea and vomiting
- Dysphagia, e.g. following stroke

Gastrointestinal disorders
- Fistula
- Reduced absorption in GI tract, e.g. short bowel syndrome, inflammatory bowel disease, gastrectomy

It is essential that a patient receiving enteral feeding has a written plan of care so that all involved with the care of that person are aware of the goals of care, interventions planned and the evaluation strategies. It is also important that the plan of care is made in partnership with the patient or client where possible and that carers are informed where appropriate. Often it seems there is a lack of clarity in care settings as to what the overall plan of care is for an individual, for example why a particular type of tube is used, when it has been placed and the duration of any side-effects.

For examples of plans of care, see Scott et al (1998) and Dougherty & Lister (2004).

The major enteral route via the nose is to the stomach (nasogastric tube), although a tube may also be inserted from the nose to the duodenum (nasoduodenal tube) or jejunum (nasojejunal tube). Post-pyloric placement is indicated when the risk of aspiration is considered high or when the patient's medical condition, e.g. obstruction by tumour, or treatment, e.g. oesophageal surgery, indicates this. Less commonly a tube may be passed via the mouth to the stomach (orogastric tube). Tubes may also be inserted through the body wall into the stomach (gastrostomy) or jejunum (jejunostomy). For short-term feeding, enteral feeding tubes are usually inserted via the nose, but if a tube is required in the longer term, a gastrostomy is the preferred route of choice. As nasogastric and gastrostomy tubes represent the most common approaches to tube feeding, they will be the focus of the rest of this section.

Nasogastric tube insertion and care

Nasogastric tube feeding is indicated when short-term nutritional support is required. As the nasogastric route interferes minimally with oral function, it can be used to supplement oral intake. The tube used should be narrow in diameter and flexible. Tubes that have a wide diameter are poorly tolerated as they are uncomfortable, can cause pressure necrosis in the nose and oropharynx and may encourage cardiac sphincter incompetence, thus increasing the risk of gastric reflux and aspiration. As fine-bore tubes are flexible, a wire introducer may be required when the nurse is inserting the tube. Fine-bore (6–8 FG) feeding tubes of PVC, silicone or polyurethane are available. PVC tubes degrade quite quickly and are less flexible but can be useful for feeding in the short term as they are less expensive. Polyurethane or silicone tubes are for longer term use and can be left in position for up to a month. The exact length of time is detailed in the manufacturer's guidelines. Some of those with a guide wire (single-patient use) may also be reused on the same patient if they are displaced, although the guide wire must only be reinserted into the tube if the tube has been removed from the patient (Bowling 2004).

Insertion of the tube must follow guidelines approved by the clinical setting. Procedures on how to insert tubes with and without guide wires are described in Dougherty and Lister (2004). Nurses may insert tubes safely and effectively in most individuals; however, the insertion of fine-bore tubes following maxillofacial surgery and laryngectomy, or in those individuals with maxillofacial or oesophageal disorders, is not straightforward and in these situations either a doctor (BAPEN 1996) or a nurse with advanced clinical skills in this procedure should place the tube.

Once the tube is in place, then its position may be checked by pH testing of aspirate using pH indicator strips or X-ray (Colagiovanni 1999, Burnham 2000). Air auscultation — the 'whoosh' test — involving the rapid injection of 20–30 mL of air down the tube while listening over the stomach with a stethoscope, is no longer recommended (National Patient Safety Agency 2005). However, no method is foolproof; gastric aspirate may be obtained from the trachea if the person has aspirated, and an X-ray is only accurate at the time it was taken. Guidelines approved by the clinical setting must be followed when ascertaining the placement of a tube and the patient carefully observed for signs of respiratory distress or general discomfort once feeding has commenced.

Following insertion, the position of the tube should be checked before administration of any solution or medication, if the patient complains that the tube feels uncomfortable, if feed is seen in the mouth and following episodes of vomiting, coughing or suctioning. Regular flushing of the tube with water is essential to reduce the chance of blockage (Colagiovanni 2000). A 50 mL syringe is considered to be the most appropriate size of syringe to use for flushing or aspirating, as use of a smaller syringe is thought to generate a higher pressure within the tube (Cannaby et al 2002). Excessive pressure should not be used to force fluids down the tube as this may split the tube wall. It has been suggested that the tube should be flushed with 30 mL of water using a 50 mL syringe at the beginning and end of

each feed and before and after giving medication (BAPEN 1999). For some patients, fluid intake may be limited due to their medical condition and therefore smaller amounts of water should be used to flush the tube. Recent guidelines from the Infection Control Nurses Association (Skipper et al 2003) suggest that sterile water should be used to flush tubes in acute health care settings and all tubes which terminate in the jejunum. In the community setting, guidelines suggest cooled, freshly boiled water or sterile water from a newly opened container should be used if the patient is immunosuppressed (National Institute for Clinical Excellence 2003). A 50 mL catheter-tipped syringe should be used to administer fluids. Syringes intended for i.v. use should not be used due to the risk of accidental parenteral administration (BAPEN 2004). Syringes used for the administration of medication or flushing should be discarded after use (Skipper et al 2003).

Premature removal of nasogastric tubes by patients is common (Pancorbo-Hidalgo et al 2001). A nasogastric tube should be secured to the nose and side of the face to prevent the tube from being displaced (Burnham 2000).

The act of eating and drinking cleanses and hydrates the mucosa of the mouth. In patients who are tube fed, frequent mouth care is a priority to keep the mouth in a clean and comfortable condition.

Gastrostomy tube insertion and care

Gastrostomy feeding is used if enteral feeding is likely to continue for longer than a month (Garrow et al 2000) or in some situations where a nasogastric tube is poorly tolerated. This has become a relatively common nutritional intervention. The procedure most commonly used to place a gastrostomy is termed a percutaneous endoscopic gastrostomy (PEG) although tubes may also be inserted radiologically or surgically (radiologically inserted gastrostomy or percutaneous fluoroscopic gastrostomy). Prior to the procedure the patient will require preoperative preparation (see Ch. 26). Gastrostomy placement is contraindicated in a number of medical conditions such as ascites, liver disease and morbid obesity (BAPEN 1996). The doctor in charge of the patient's medical care will assess their suitability for gastrostomy placement prior to the procedure and obtain the patient's written consent. A gastrostomy is normally performed after the patient has received a sedative medication, therefore postoperative care should follow the general guidelines following an operative procedure under sedation outlined in Chapter 26. Complications of gastrostomy insertion can occur, such as bleeding and pneumoperitoneum (BAPEN 1999) and the nurse should observe the patient's condition in the postoperative period carefully.

Following the procedure, tube feeding can usually commence within 6 h but local clinical setting guidelines must be followed because opinion as to when it is safe to proceed with feeding varies (Srinivasan & Fisher 2000). Usually a dressing is not required over the gastrostomy site. Once the site has healed and the stoma formed, the site should be washed daily with water and dried thoroughly (National Institute for Clinical Excellence 2003). Some types of gastrostomy tube need to be rotated regularly once the tract is healed to prevent skin from growing around the tube. The frequency with which this should be carried out is variable, therefore local clinical guidelines must be followed. It is suggested that the tube should be gently pushed in by 1 cm and then returned to its original position whilst rotating it through 360°. The fixation plate should be approximately 5 mm distance from the abdomen and should be undone and pulled back to facilitate cleaning. The patient with a gastrostomy tube should not swim or bathe until the tract has healed.

If the gastrostomy tube is removed accidentally, then immediate action must be taken as the tract will close over within a matter of hours. If the tube cannot be reinserted by the Nutrition Nurse Specialist or doctor within a short period of time, then a replacement may be inserted to keep the stoma patent; fluid should never be infused until the position of the tube has been confirmed by a health care professional experienced in the care of gastrostomy tubes.

Complications as a result of gastrostomy formation are not uncommon and may include infection and leakage (Platt & Roe 2000). Overgranulation of the stoma may also occur; advice on this may be sought from the Nutrition Nurse Specialist or in some situations from the Tissue Viability Nurse. Local guidelines on how to prepare and care for individuals post procedure must be adhered to.

The procedure for the removal of a gastrostomy tube varies according to the type of tube placed. Some tubes can be withdrawn through the stoma, following deflation of the retainer in the stomach; some tubes may be cut and the portion remaining in the stomach removed endoscopically or allowed to pass through the GI tract. If a tube is to be removed, local clinical area guidelines should be followed or the advice of the Nutrition Nurse Specialist or Unit personnel who have placed the tube should be obtained.

