HAE is commonly categorized as laryngeal, gastrointestinal, or cutaneous. Swelling of the skin is usually diffuse, nonpruritic, and not accompanied by urticaria. Attacks of swelling in patients with HAE generally involve the extremities, abdomen, genitourinary tract, face, oropharynx, or larynx and follow a stereotypical pattern in which the swelling worsens over 24 hours, peaks, and then slowly resolves over the following 48 hours. Gastrointestinal edema may cause abdominal pain severe enough to be incapacitating. Typically, attacks last 2 to 4 days and resolve without intervention; however, attacks can occasionally affect the subcutaneous and submucosal tissues in the region of the upper airway and can be associated with respiratory obstruction and asphyxiation (Cicardi & Zuraw, 2018a).

Medical Management

Attacks usually subside within 2 to 4 days, but during this time the patient should be observed carefully for signs of laryngeal obstruction, which may necessitate tracheostomy as a lifesaving measure. Epinephrine, antihistamines, and corticosteroids are commonly administered in an attempt to relieve HAE; however, these are often ineffective. A trial of high doses of second-generation H_1 antihistamines for 1 month may be effective in some patients. If this proves unsuccessful, C1INH concentrate, derived from human plasma, recombinant human C1INH (rhC1INH, conestat alfa), icatibant, a synthetic bradykinin beta-2-receptor antagonist and ecallantide, a recombinant plasma kallikrein inhibitor are agents that are available (Cicardi & Zuraw, 2018b). Nurses need to be prepared to use different emergency approaches in the treatment of HAE and to have lifesaving equipment readily available.

Cold Urticaria

Cold urticaria is a type of physical urticaria. Physical urticarias are inducible urticarias that are stimulated by environmental triggers. Cold urticaria is the development of wheals (hives) or angioedema due to exposure to cold. Mast

cells release histamine and inflammatory mediators are stimulated in response to skin contact with cold objects, cold fluids, or cold air. It is an IgE-mediated atopic immune reaction. Cold urticaria most commonly affects young adults as a self-limited disorder that occurs over a period of 5 to 6 years.

Clinical Manifestations

The patient feels a burning or pruritic sensation and the skin is erythematous due to activation of sensory nerves and vasodilation of arterioles. Most commonly it is a localized reaction in areas exposed to cold. However, extensive cold contact, such as swimming in cold water, may result in systemic reactions, ranging from generalized urticaria to anaphylaxis, with symptoms involving the respiratory, gastrointestinal, and/or cardiovascular systems. Oropharyngeal angioedema, which can cause suffocation and severe hypotension, has been observed in some persons with the disorder (Maurer, 2019).

Medical Management

Cold urticaria is diagnosed by cold stimulation testing. An ice cube within a thin plastic bag of cold water is applied to the volar aspect of the forearm for 1 to 5 minutes. A positive test results in development of urticaria at the site. The test is considered positive if the test site shows a palpable and clearly visible wheal-and-flare skin reaction upon rewarming. All patients with any form of cold urticaria should carry an autoinjectable epinephrine device for emergency use because hives can progress to anaphylaxis. Pretreatment with an antihistamine prior to predictable cold exposure is recommended, because clinical experience suggests that antihistamine pretreatment can prevent skin reactions and systemic reactions (Maurer, 2019). Patients with cold urticaria refractory to antihistamines can be treated with immunomodulator agents, such as omalizumab, certain antibiotics, leukotriene receptor antagonists, or cold desensitization therapy (Khan, 2019b).

Nursing Management

Prevention involves avoidance of cold stimuli. Patient education is needed about what environmental conditions can stimulate a reaction. For instance, patients should be instructed to expose a small section of the body to the water of a swimming pool prior to submerging the body in water. A wet suit can be used during swimming. Patients should understand that cold foods and beverages can stimulate oropharyngeal angioedema or anaphylaxis and should be avoided. Patients anticipating surgery may develop a reaction to the cold air within operating rooms and are instructed to alert surgical personnel that they

have cold uriticaria and should be kept warm during any procedures. Cold intravenous solutions can also provoke a reaction (Singleton & Halverstam, 2016).

Food Allergy

Food allergy is an adverse reaction to certain foods due to immunologic mechanisms. Food allergies are categorized as either IgE-mediated or non–IgE-mediated allergies. IgE-mediated food allergy, a type I hypersensitivity reaction, occurs in about 5% of adults. IgE-mediated food allergy is more common and better understood than non–IgE-mediated food allergy (Commins, 2019). Recent studies show that within the population there are many with the misconception that they have a food allergy (19%) compared to persons with true immune-mediated food allergy (10%) (Gupta, Warren, & Smith, 2019).

Almost any food can cause an IgE-mediated allergic reaction. Allergic reactions can range from cutaneous urticaria to anaphylaxis. Fish and shellfish (e.g., lobster, shrimp, crab, clams, fin fish) as well as peanuts and tree nuts (e.g., cashew, walnut) are the two food groups that cause the majority of adult food allergies (Gupta et al., 2019). Other common foods causing allergy include cow's milk, eggs, soy, and wheat. Allergens are proteins and there is a danger that cross-reactivity can occur in foods containing similar proteins (AAAAI, 2018).

OAS, or pollen-food allergy syndrome (PFAS or PFS), is the most common form of IgE-mediated food allergy in adults. OAS often occurs in persons who are also allergic to pollen that causes seasonal allergic rhinitis. Raw fruits and vegetables often cause OAS but cooked fruit and vegetables do not (Burks, 2019).

Non–IgE-mediated food allergies present as more subacute and/or chronic symptoms that are typically isolated to the gastrointestinal tract and/or skin.

Clinical Manifestations

Acute urticaria and angioedema (swelling of the mouth, face, lips, tongue, and throat) are the most common clinical manifestations of food allergy. The reaction develops within minutes to hours after eating the offending food. The clinical symptoms may include wheezing, cough, laryngeal edema, and gastrointestinal symptoms (abdominal pain, nausea, cramps, vomiting, and diarrhea). Tree nuts and peanuts can cause the most severe allergic reactions evolving into anaphylaxis.

Assessment and Diagnostic Findings

Diagnosis of food allergy requires clinical history, physical examination, trial elimination diets, diet diaries, skin prick testing (SPT), and allergen-specific serum IgE immunoassay. A patch test is used if non–IgE-mediated food allergy is suspected. However, the standard is clinician-supervised oral food challenges to confirm or rule out the diagnosis. SPT is used to identify the source of symptoms and assists in identifying specific foods as causative agents. The patient is injected with a minute quantity of food antigen under the skin. Then the patient and primary provider wait to observe if hives and erythema arise within the 15 minute period. If the allergen triggers mast cells to release histamine, a localized wheal will be raised in the skin. A positive skin prick test for IgE-mediated food allergy is diagnosed when a wheal of 3 mm in diameter is raised within 15 minutes. A different kind of test, referred to as a 48-hour atopy patch test, is used for non–IgE-mediated food allergy. This is a topical application of food allergen that is applied to the small surface area of skin. This is a delayed reaction that requires 48 hours of observation (Andreae & Schreffler, 2019).

Medical Management

Therapy for food hypersensitivity includes avoidance of the food responsible for the hypersensitivity. Pharmacologic therapy is necessary for patients who cannot avoid exposure to offending foods and for patients with multiple food sensitivities not responsive to avoidance measures. Medication therapy involves the use of H_1 blockers, antihistamines, adrenergic agents, corticosteroids, and cromolyn sodium. All patients with food allergies, especially seafood and nuts, should have an autoinjectable epinephrine device prescribed. Another essential aspect of management is educating patients and family members about how to recognize and manage the early stages of an acute anaphylactic reaction.

Oral immunotherapy (OIT), or tolerance induction, is an increasingly used treatment. The patient ingests very small amounts of the allergen in increasing dosages over several months. OIT is not a curative treatment. The goal of OIT is to increase the threshold that triggers a reaction. OIT can be used to achieve desensitization or sustained unresponsiveness to a food allergen (AAAAI, 2018).

Initially, OIT has to be administered in a clinical setting equipped for treatment of potential anaphylaxis. Patients are generally started on a very small daily dose of the food (e.g., 3 to 6 mg of food protein) and advanced periodically (usually every 2 weeks) to a maintenance dose (e.g., 300 mg or, depending on the food and goals, 1 to 2 g of food protein daily) over several months (Nowak-Wegrzyn, 2019).

Peanut, egg, and milk OIT have been shown to desensitize approximately 60% to 80% of patients studied. OIT has not cured food allergy in these

individuals; it has raised the patient's tolerance of the offending food. Most children outgrow their allergies to cow's milk, egg, soy and wheat, even if they have a history of a severe reaction. However, peanut, tree nuts, fish, and shellfish allergies tend to persist through adulthood (AAAAI, 2018).

Chart 33-7 HOME CARE CHECKLIST

Managing Food Allergies

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of food allergies on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Verbalize understanding of the need to maintain an allergen-free diet.
- Demonstrate reading of food labels to identify hidden allergens in food.
- Identify ways to manage an allergen-free diet when eating away from home.
- State the need to wear medical identification bracelet or necklace.
- List symptoms of food allergy.
- Demonstrate emergency administration of epinephrine.
- State the importance of replacing epinephrine when outdated.
- State the importance of prompt treatment of allergic reactions and health care follow-up.
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, testing.
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Nursing Management

In addition to participating in management of the allergic reaction, the nurse focuses on preventing future exposure of the patient to the food allergen. The nurse should educate the patient about the signs of anaphylaxis and devise an action plan with the patient. If a severe allergic or anaphylactic reaction to food allergens has occurred, the nurse must instruct the patient and family about avoidance strategies to prevent its recurrence (see Chart 33-7). All patient allergies, including food allergies, should be noted on patient medical

records, as dietary restrictions would be necessary in the case of hospitalization. Also, there may be risk of cross-reactivity with some medications containing similar substances. The patient also needs to understand how to select and specify preparation of restaurant food (Sicherer, 2019).

Latex Allergy

Latex allergy—the allergic reaction to the proteins in the saplike fluid of a rubber tree—has been implicated in rhinitis, conjunctivitis, contact dermatitis, urticaria, asthma, and anaphylaxis. The prevalence is estimated at 4% to 7% of the population, but this has been steadily declining because of the use of nonpowdered latex and latex-free gloves (Hamilton, 2017a).

The sap of the rubber tree (*Hevea brasiliensis*) contains 250 different polypeptides that can react with IgE. The polypeptides and proteins in natural rubber latex (Hevea proteins) or the various chemicals that are used in the manufacturing process are thought to be the source of the allergic reactions.

Those at risk include health care workers, patients who have undergone multiple surgeries, people working in factories that manufacture latex products, and patients with spina bifida. Patients with spina bifida are at risk because they have had multiple surgeries, multiple urinary catheterization procedures, and other treatments involving use of latex products (Hamilton, 2017a). Because food handlers, hairdressers, automobile mechanics, and police may wear latex gloves and use latex products, they are also at risk for latex allergy. Increasingly, however, nonlatex gloves are being used in various occupational settings. Risk factors include occupational exposure to latex and atopic tendency in the affected person. Patients are at risk for anaphylactic reactions as a result of contact with latex during medical treatments, particularly surgical procedures (AAAAI, 2019d).

Persons with latex allergy are also prone to cross-reactions to pollen and some fruits; such as kiwis, bananas, pineapples, mangoes, passion fruit, avocados, and chestnuts (Hamilton, 2017a).

Routes of exposure to latex products can be cutaneous, percutaneous, mucosal, parenteral, or aerosol. The most frequent source of exposure is cutaneous, which usually involves the wearing of natural latex gloves. The powder used to facilitate putting on latex gloves can become a carrier of latex proteins from the gloves; when the gloves are put on or removed, the particles become airborne and can be inhaled or settle on skin, mucous membranes, or clothing (AAAAI, 2019d). Mucosal exposure can occur from the use of latex condoms, catheters, airways, and nipples. Parenteral exposure can occur from intravenous lines or hemodialysis equipment. In addition to latex-derived medical devices, many household items also contain latex. Examples of

medical and household items containing latex and a list of alternative products are found in Table 33-5. It is estimated that more than 40,000 medical devices and nonmedical products contain latex (AAAAI, 2019d).

Clinical Manifestations

Many different types of reactions to latex are possible (see Table 33-6). Irritant contact dermatitis, a nonimmunologic response, may be caused by mechanical skin irritation or an alkaline pH associated with latex gloves. Common symptoms of irritant dermatitis include erythema and pruritus.

Delayed hypersensitivity to latex, a type IV reaction mediated by T cells, is localized to the area of exposure and is characterized by symptoms of contact dermatitis. These include vesicular skin lesions, papules, pruritus, edema, erythema, and crusting and thickening of the skin. These symptoms usually appear on the back of the hands 1 to 4 days postcontact. It is the most common allergic reaction to latex. Although usually not life-threatening, delayed hypersensitivity reactions often require major changes in the patient's home and work environment to avoid further exposure (AAAAI, 2019d).