Administration of medications via enteral tube

The pharmacist should be consulted if medication is to be given via an enteral tube as there are risks associated with this route of administration such as tube blockage, drug toxicity and a reduction in drug efficacy. The pharmacist is able to advise on the appropriate route, formulation, timing and monitoring. Nurses must be aware that administration of a licensed medicine via an enteral tube is an unlicensed use and that they are professionally accountable for any adverse effects experienced as a result of using this route (Bowling 2004).

The location of the enteral tube needs to be considered before medication is given as some drugs are not absorbed effectively when delivered directly into the small intestine rather than to the stomach. Medications in the form of oral liquid and dispersible tablets are most easily administered via an enteral tube. However, some liquids may be hyperosmolar and cause diarrhoea, especially if directly administered further down the small intestine. Some viscous oral liquids may be diluted with water to ease administration. Tablets may be crushed, but the advice of the pharmacist must be sought. Medication which is coated (film or enteric) is rarely suitable for administration via an enteral tube. Tablets or capsules of cytotoxic, hormonal, steroidal or anti-

biotic medications should not be crushed or opened because of the potential risk of exposure to staff and others.

The pharmacist is also able to advise on the potential for drug–nutrient interactions; for example, the drugs phenytoin, carbamazepine and tetracycline should not be administered with feed as this can affect the amount of drug absorbed from the GI tract. If several medications are to be given at one time, the tube should be flushed with at least 10 mL of water between each medication (BAPEN 2004) or advice on the suitability of mixing medications sought from the pharmacist. Two drugs may interact with each other and their effects may change as a result.

Selection of enteral solution

There is a wide range of commercially prepared enteral solutions ('feeds') that may be prescribed. Commercially prepared feeds are of a known nutritional content, are sterile and are designed for ease of administration. The dietitian will choose the most appropriate feeding regimen for the patient, basing such choice on assessment of the patient's needs and medical condition. Generally, the dietitian will also order the feed and ensure it is available for the nurses to administer. Feeds may cause GI disturbances when feeding is being initiated or if they are infused too rapidly. Enteral solutions should be administered at room temperature, as administration of a cold feed can cause the patient to experience abdominal discomfort. Enteral solution should be stored according to the manufacturer's instructions and usually requires shaking prior to administration to disperse any sediment formed. 'Use by' dates should always be checked prior to administration.

Method of administration of enteral solution

The equipment for feeding consists of a reservoir, the nasogastric tube, and usually a giving set that connects to the reservoir and a pump. The reservoir may be a bottle or soft pack and may require filling or may be filled with feed at the manufacturing stage. Nasogastric feeds can be delivered intermittently or continuously. Intermittent feeding is the administration of a 'bolus' of feed periodically. Continuous feeding involves the delivery of a feed over a period of many hours. In clinical settings, enteral feeding pumps are commonly used to deliver a steady flow of solution over a period of time. Feeding intermittently reflects more closely the normal eating pattern and permits free movement between feeds; however, it may be more likely to result in feelings of nausea, intestinal distension, cramps and diarrhoea. There may also be an increased risk of reflux and aspiration. The dietitian will prescribe the rate at which a solution should be administered following assessment of the individual. During feeding and for 1 h after, unless contraindicated, the patient should sit up at 30° or higher to reduce the risk of aspiration (BAPEN 1999). The amount of feed remaining in the stomach (gastric residue) can be checked if the individual complains of nausea or gastric distension. In some clinical settings, e.g. intensive care units, checking the amount of feed in the stomach should be carried out periodically; local guidelines should be consulted on this issue.

Monitoring and complications of enteral feeding

Monitoring of a patient on enteral feeding is essential to observe for signs of complications and to ensure nutritional goals are being met:

- Food and fluid intake and urine output should be recorded to identify any changes in fluid balance.
- Temperature, pulse and respiration should be recorded at least twice weekly.
- The patient should be observed for any signs of respiratory distress and their general clinical condition monitored.
- If a gastrostomy is present, the site should be observed daily for signs of infection, skin irritation, leakage, stoma overgrowth or excessive movement of the tube.
- Stool frequency should be recorded.
- Biochemical monitoring should be carried out as directed (BAPEN 1999).
- The patient should be weighed weekly.

Complications of enteral feeding can be categorised into three broad groups: mechanical, biochemical and gastrointestinal/infectious (see Box 21.5). The psychological effects of tube feeding should also be considered, since food has a profound influence on psychosocial well-being. One study highlighted that the placement of a gastrostomy has a major impact on the lifestyle of patients and their carers which can lead to feelings of frustration, loss of freedom, embarrassment and anxiety (Rickman 1998). Those who felt they coped best were those who felt supported by professionals. The enteral tube may affect self-image and impose feelings of loss of control. The nurse should ensure that the nursing care recognises and meets the patient's and carer's needs.

If a patient is likely to be discharged from hospital with an enteral feeding tube in situ, then it is essential that appropriate discharge arrangements are made for the continuation of nutritional care (BAPEN 1994). Russell and Rollins (2002) highlight that there are more people receiving enteral tube feeding in a community setting than in the hospital setting.

PARENTERAL NUTRITION

In parenteral feeding, nutrients in solution are infused directly into the venous system (Finlay 1997). Parenteral nutrition (PN) may be used as a supplement to oral or enteral feeding or it can be the sole form of feeding. The term TPN (total parenteral nutrition) is commonly used, but PN is preferred. This invasive technique is associated with several hazards and problems and should be used only when other methods have been excluded. Appropriate early intervention by PN can prevent or reduce the likelihood of malnutrition developing.

Indications for PN

The risks and expense associated with PN are significant and the key factor to consider when deciding to use this form of feeding is the availability of the GI system. PN will be the method of choice if the GI system is unavailable,

Box 21.5

Complications associated with enteral feeding

Mechanical complications of enteral feeding

Potential complication	Prevention/management
Tube blockage	Flush tube with water regularly (Cannaby et al 2002) Maintain continuous flow of feed Replace tube as required Consult pharmacist concerning appropriate medications Clear tube blockage using solution detailed in local guidelines; these may include carbonated drinks or enzymes
Knotted tubes	Note any pain on tube withdrawal Consult Nutrition Nurse Specialist or doctor if pain is present
Tube displacement	Use correct procedure to insert tube Use appropriate type and length of tube Secure tube firmly Explain need for tube to patient
Aspiration of feed	Elevate head and shoulders by 30° or more whilst feeding and for 1 h after Confirm position of tube prior to use Check gastric residual volume as indicated
Discomfort	Give mouthcare regularly Lubricate lips Use smallest appropriate bore of tube Use alternate nostril for tube insertion
Excessive or inadequate feed flow	Use appropriate procedure to administer feeds Use an enteral feeding pump to administer feeds or follow dietitian's instruction concerning bolus feed administration

Biochemical complications of enteral feeding

Potential complication	Prevention/management
Changes in electrolyte levels	Monitor electrolyte levels in blood as required and act promptly if changes detected
Changes in hydration status	Record fluid input and output Weigh the patient weekly
Refeeding syndrome	Follow dietitian's instructions concerning rate and type of feed Monitor electrolyte levels in blood (see Bowling 2004) Record temperature, blood pressure, pulse and respiration frequently initially Record fluid input and output

Gastrointestinal and infectious complications of enteral feeding

Potential complication	Prevention/management
Nausea and vomiting	Avoid administering high osmolality fluids Avoid rapid infusion rates Administer fluids at room temperature Consult dietitian if nausea is experienced Check residual gastric volume if nausea is experienced Stop feed if vomiting is experienced and consult dietitian Consider antiemetic administration Review procedures used to administer feeds and ensure giving set changed according to clinical setting guidelines
Diarrhoea	Establish cause of diarrhoea: consider medications used, e.g. antibiotic therapy, laxatives and high osmolality fluids, and medical diagnosis Consult dietitian as feed type and rate may need reviewing Administer feed at room temperature If diarrhoea persists, send a stool sample for culture Review procedures used to administer feeds and ensure giving set changed according to clinical setting guidelines
Constipation	Monitor frequency and consistency of stool Contact dietitian, as feed type may need reviewing Encourage mobility Give laxatives as prescribed Ensure adequate water intake
Distension/cramps	Check gastric residual volume of feed Follow dietitian's instructions concerning rate and type of feed Consider antiemetic or antispasmodic use
Stoma site inflammation	Clean site daily Ensure fixation device is in the appropriate position to avoid external pressure at stoma site Avoid the use of a dressing around the site Rotate tube according to clinical setting guidelines Consult Nutrition Nurse Specialist or Tissue Viability Nurse Specialist for advice Send swab from site for microbiological analysis Observe for signs of systemic infection

i.e. cannot be accessed or there is GI failure. Severely malnourished patients may not be able to tolerate the oral or enteral intake required to rectify their nutrition deficits, and supplementary parenteral feeding may be considered. Severe trauma, including extensive surgery, some malignancies and major sepsis can induce a state of hypercatabolism that imposes an enormous demand on nutritional resources. If exogenous nutrients are not available, the catabolic demands can result in a marked loss of body tissues. PN should be considered if a person is likely to be starved for 7 days or more, or, if severely malnourished, after 3 days (BAPEN 1996). Indications for PN include:

- trauma to the GI system which may result in an inability to ingest or absorb foods, e.g. fistulae, perforated bowel
- preoperative malnutrition, e.g. BMI <18 or 20% weight loss
- postoperative complications delaying enteral feeding, e.g. paralytic ileus, obstruction, short bowel syndrome, fistulae, peritoneal sepsis
- acute or chronic GI inflammation which is not responding to treatment, e.g. Crohn's disease, ulcerative colitis, severe gastroenteritis
- malabsorption, e.g. in cancer and cancer chemotherapy or radiotherapy, where there is inflammation of the mucosa
- severe trauma, burns, sepsis and other conditions resulting in a hypermetabolic state
- some cases of pancreatitis
- nausea and vomiting secondary to disease of the central nervous system.

Many people will require only short-term PN, for less than 2 weeks, until GI function has improved sufficiently. Some, however, with prolonged GI failure, will need long-term PN, either at home or in hospital. Whilst there may be 'typical' indications for PN, each patient will have individual needs. In order to support and maintain a patient with PN successfully, a team approach is needed, involving not only the nursing and medical staff, but also the biochemist, pharmacist and dietitian, and the primary care team if the patient is to receive PN at home. Specialist nutrition teams assist patients and their carers to manage PN successfully at home, giving advice on such things as storage of PN bags, management of the regimen and equipment use.

Venous access for PN

PN can be administered through a peripheral or central vein. Central venous catheterisation is currently the route of choice for long-term PN and for those with inaccessible peripheral veins. Infusion into the superior vena cava promotes rapid dilution of the hyperosmolar fluids. The vena cava can be accessed by direct cannulation via the subclavian, external jugular, internal jugular or brachiocephalic veins. Catheters can be inserted by percutaneous puncture or a cutdown procedure. For long-term feeding, i.e. >1 month, then this may be tunnelled. With tunnelling, there is some distance between where the catheter enters the skin and the point at which it enters the vein, which may facilitate better positioning of the catheter and reduce the risk of infection. Increasingly, central venous catheterisation is being carried out through a peripheral vein in the antecubital fossa, using a long catheter that is threaded up to the vena cava (peripherally inserted central catheter, or PICC line). PICC lines are suitable for medium- to long-term PN.

Peripheral lines are often referred to as PIC lines (peripherally inserted catheters) and include both peripheral cannulae and midline catheters. Peripheral cannulation is not suitable for long-term parenteral feeding as the solutions infused are often hypertonic and chemical irritation will result in thrombophlebitis (Kingsbury 1999), but Colagiovanni (1997) advocates peripheral vein access for short-term use, if there is no alternative. The cannula should only be in place for 24–48 h before re-siting it in the opposite arm. The leg veins should not be used for PN because of the risk of deep vein thrombosis and phlebitis. Peripheral midline catheters are typically 20 cm, 22 FG catheters, which are sited in the antecubital fossa and stretch along the vein toward the superior vena cava. These catheters are suitable for short- to medium-term use.

Regardless of the approach adopted, an aseptic insertion technique and careful insertion site management are essential (see Ch. 20). The central venous line should be inserted either in the operating theatre, where maximum control of the environment is possible, or on the ward, using barrier or expanded infection control measures (see Ch. 16). After insertion of a central catheter, an X-ray should be performed to ensure that the line is in the correct position and complications have not occurred.

Administration equipment

All nutrient solutions should be administered through a dedicated feeding line, using a volumetric pump as flow control is important (BAPEN 1996). A large variety of i.v. catheters is available for parenteral feeding. A rigid catheter is more likely to damage the internal lining of the vein and cause phlebitis. A flexible, strong catheter made from an inert, soft material is ideal. It should also be detectable by X-ray, so that the tip position can be checked prior to PN commencing. Silicone or polyurethane catheters are often used, as they appear to be less thrombogenic, although other materials are also common. For peripheral PN, fine-bore catheters (22–23 FG) are being increasingly used. Infusion sets with Luer locks should be used, to allow access to the catheter whilst maintaining a closed system. In-line filters can be used to reduce particulate matter and may help to reduce bacterial contamination, depending on the type of filter employed.

Solutions for PN

Parenteral nutrition, if used exclusively, must meet, as closely as possible, all of a patient's requirements for water, energy, macro- and micronutrients. The fluid and electrolyte intake should cover loss via urine, faeces (especially if diarrhoea occurs), respiration, perspiration and any abnormal losses via wounds or drains. Energy is most commonly provided by glucose and lipid solutions, compounded with other nutrients in a single bag. Lipid solutions provide essential fatty acids and supply 40–50% of the energy. A mixture is better tolerated than glucose alone, as fat reduces

the overall concentration of the infusate, relative to glucose, which will reduce the risk of thrombophlebitis.

Nitrogen is generally supplied by amino acid solutions with varying proportions of essential and non-essential amino acids. Micronutrients can be provided by a number of additive preparations that should be added to the bag in pharmacy, as close in time to administration as possible. All nutrient solutions should be compounded, under aseptic conditions, by the pharmacy department or a licensed manufacturer. This will ensure stability of solutions and minimise the risk of microbial contamination.

Complications of PN

General complications associated with PN can be classed as:

- catheter-related complications
- complications associated with the feeding regimen
- difficulties arising from coexisting medical problems
- the psychosocial impact of parenteral nutrition.

Catheter-related complications

Chapter 20 considers the general problems of i.v. therapy. In PN, the particular risks are those related to the long-term use of a central venous catheter and the administration of large quantities of viscous and hypertonic fluid. Chapter 26 discusses the complications which may arise from the insertion of a central venous catheter. Displacement of a peripheral PN catheter can result in damaging extravasation and tissue necrosis. Catheters should be well secured when initially inserted. Catheter fracture can occur from frequent clamping and unclamping of the catheter and can result in air or bacteria entering the system. Air embolism can result from detachment of the catheter from the tubing and is potentially fatal. However, it is quite rare with modern equipment.

Catheter blockage can occur due to blood clots, lipid deposits or precipitation of drugs within the lumen of the catheter, or to equipment failure. The need to change PN bags should be foreseen and changeover accomplished with minimum delay. There is insufficient evidence to support or reject the use of heparin to reduce the incidence of catheter-related thrombosis. Catheters should be irrigated with caution and never if there is no blood return. As with all i.v. therapy, local and systemic infections are a serious risk. It is a particular risk for the patient with a long-term cannula who may be immunocompromised and is receiving PN, as this forms an ideal growth medium if there is any breach of sterility. The sources of infection in PN are essentially the same as those discussed in Chapter 20 for i.v. lines. Thrombophlebitis is often cited as the most common complication associated with peripheral PN (Kingsbury 1999). It is also important to reduce the number of 'breaks' in the infusion system. Feeding lines should not be used for the administration of medications or the withdrawal of blood.

These complications can be avoided or reduced if attention is paid to the management of the line. The emphasis should be on prevention of catheter-related complications. Scrupulous attention to the care of the insertion site, infusion lines and bag changes is essential, and hospital protocols should be observed. Management by Nutrition Support Teams or Nutrition Nurse Specialists has significantly reduced the problem (Lennard-Jones 1992). Usually, changing of PN infusion bags is considered an extended role for the nurse.