TABLE 33-5 Select Products Containing Natural Rubber Latex and Latex-Free Alternatives

Products Containing Latex	Examples of Latex-Safe Alternatives[a]
Hospital Environment	
Ace bandage (brown)	Ace bandage, white all cotton
Adhesive bandages, Band-Aid dressing, Telfa	Cotton pads and plastic or silk tape, Active Strips (3M), DuoDERM
Anesthesia equipment	Neoprene anesthesia kit (King)
Blood pressure cuff, tubing, and bladder	Clean Cuff, single-use nylon or vinyl blood pressure cuffs or wrap with stockinette or apply over clothing
Catheters	All-silicone or vinyl catheters
Catheter leg bag straps	Velcro straps
Crutch axillary pads and hand grips, tips	Cover with cloth, tape
ECG pads	Baxter, Red Dot 3M ECG pads
Elastic compression stockings	Kendall SCD stockings with stockinette
Gloves	Derma Prene, neoprene, polymer, or vinyl gloves
IV catheters	Jelco, Deseret IV catheters
IV rubber injection ports	Cover Y-sites and ports; do not puncture. Use three-way stopcocks on plastic tubing
Levin tube	Salem sump tube
Medication vials	Remove rubber stopper
Penrose drains	Jackson-Pratt, Zimmer Hemovac drains
Prepackaged enema kits	Therevac, Fleet Ready-to-Use
Pulse oximeters	Noninoximeters
Resuscitation bags	Laerdal, Puritan Bennett, *certain* Ambu
Stethoscope tubing	PVC tubing; cover with latex-free stockinette
Suction tubing	PVC (Davol, Laerdal)
Syringes—single use (Monoject, BD)	Terumo syringes, Abbott PCA Abboject
Tapes	Dermicel, Micropore
Theraband	New Thera-band Exercisers, plastic tubing
Thermometer probes	Diatek probe covers
Tourniquets	X-Tourn straps (Avcor)
Home Environment	
Balloons	Mylar balloons
Condoms, diaphragms	Polyurethane products, Durex Avanti and Reality products (female condom)
Diapers, incontinence pads	Huggies, Always, *some* Attends

Feminine hygiene pads	Kimberly-Clark products
Wheelchair cushions	ROHO cushions, Sof Care bed/chair cushions

[a]Confirmation is essential to verify that all items are latex free before using, especially if risk of latex allergy is present.

ECG, electrocardiogram; IV, intravenous; PVC, polyvinyl chloride.

Retrieved on 12/2/2019 at: www.cdc.gov/niosh/docs/98-113/default.html; Mayo Foundation for Medical Education and Research. (2019). Diseases and conditions: Latex allergy. Retrieved on 12/2/2019 at: www.mayoclinic.org/diseases-conditions/latex-allergy/basics/definition/CON-20024233

Latex allergy can also be an immediate hypersensitivity, type I allergic reaction, mediated by IgE. Localized itching, erythema, or local urticaria within 10 to 15 minutes after exposure to latex are often the initial symptoms (Hamilton, 2017a). Symptoms commonly include rhinitis, conjunctivitis, and nasal congestion. An asthma attack can be triggered. Severe anaphylaxis can occur, which includes generalized urticaria, angioedema, bronchospasm, and hypotension minutes after dermal or mucosal exposure to latex.

Assessment and Diagnostic Findings

The diagnosis of latex allergy is based on the history, physical examination, and diagnostic test results. Sensitization is detected by skin testing; serum-specific IgE, EIA, or ELISA; or the level of Hevea latex-specific IgE antibody in the serum. Testing for the chemicals found in the rubber production that makes latex is performed using the patch test. Skin patch testing is the preferred method for patients with contact allergies. The TRUE test and other skin tests should be performed only by primary providers who have expertise in their administration and interpretation and who have the necessary equipment available to treat local or systemic allergic reactions to the reagent (Hamilton, 2017a).

Medical Management

The best prevention strategy for latex allergy is the avoidance of latex-based products. A new, natural derivative from the desert plant guayule is now being used as a replacement for latex in many products. The predominant nonsterile, nonlatex examination gloves used in medical institutions today are made of nitrile, neoprene, vinyl, or synthetic polyisoprene rubber that is extracted from oil. Nonlatex condoms are available for contraception but these do not prevent transmission of HIV or other sexually transmitted infections (STIs). Persons allergic to latex should be cautioned to not blow up latex balloons or be in

enclosed spaces where these are used, as these balloons are still used as decorations (AAAAI, 2019d).

Patients at risk for an anaphylactic reaction to latex should be instructed to carry auto-injectable epinephrine in case of a reaction (Hamilton, 2017b).

Patients should report their allergy prior to any medical, dental, gynecologic, or surgical procedure and request a latex-safe environment (Hamilton, 2017b).

TABLE 33-6 Types of Reactions to Latex

Type of Reaction	Cause	Signs/Symptoms	Treatment
Irritant contact dermatitis	Damage to skin because of irritation and loss of epidermoid skin layer; not an allergic reaction. Can be caused by excessive use of soaps and cleansers, repeated handwashing, inadequate hand drying, mechanical irritation (e.g., sweating, rubbing inside powdered gloves), exposure to chemicals added during the manufacturing of gloves, and alkaline pH of powdered gloves. Reaction may occur with first exposure, is usually benign, and is not life-threatening.	*Acute:* Redness, edema, burning, discomfort, itching *Chronic:* Dry, thickened, cracked skin	Referral for diagnostic testing Avoidance of exposure to irritant Thorough washing and drying of hands Use of powder-free gloves with more frequent changes of gloves Changing glove types Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based skin agents with latex products, because they cause breakdown of the latex product
Allergic contact dermatitis	Delayed hypersensitivity (type IV) reaction. Usually affects only area in contact with latex; reaction is usually to chemical additives used in the manufacturing process rather than to latex itself. Cause of reaction is T-cell–mediated sensitization to additives of latex. Reaction is not life-threatening and is far more common than a type I reaction.	Pruritus, erythema, swelling, crusty thickened skin, blisters, other skin lesions	Referral for diagnosis (patch tests) and treatment Thorough washing and drying of hands Use of water- or silicone-based moisturizing creams,

	Slow onset; occurs 18–24 h after exposure. Resolves within 3–4 days after exposure. More severe reactions may occur with subsequent exposures.		lotions, or topical barrier agents Avoidance of oil- or petroleum-based products unless they are latex compatible Avoidance of identified causative agent, because continued exposure to latex products in presence of breaks in skin may contribute to latex protein sensitization
Latex allergy	Type I IgE-mediated immediate hypersensitivity to plant proteins in natural rubber latex. In sensitized people, antilatex IgE antibody stimulates mast cell proliferation and basophil histamine release. Exposure can be through contact with the skin, mucous membranes, or internal tissues, or through inhalation of traces of powder from latex gloves. Severe reactions usually occur shortly after parenteral or mucous membrane exposure. People with any type I reaction to latex are at high risk for anaphylaxis. Local swelling, redness, edema, itching, and systemic reactions, including anaphylaxis, occur within minutes after exposure.	Rhinitis, flushing, conjunctivitis, urticaria, laryngeal edema, bronchospasm, asthma, severe vasodilation angioedema, anaphylaxis, cardiovascular collapse, death	Immediate treatment of reaction with epinephrine, fluids, vasopressors, and corticosteroids, and airway and ventilator support, with close monitoring for recurrence for the next 12–14 h Prompt referral for diagnostic evaluation Treatment and diagnostic evaluation in latex-free environment Assessment of all patients for symptoms of latex allergy

	Educating patients and family members about the disorder and the importance of preventing future reactions by avoiding latex (e.g., wearing medical identification, carrying and autoinjector of epinephrine)

IgE, immunoglobulin E.

Nursing Management

The nurse can assume a pivotal role in the management of latex allergies in both patients and staff. All patients should be asked about latex allergy. Every time an invasive procedure must be performed, the nurse should consider the possibility of latex allergies. Nurses working in operating rooms, intensive care units, short procedure units, and EDs need to pay particular attention to latex allergy (Hamilton, 2017b). See Chapter 14, Figure 14-2, for a sample latex allergy assessment form.

Although the type I reaction is the most significant of the reactions to latex, care must be taken in the presence of irritant contact dermatitis and delayed hypersensitivity reaction to avoid further exposure of the person to latex. Patients with latex allergy are advised to notify their health care providers and to wear medical identification. Patients must become knowledgeable about what products contain latex and what products are safe, nonlatex alternatives. They must also become knowledgeable about signs and symptoms of latex allergy and emergency treatment and self-injection of epinephrine in case of allergic reaction (Hamilton, 2017b).

CRITICAL THINKING EXERCISES

1 ipc You are the nurse working in an outpatient walk-in clinic. A 28-year-old patient is newly diagnosed with allergic rhinitis. What nursing and interprofessional assessments are indicated? What interventions, including patient education, will you implement? What interprofessional referrals would be appropriate?

2 ebp A 44-year-old presents to the emergency department (ED) complaining of dyspnea after eating at a new restaurant. The patient states that this has happened two other times in the past and seems to be worse each time. What is the evidence for management of this patient? Describe the strength of the evidence and criteria used to assess its strength.

34 Assessment and Management of Patients with Inflammatory Rheumatic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Explain the pathophysiology of inflammatory rheumatic diseases and describe the assessment and diagnostic findings seen in patients with these disorders.
2. Use the nursing process as a framework for care of the patient with an inflammatory rheumatic disorder.
3. Devise an education plan for the patient with newly diagnosed inflammatory rheumatic disease.
4. Identify modifications in interventions to accommodate changes in patients' functional ability that may occur with disease progression.

NURSING CONCEPTS

Assessment
Cellular Regulation
Comfort
Immunity
Infection
Inflammation

GLOSSARY

arthritis: inflammation of a joint
cytokines: cell signaling proteins that are vital to regulation of hematopoiesis, apoptosis, and immune responses
exacerbation: period when disease symptoms occur or increase
pannus: proliferation of newly formed synovial tissue infiltrated with inflammatory cells
remission: period when disease symptoms are reduced or absent
rheumatic diseases: numerous disorders affecting skeletal muscles, bones, cartilage, ligaments, tendons, and joints
rheumatoid arthritis: a systemic autoimmune disease with symmetric arthritic manifestations and multiple extra-articular features
subchondral bone: bony plate that supports the articular cartilage
tophi: accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage

The **rheumatic diseases** encompass autoimmune, degenerative, inflammatory, and systemic conditions that affect the joints, muscles, and soft tissues of the body. Rheumatic diseases most commonly manifest the clinical features of **arthritis** (inflammation of a joint) and pain. There are more than 100 types of rheumatic diseases. The problems caused by rheumatic diseases include limitations in mobility and activities of daily living, pain, fatigue, altered self-image, and sleep disturbances, as well as systemic effects that can lead to organ failure and death. An understanding of inflammatory rheumatic diseases and their effects on a patient's function and well-being is essential to developing an appropriate plan of nursing care.

Rheumatic Diseases

Rheumatic disease processes affect males and females of all ages and ethnic groups. Some disorders are more likely to occur at a particular time of life or

to affect one gender more often than the other. In general, women are two to nine times more commonly affected by rheumatic diseases than men (Norris, 2019). Arthritis and other rheumatic diseases and the physical limitations that occur with them are becoming more prominent and a larger public health issue, which can be attributed to the increased number of older adults in the United States.

The onset of these conditions may be acute or insidious, with a course possibly marked by periods of **remission** (a period when disease symptoms are reduced or absent) and **exacerbation** (a period when symptoms occur or increase). Treatment can be simple, aimed at localized relief, or it can be complex, directed toward relief of systemic effects. Permanent changes and disability may result from these disorders.

Nurses need to understand the classification of rheumatic diseases. One system is to classify disease as either monoarticular (affecting a single joint) or polyarticular (affecting multiple joints). Another system is to classify the disease as either inflammatory or noninflammatory. This chapter focuses on inflammatory rheumatic diseases, while noninflammatory rheumatic diseases (i.e., osteoarthritis) are covered in Chapter 36. Conditions that may secondarily affect the musculoskeletal structure are also considered in disease classification.

Pathophysiology

Each of the inflammatory rheumatic diseases exhibits unique pathophysiologic features. Three distinct characteristics of pathophysiology include inflammation, autoimmunity, and degeneration.

Inflammation

Inflammation is a complex physiologic process mediated by the immune system that occurs in response to harmful stimuli like damaged cells or antigens, which may include pathogens (e.g., viruses, bacteria). Inflammation is meant to protect the body from insult by removing the triggering antigen or event. In response to a triggering episode, the antigen stimulus activates the body's immune system to form antibodies like monocytes and T lymphocytes (also referred to as T cells). Next, the immunoglobulin antibodies form immune complexes with antigens. Phagocytosis of the immune complexes is initiated, generating an inflammatory reaction (joint effusion, pain, and edema) (see Fig. 34-1). Phagocytosis produces chemicals such as leukotrienes and prostaglandins. Leukotrienes contribute to the inflammatory process by attracting other white blood cells to the area. Prostaglandins act as modifiers to inflammation. In some cases, they increase inflammation; in other cases, they decrease it. Leukotrienes and prostaglandins produce enzymes such as collagenase that break down collagen, which is a vital part of a normal joint.

The release of these enzymes in the joint causes edema and proliferation of synovial membrane. In patients with chronic inflammation, the immune response can deviate from normal. Instead of resolution of swelling and joint pain once the triggering event has subsided, **pannus** (proliferation of newly formed synovial tissue infiltrated with inflammatory cells) formation occurs. Destruction of the joint's cartilage and erosion of bone soon follow (Norris, 2019).

The immunologic inflammatory process begins when antigens are presented to T lymphocytes, leading to a proliferation of T and B cells. B cells (also referred to as plasma cells) are a source of antibody-forming cells. In response to specific antigens, plasma cells produce and release antibodies. Antibodies combine with corresponding antigens to form pairs, or immune complexes. The immune complexes build up and are deposited in synovial tissue or other organs in the body, triggering the inflammatory reaction that can ultimately damage the involved tissue (Norris, 2019).

Autoimmunity

A hallmark of inflammatory rheumatic diseases is autoimmunity, where the body mistakenly recognizes its own tissue as a foreign antigen. Autoimmunity leads to destruction of tissue via the same inflammatory process as discussed earlier, along with chronic and long-standing pain. Although focused in the joints, inflammation and autoimmunity also involve other areas. The blood vessels (vasculitis and arteritis), lungs, heart, and kidneys may be affected by the autoimmunity and inflammation. See Chapter 32 for more information on autoimmune disease. A large group of genes, called *human leukocyte antigen* (HLA) genes, has been linked to the immune response and the development of multiple rheumatic diseases (Norris, 2019).