Complications associated with the feeding regimen

An understanding of the processes involved in the absorption and metabolism of the nutrients used in PN enables the nurse to appreciate the potential complications that may arise during therapy. On the whole, these complications are metabolic or are associated with the nature of the fluid being administered or the speed of administration, i.e. over- or underinfusion. All feeds should be commenced at the prescribed rate, to reduce the risk of metabolic complications. As with enteral feeding, if the patient has been starved for a long period, problems can arise from sudden feeding, known as re-feeding syndrome. This is caused by a rapid shift of electrolytes, glucose and water, from extracellular to intracellular compartments, and can cause deficits in the extracellular fluid. In severely malnourished patients, feeding should always be commenced very slowly, to avoid this complication, and liaison with the Nutrition Support Team is essential (Riley 2002). The biochemical problems arise because the body's attempts to utilise different energy sources have metabolic effects and the body may not be able to cope with them. For example, high-carbohydrate infusions produce raised levels of carbon dioxide, which in turn influence the respiratory pattern, particularly of patients with concurrent respiratory problems.

Monitoring of PN

Patients need careful monitoring of clinical, laboratory and nutritional indices. These are defined in the BAPEN standards (BAPEN 1996). Baseline measurements of weight, height, temperature, pulse, respiration, blood pressure, full blood count, urea and electrolytes and liver function tests must be established. Monitoring of vital signs, weight, blood glucose and lipidaemia is critical during the immediate period following initiation of PN and regular checks are still required, daily, once PN has been established (Hamilton 2000). For those patients with diabetes, controlled with insulin, use of sliding scale prior to PN is recommended (see Ch. 5, Part 2). Those not controlled with insulin should have blood glucose monitored closely and, if it is regularly above 11 mmol/L, it is recommended that sliding scale insulin is commenced. Local protocols for monitoring the progress of PN should be consulted.

Difficulties arising from coexisting medical problems

The complexity of managing the patient receiving PN is often related to underlying medical problems, e.g. patients with hypertension, arthritis, diabetes, and renal, hepatic or respiratory diseases. Whatever the coexisting medical problems, they will influence the patient's need for, or response to, nutritional support and must be considered in the patient's nursing and medical management.

The psychosocial impact of PN

Many patients receiving PN take nothing by mouth and may have altered sensations and drives associated with both the physical and social aspects of eating. For instance, some individuals experience taste disturbances. A number may be affected by alterations to body image (McDermott 1995). Social and leisure activities may be disrupted and dress code affected by the presence of the line. It is important to support the patient and family and involve them, helping them to explore ways of adjusting or coping with the restrictions. They may require appropriate counselling. Patients on Intravenous and Naso-gastric Nutrition Therapy (PINNT) is a self-help group set up to provide support and network between patients receiving long-term PN and enteral nutrition by tube (see 'Useful websites', p. 812).

THE ROLE OF THE NUTRITION SUPPORT TEAM AND THE CLINICAL NURSE SPECIALIST IN NUTRITION

The establishment of an expert, multidisciplinary nutrition team within care settings to coordinate nutritional care has been recommended by a number of authorities (Silk 1994). Such a team is usually termed a Nutrition Support Team. In a recent UK survey, 41% of hospitals who responded reported they had a Nutrition Support Team (Elia 2002). Membership of a Nutrition Support Team varies between practice settings, but at a minimum usually includes a senior medical doctor, a Nutrition Nurse Specialist, a dietitian and a pharmacist. The team may also include a chemical pathologist and a microbiologist. The responsibilities of a team vary according to the practice setting but usually include ensuring enteral and parenteral nutrition is administered appropriately, providing nutritional education and training, conducting audit and setting standards of clinical practice in nutritional support through the development of policies and procedures. It has been suggested that the presence of a coordinated team approach leads to a reduction in complications associated with enteral and parenteral feeding (Silk 1994, BAPEN 2003). The team can also ensure that the nutritional care of patients within each care setting is standard and follows local and national policy and guidelines.

The Nutrition Nurse Specialist (NNS) is a clinical nurse specialist who works with the Nutrition Support Team. The NNS acts to ensure nursing practice concerning nutritional care is appropriate, follows policy and guidelines and is patient centred. The role of the NNS varies according to the practice setting but generally includes clinical practice, education and training, management, audit and provision of advice and guidance. Research activity may also form part of the role of the NNS.

FUTURE DIRECTIONS

Currently the nutritional care of patients in care settings does vary, both at a regional and a national level. The Council of Europe has recently published national guidelines for hospital food provision, nutritional care and support in response to concerns about levels of malnutrition in hospitals (Council of Europe 2002). In the UK, the advent of national guidelines is a big step forward in ensuring that the practice of health care professionals in the UK is guided by appropriate evidence. Within Scotland, the Nursing and Midwifery Practice Development Unit of NHS Scotland has developed several 'Best Practice Statements' which address nutritional aspects of care (see 'Useful websites', p. 812). The Clinical Resource Efficiency Support Team in Northern Ireland is developing guidelines concerning nutritional care, including home enteral tube feeding, and obesity (see 'Useful websites', p. 812). In England and Wales, the National Institute for Clinical Excellence (NICE) is currently developing guidelines focusing on nutritional support (see 'Useful websites', p. 812).

CONCLUSION

Nutritional care of patients is fundamental to good nursing practice. The importance of the role of the nurse in ensuring nutritional care is carried out appropriately and in accordance with the patient's wishes cannot be underestimated. However, the nurse does not act independently to ensure nutritional needs are met — the involvement of the whole health care team is crucial. The dietitian is central to the nutritional care of the patient and other members of the team make important contributions.

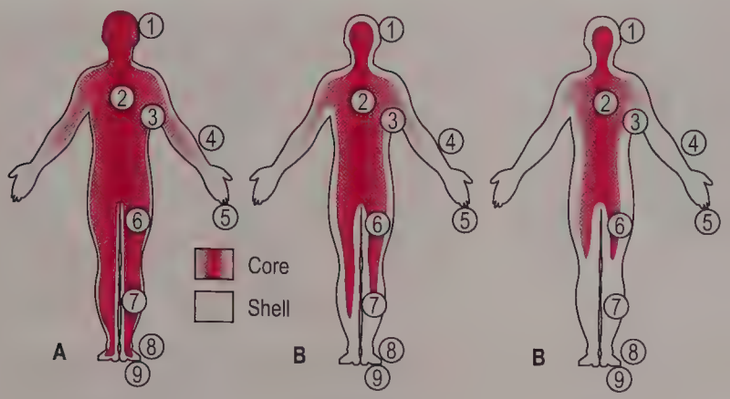
INTRODUCTION

The aim of this chapter is to provide an understanding of the factors and processes involved in thermoregulation, i.e. the maintenance of body temperature at a near-constant level. An understanding of the physical, physiological and biological mechanisms will facilitate provision of rational treatment for patients whose thermoregulatory system is disturbed (Edwards 1998). There are a number of reasons why body temperature might rise or fall from the 'normal' range, but before any decisions are made about treatment, the first step is to ensure that measurement is accurate.

Taking a person's temperature is one of the most commonly used methods for detecting disturbances in health, e.g. fever. It is therefore an extremely important clinical measurement but one which is often based on ritual rather than on rational decision making (Edwards et al 2003). The responsibility of the nurse, whether practising in the home or in hospital, is to:

- understand the mechanisms for 'normal' control of body temperature at approximately 37°C
- ensure that temperature measurements are accurate and that the body site used for temperature measurement is appropriate
- monitor and evaluate the impact of any treatments used to regulate body temperature.

It is for the above reasons that patients should have their temperature measured and assessed by a qualified nurse or nursing student under supervision.



NORMAL BODY TEMPERATURE

'Body temperature' is a rather imprecise term, because the body is not at a uniform temperature. For example, skin temperature varies considerably. The skin has been described as a mosaic of temperatures and even 'core' (deep body) temperature can vary slightly. For this reason it is good practice to use the same body site for each temperature measurement and to report the temperature of the site used, e.g. 'Axilla temperature of Mr A on admission to hospital was 36.9°C' or 'Oral temperature of Mrs B was 37.1°C'.

The temperature of the tissues of the body

Surface temperature

Under most circumstances, the skin surface or 'body shell' is the coolest part of the body. The organs, blood and deeper tissues are described as the body 'core' (Tortora & Derrickson 2006). Because the temperature of the skin is influenced greatly by the temperature and humidity of the air (ambient conditions) (see Fig. 22.1), thermometers which measure skin temperature (see 'Infrared radiation thermometers', p. 820) are not sufficiently accurate for precise monitoring of temperature in sick patients where deep body temperature measurements are more reliable. In most circumstances the skin temperature will be lower than the temperature of the axilla, ear, mouth or rectum.

	Site	A (°C)	B (°C)	C (°C)
1	Scalp	36.0	34.8	32.8
2	Chest	35.8	34.5	31.3
3	Axilla	36.5	36.4	36.4
4	Arm	35.9	33.5	27.6
5	Finger	35.9	33.2	21.0
6	Thigh	35.2	33.4	27.8
7	Leg	35.3	30.1	25.2
8	Foot	35.5	29.7	22.7
9	Toe	36.2	29.1	21.4

Fig. 22.1 Core temperature and temperature of the skin surface at various sites in a hot, a thermoneutral and a cold environment. (Based on an original figure by Aschoff & Wever, cited in Stainer et al 1984, with additional data from Childs C.)

22.1 After examining the temperature data given in Figure 22.1, answer the following questions:

(a) What is the reason for the change in the size of the shell between A and C?
(b) What is the explanation for the higher skin temperatures at the extremities in A compared with C?
(c) What do you notice about the skin temperatures measured over the thigh, leg, foot and toe in A? Why is the pattern of skin temperature in A different from the patterns in B and C?

Deep body (core) temperature

The organs, e.g. heart, liver and brain, and blood (i.e. body core tissues) are 'insulated' from environmental conditions by body fat and skin. The temperature of the body core is generally higher than skin temperature. The liver, kidneys, brain and myocardium have a high metabolic rate and consequently a higher temperature than tissues with a lower rate of metabolic activity such as smooth muscle (Houdas & Ring 1982). Just how much the different core temperatures vary has been the subject of a study by LeFrant et al (2003). This study supports earlier work demonstrating that whilst differences exist between body core sites such as rectum and urinary bladder, any differences are small (Childs et al 1999). This goes some way to dispel the notion that rectal temperature 'lags behind' other core sites.

REGULATION OF BODY TEMPERATURE

Current understanding is that mammalian thermoregulation is controlled by the brain. Observations made in the early 19th century revealed that the body cooled down after severe damage to the spinal cord. Over a century later, the importance of the hypothalamus in the control of body temperature, specifically the pre-optic region within the anterior portion of the hypothalamus (POAH), became recognised as the integrating centre for temperature regulation in the mammalian brain (Berner & Heller 1998). Sensory signals (afferents) from thermoreceptors in the skin and organs are transmitted to and integrated within the POAH, which then responds appropriately by transmitting outgoing (efferent) signals to effector organs. If incoming signals indicate that the body is above the 'normal' thermostat temperature, i.e. >37°C, often referred to as the temperature 'set-point', an 'error signal' is received. The error signal is a useful concept borrowed from engineering theory to describe incoming sensory signals which differ from the brain's thermostat reference temperature. When an error signal is received, the nervous system stimulates activities which protect the person from overheating or from becoming too cold.

For example, if the temperature of the blood bathing the cells of the hypothalamus starts to rise above 'normal' (37°C), as in a fever, the outgoing, or efferent, signals stimulate 'effector' mechanisms so that heat is lost from the body. Conversely, if the incoming blood is at a lower temperature than the reference (set-point) temperature (i.e. <37°C), mechanisms to conserve or produce heat will be activated. In this way, deep body temperature is prevented from fluctuating greatly from its biological set-point of 37°C. The pathways which help maintain body temperature at a constant level are discussed below (see also Fig. 22.2A).

Mechanisms of heat conservation and heat production

Heat conservation

If skin or blood temperature falls, signals from peripheral thermoreceptors, e.g. in skin, are interpreted at the POAH and the heat-promoting centre stimulates mechanisms to retain heat as well as to increase the amount of heat produced within the body (endogenous heat production).

Behavioural thermoregulation The ability of humans to conserve heat by putting on more clothes or seeking shelter from a 'hostile' environment is often overlooked or forgotten, but such behaviours are the most fundamental of the protective thermoregulatory activities and are the 'first line' of defence against extreme heat or cold. Very young and very old people, as well as those who are immobile due to illness or sedation, are unable to protect themselves from heat or cold in this way and are therefore more vulnerable to changes in environmental temperature. It then becomes the responsibility of the nurse to place the patient in a warm and comfortable environment to ensure that thermal homeostasis is achieved.

Peripheral vasoconstriction At about the same time that a person begins to feel cold, changes in the flow of blood

to the skin also occur. Nerve impulses from the POAH which are concerned with heat conservation cause blood vessels, particularly in the hands, feet, ears and nose, to constrict. Sympathetic stimulation to nerves supplying the blood vessels in these acral regions results in both peripheral vasoconstriction and a reduction in the flow of warm blood from internal organs to the skin. The result is that heat is retained or stored within the body, where it helps maintain the core tissues at or close to 37°C.

In situations where body temperature continues to fall, despite the above measures, additional mechanisms that involve endogenous metabolic heat production come into play in order to restore body temperature to normal (see non-shivering and shivering thermogenesis below).

22.2 What steps should be taken by a nurse to help a patient with a low core temperature to retain body heat? What are the harmful or adverse effects of allowing a patient to shiver continuously?

Heat production

In a healthy young adult, the metabolic rate is between 35 and 39 kcal/m^2 body surface/h. In an infant, metabolic rate is 53 kcal/m^2 body surface/h. This difference can be explained by the fact that the rapid synthesis of cells in the growing body of a child contributes to an increased metabolic heat production. Metabolic rate may rise well above the normal limit for a given age in sick or injured patients, particularly those who are febrile and/or have an infection (Childs & Little 1994, Jenney et al 1995).

In early studies (Wilmore 1977), patients suffering from serious burns (see Ch. 30) were found to have a very high metabolic rate; consequently endogenous heat production was almost double that of a healthy person of the same age. The high metabolic rate and heat production were thought to contribute to the very high fever which developed after a major burn. More recent studies suggest, however, that improvements in surgical management, wound care and analgesia have ameliorated the enormous increases in metabolic rate and demand for energy (Childs 1994). As a consequence, the metabolic response to major burn injury is lower than shown in earlier studies; however, fever persists as a common symptom of burn injury (Childs 1994).

Any activity or event which increases the rate of chemical reactions in cells and rate of oxygen uptake by the cell increases metabolic rate and thus the amount of metabolically produced heat (Frayn 1997). Body heat is produced in two ways: chemically by non-shivering thermogenesis and physically by the rhythmical contraction of skeletal muscle, i.e. shivering thermogenesis.

Non-shivering thermogenesis Although peripheral vasoconstriction is very effective in helping to conserve heat, additional heat may be needed to restore body temperature to 'normal'. Initially, this is achieved by non-shivering thermogenesis (NST). As its name implies, NST does not involve muscular contraction to stimulate endogenous heat production, but relies upon release of the thermogenic hormone noradrenaline under the control of the sympathetic nervous system. Although muscle tissue is the most important source of chemically produced heat, other important heat-producing organs are the brain and liver.

Shivering thermogenesis People who are cold shiver, but it should be remembered that shivering does not continue indefinitely (see 'Hypothermia', p. 827). The heat conservation area of the brain stimulates an increase in muscle tone, i.e. shivering, which can increase heat production to five times the basal rate. Shivering occurs in most skeletal muscles but the greatest intensity of shivering thermogenesis is in the jaw and neck and is least in the legs. The repetitive contraction of muscle is not, however, a very economical process, as only 40% of the heat generated in shivering is retained by the body.

Mechanisms of heat loss (see Fig. 22.2B)

High air temperatures and strenuous exercise will raise the temperature of the blood. If the heat gained during the exercise is not matched by an equivalent rate of heat loss, heat-losing mechanisms are initiated and heat-conserving mechanisms are inhibited. The series of events which protect the brain and core tissues from reaching dangerously high temperatures are as follows:

- A high air temperature warms the skin. The rise in skin temperature is detected by skin thermoreceptors which send afferent signals to the thermoregulatory centre in the POAH.
- The first reaction of the person is to reduce body insulation by removing some clothing.
- At the same time, blood vessels in acral regions (hands, feet, ear lobes and nose) dilate so that more blood is brought to the surface of the skin. Areas of the body, such as the face and ears, will then appear 'flushed', pink and warm.
- Providing the air temperature is lower than the skin temperature, heat will be lost by radiation and convection (see Table 22.1). If, however, the air temperature is higher than skin temperature, the person will gain heat from the environment. This is why evaporative heat loss becomes so important when the temperature gradient between skin and air is narrow, i.e. when skin temperature is close to air temperature.
- Stimulation of sweat glands in hot conditions is controlled by the sympathetic nervous system. Production of a fluid consisting mostly of water, but also containing salt, urea, lactic acid and potassium ions, onto the skin causes cooling when the thermal energy needed to transfer the fluid to a gas is removed from the body, i.e. from the skin surface to the air. This transfer of energy from a fluid to a gaseous state is called vaporisational heat loss and occurs during heat loss by sweating.