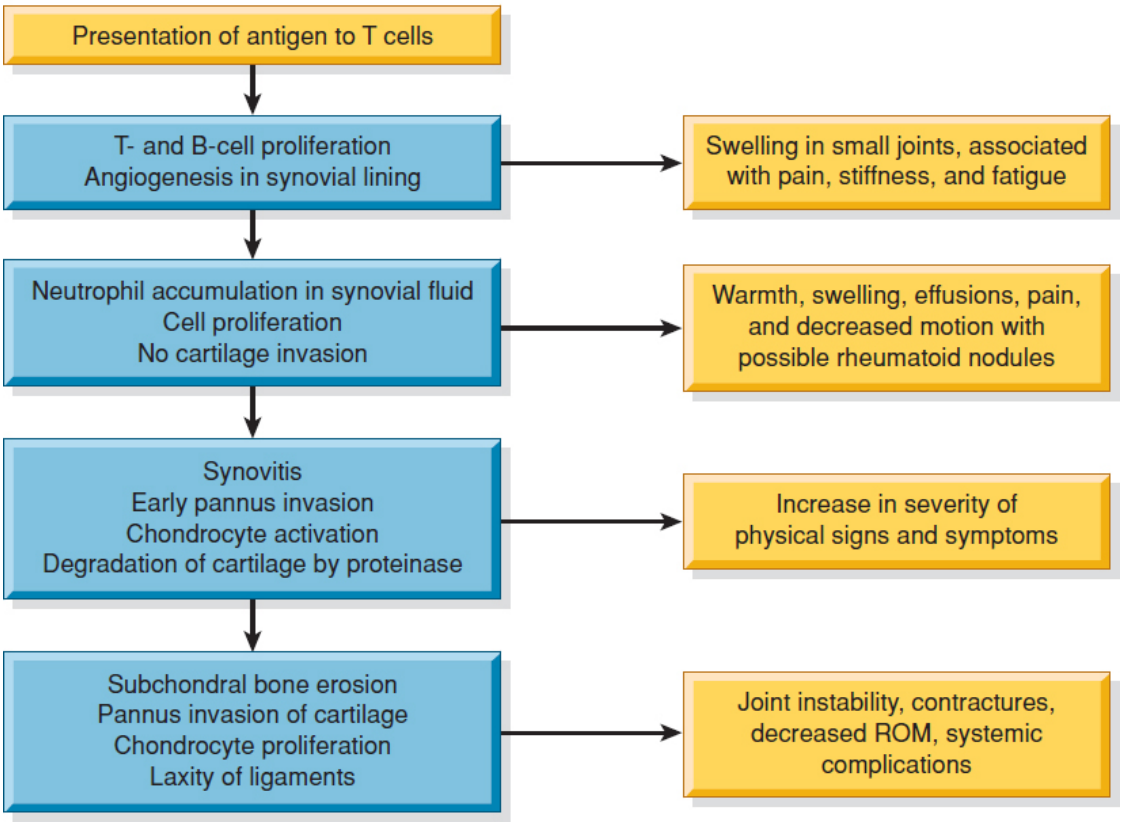

Figure 34-1 • Pathophysiology and associated physical signs of rheumatoid arthritis. ROM, range of motion.

Degeneration

In degenerative rheumatic diseases, inflammation also occurs, but as a secondary process. Although the cause of degeneration of the articular cartilage is poorly understood, the process is known to be metabolically active and therefore is more accurately called *degradation.* One theory of degradation is that genetic or hormonal influences, mechanical factors, and prior joint damage cause cartilage failure. Degradation of cartilage ensues, and increased mechanical stress on bone ends causes stiffening of bone tissue. Another theory is that bone stiffening occurs and results in increased mechanical stress on cartilage, which in turn initiates the processes of degradation. See Chapter 35 for more information on the structure and function of the articular system.

Clinical Manifestations

The most common symptom in the rheumatic diseases is pain. Other common symptoms include joint swelling, limited movement, stiffness, weakness, and fatigue.

Assessment and Diagnostic Findings

Assessment begins with a general health history, which includes the onset of symptoms and how they evolved, family history, past health history, and any other contributing factors. Because many of the rheumatic diseases are chronic conditions, the health history should also include information about the patient's perception of the problem, previous treatments and their effectiveness, the patient's support systems, and the patient's current knowledge base and the source of that information. A complete health history is followed by a complete physical assessment (see Chapter 4).

Assessment for rheumatic diseases combines the physical examination with a functional assessment (Eliopoulos, 2021). Inspection of the patient's general appearance occurs during the initial contact. Gait, posture, and general musculoskeletal size and structure are observed. Gross deformities and abnormalities in movement are noted. The symmetry, size, and contour of other connective tissues, such as the skin and adipose tissue, are also noted and recorded (Weber & Kelley, 2019). Chart 34-1 outlines the important areas for consideration during the physical assessment. The functional assessment is a combination of history (what the patient reports that they can and cannot do) and examination (observation of activities, in which the patient demonstrates what they can and cannot do, such as dressing and getting in and out of a chair). Observation also includes the adaptations and adjustments the patient may have made (sometimes without awareness)—for example, with shoulder or elbow involvement, the person may bend over to reach a fork rather than raising the fork to the mouth.

Laboratory Studies

In Table 34-1 common laboratory studies are listed with their corresponding normal ranges and significance. Many of the tests require special laboratory techniques and may not be performed in every health care facility. The primary provider determines which tests are necessary based on symptoms, stage of disease, cost, and likely benefit. In some instances, tests are used to monitor the course of the disease.

Other Diagnostic Studies

Imaging studies commonly used for patients with rheumatic diseases include x-ray studies, computed tomography (CT) scans, magnetic resonance imaging (MRI) scans, and arthrography. See Chapter 35 for further information about these and other diagnostic studies.

Medical Management

The chronic nature of rheumatic conditions requires cooperation between the patient and the provider. Patient education regarding the disease process and treatment options is imperative to enable patients to make informed decisions regarding their care. Management of rheumatic diseases is based on a shared decision process between the provider and patient that takes into account the patient's values, preferences, and comorbidities (Singh, Saag, Bridges, et al., 2016).

Pharmacologic Therapy

Medications are used with the rheumatic diseases to manage symptoms, to control inflammation, and, in some instances, to modify the disease. Useful medications include the salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and both biologic and nonbiologic disease-modifying antirheumatic drugs (DMARDs). As their name suggests, DMARDs have the ability to suppress the autoimmune response; alter disease progression; and stop or decrease further tissue damage on the joints, cartilage, and organs. DMARDs have been found to halt the progression of bone loss and destruction and can induce remission (Singh et al., 2016). Nonbiologic DMARDs are thought to reduce proinflammatory **cytokines** (cell signaling proteins vital to regulation of hematopoiesis, apoptosis, and immune responses) and increase anti-inflammatory cytokines. Biologic DMARDs, in contrast, have been specifically engineered to target a certain cell or molecule within the immune system to treat the specific rheumatic condition. Specific biologic DMARDs target tumor necrosis factor alpha (TNF-α), B cells, T cells, interleukin 1 (IL-1), and interleukin 6 (IL-6). Table 34-2 reviews select medications.

Controlling the inflammation related to the disease process helps manage pain, but this is often a delayed response. Nonopioid medications are often used for pain management, especially early in the treatment program, until other measures can be instituted.

Nonpharmacologic Pain Management

Nonpharmacologic methods of pain management are important. Heat applications are helpful in relieving pain, stiffness, and muscle spasm (Kapale, Vardharajulu, & Warude, 2017). Superficial heat may be applied in the form of warm tub baths or showers and warm moist compresses. Paraffin baths (dips), which offer concentrated heat, are helpful to patients with wrist and small-joint involvement. Maximum benefit is achieved within 20 minutes after application. More frequent use for shorter lengths of time is most beneficial. Therapeutic exercises can be carried out more comfortably and effectively after heat has been applied (Kapale et al., 2017).

Chart 34-1  ASSESSMENT

Assessing for Rheumatic Disorders

In addition to the head-to-toe assessment or systems review, the following are important areas of consideration to be noted when performing the complete physical assessment of a patient with a known or suspected rheumatic disorder.

Manifestation	Significance
Skin (inquire and inspect)	
Rash, lesions	Associated with systemic lupus erythematosus (SLE) vasculitis, adverse effect of medication
Increased bruising	Associated with several rheumatic diseases and adverse effect of medication
Erythema	Sign of inflammation
Thinning	Adverse effect of medication
Warmth	Sign of inflammation
Photosensitivity	Associated with SLE, dermatomyositis, adverse effect of medication
Hair (inquire and inspect)	
Alopecia or thinning	Associated with rheumatic diseases or adverse effect of medication
Eye (inquire and inspect)	
Dryness, grittiness	Associated with Sjögren's syndrome (commonly occurring with rheumatoid arthritis [RA] and SLE)
Decreased acuity or blindness	Associated with temporal arteritis, medication complications
Cataracts	Adverse effect of medication
Decreased peripheral vision	Adverse effect of medication
Conjunctivitis, uveitis	Associated with ankylosing spondylitis and Reiter's syndrome
Ear (inquire)	
Tinnitus	Adverse effect of medication
Decreased acuity	Adverse effect of medication
Mouth (inquire and inspect)	
Buccal, sublingual lesions	Associated with vasculitis, dermatomyositis, adverse effect of medication
Altered sense of taste	Adverse effect of medication
Dryness	Associated with Sjögren's syndrome
Dysphagia	Associated with myositis
Difficulty chewing	Associated with decreased range of motion of jaw
Chest (inspect and inquire)	
Pleuritic pain	Associated with RA and SLE
Decreased chest expansion	Associated with ankylosing spondylitis
Activity intolerance (dyspnea)	Associated with pulmonary hypertension in scleroderma
Cardiovascular system (inquire, inspect, palpate)	

Blanching of fingers on exposure to cold	Associated with Raynaud's phenomenon
Peripheral pulses	Deficit may indicate vascular involvement or edema associated with medication effect or rheumatic diseases, especially SLE or scleroderma
Abdomen (inquire and palpate)	
Altered bowel habits	Associated with scleroderma, spondylosis, ulcerative colitis, decreased physical mobility, medication effect
Nausea, vomiting, bloating, and pain	Adverse effect of medication
Weight change (measure)	Associated with RA (decreased), adverse effect of medication (increased or decreased)
Genitalia (inquire and inspect)	
Dryness, itching	Associated with Sjögren's syndrome
Abnormal menses	Adverse effect of medication
Altered sexual performance	Fear of pain (or of pain caused by partner) and limitation of motion may affect sexual mobility
Hygiene	Poor hygiene may be related to limitations in activities of daily living
Urethritis, dysuria	Associated with ankylosing spondylitis and Reiter's syndrome
Lesions	Associated with vasculitis
Neurologic (inquire and inspect)	
Paresthesias of extremities; abnormal reflex pattern	Nerve compressions (e.g., carpal tunnel syndrome, spinal stenosis)
Headaches	Associated with temporal arteritis, adverse effect of medication
Musculoskeletal (inspect and palpate)	
Joint redness, warmth, swelling, tenderness, deformity—location of first joint involved, pattern of progression, symmetry, acute vs. chronic nature	Signs of inflammation
Joint range of motion	Decreased range of motion may indicate severity or progression of disease
Surrounding tissue findings	
Muscle atrophy, subcutaneous nodules, popliteal cyst	Extra-articular manifestations
Muscle strength (grip)	Muscle strength decreases with increased disease activity

Adapted from Weber, J. R., & Kelley, J. H. (2019). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

TABLE 34-1 Common Blood Studies for Rheumatic Diseases

Test	Normal Value	Significance
Serum		
Creatinine		
Metabolic waste excreted through the kidneys	*Men*: 0.6–1.2 mg/dL (71–106 mmol/L) *Women*: 0.4–1.0 mg/dL (36–90 mmol/L)	Increase may indicate kidney damage in SLE, scleroderma, and polyarteritis.
Erythrocyte Count		
Measures circulating erythrocytes	*Men:* 4,200,000–5,400,000/mm^3 ($4.2–5.4 \times 10^{12}$/L) *Women:* 3,600,000–5,000,000/mm^3 ($3.6–5.0 \times 10^{12}$/L)	Decrease can be seen in RA, SLE.
Erythrocyte Sedimentation Rate (ESR)		
Measures the rate at which RBCs settle out of unclotted blood in 1 hour	Westergren: Men under 50 yr: <15 mm/h Men over 50 yr: <20 mm/h Women under 50 yr: <20 mm/h Women over 50 yr: <30 mm/h	Increase is usually seen in inflammatory connective tissue diseases. An increase indicates rising inflammation, resulting in clustering of RBCs, which makes them heavier than normal. The higher the ESR, the greater the inflammatory activity.
Hematocrit		
Measures the size, capacity, and number of cells present in blood	*Men:* 42–52% *Women:* 36–48%	Decrease can be seen in chronic inflammation (anemia of chronic disease); also, blood loss through GI bleed.
White Blood Cell Count		
Measures circulating leukocytes	4,500–11,000 cells/mm^3	Decrease may be seen in SLE.
Uric Acid		
Measures level of uric acid in serum	*Men:* 3.4–7 mg/dL (202–416 µmol/L) *Women:* 2.4–6 mg/dL (143–357 µmol/L)	Increase is seen with gout. During acute flare, levels may be normal. After flare has subsided, levels will be elevated in gout.