22.3 What is the most important route for heat loss in a warm environment?

22.4 What is the collective term used to describe heat loss by radiation and convection?

22.5 Find out which areas of the body are described as 'acral regions'. What is their specific function in thermoregulation?

22.6 After a bath, patients often feel cold and uncomfortable if the nurse is slow in helping them to dry themselves. What is the cause of this feeling of

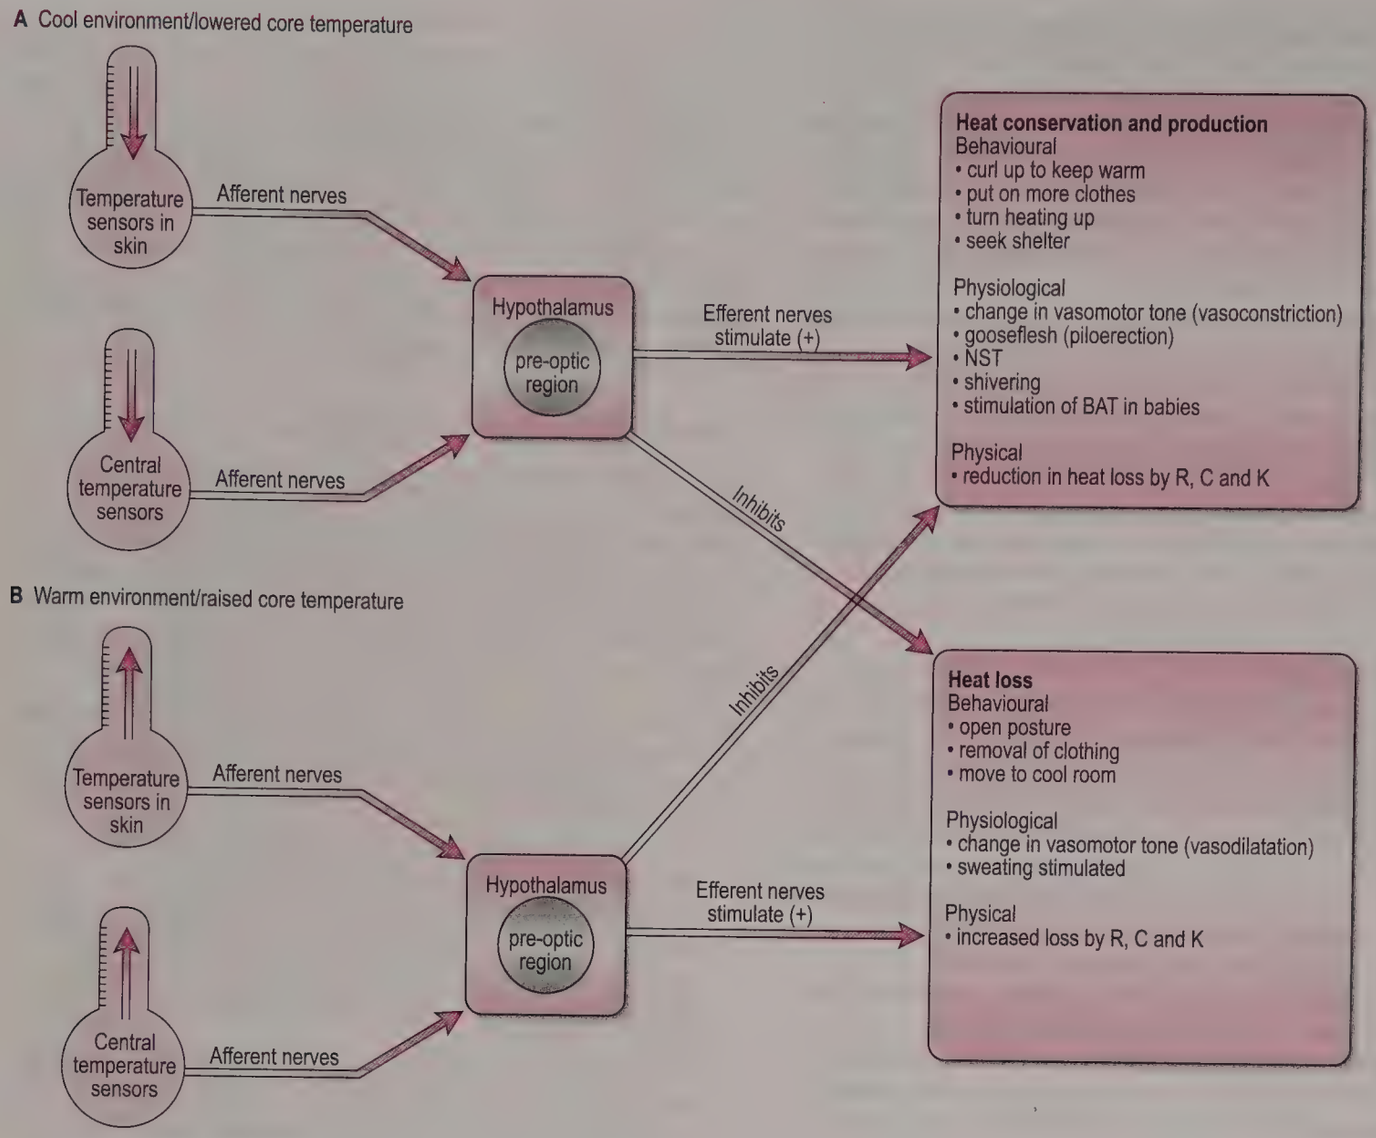


Fig. 22.2 Control of body temperature. A: Responses to a cool environment or lowered core temperature. B: Responses to a warm environment or raised core temperature.

discomfort when the body is wet and the room temperature low? Why would leaving the door of the bathroom open make the patient feel cold? How can the nurse improve the patient's comfort when preparing them for a bath?

FLUCTUATIONS IN A HEALTHY PERSON'S TEMPERATURE

Humans are able to make both physiological and behavioural adjustments to maintain deep body temperature close to 37°C. Like many mammals, humans have the ability to increase the amount of heat in the body as air temperature falls, or to increase heat loss when conditions become uncomfortably hot. It is for this reason that humans are able to survive in most climates on Earth.

Normal temperature range

Although central or hypothalamic temperature is 'set' at a relatively constant level, fluctuations do occur in healthy people, e.g. following exercise. No harm is done to the cells of the body by a change in temperature, providing core temperature does not rise above or fall below certain limits. Indeed, the ability of the thermoregulatory system to stimulate changes in heat production or heat loss indicates that the system is operating efficiently.

In his classic monograph, DuBois (1948) illustrates the range of 'normal' temperature in health. In the early morning or during cold weather, body temperature may fall to 35–36°C. After moderate exercise, and also, for example, in crying babies, core temperature may rise to approximately 38°C; after hard exercise, body temperature can reach 40°C without causing harm. However, an increase of approximately 5°C above 37°C indicates a serious disruption of thermoregulation and a person's life may be at risk if deep body temperature rises above 43°C or falls below 24°C.

22.7 During one shift of duty, find out how many patients have a high temperature and then answer the following questions:

(a) Give the highest and lowest measured temperatures for each of the patients you have identified as having a pyrexia.
(b) State the site used to measure deep body temperature for each patient.
(c) Has the pyrexia been reported?

Table 22.1 Principles of heat transfer

Route for heat loss	Principle	Relevance to clinical practice
Radiation (R)	Transfer of energy in the form of electromagnetic waves. The human body emits heat as infrared radiation. At the same time all dense objects (furniture, buildings, other people) are also radiating heat. The rate at which heat is emitted from the human body is dependent upon the temperature difference (gradient) between the skin and other objects and surfaces in the room. If the skin is hotter than the average temperature of objects in the room, heat will be lost. If the objects in the room are hotter, the body will gain heat	A person, naked, sitting quietly in a room at 25°C loses between 50 and 70% of heat by R, the major route for heat loss under such conditions. As air temperature increases, the temperature gradient between skin and air falls such that less heat is lost by this route. As air temperature rises towards skin temperature (35°C), the gradient will be so small that very little heat loss can take place by this route. Evaporative heat loss then becomes an important route for heat loss
Convection (C)	Air (or water) next to the body warms and moves slowly away because warm air is less dense and rises. As it moves away from the body, cooler air replaces it. This process can be speeded up if a strong draught (e.g. electric fan) is used to force the air away and cause a rapid replacement of warmed air with cool air	Nurses frequently increase the rate of heat loss by convection by placing electric fans close to their patients. This can be a very efficient way to lower skin temperature, but frequently the cool stimulus results in an inappropriate response, i.e. peripheral vasoconstriction. Heat retention within core tissues then causes core temperature to rise rather than fall. In febrile patients who have an elevated set-point, the use of electric fans is likely to exacerbate the problem of pyrexia
Conduction (K)	Heat loss by K involves transfer of thermal energy from atom to atom. The skin must be in contact with cooler or hotter objects for heat exchange to take place by K	Critically ill patients are often nursed on special beds designed to reduce the incidence of pressure ulcers. These beds are often maintained at a constant temperature to help prevent heat loss from the body. Sometimes the thermostat can fail and patients have been known to overheat or to cool because the temperature of the bed is too high or too low. Patients must be protected from body temperature disturbances of such an iatrogenic nature
Evaporation (E)	Evaporation of water from the skin and respiratory passages is the most important route for heat loss in hot conditions. The evaporation of water occurs when energy transforms water and sweat droplets to a gas. The heat (or thermal energy) needed to drive this process is taken from the body. Thus the more water there is on the skin, the more heat is taken from the body to turn it into a gas (vaporisation). The more heat removed from the body in the process of E, the more the body cools. The function of sweat (produced under the control of the sympathetic nervous system) as an agent for vaporisational heat loss can be enhanced by spraying the body with a fine mist of warm water	Patients with a high core temperature may not always sweat. During a rise in rectal temperature the body responds as though it were too cold and if patients are observed carefully it will be seen that their skin is dry. At this stage the hypothalamic set-point is above normal but the body continues to activate heat-conserving mechanisms to achieve the new set-point temperature. Only when the patient has reached the new central temperature set-point will heat loss by all routes (E included) be activated. Thus when nurses notice that patients with a high core temperature are sweating, it is more likely to indicate that core temperature has reached the new set-point. A fall in body temperature may then follow

(d) What are the possible reasons for the pyrexia?
(e) Has the cause been identified and treated?
(f) How frequently is the temperature being monitored?

Circadian rhythm

Body temperature fluctuates in a characteristic pattern over a 24-h period. It is thought that this pattern is a result of regular, but normal, deviations of the body's own thermostat or hypothalamic set-point temperature. As with many other physiological functions, thermoregulation displays a circadian rhythm or diurnal variation. This rhythm persists during short periods of night work. Eventually, however, regular night work will reverse the normal pattern so that lower temperatures occur during the day and higher temperatures at night.

In general, the lowest temperatures recorded over a 24-h cycle will be approximately 0.5°C lower than the afternoon temperature. By the evening, body temperature may be as much as 1.0°C above the early morning temperature. In the newborn, a circadian rhythm of core temperature is not fully developed (Waterhouse et al 2000).

An awareness of the normal changes in deep body temperature in health is necessary if nurses are to interpret

temperature measurements correctly. For example, a moderately elevated axilla temperature recorded during the afternoon should be monitored closely before any action is taken because of the cyclical nature of body temperature, otherwise treatment for pyrexia could be instigated unnecessarily.

22.8 For this project you will need to measure the temperature of a healthy person every 2–4 h. You will need to ask for help from your partner, parents, siblings or friends — someone who will not mind being woken at night for the sake of this exercise. Plot your subject's oral temperature every 2–4 h for 24 h onto graph paper. From the data you collect, try to identify a circadian rhythm in your subject. State the highest and lowest temperatures recorded over the 24-h period. You should now be able to state the overall variation in body temperature of a healthy subject.

Other factors affecting a healthy person's temperature

Age The age of a patient must be taken into account in the interpretation of body temperature.

Babies and young children As long ago as 1937, Bayley and Stolz showed that rectal temperature begins to rise during the first 7 months of life, remaining fairly constant until the age of 2 years, after which it begins to fall. Average rectal temperature at age 1 month was reported to be 37.1–37.2°C, at 8 months 37.6–37.7°C, and at 18 months 37.7°C. By the time the children in the Bayley and Stolz study approached their third birthday, rectal temperature had settled to 37.1°C.

Healthy children tend to have a higher deep body temperature than adults and therefore their 'normal' range differs slightly. Higher temperatures in early childhood are thought to be a result of increased cellular and metabolic activity. The young of most mammals have a large body surface area relative to their body weight. As a result, babies have a higher risk of hypothermia because they cannot shiver and cannot increase their body insulation, as can adults, by putting on more clothes. This means that the naked baby will lose relatively more heat than the adult for every square metre of their body surface. Babies are therefore reliant on parents and carers to protect them from extremes of environmental temperature.

To counteract their vulnerability to increased heat loss, babies have an important source of body heat in the form of brown adipose tissue (BAT), a specialised type of fat cell (Cannon & Nedergaard 2004). BAT is a unique type of adipose tissue, shown by Hull (1976) to be an important source for heat production in small hibernating mammals and has been described as the 'hibernating gland'. BAT is also stimulated in the human newborn infant. Under the control of the sympathetic nervous system, the function of BAT is to transfer energy from food into heat (Cannon & Nedergaard 2004). BAT is activated after birth. In babies, BAT has probably played a role in the evolutionary success of mammals. BAT can be found around the kidneys, between the shoulder blades, around the great vessels and deep within the axillae (Frayn 1997). BAT is richly supplied with blood and oxygen and this dense blood supply is responsible for its brown colour. It becomes much less important in maintaining the temperature of the body as a baby gets older. In adults, BAT is scarce and probably not functional (Klaus 2004).

Adults and older people Unlike small infants, who rely principally on 'switching on' heat production to maintain a stable deep body temperature, adults are more efficient at conserving body heat. In other words, they rely on preventing body heat from being lost, either by putting on more clothes (behavioural thermoregulation) or by vasoconstriction at the extremities (physiological thermoregulation).

Older people, however, often have a lower body temperature than children or younger adults, for which there are a number of reasons:

- After the age of about 50 years, the metabolic rate starts to decline and, correspondingly, metabolic heat production also falls. Consequently, deep body temperature tends to be lower.
- Social and economic factors contribute to the inability of some older people to keep warm, particularly in winter, because, as people grow older, it is more difficult for them to detect extremes in temperature (see Ch. 35). This puts them at risk of hypothermia (see Box 22.1).
- In warm conditions, deep body temperature in older people may rise slightly because the ability to sweat is reduced. Evaporative heat loss is therefore less efficient at a time when increased heat loss is needed to keep the temperature within the normal range.

22.9 When you have the opportunity, either at work or at home, record the temperatures of three or four people before and after they take a hot drink and before and after they smoke a cigarette. What differences do you observe?

Exercise Vigorous exercise can raise both oral and rectal temperature by several degrees. Temperatures above 40°C have been recorded in marathon runners and, after a game of rugby, rectal temperatures over 39°C can occur. This rise in temperature can persist for many hours and represents an imbalance between heat production and heat loss (see pp. 814–816).

The menstrual cycle It is now well recognised that 80% of healthy women have higher oral temperatures at the time of ovulation and a record of early morning oral temperature is used to reflect this.

On waking, oral temperature should be recorded before getting out of bed. This provides a resting, baseline temperature. Body temperature should then be recorded at the same time every day throughout the cycle. A slight drop in temperature occurs 24–36 h after ovulation. Temperature then rises abruptly by 0.3–0.4°C and continues at this slightly higher level for the rest of the cycle. Three days after the onset of the higher temperature is generally thought to coincide with the end of the fertile phase. The 'hot flushes' associated with the menopause are discussed in Box 22.2.

Eating a meal Mastication, digestion, absorption and assimilation of nutrients produce body heat. This metabolic heat production was originally described as the specific

Box 22.1

Helping older people to keep warm in winter

There will always be cold spells during the winter months and some will be much worse than others. Weathermen frequently refer to the more extreme conditions as a 'cold snap' and their advice, particularly to older people who are watching their forecast on television, is to make sure that they keep warm. The problem is that keeping warm usually means keeping the heating on for longer than usual, with a consequent rise in heating bills. In recognition of this, the government provides a small annual winter fuel payment to all pensioners. However, older people become cold for many reasons and not only during extremely cold spells.