Serum Immunology		
Antinuclear Antibody (ANA)		
Measures antibodies that react with a variety of nuclear antigens If antibodies are present, further testing determines the type of ANA circulating in the blood (anti-DNA, anti-RNP).	Negative Healthy adults may also have a positive ANA.	Positive test may be associated with SLE, RA, scleroderma, Raynaud's disease, Sjögren's syndrome, necrotizing arteritis. The higher the titer, the greater the inflammation. The pattern of immunofluorescence (speckled, homogeneous, or nucleolar) helps determine the diagnosis.
Anti-DNA, DNA Binding		
Titer measurement of antibody to double-stranded DNA	Negative	High titer is seen in SLE; increases in titer may indicate an increase in disease activity.
C-Reactive Protein (CRP)		
Shows presence of abnormal glycoprotein due to inflammatory process	<1 mg/dL (<10 mg/L)	A positive reading indicates active inflammation.
Immunoglobulin Electrophoresis		
Measures the values of immunoglobulins	*IgA:* 60–400 mg/dL (600–4000 mg/L) *IgG:* 700–1,500 mg/dL (7–15 g/L) *IgM:* 60–300 mg/dL (600–3000 mg/L)	Increased levels are found in people who have autoimmune disorders.
Rheumatoid Factor (RF)		
Determines the presence of abnormal antibodies seen in connective tissue disease	Negative	Positive titer >1:80 Present in 80% of those with RA Positive RF may also suggest SLE, Sjögren's syndrome, or mixed connective tissue disease. The higher the titer (number at right of colon), the greater the inflammation.
Tissue Typing		
HLA-B27 Antigen		
Measures presence of HLA antigens, which are used for tissue recognition	Negative	Found in 80–90% of those with ankylosing spondylitis and Reiter's syndrome

DNA, deoxyribonucleic acid; GI, gastrointestinal; HLA, human leukocyte antigen; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M; RA, rheumatoid arthritis; RBCs, red blood cells; RNP, ribonucleoprotein; SLE, system lupus erythematosus.

Adapted from Fischbach, F. T., & Fischbach, M. A. (2018). *A manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Wolters Kluwer.

TABLE 34-2  Select Medications Used in Rheumatic Diseases

Medication	Action, Use, and Indication	Nursing Considerations
Salicylates		
Acetylated: aspirin *Nonacetylated:* choline trilisalicylate, salsalate, sodium salicylate	*Action:* Anti-inflammatory, analgesic, antipyretic Acetylated salicylates are platelet aggregation inhibitors	Administer with food, milk, antacids or large glass of water to reduce GI effects. Assess for tinnitus, gastric intolerance, GI bleeding, and purpura. Administer enteric coated or extended release whole, do not crush.
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)		
diclofenac, diflunisal, etodolac, ibuprofen, ketoprofen, meloxicam, nabumetone, naproxen, piroxicam, sulindac *COX-2 enzyme blockers:* celecoxib	*Action:* Anti-inflammatory, analgesic, antipyretic, platelet aggregation inhibitor Anti-inflammatory effect occurs 2–4 wk after initiation All NSAIDs are useful for short-term treatment of acute gout attack NSAIDs are an alternative to salicylates for first-line therapy in several rheumatic diseases *Action:* Inhibit only COX-2 enzymes, which are produced during inflammation, and spare COX-1 enzymes, which can be protective to the stomach	Administer NSAIDs with food. Monitor for GI, CNS, cardiovascular, renal, hematologic, and dermatologic adverse effects. Avoid salicylates; use acetaminophen for additional analgesia. Watch for possible confusion in older adults. Monitoring is the same as for other NSAIDs. Increased risk of cardiovascular events, including myocardial infarction and stroke. Appropriate for older adults and patients who are at high risk for gastric ulcers.
Disease-Modifying Antirheumatic Drugs (DMARDs)		
Antimalarials: hydroxychloroquine, chloroquine	*Action:* Anti-inflammatory, inhibit lysosomal enzymes Slow acting; onset may take 2–4 mo. May be used in conjunction with other DMARD therapy. Useful in RA and SLE.	May be administered concurrently with NSAIDs. Assess for visual changes, GI upset, skin rash, headaches, photosensitivity, bleaching of hair. Emphasize need for ophthalmologic

		examinations (every 6–12 mo).
Janus Kinase (JAK) inhibitors		
tofacitinibic, baricitinic	*Action*: Enters the cell and binds to the active JAK site, inhibits autophosphorylation and JAK activation that inhibits cytokine production. May be used in combination with methotrexate or other nonbiologic DMARDs. May also be used as monotherapy.	Administer twice a day (immediate release) or once daily (extended release). Do not administer with biologic DMARDs or potent immunosuppressants. Test for latent TB before initiation of therapy. Monitor liver enzymes routinely.
sulfasalazine	*Action:* Anti-inflammatory, reduces lymphocyte response, inhibits angiogenesis Useful in RA, seronegative spondyloarthropathies	Administer concurrently with NSAIDs. Do not use in patients with allergy to sulfa medications or salicylates. Emphasize adequate fluid intake. Assess for GI upset, skin rash, headache, liver abnormalities, anemia.
Immunosuppressives: methotrexate, azathioprine, cyclophosphamide	*Action:* Nonbiologic immune suppression, affect DNA synthesis and other cellular effects Have teratogenic potential; azathioprine and cyclophosphamide reserved for more aggressive or unresponsive disease Methotrexate is generally the first-line agent for RA treatment; also useful in SLE. Methotrexate may be given orally or by intramuscular or subcutaneous injection	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections. Monitor CBC, liver enzymes, creatinine at 6 wk after initiation, then every 2–3 mo or accordingly. Advise patient of contraceptive measures because of teratogenicity.
cyclosporine	*Action:* Nonbiologic immune suppression by inhibiting T lymphocytes Used for severe, progressive RA, unresponsive to other DMARDs Used in combination with methotrexate	Assess slow dose titration upward until response noted or toxicity occurs. Assess for toxic effects, such as bleeding gums,

		fluid retention, hair growth, tremors. Monitor blood pressure and renal function (creatinine) every 2 wk until stable.
Immunomodulators		
Pyrimidine synthesis inhibitor: leflunomide	*Action:* Nonbiologic with antiproliferative and anti-inflammatory effects; used in moderate to severe RA May be used alone or in combination with other DMARDs	Long half-life; requires loading dose followed by daily administration. Assess for diarrhea, hair loss, skin rash, mouth sores. Monitor liver function tests. Contraindicated in pregnancy and breast-feeding. Given orally.
TNF-blocking agents: adalimumab, certolizumabpegol, etanercept, infliximab, golimumab	*Action:* Biologic response modifier that binds to TNF, a cytokine involved in inflammatory and immune responses. Used in moderate to severe RA. Can be used alone or with methotrexate or other nonbiologic DMARDs. Adalimumab is given by subcutaneous injection every 2 wk, but may be used every week if efficacy not reached. Certolizumabpegol is given by subcutaneous injection every 2 wk. Etanercept is given by subcutaneous injection weekly. Infliximab is given intravenously over 2 h or more. Medication must be refrigerated. Golimumab is given by subcutaneous injection once a month. Golimumab SQ is a second alternative that is administered intravenously every 8 wk after initial 2 loading doses	Patient should be tested for tuberculosis before beginning this medication. Educate patient about subcutaneous self-injection. Monitor for injection site reactions. Educate patient about increased risk for infection and to withhold medication if fever occurs. Notify provider if any illness or infection occurs and medication is held.
T-cell costimulation modulator: abatacept	*Action:* Blocks one of the pathways needed to fully activate T cells, decreasing inflammatory and immunologic responses. Used in moderate to severe RA	Administered IV initially, then transitions to subcutaneous dosage once weekly. Educate patient about

	unresponsive to TNF inhibitors. Used with methotrexate or DMARDs other than TNF inhibitors or anakinra.	subcutaneous self-injections given daily. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs. IV infusions are given every 4 wk over 30-min infusion.
B-cell production blocker: rituximab	*Action:* Binds to B-lymphocyte CD20 surface antigens. Used in refractory RA in patients with inadequate response to TNF antagonist. Given with methotrexate.	Rituximab is given as two 1000-mg doses via IV infusion separated by 2 wk. Given on wk 0 and 2, and then subsequent doses are infused 24 wk later or based on clinical diagnosis (commonly given every 6 mo). Premedicate with acetaminophen, antihistamine, and methylprednisolone 30 min prior to infusion of rituximab. Educate patient about increased risk of infection.
Human IL-1 receptor antagonist: anakinra	*Action:* Blocks IL-1 receptors, decreasing inflammatory and immunologic responses. Used in moderate to severe RA. Can be used alone or with methotrexate or DMARDs other than TNF-blocking agents	Given daily by subcutaneous injection. Educate patient about subcutaneous self-injections given daily. Medication must be refrigerated. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs.
Human IL-6 receptor antagonist: tocilizumab	*Action:* Binds to and inhibits IL-6 receptors, decreasing inflammatory and immunologic responses. Can be used alone or with methotrexate or in combination with other nonbiologic DMARDs	Administered IV every 4 wk. Educate patient about increased risk of infection.

Corticosteroids		
prednisone, prednisolone, hydrocortisone	*Action:* Anti-inflammatory. Used for shortest duration and at lowest dose possible to minimize adverse effects. Useful for unremitting RA, SLE, polymyalgia rheumatica, myositis, arteritis Fast acting; onset in days Intra-articular injections useful for joints unresponsive to NSAIDs	Assess for toxicity: Cataracts, GI irritation, hyperglycemia, hypertension, fractures, avascular necrosis, hirsutism, psychosis. Joints most amenable to injections include ankles, knees, hips, shoulders, and hands. Repeated injections can cause joint damage. Use caution in patients diagnosed with diabetes, due to effects causing elevation in blood sugar.

CBC, complete blood count; CNS, central nervous system; COX, cyclo-oxygenase; GI, gastrointestinal; IL-1, interleukin 1; IL-6, interleukin 6; IV, intravenous; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor.

Baricitinic: The second FDA approved JAK inhibitor for the treatment of rheumatoid arthritis. *Annals of Pharmacotherapy*, *53*(9), 947–953.

Devices such as braces, splints, and assistive devices for ambulation (e.g., canes, crutches, walkers) ease pain by limiting movement or stress from putting weight on painful joints. Acutely inflamed joints can be rested by applying splints to limit motion. Splints also support the joint to relieve spasm. Canes and crutches can relieve stress from inflamed and painful weight-bearing joints while promoting safe ambulation. Cervical collars may be used to support the weight of the head and limit cervical motion. A metatarsal bar or special pads may be put into the patient's shoes if foot pain or deformity is present. A combination of methods may be required, because different methods often work better at different times.

Exercise and Activity

The ongoing nature of most rheumatic diseases makes it important to maintain and, when possible, improve joint mobility and overall functional status. Appropriate programs of exercise have been shown to decrease pain and improve function (Eliopoulos, 2021). Changes in gait as well as joint limitations commonly require referral for rehabilitation therapy. An individualized exercise program is crucial to improve movement. Table 34-3

summarizes the exercises appropriate for patients with rheumatic diseases. Physical and occupational therapy programs and interventions are beneficial in improving physical activity and maintaining range of motion. Such interventions may include stretching exercises, muscle conditioning, aerobic exercise, massage, acupuncture, and chiropractic and osteopathic manipulation. Other strategies for decreasing pain include muscle relaxation techniques, imagery, self-hypnosis, and distraction. A mild analgesic agent may be suggested before exercise to improve pain during exercise. A weight reduction program may be recommended to relieve stress on painful joints for patients who are overweight. Any patient who experiences acute or prolonged pain associated with exercise should report the symptoms to their primary provider for evaluation.

TABLE 34-3 Exercise to Promote Mobility

Type of Exercise	Purpose	Recommended Performance	Precautions
Range of motion	Maintain flexibility and joint motion	Active or active/self-assisted at least daily	Reduce the number of repetitions when inflammation is present
Isometric exercise	Improve muscle tone, static endurance, and strength; prepare for dynamic and weight-bearing exercises	Perform at 70% of maximal voluntary contraction daily	Monitor blood pressure; isometric exercises may increase blood pressure and decrease blood flow to muscles
Dynamic exercise	Maintain or increase dynamic strength and endurance; increase muscle power; enhance synovial blood flow; promote strength of bone and cartilage	Start with repetitions against gravity and add progressive resistance; perform 2–3 days per week	May increase biomechanical stress on unstable or misaligned joints
Aerobic exercise	Improve cardiovascular fitness and endurance	Perform 3–5 days per week for 20–30 min of moderate-intensity exercise	Progress slowly as activity tolerance and fitness improve
Pool exercise	Water supports or resists movement; warm water may provide muscle relaxation	Provide buoyant medium for performance of dynamic or aerobic exercise	Heated swimming pool; deep water to minimize joint compression; nonslip footwear for safety and comfort. Receive appropriate education in a program designed for people with arthritis

Adapted from Kapale, P., Vardharajulu, G., & Warude, T. (2017). Effect of free exercise and rheumatoid arthritis. *Indian Journal of Physiotherapy and Occupational Therapy*, *11*(3), 62–65.

The major challenge for the patient and the health care provider is the need to adjust all aspects of treatment according to the activity of the disease. Especially for the patient with an active diffuse connective tissue disease, such as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE), activity levels may vary from day to day and even within a single day.

Sleep

Short-term use of low-dose antidepressant medications, such as amitriptyline, may be prescribed to reestablish adequate sleep patterns and improve pain management (Comerford & Durkin, 2020). Patients need restful sleep so that they can cope with pain, minimize physical fatigue, and deal with the changes related to having a chronic disease. In patients with acute disease, sleep time is frequently reduced and fragmented by prolonged awakenings. Stiffness, depression, and medications may also compromise the quality of sleep and increase daytime fatigue. A sleep-inducing routine, medication, and comfort measures may help improve the quality of sleep.

Education about sleep hygiene strategies may help promote restorative sleep. These strategies include establishing a set time to sleep and a regular wake-up time, creating a quiet sleep environment with a comfortable room temperature, avoiding factors that interfere with sleep (e.g., the use of alcohol and caffeine), using relaxation exercises, and getting out of bed and engaging in another activity (e.g., reading) if unable to sleep.

Nursing Management

Much of the care of patients with arthritis involves self-management; thus, using a standardized assessment of self-management behaviors will help plan effective on-going care and treatment targets (Oh, Han, Kim, et al., 2018). The Nursing Research Profile in Chart 34-2 describes one such tool. Chart 34-3 details the nursing diagnoses, interventions, and expected outcomes for the patient with a rheumatic disorder.

Gerontologic Considerations

The various rheumatic disease conditions in the older adult pose unique challenges. These challenges relate to disability, cognitive changes, comorbid conditions, and diagnosis. Musculoskeletal problems are the most frequently reported conditions in older adults (Eliopoulos, 2021) and will be seen more frequently by health professionals in the coming years along with associated disability, especially among frail older adults.

Comorbid conditions pose a unique challenge in diagnosing rheumatic disease in older adults because they have the potential to mask or alter presenting symptoms. The frequency, pattern of onset, clinical features, severity, and effects on function of the rheumatic disease in older patients needs to be assessed. One study reported that functional disability was correlated with disease state and thus must be addressed in planning care (Omma, Celik, Bes, et al., 2018). Additional medical conditions may take precedence over the rheumatic disease, causing it to become a secondary diagnosis and concern. Decreased vision and altered balance, often present in older adults, may be problematic if rheumatic disease in the lower extremities

affects locomotion. The combination of decreased hearing and visual acuity, memory loss, and depression contributes to failure to follow the treatment regimen in older adult patients as well (Eliopoulos, 2021). Special techniques for promoting patient safety, self-management, and strategies such as memory aids for medications may be necessary.

Chart 34-2 NURSING RESEARCH PROFILE

Assessing Self-Management in Patients with Arthritis

Oh, H. S., Han, S. Y., Kim, S. H., et al. (2018). Development and validity testing of an arthritis self-management assessment tool. *Orthopaedic Nursing*, *37*(1), 24–35.

Purpose

Self-management is central to arthritis treatment; yet, no instrument existed to measure arthritis self-management ability. Therefore, the purpose of this research was to develop and test the reliability and validity of a comprehensive tool to assess self-management in patients with arthritis.

Design

A nonexperimental correlational design was used for this study. Items for inclusion on the Arthritis Self-Management Assessment Tool (ASMAT) were generated using a chronic illness management model. Content validity of the initial 42 items were reviewed by a panel of experts and decreased to 32 items. The tool was then tested with 150 patients with arthritis in an outpatient setting. Factor analysis was used to test construct validity.

Findings

The mean age of participants was 52 years and approximately 60% were male. There were 32 items generated and tested in the final version of the ASMAT. The 32 items were validated and the scale was found to have 3 subscales: that of medical management tasks (10 items), behavioral management tasks (13 items), and psycho-emotional management tasks (9 items). Confirmatory factor analysis showed construct validity for the 32 item tool. Cronbach α levels showed the overall toll and the 3 subscales to be reliable.

Nursing Implications

Nurses are in a key position to assist patients with arthritis to self-manage their care. Performing an ASMAT helps evaluate the patient's self-management abilities and the effectiveness of self-management interventions. Early identification of barriers to adoption of self-management strategies can lead to improved symptom management, independence, and improved quality of life.

Behavioral clues such as gait patterns, guarding, and joint flexion may aid the nurse in assessing the patient's pain when cognitive impairment is present. Older adults, especially men, may also neglect to communicate their pain unless elicited by the provider. Pain, in general, in this population that is not treated or undertreated may impact the quality of life for these patients, which can exacerbate all other medical conditions.

Chart 34-3 PLAN OF NURSING CARE

Care of the Patient with a Rheumatic Disorder

Nursing Diagnosis: Acute and chronic pain associated with inflammation and increased disease activity, tissue damage, fatigue, or lowered tolerance level

Goal: Improvement in comfort level; incorporation of pain management techniques into daily life

Nursing Interventions	Rationale	Expected Outcomes
1. Provide variety of comfort measures: a. Application of heat or cold b. Massage, position changes, rest c. Foam mattress, supportive pillow, splints d. Relaxation techniques, diversional activities 2. Administer anti-inflammatory, analgesic, and slow-acting antirheumatic medications as prescribed. 3. Individualize medication schedule to meet patient's need for pain management. 4. Encourage verbalization of feelings about pain and chronicity of disease. 5. Assess for subjective changes in pain.	1. Pain may respond to nonpharmacologic interventions, such as exercise, relaxation, and thermal modalities. 2. Pain of rheumatic disease responds to monotherapy or combination medication regimens. 3. Previous pain experiences and management strategies may be different from those needed for persistent pain. 4. Verbalization promotes coping. 5. The impact of pain on an individual's life often leads to misconceptions about pain and pain management techniques. The individual's description of pain is a more reliable indicator than objective measurements	• Identifies factors that exacerbate or influence pain response • Identifies and uses pain management strategies • Verbalizes decrease in pain • Reports signs and symptoms of side effects in timely manner to prevent additional problems • Verbalizes that pain is characteristic of rheumatic disease • Establishes realistic pain relief goals • Identifies changes in quality or intensity of pain

	such as change in vital signs, body movement, and facial expression.	
NURSING DIAGNOSIS: Fatigue associated with increased disease activity, pain, inadequate sleep/rest, deconditioning, inadequate nutrition, emotional stress, anxiety, and depressive symptoms **Goal:** Incorporates as part of daily activities strategies necessary to modify fatigue		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Provide education about fatigue. a. Describe relationship of disease activity to fatigue. b. Describe comfort measures while providing them. c. Develop and encourage a sleep routine (warm bath and relaxation techniques that promote sleep). d. Explain importance of rest for relieving systematic, articular, and emotional stress. e. Explain how to use energy conservation techniques (pacing, delegating, setting priorities). f. Identify physical and emotional factors that can cause fatigue.	1. The patient's understanding of fatigue will affect their actions. a. The amount of fatigue is directly related to the activity of the disease. b. Relief of discomfort can relieve fatigue. c. Effective bedtime routine promotes restorative sleep. d. Different kinds of rest are needed to relieve fatigue and are based on patient's need and response. e. A variety of measures can be used to conserve energy.	• Self-evaluates and monitors fatigue pattern • Verbalizes the relationship of fatigue to disease activity • Uses comfort measures as appropriate • Practices effective sleep hygiene and routine • Makes use of various assistive devices (splints, canes) and strategies (bed rest, relaxation techniques) to ease different kinds of fatigue • Incorporates time management

2. Facilitate development of appropriate activity/rest schedule. 3. Encourage adherence to the treatment program. 4. Refer to and encourage a conditioning program. 5. Encourage adequate nutrition, including source of iron from food and supplements.	f. Awareness of the various causes of fatigue provides the basis for measures to modify the fatigue. 2. Alternating rest and activity conserves energy while allowing most productivity. 3. Overall control of disease activity can decrease the amount of fatigue. 4. Deconditioning resulting from lack of mobility, understanding, and disease activity contributes to fatigue. 5. A nutritious diet can help counteract fatigue.	strategies in daily activities • Uses appropriate measures to prevent physical and emotional fatigue • Has an established plan to ensure well-paced, therapeutic activity schedule • Adheres to therapeutic program • Follows a planned conditioning program • Consumes a nutritious diet consisting of the five major groups and recommended daily allowance of vitamins and minerals

Nursing Diagnosis: Impaired mobility associated with decreased range of motion, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices

Goal: Attains and maintains optimal functional mobility

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage verbalization	1. Mobility is not necessarily	• Identifies factors that

regarding limitations in mobility. 2. Assess need for occupational or physical therapy consultation. a. Emphasize range of motion of affected joints. b. Promote the use of assistive ambulatory devices. c. Explain the use of safe footwear. d. Use individual appropriate positioning/posture. 3. Assist to identify environmental barriers. 4. Encourage independence in mobility and assist as needed. a. Allow ample time for activity. b. Provide rest period after activity. c. Reinforce principles of pacing and work simplification. 5. Initiate referral to community health agency.	related to deformity. Pain, stiffness, and fatigue may temporarily limit mobility. The degree of mobility is not synonymous with the degree of independence. Decreased mobility may influence a person's self-concept and lead to social isolation. 2. Therapeutic exercises, proper footwear, and assistive equipment may improve mobility. Correct posture and positioning are necessary for maintaining optimal mobility. 3. Furniture and architectural adaptations may enhance mobility. 4. Changes in mobility may lead to a decrease in personal safety. 5. The degree of mobility may be slow to improve or may not improve with intervention.	interfere with mobility • Describes and uses measures to prevent loss of motion • Identifies environmental (home, school, work, community) barriers to optimal mobility • Uses appropriate techniques, assistive equipment, or both to aid mobility • Identifies community resources available to assist in managing decreased mobility
Nursing Diagnosis: Able to perform self care associated with contractures, fatigue, or loss of motion		

Goal: Performs self-care activities independently or with the use of resources

Nursing Interventions	Rationale	Expected Outcomes
1. Assist patient to identify self-care deficits and factors that interfere with ability to perform self-care activities. 2. Develop a plan based on the patient's perceptions and priorities on how to establish and achieve goals to meet self-care needs, incorporating energy conservation, and work simplification concepts. a. Provide appropriate assistive devices. b. Reinforce correct and safe use of assistive devices. c. Allow patient to control timing of self-care activities. d. Explore with the patient different ways to perform difficult tasks or ways to enlist the help of someone else. 3. Consult with community health care agencies when individuals have attained a maximum level of self-care yet still have some	1. The ability to perform self-care activities is influenced by the disease activity and the accompanying pain, stiffness, fatigue, muscle weakness, loss of motion, and depression. 2. Assistive devices may enhance self-care abilities. Effective planning for changes must include the patient, who must accept and adopt the plan. 3. Individuals differ in ability and willingness to perform self-care activities. Changes in ability to care for self may lead to a decrease in personal safety.	• Identifies factors that interfere with the ability to perform self-care activities • Identifies alternative methods for meeting self-care needs • Uses alternative methods for meeting self-care needs • Identifies and uses other health care resources for meeting self-care needs

deficits, especially regarding safety.

Nursing Diagnosis: Disturbed body image associated with physical and psychological changes and dependency imposed by chronic illness
Goal: Adapts to physical and psychological changes imposed by the rheumatic disease

Nursing Interventions	Rationale	Expected Outcomes
1. Help patient identify elements of control over disease symptoms and treatment. 2. Encourage patient's verbalization of feelings, perceptions, and fears. a. Help to assess present situation and identify problems.	1. The individual's self-concept may be altered by the disease or its treatment. 2. The individual's coping strategies reflect the strength of their self-concept.	• Verbalizes an awareness that changes taking place in self-concept are normal responses to rheumatic disease and other chronic illnesses • Identifies strategies to cope with altered self-concept

Nursing Diagnosis: Difficulty coping associated with actual or perceived lifestyle or role changes

Goal: Use of effective coping behaviors for dealing with actual or perceived limitations and role changes

Nursing Interventions	Rationale	Expected Outcomes
1. Identify areas of life affected by disease. Answer questions and dispel possible myths. a. Assist to identify past coping mechanisms. b. Assist to identify effective coping mechanisms. 2. Develop plan for managing symptoms and enlisting support of family and friends to promote daily function.	1. The effects of disease may be more or less manageable once identified and explored reasonably. 2. By taking action and involving others appropriately, patient develops or draws on coping skills and community support.	• Names functions and roles affected and not affected by disease process • Describes therapeutic regimen and states actions to take to improve, change, or accept a particular situation, function, or role

Collaborative Problems: Complications secondary to effects of medications

Goal: Absence or resolution of complications

Nursing Interventions	Rationale	Expected Outcomes
1. Perform periodic clinical assessment and laboratory evaluation.	1. Skillful assessment helps detect early symptoms of side effects of medications.	• Adheres to monitoring procedures and experiences minimal side effects

Provide 2. education about correct self-administration, potential side effects, and importance of monitoring. 3. Counsel regarding methods to reduce side effects and manage symptoms. 4. Administer medications in modified doses as prescribed if complications occur.	2. The patient needs accurate information about medications and potential side effects to avoid or manage them. 3. Appropriate identification and early intervention may minimize complications. 4. Modifications may help minimize side effects or other complications.	Takes medication as • prescribed and lists potential side effects • Identifies strategies to reduce or manage side effects • Reports that side effects or complications have subsided

Pharmacologic therapy (including analgesic agents), exercise, postural assistance, modification of activities of daily living, and psychological support are useful components of a self-management program for the older adult (Oh et al., 2018).

Identifying the effects of the rheumatic disease on the patient's lifestyle, independence, and psychological status is important and can improve the quality of life for older adults. Depressed mood is routinely found in those suffering from chronic joint disease. The body image and self-esteem of the older adult with rheumatic disease, combined with underlying depression, may interfere with the use of assistive devices such as canes. The use of adaptive equipment such as long-handled reachers or tongs may be viewed by the older adult as evidence of aging rather than as a means of increasing independence.

Because most rheumatic diseases involve pain, especially with joints, some older adults may consider their symptoms as inevitable consequences of aging. In fact, many older adults expect and accept the immobility and self-care problems related to the rheumatic diseases and do not seek help, thinking that nothing can be done.

The older adult usually has a lifelong pattern of dealing with the stresses of daily life. Depending on the success of that pattern, the older adult can often maintain a positive attitude and self-esteem when faced with a rheumatic disease, especially if support is available. Previous stress management strategies are assessed. If these strategies have been effective, the patient is

encouraged and supported in their use. If they were ineffective, the nurse assists the patient in identifying alternative strategies, encourages the use of new strategies, and assesses their effectiveness.

Pharmacologic treatment of rheumatic disease in older patients is more difficult than in younger patients. If therapeutic medications have an effect on the senses (hearing, cognition), this effect is intensified in the older adult. The cumulative effect of medications, in general, is accentuated because of the physiologic changes of aging. For example, decreased renal function in the older adult alters the metabolism of certain medications, such as NSAIDs. Older adults are more prone to side effects associated with the use of multiple-drug therapy.

Partly because of the more frequent contact of older adults with health care providers for a variety of health issues, overtreatment or inappropriate treatment is possible. Complaints of pain may be met with a prescription for analgesic agents rather than instructions for rest, the use of an assistive device, and local comfort measures such as heat or cold. Acetaminophen may be appropriate and worth trying before other medications that pose a greater chance of side effects. NSAIDs can be used; however, long-term use of NSAIDs can increase the risks of peptic ulcers, hemorrhage, and cardiovascular toxicity (Comerford & Durkin, 2020).

Intra-articular corticosteroid injections, with their usually rapid relief of symptoms, may be requested by the patient who is unaware of the consequences of too-frequent use of this treatment. In addition, exercise programs may not be instituted or may be ineffective because the patient expects results to occur quickly or fails to appreciate the effectiveness of a program of exercise. In fact, strength training is encouraged in the older adult with chronic diseases.

Diffuse Connective Tissue Diseases

Diffuse connective tissue disease refers to a group of systemic disorders that are chronic in nature and are characterized by diffuse inflammation and degeneration in the connective tissues. These disorders share similar clinical features and may affect some of the same organs. The characteristic clinical course is one of exacerbations and remissions. Although diffuse connective tissue diseases have unknown causes, they are thought to be the result of immunologic abnormalities. They include RA, SLE, Sjögren's syndrome, scleroderma, polymyositis, polymyalgia rheumatica (PMR), and giant cell arteritis (GCA).

Rheumatoid Arthritis

Rheumatoid arthritis is an autoimmune disease of unknown origin that affects 1% to 2% of the population worldwide, with females having a three times greater incidence than males. It may occur at any age but the onset commonly occurs between the third and sixth decade of life. The incidence of RA increases after the sixth decade of life (Norris, 2019). RA that occurs after the age of 65 is referred to as elderly onset RA (Norris, 2019). Additional risks that have been identified include family history, environmental influences such as diet or geographic location, nulliparity, as well as the modifiable factors of smoking and obesity (Mogul, Corsi, & McAuliffe, 2019).

Pathophysiology

The exact mechanism of action for the etiology of RA is unknown. Evidence points to a genetic predisposition and the development of immunologically mediated joint inflammation (Eliopoulos, 2021; Norris, 2019). An autoimmune reaction (see Fig. 34-1) occurs in the synovial tissue. RA synovium breaks down collagen, causing edema, proliferation of the synovial membrane, and ultimately pannus formation. Pannus destroys cartilage and erodes the bone. The consequence is the loss of articular surfaces and joint motion. Muscle fibers undergo degenerative changes. Tendon and ligament elasticity and contractile power are lost.

The RA inflammatory process has also been implicated in other disease processes (i.e., arteriosclerosis). It is hypothesized that the RA disease process somehow interferes with the production of high-density lipoprotein cholesterol, which is the form of cholesterol responsible for decreasing cellular lipids and, therefore, is considered antiatherosclerotic.

The nervous system is also affected by the RA inflammatory process. The synovial inflammation can compress the adjacent nerve, causing neuropathies and paresthesias. Axonal degeneration and neuronal demyelination are also possible due to the infiltration of polymorphonuclear leukocytes, eosinophils, and mononuclear cells, causing necrotizing or occlusive vasculitis (Norris, 2019).

Clinical Manifestations

The American College of Rheumatology and the European League Against Rheumatism have collaborated and established criteria for classifying RA. These criteria are based on a point system where a total score of 6 or greater is required for the diagnosis of RA. The scoring system is based on joint involvement (number of joints affected), serology (low positive or high positive rheumatoid factor [RF] or anti-citrullinated peptide antibody [ACPA]), abnormal results of the acute phase reactants (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]), and duration of symptoms greater than 6

weeks. Patients diagnosed with RA who are excluded from these diagnostic criteria include: (1) patients who have one joint with synovitis that is not related to any other clinical disease and who also score at least 6 to 10 points on the scale, and (2) patients diagnosed with bony erosions on x-ray (Aletaha, Neogi, Silman, et al., 2010; Molano-Gonzalez, Olivares-Matinez, Anaya, et al., 2019).

The initial clinical manifestations of RA include symmetric joint pain and morning joint stiffness lasting longer than 1 hour. Over the course of the disease, clinical manifestations of RA vary, usually reflecting the stage and severity of the disease. Symmetric joint pain, swelling, warmth, erythema, and lack of function are classic symptoms. Palpation of the joints reveals spongy or boggy tissue. Often, fluid can be aspirated from the inflamed joint. Characteristically, the pattern of joint involvement begins in the small joints of the hands, wrists, and feet (Omma et al., 2018). As the disease progresses, the knees, shoulders, hips, elbows, ankles, cervical spine, and temporomandibular joints may be affected. The onset of symptoms is usually acute. Symptoms are usually bilateral and symmetric.

In the early stages of disease, even before the presentation of bony changes, limitation in function can occur when there is active inflammation in the joints. Joints that are hot, swollen, and painful are not easily moved. The patient tends to guard or protect these joints by immobilizing them. Immobilization for extended periods can lead to contractures, creating soft tissue deformity.

Deformities of the hands (e.g., ulnar deviation and swan neck deformity) and feet are common in RA (see Chapter 35, Fig. 35-6). The deformity may be caused by misalignment resulting from swelling, progressive joint destruction, or the subluxation (partial dislocation) that occurs when one bone slips over another and eliminates the joint space. Deformities of RA differ from those seen with osteoarthritis (OA), such as Heberden's and Bouchard's nodes (see Chapter 36).

RA is a systemic disease with multiple extra-articular features. Most common are fever, weight loss, fatigue, anemia, lymph node enlargement, and Raynaud's phenomenon (cold- and stress-induced vasospasm causing episodes of digital blanching or cyanosis). Rheumatoid nodules are common in patients with more advanced RA. These nodules are usually nontender and movable in the subcutaneous tissue. They usually appear over bony prominences such as the elbow, are varied in size, and can disappear spontaneously or progress to ulceration (Weber & Kelley, 2019; Young, 2019). Nodules occur only in people who have rheumatoid factor. Other extra-articular features include arteritis, neuropathy, pericarditis, splenomegaly, and Sjögren's syndrome (dry eyes and dry mucous membranes).

Assessment and Diagnostic Findings

Several assessment findings are associated with RA: rheumatoid nodules, joint inflammation detected on palpation, and certain laboratory findings. The history and physical examination focus on manifestations, such as bilateral and symmetric stiffness, tenderness, swelling, and temperature changes in the joints (Weber & Kelley, 2019). The patient is also assessed for extra-articular changes; these often include weight loss, sensory changes, lymph node enlargement, and fatigue. Symptoms and examination findings are often recorded using a disease activity score, a variety of which are in use, to evaluate disease activity, help guide treatment decisions, and monitor treatment efficacy (Mahmood, van Tuyl, Schoonmade, et al., 2019).

Rheumatoid factor is present in many patients with RA, but its presence alone is not diagnostic of RA, and its absence does not rule out the diagnosis. Antibodies to cyclic citrullinated peptide (anti-CCP) have a specificity of approximately 95% at detecting RA (Norris, 2019). The ESR and CRP tend to be significantly elevated in the acute phases of RA and are therefore useful in monitoring active disease and disease progression. The complete blood count (CBC) should be assessed to establish a baseline count especially prior to starting medications (Fischbach & Fischbach, 2018). Patients may exhibit anemia, and platelets may be elevated due to the inflammatory process. A tuberculin (TB) skin test should be done prior to the initiation of certain medications to rule out tuberculosis. In the event the patient has latent TB and has never been treated, the infection can be reactivated. The patient should also be assessed for hepatitis B and hepatitis C, which could impact treatment strategies if positive. If the client tests positive for hepatitis, the infection should be treated prior to starting medication. Liver and kidney monitoring are recommended for most DMARD therapy because it can cause elevation of the liver enzymes and can also affect kidney function.

X-ray, ultrasound, or both of the hands, wrists, and feet can be useful in establishing a baseline for joint evaluation, and assessing the joints for erosions and synovitis. Joint damage may occur within the first 6 to 12 months of diagnosis and should be followed as indicated. Plain x-ray is the most common radiographic study used to track disease progression as it is inexpensive, reliable, and reproducible (Mahmood et al., 2019). MRI can also be useful to detect small erosions that may not be visible on x-ray or ultrasound.

Medical Management

The goal of treatment at all phases of the RA disease process is to decrease joint pain and swelling, achieve clinical remission, decrease the likelihood of joint deformity, and minimize disability. Initial treatment delays have been implicated in greater long-term joint deformity. Aggressive and early treatment

regimens are warranted. The use of a targeted pharmacologic treatment strategy is recommended to decrease RA disease activity (Singh et al., 2016).

Early Rheumatoid Arthritis

Once the diagnosis of RA is made, treatment should begin with either a nonbiologic or biologic DMARD. The goal of using DMARD therapy is preventing inflammation and joint damage.

Recommended treatment guidelines include beginning with the nonbiologic DMARDs (methotrexate is the preferred agent but leflunomide, sulfasalazine, or hydroxychloroquine are also used) biologics, or tofacitinibic within 3 months of disease onset. Care should be used with each of these medications by performing routine blood testing for liver and kidney function, along with monitoring the CBC for anemia. Dosage may need to be modified for patients with renal impairment (Comerford & Durkin, 2020).

Another treatment approach for RA is the use of biologic DMARDs. These agents have been specifically engineered to target the most prominent proinflammatory mediators in RA—TNF-α, B cells, T cells, IL-1, and IL-6 (see Table 34-2). Biologic DMARDs are the first targeted therapy for RA. Clinical evidence suggests that biologic DMARDs work more quickly and show a greater delay in radiologic disease progression when compared to nonbiologic DMARDs. The biologic DMARDs are more expensive and have fewer years of usage with the RA population. Therefore, they tend to be reserved for patients with persistent moderate to severe RA who have not responded adequately to synthetic DMARDs (Singh et al., 2016).

After initiating treatment with a DMARD, patients generally report a beneficial effect within 6 weeks and tolerate the medication relatively well. However, some patients may take longer to see improvement. Corticosteroids are recommended as a "bridge" in the early treatment but are not recommended for long-term therapy due to side effects (Singh et al., 2016).

A newer class of drugs, the Janus Kinase (JAK) inhibitors, bind to the active JAK enzyme sites, inhibiting autophosphorylation and thus inhibiting cytokine production and decreasing the immune response (Mogul et al., 2019). JAK inhibitors are used in combination with methotrexate or other nonbiologic DMARDs. They may also be used as monotherapy (Mogul et al., 2019; Singh et al., 2016).

NSAIDs and specifically the cyclo-oxygenase 2 (COX-2) enzyme blockers are used for pain and inflammation relief. NSAIDs, such as ibuprofen and naproxen, are commonly prescribed because of their low cost and analgesic properties. They must be used with caution, however, in long-term chronic diseases because of the possibility of gastric ulcers. Several COX-2 enzyme blockers have been approved for treatment of RA. Cyclo-oxygenase is an enzyme that is involved in the inflammatory process. COX-2 medications block the enzyme involved in inflammation (COX-2) while leaving intact the

enzyme involved in protecting the stomach lining (COX-1). As a result, COX-2 enzyme blockers are less likely to cause gastric irritation and ulceration than other NSAIDs; however, they are associated with increased risk of cardiovascular disease and must be used with caution (Comerford & Durkin, 2020). The nurse should be aware that NSAIDs do not prevent erosions or alter disease progression and, consequently, are medications useful only for symptom relief (Singh et al., 2016).

Additional analgesia may be prescribed for periods of extreme pain. Opioid analgesic agents are avoided because of the potential for continuing need for pain relief. Nonpharmacologic pain management techniques (e.g., relaxation techniques, heat and cold applications) are taught.

Established Rheumatoid Arthritis

In patients with established RA, a formal program with occupational and physical therapy is prescribed to educate the patient about principles of pacing activities, work simplification, range of motion, and muscle-strengthening exercises. The patient is encouraged to participate actively in the management program. The medication program is reevaluated periodically, and appropriate changes are made if disease progression is occurring despite pharmacologic treatment. Additional agents may be added to enhance the disease-modifying effect of methotrexate. Combination therapy using one nonbiologic DMARD and one biologic DMARD is common (Singh et al., 2016).

For more established RA, reconstructive surgery and corticosteroids are often used. Reconstructive surgery is indicated when pain cannot be relieved by conservative measures and the threat of loss of independence is eminent. Surgical procedures include synovectomy (excision of the synovial membrane), tenorrhaphy (suturing of a tendon), arthrodesis (surgical fusion of the joint), surgical repair, and replacement of the joint. Surgery is not performed during exacerbations.

Systemic corticosteroids are used when the patient has unremitting inflammation and pain or needs a “bridging” medication while waiting for the slower DMARDs (e.g., methotrexate) to begin taking effect. Low-dose corticosteroid therapy is prescribed for the shortest time necessary to minimize side effects (Singh et al., 2016). Single large joints that are severely inflamed and fail to respond promptly to the measures outlined previously may be treated by local injection of a corticosteroid.

Topical analgesic agents such as capsaicin and methylsalicylate are often prescribed. Topical diclofenac sodium gel may help with joint pain in the hands and knees (Comerford & Durkin, 2020).

For most patients with RA, the emotional and possible financial burden of the disease can lead to depressive symptoms and sleep deprivation. The patient may require the short-term use of low-dose antidepressant medications, such as amitriptyline, paroxetine, or sertraline, to reestablish an adequate sleep

pattern and manage depressive symptoms. Patients may benefit from referrals for talk therapy or group support.

Obesity Considerations

The prevalence of obesity is increasing in the general population and in patients with RA. One large study reported that the prevalence of obesity, diagnosed with a body mass index (BMI) of greater than or equal to 30 kg/m^2, was approximately 20% at diagnosis and increased each year (Nikiphorou, Norton, Young, et al., 2018). Furthermore, the presence of obesity adversely affected disease progression, function, and quality of life in patients with RA followed for 10 to 25 years (Nikiphorou et al., 2018). Management of obesity in the patient with RA is essential.

Certain medications (i.e., oral corticosteroids) used in RA treatment stimulate the appetite and, when combined with decreased activity, may lead to weight gain. In fact, one study reported that approximately half the increase in BMI within the first year of diagnosis with RA could be attributed to steroid use (Nikiphorou et al., 2018).

A dietician can counsel the patient about better food choices. Food selection should include the five major groups (grains, vegetables, fruits, dairy, and protein), with emphasis on foods high in vitamins, protein, and iron for tissue building and repair. Patients who are overweight or have obesity need to be counseled about eating a healthy, calorie-restricted diet.

Nursing Management

Nursing care of the patient with RA follows the basic plan of care presented earlier (see Chart 34-3). The most common issues for the patient with RA include pain, sleep disturbance, fatigue, altered mood, and limited mobility. The patient with newly diagnosed RA needs information about the disease to make daily self-management decisions and cope with having a chronic disease. Consultation with a dietician for assessment and assistance with appropriate food choices may be helpful.

Monitoring and Managing Potential Complications

Patients commonly have comorbid conditions such as cardiovascular disease that can lead to complications. It has been estimated that the primary cause of death for up to 40% of patients diagnosed with RA is cardiovascular disease. The cause of cardiovascular disease in these patients is thought to be due to elevated lipid values, chronic inflammation, dysfunction of the endothelium, and/or abnormal homocysteine levels (Norris, 2019).

Medications used for treating RA may cause serious and adverse effects. The primary provider bases the prescribed medication regimen on clinical findings and past medical history, and then, with the help of the nurse, monitors for side effects using periodic clinical assessments and laboratory testing. The nurse, who can be available for consultation between visits with the primary provider, works to help the patient recognize and deal with these side effects (see Table 34-2). Medication may need to be stopped or the dose reduced. If the patient experiences an increase in symptoms while the complication is being resolved or a new medication is being initiated, the nurse's counseling regarding symptom management may relieve potential anxiety and distress.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education is an essential aspect in nursing care of the patient with RA to enable the patient to maintain as much independence as possible, to take medications accurately and safely, and to use adaptive devices correctly (Oh et al., 2018). Patient education focuses on self-management related to the disorder, the therapeutic regimen prescribed to treat it, and the potential side effects of medications. Patients undergoing surgery need education as well. The nurse works with the patient and family on strategies to maintain independence, function, and safety in the home (see Chart 34-4).

The patient and family are encouraged to verbalize their concerns and ask questions. Because RA commonly affects young women, major concerns may be related to the effects of the disease on childbearing potential, caring for family, or work responsibilities. The patient with a chronic illness may seek a "cure" or have questions about alternative therapies. Research indicates that acupuncture is safe and may be beneficial for patients with RA (Chou & Chu, 2018). There is not enough evidence of the effectiveness of other complementary, alternative, and integrative health therapies, and more rigorous research is needed (Chou & Chu, 2018; Katz-Talmor, Katz, Porta-Katz, et al., 2018).

The nurse educates patients using topical analgesic agents to apply sparingly, avoid areas of open skin, and avoid contact with eyes and mucous membranes. Patients should also wash their hands carefully after application and assess for local skin irritation. Pain, fatigue, and depressive symptoms can interfere with the patient's ability to learn and should be addressed before the education is initiated. Various educational strategies may then be used, depending on the patient's previous knowledge base, interest level, degree of comfort, social or cultural influences, and readiness to learn. The nurse

educates the patient about basic disease management and necessary adaptations in lifestyle. Some types of aerobic exercise and strength training should be discussed (Kapale et al., 2017). Because suppression of inflammation and autoimmune responses require the use of anti-inflammatory, disease-modifying antirheumatic, and immunosuppressive agents, the patient is taught about prescribed medications, including type, dosage, rationale, potential side effects, self-administration, and required monitoring procedures. If hospitalized, the patient is encouraged to practice new self-management skills with support from caregivers and significant others. The nurse then reinforces disease management skills during each patient contact. Barriers are assessed, and measures are taken to promote adherence to medications and the treatment program.

Chart 34-4  HOME CARE CHECKLIST

At the completion of education, the patient and/or caregiver will be able to:

State the impact of rheumatoid arthritis on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.

- State changes in lifestyle (e.g., diet, activity, rest) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate accurate and safe self-administration of medications.
- Describe and demonstrate the use of pain management techniques.
- Demonstrate ability to perform ADLs independently or with assistive devices/adaptive equipment.
- Verbalize ways to cope with stress successfully, plans for regular, safe exercise, and rationale for obtaining adequate rest. Demonstrate a relaxation technique.
- Verbalize a dietary plan that includes maintaining or losing weight while maximizing vitamins, protein, and iron for tissue building and repair
- State how to reach primary provider with questions or complications
- State time and date of follow-up appointments, testing
- Identify the need for health promotion, disease prevention, and screening activities
- Identify community resources for peer and caregiver/family information and support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify the contact details for support services for patients and their caregivers/families

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care

Depending on the severity of the disease and the patient's resources and supports, referral for home care may be warranted. For example, the patient who is an older adult or frail, has RA that limits function significantly, and lives alone may need referral for home care.

The impact of RA on everyday life is not always evident when the patient is seen in the hospital or in an ambulatory care setting. The increased frequency with which nurses see patients in the home provides opportunities for recognizing problems and implementing interventions aimed at improving the quality of life of patients with RA.

During home visits, the nurse has the opportunity to assess the home environment and its adequacy for patient safety and management of the disorder. Adherence to the treatment program can be more easily monitored in the home setting, where physical and social barriers to adherence are more readily identified. For example, a patient who also has diabetes and requires insulin may be unable to fill the syringe accurately or unable to administer the insulin because of impaired joint mobility. Appropriate adaptive equipment needed for increased independence is often identified more readily when the nurse sees how the patient functions in the home. Any barriers to adherence are identified, and appropriate referrals are made.

For patients at risk for impaired skin integrity, the home health nurse can closely monitor skin status and also educate, provide, or supervise the patient and family in preventive skin care measures. The nurse also assesses the patient's need for assistance in the home and supervises home health aides, who may meet many of the needs of the patient with RA. Referrals to physical and occupational therapists may be made as problems are identified and limitations increase. A home health nurse may visit the home to make sure that the patient can function as independently as possible despite mobility problems and can safely manage treatments, including pharmacotherapy. The patient and family should be informed about support services such as Meals on Wheels and local Arthritis Foundation chapters.

Because many of the medications used to suppress inflammation are injectable, the nurse may administer the medication to the patient or educate about self-injection. These frequent contacts allow the nurse to reinforce other disease management techniques.

The nurse also assesses the patient's physical and psychological status, adequacy of symptom management, and adherence to the management plan. Patients should know which type of rheumatic disease they have, not just that they have "arthritis" or "arthritis of the knee." The importance of attending follow-up appointments is emphasized to the patient and family, and they should be reminded about the importance of participating in other health promotion activities and health screening.

Systemic Lupus Erythematosus

SLE is an inflammatory, autoimmune disorder that affects nearly every organ in the body. The overall incidence of SLE is estimated to be 1.8 to 7.6 per 100,000 people (Centers for Disease Control and Prevention [CDC], 2018). It occurs 4 to 12 times more frequently in women than in men and occurs more often in African Americans, Hispanics/Latino Americans, Asians, and American Indians/Alaska Natives than among White Americans (CDC, 2018). In addition to SLE, other forms of adult lupus exist, including subacute

cutaneous or discoid lupus erythematous, and drug-induced lupus (Aringer, Costenbader, Daikh, et al., 2019).

Pathophysiology

While the exact cause is not known, SLE starts with the body's immune system inaccurately recognizing one or more components of the cell's nucleus as foreign, seeing it as an antigen. The immune system starts to develop antibodies to the nuclear antigen. In particular, B cells begin to overproduce antibodies with the help of multiple cytokines such as B-lymphocyte stimulator (BLyS), which is overexpressed in SLE. The antibodies and antigens form antigen–antibody complexes and have the propensity to get trapped in the capillaries of visceral structures. The antibodies also act to destroy host cells. It is thought that those two mechanisms are responsible for the majority of the clinical manifestations of this disease process. The immunoregulatory disturbance is thought to be brought about by some combination of four distinct factors: genetic, immunologic, hormonal, and environmental (Norris, 2019).

Research into the genetic origins of SLE has thus far revealed that multiple genes are likely implicated in the development of SLE (Norris, 2019). The large majority of SLE cases, however, remain sporadic and unrelated to family medical history.

Given the high number of women with SLE compared with men, it is hypothesized that female sex hormones (estrogen) play a role in the predisposition to SLE. Estrogen may contribute to the body's response of overreacting to the body's own tissues.

Although genetics and hormones likely play a role in the predisposition of SLE, it is hypothesized that exogenous or environmental triggers are also implicated in the onset of the disease process. These triggers may include cigarette smoke, ultraviolet rays, exposure from sunlight and fluorescent light bulbs, medications (hydralazine, minocyline, or procainamide), viral infections, emotional stress, stress on the body (e.g., surgery, pregnancy), and silica dust exposure in the occupational setting (Norris, 2019).

Clinical Manifestations

SLE is an autoimmune, systemic disease that can affect any body system (Fig. 34-2). The disease process involves chronic states where symptoms are minimal or absent and acute flares where symptoms and lab results are elevated. Symptoms most often include fever, fatigue, skin rashes, as well as joint pain and swelling (Aringer et al., 2019; CDC, 2018). The mucocutaneous, musculoskeletal, renal, nervous, cardiovascular, and respiratory systems are

most commonly involved. Less commonly affected are the gastrointestinal tract and liver as well as the ocular system.

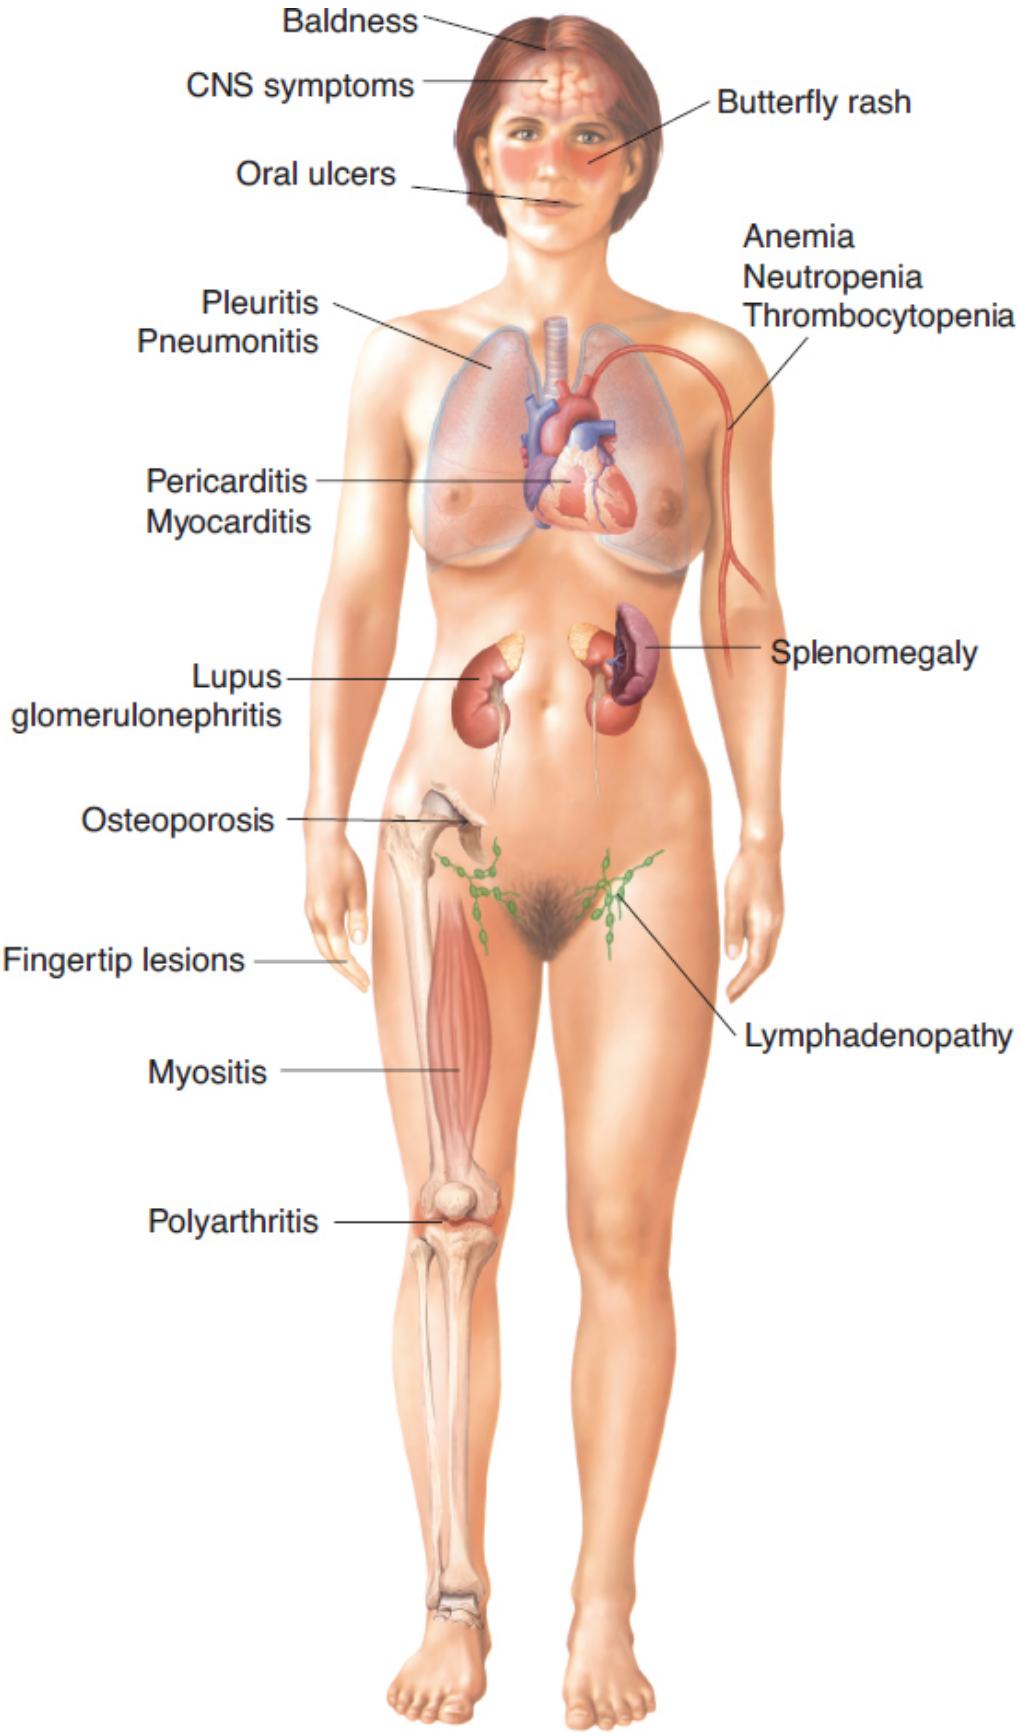

Figure 34-2 • Clinical manifestations of SLE. Reprinted with permission from Norris, T. L. (2019). *Porth's pathophysiology:*

Concepts of altered health states (10th ed., Fig. 50.5). Philadelphia, PA: Wolters Kluwer.

Some type of cutaneous system manifestation is experienced in up to 85% of patients with SLE (Norris, 2019). Several skin manifestations may occur in patients with SLE, including subacute cutaneous lupus erythematosus, which involves papulosquamous or annular polycyclic lesions, and a discoid rash, which is a chronic rash with erythematous papules or plaques and scaling and can cause scarring and pigmentation changes (Aringer et al., 2019). In some cases, the only skin involvement may be a discoid rash. In some patients with SLE, the initial skin involvement is the precursor to more systemic involvement. The lesions often worsen during **exacerbations** (flares) of the systemic disease and possibly are provoked by sunlight or artificial ultraviolet light (Norris, 2019). Oral ulcers, which may accompany skin lesions, may involve the buccal mucosa or the hard palate, occur in crops, and are often associated with exacerbations. Other cutaneous manifestations include splinter hemorrhages, alopecia, and Raynaud's phenomenon.

Joint pain and swelling occur in more than 90% of patients with SLE (Norris, 2019). Joint swelling, tenderness, and pain on movement are also common. Frequently, these are accompanied by morning stiffness.

The cardiac system is also commonly affected in SLE. Pericarditis is the most common cardiac manifestation (Norris, 2019). Patients may present with substernal chest pain that is aggravated by movement or inspiration. Symptoms can be acute and severe or last for weeks at a time. Other cardiac symptoms may involve myocarditis, hypertension, cardiac arrhythmias, and valvular incompetence.

Nephritis as a result of SLE, also referred to as lupus nephritis, occurs due to a buildup of antibodies and immune complexes that cause damage to the nephrons. Serum creatinine levels and urinalysis are used in screening for renal involvement. Early detection allows for prompt treatment so that renal damage can be prevented. Renal involvement may lead to hypertension, which also requires careful monitoring and management (see Chapter 27).

Central nervous system involvement is widespread, encompassing the entire range of neurologic disease. The varied and frequent neuropsychiatric presentations of SLE are now widely recognized and include psychosis, cognitive impairment, seizures, peripheral and cranial neuropathies, transverse myelitis, and strokes. These are generally demonstrated by subtle changes in behavior patterns or cognitive ability.

Assessment and Diagnostic Findings

Diagnosis of SLE is based on a complete history, physical examination, and blood tests. In addition to the general assessment performed for any patient

with a rheumatic disease, assessment for known or suspected SLE has special features. The skin is inspected for erythematous rashes. Cutaneous erythematous plaques with an adherent scale may be observed on the scalp, face, or neck. Areas of hyperpigmentation or depigmentation may be noted, depending on the phase and type of disease. The patient should be questioned about skin changes (because these may be transitory) and specifically about sensitivity to sunlight or artificial ultraviolet light. The scalp should be inspected for alopecia and the mouth and throat for ulcerations reflecting gastrointestinal involvement.

Cardiovascular assessment includes auscultation for pericardial friction rub, possibly associated with myocarditis and accompanying pleural effusions. The pleural effusions and infiltrations, which reflect respiratory insufficiency, are demonstrated by abnormal lung sounds. Papular, erythematous, and purpuric lesions developing on the fingertips, elbows, toes, and extensor surfaces of the forearms or lateral sides of the hand that may become necrotic suggest vascular involvement.

Joint swelling, tenderness, warmth, pain on movement, stiffness, and edema may be detected on physical examination. The joint involvement is often symmetric and similar to that found in RA.

The neurologic assessment is directed at identifying and describing any central nervous system changes. The patient and family members are asked about any behavioral changes, including manifestations of neurosis or psychosis. Signs of depression are noted, as are reports of seizures, chorea, or other central nervous system manifestations.

The antinuclear antibody (ANA) is positive in more than 95% of patients with SLE, indicating exceptional specificity (Aringer et al., 2019). Other laboratory tests include anti-DNA (antibody that develops against the patient's own DNA), anti-ds DNA (antibody against DNA that is highly specific to SLE, which helps differentiate it from drug-induced lupus), and anti-Sm (antibody against Sm, which is a specific protein found in the nucleus). Other blood work includes the CBC, which may reveal anemia, thrombocytopenia, leukocytosis, or leukopenia.

Medical Management

SLE can be life-threatening, but advances in its treatment have led to improved survival and reduced morbidity. Acute disease requires interventions directed at controlling increased disease activity or exacerbations that can involve any organ system. Disease activity is a composite of clinical and laboratory features that reflect active inflammation secondary to SLE. Management of the more chronic condition involves periodic monitoring and recognition of meaningful clinical changes requiring adjustments in therapy.

The goals of treatment include preventing progressive loss of organ function, reducing the likelihood of acute disease, minimizing disease-related disability, and preventing complications from therapy. Management of SLE involves regular monitoring to assess disease activity and therapeutic effectiveness.

Pharmacologic Therapy

The mainstay of SLE treatment is based on pain management and nonspecific immunosuppression. Therapy includes monoclonal antibodies, corticosteroids, antimalarial agents, NSAIDs, and immunosuppressive agents. Each of these medications has potentially serious side effects, including organ damage.

Belimumab is a monoclonal antibody that specifically recognizes and binds to BLyS. BLyS acts to stimulate B cells to produce antibodies against the body's own nuclei, which is an integral part of the disease process in SLE. Belimumab acts to render BLyS inactive, preventing it from binding to B-cell surfaces and stimulating B-cell activity. This action then halts the production of unnecessary antibodies and decreases disease activity in SLE. Live vaccines are contraindicated for 30 days before taking this medication (Comerford & Durkin, 2020). Rituximaub is an additional monoclonal antibody used in the treatment of SLE for its immune modulating effects (MacIsaac, Siddiqui, Jamula, et al., 2018).

Corticosteroids are another medication used topically for cutaneous manifestations, in low oral doses for minor disease activity, and in high doses for major disease activity. Intravenous (IV) administration of corticosteroids is an alternative to traditional high-dose oral administration. One of the most important risk factors associated with the use of corticosteroids in SLE is osteoporosis and fractures (Comerford & Durkin, 2020).

An antimalarial medication, hydroxychloroquine, is effective for managing cutaneous, musculoskeletal, and mild systemic features of SLE (Comerford & Durkin, 2020). The NSAIDs used for minor clinical manifestations are often used in conjunction with corticosteroids in an effort to minimize corticosteroid requirements.

Immunosuppressive agents (alkylating agents and purine analogues) are used because of their effect on overall immune function. These medications are generally reserved for patients who have serious forms of SLE that have not responded to conservative therapies. Examples include cyclophosphamide, azathioprine, mycophenolic acid, and methotrexate, which are contraindicated in pregnancy and have been used most frequently in SLE nephritis (Comerford & Durkin, 2020).

Nursing Management

Nursing care of the patient with SLE is based on the fundamental plan presented earlier in the chapter (see Chart 34-3). The most common nursing diagnoses include fatigue, impaired skin integrity, body image disturbance, and lack of knowledge for self-management decisions. The disease or its treatment may produce dramatic changes in appearance and considerable distress for the patient. The changes and the unpredictable course of SLE necessitate expert assessment skills and nursing care with sensitivity to the psychological reactions of the patient. The patient may benefit from participation in support groups, which can provide disease information, daily management tips, and social support. Because sun and ultraviolet light exposure can increase disease activity or cause an exacerbation, patients should be instructed to avoid exposure or to protect themselves with sunscreen and appropriate clothing.

Because of the increased risk of involvement of multiple organ systems, patients should understand the need for routine periodic screenings as well as health promotion activities. A dietary consultation may be indicated to ensure that the patient is knowledgeable about dietary recommendations, given the increased risk of cardiovascular disease, including hypertension and atherosclerosis.

In the healthy population, smoking and using electronic nicotine delivery systems (ENDS) including e-cigarettes, e-pens, e-pipes, e-hookah, and e-cigars clearly poses health risks. Smoking increases the incidence of respiratory infections, lung cancer, risk of coronary artery disease; increases blood pressure, which can worsen kidney function; inhibits liver function (which can also inhibit treatment medications from working appropriately, such as hydroxychloroquine); increases the risk for skin diseases; and increases the risk for osteoporosis. The health risks of ENDS use is under investigation. Patients diagnosed with SLE are at even higher risk of developing lung cancer and other rare cancers. Therefore, smoking cessation programs should be offered to all patients who report smoking habits (Montes, Mocarzel, Lanzieri, et al., 2016).

The nurse educates the patient about the importance of continuing prescribed medications and addresses the changes and potential side effects that are likely to occur with their use. The patient is reminded of the importance of monitoring because of the increased risk of systemic involvement, including renal and cardiovascular effects.

Because of the immunosuppression associated with systemic corticosteroid usage, the nurse must watch for signs and symptoms of infection, especially with patients who are acutely ill.

The nurse should also screen the patient for osteoporosis, because long-term use of corticosteroids increases the incidence of osteoporosis. Patients should have a bone mineral density test performed at diagnosis and prior to beginning steroid use to determine a baseline status and then every 2 years thereafter. Educating the patient regarding calcium and vitamin D supplementation daily

is encouraged, along with the benefits of weight-bearing activities to support bone health.

Primary Sjögren's Syndrome

Primary Sjögren's syndrome is a rare systemic autoimmune disease that predominantly affects middle-aged women (Cornec, Devauchelle-Pensec, Mariette, et al., 2017).

Sjögren's syndrome often manifests in conjunction with other autoimmune diseases, most commonly autoimmune thyroid disease, RA, and SLE (MacIsaac et al., 2018; Molano-Gonzalez et al., 2019).

Pathophysiology

Primary Sjögren's is a multisystem disease characterized by lymphocytic infiltration leading to failure of the lacrimal and salivary glands (Cui, Li, Yin, et al., 2018).

Clinical Manifestations

The most common symptoms involve kerotoconjunctivitis sicca (dry eyes), xerostomia (dry mouth), pain, and fatigue (Cornec et al., 2017; Cui et al., 2018). Some patients will complain that their eyes feel "gritty," as if there is sand present. The patient's eyes will exhibit increased redness and lack of tearing. The mouth will have dry and sticky mucous membranes. The reduced saliva production may lead to difficulty swallowing.

Sjögren's syndrome can also exhibit symptoms in many other organ systems. Lesions may ulcerate and can be painful. Optic neuritis, trigeminal neuralgia, and sensory neuropathy may be present, with symptoms such as burning pain in the extremities, numbness, vertigo, arthralgia, and/or myalgia. Raynaud's phenomenon, which involves blood vessel spasms leading to decreased circulation to the toes, fingers, nose, and ears, may be reported. Patients experience symptoms of pain, fatigue, depression, and anxiety (Cui et al., 2018). Sleep disturbances are frequently reported and may be related to pain, fatigue, and depressive symptoms (Hackett, Gotts, Ellis, et al., 2017).

Assessment and Diagnostic Findings

The classification criteria for diagnosis of Sjögren's syndrome identify six distinct indices (Klippel, Stone, Crofford, et al., 2008):

- Ocular symptoms such as chronic dry eye (Kerotoconjunctivitis Sicca).

- Positive ocular tests (evaluating tear production, corneal, and conjunctival damage). Ocular testing may include Schemer tear test or Rose