The housing stock in which many older people live becomes damp and cold if maintenance and repairs are not kept up to date. It is expensive to keep old houses warm at any time of year, but especially in winter. If older people cannot be persuaded to keep their heating on during the winter, it can be helpful for family, friends and neighbours to offer good advice about keeping warm.

The obvious suggestion for someone on a low income would be to heat just one room, i.e. the room in which most time is spent. An alternative is to conserve body heat by wearing extra layers of clothes. These should be comfortable but effective in retaining body heat. The most important principle to remember is that there is no particular merit in one kind of material compared to another, except in its capacity to trap air. Clothes made of cotton are as good as down feathers in this respect. The problem is that feathers can be easily compressed, and when this happens the insulating properties are reduced. It is worth advising people who use a down quilt to keep it 'fluffed' for maximum insulation.

Covering parts of the body exposed to draughts, i.e. hands, feet and head, should be done in much the same way as for a person in a cold climate. Although the head is generally heated by a plume of warm air rising upwards from the body, this band of warm air can be blown away if the person is sitting in a draught. People who spend a lot of time relatively immobile in a draughty house should be advised to wear something on their head like a hat, cap or even a Balaclava. The reasons for taking so much care to keep warm are obvious: lives can be saved by these simple yet effective actions.

In December 2003, the discovery of two pensioners who had died weeks after their gas supply was cut off, because of an unpaid bill, sparked huge media coverage and general concern about the plight of older people dying as a result of fuel debt. Age Concern has published data on their website (see 'Useful websites'), stating that in 2001 there were 10.8 million older people in the UK. In the year 2000, 165 people aged 65 years or over died as a direct result of hypothermia. These data were obtained from the information given on the death certificate. However, many more deaths may be indirectly related to accidental hypothermia in our older population.

The UK remains one of the worst countries in the world at coping with unseasonal low temperatures and everyone needs to be vigilant about looking after older family members and neighbours during a 'cold snap'.

Box 22.2

Hot flushes

The exact cause of 'hot flushes' in menopausal women is not known, but there is evidence that a defect in thermoregulatory function may be responsible for the discomfort and distress associated with the hot flush. The two physiological changes which characterise hot flushes are sweating and cutaneous vasodilatation. During a hot flush, central temperature falls in response to heat lost from the skin surface after peripheral vasodilatation and sweating. Sufferers feel very warm and uncomfortable and want to cool themselves. Since the flushes frequently occur at night (night sweats), they can cause great distress and make it difficult to get a good night's sleep.

It is thought that hot flushes are the result of a sudden fall in the central hypothalamic thermostat. This would result in the body being too hot and stimulating heat loss mechanisms such as sweating and vasodilatation. Over 25% of women who had between 3 and 12 months' amenorrhoea, and 37% who were menopausal, experienced hot flushes several times a day (Guthrie et al 1996). Because hot flushes occur during the climacteric and are associated with cessation of ovarian function, their underlying cause is thought to lie in changes in the endocrine system.

Reporting of hot flushes is greatest 3 months or more after the final menstrual period. The frequency of hot flushes is associated with increasing follicle-stimulating hormone (FSH), a reduction in estradiol and a history of menstrual complaints. Since oral oestrogen replacement therapy is highly effective in alleviating hot flushes and night sweats, a hormonal cause for the symptoms seems evident (MacLennan et al 2001).

dynamic action (SDA) of food. Metabolism of protein has a greater effect in generating heat than the metabolism of carbohydrate or fat. Today, the term 'diet-induced thermogenesis' (DIT) is more often used (Frayn 1997).

The source of body heat — chemical thermogenesis

Heat is expressed in 'energy units' called calories (cal), or more usually in larger units, kilocalories (1 kcal = 1000 cal). The SI unit for energy is the kilojoule (1 kJ = 4.18 kcal).

Since nurses are involved in measuring body temperature, it is important for them to understand how body heat is generated. Most of the energy needed for growth and repair of tissues, for work and for body warmth comes from the food we eat. Most packaged foods have a label which gives the amount of energy (in kcal or kJ) contained in an average serving (or per 100 g) when oxidised or burned by the body. Heat is a by-product of oxidation and the process by which it is produced is called chemical thermogenesis. The rate at which heat is produced in the body is referred to as the metabolic rate.

Metabolic rate

If an awake, resting, lightly clothed man fasts overnight for 12 h in a warm (28–30°C) room, his metabolic rate, and thus his energy expenditure, will be at a minimum or basal level (basal metabolic rate, BMR). If the man increases his activity, by walking, exercising or even shivering, metabolic rate will rise because more oxygen is being utilised. When this happens, some of the additional energy will be used in order to perform the exercise, i.e. to move from sitting to walking (between 2 and 25%, depending on the activity), but most will be lost as heat.

A business man or woman spending most of the day at the office and taking little exercise has a relatively sedentary lifestyle. They can expect to increase their energy requirements by 25–40% above the basal rate during the course of a day. Assuming that all their energy requirements were provided from the food they ate on that day (100%) and no energy was stored, approximately 10% would be lost as heat, as a by-product of the work involved in processing their food, 50% would be lost as heat in the conversion of potential energy in food to high-energy biochemical bonds, and 20% would be lost as heat as a result of internal work, e.g. respiration, cell pumps, glandular activity. In this example, only 20% of the individual's energy intake would be used for external work, e.g. muscular contraction for walking, and the remaining 80% is lost as heat (Wilmore 1977). It is clear that utilisation of food energy is a very inefficient process because most of our energy intake is lost as heat. However, the rate at which heat is produced does not necessarily reflect the rate at which it is lost from the body, because heat can be retained and stored. One of the most important stimuli for body heat storage is a slight fall in core temperature, particularly if the person is in a cool environment. Although a large amount of the energy from food is lost from the body as heat, it is known that many people eat more than is required. Thus, if the amount of calories ingested in food is in excess of the amount of calories used, then energy is stored and the person gains weight. If this is the case, the person is said to be in positive energy balance (see Ch. 21).

THE MEASUREMENT OF BODY TEMPERATURE

Thermometers

The clinical thermometer

The development of a reliable thermometer was made possible only after scientists came to an agreement about the meaning of temperature and devised a scale to measure it. The scale with which most nurses will be familiar in clinical practice is the Celsius or centigrade scale determined by Anders Celsius (1701–1744). The mercury-in-glass thermometer has been the standard temperature-taking instrument for the last century. For many years it was the most practical way of measuring oral, axilla and even rectal temperature, but with modern instruments and techniques the mercury-in-glass thermometer is now rarely used.

Infrared radiation thermometers

Radiation from the sun travels through space mostly in the form of visible light and infrared rays. On striking a body, these waves are partly reflected and partly absorbed and can cause a rise in temperature. The skin absorbs as well as radiates infrared waves (infrared radiation). These waves are part of a 'family' of waves called the electromagnetic spectrum and can be detected with the aid of a special lens (detector) incorporated into a hand-held thermometer.

The tympanic thermometer

This is the basic principle behind the tympanic (ear) thermometer which detects radiant heat emitted from the tympanic membrane. Since the tympanum (ear drum) shares a blood supply with deep parts of the brain, tympanic temperature is considered to be a very good substitute for deep body, even brain temperature.

The key point in this measurement technique is to ensure that the 'lens' is inserted correctly so that it can 'see' the tympanum. If the lens is focused towards the skin of the ear canal, the measurement is likely to be inaccurate. Tympanic thermometers are safe for use even in babies, do not present any risk of perforation to the ear drum and a recording is available in 1–2 s. The problem is that the accuracy of tympanic thermometers has been questioned. When comparisons were made of results from three different brands of tympanic thermometer with results from rectal thermometers, the data suggested that the tympanic thermometers had an unacceptable sensitivity (Hoffman et al 1999). In the Emergency Department where the thermometers were tested, differences between tympanic and rectal temperature were as much as 2°C. These data support the results of earlier studies (Talo et al 1991, Brogan et al 1993, Childs et al 1999) and a more recent meta-analysis (Craig et al 2002) confirmed that tympanic thermometers are frequently unreliable as a surrogate for 'true' core temperature.

Skin surface thermometers

Small infrared thermometers have also been developed to measure the skin surface temperature. The great benefit of these instruments is that they can be held in the nurse's hand just a few centimetres from the skin surface and a measurement can be made in a few seconds. The thermometer does not need to touch the skin. This is a useful way to measure skin temperature, e.g. after trauma or vascular surgery, since the temperature of the skin surface gives a reasonable indication of skin blood flow (Stoner et al 1991).
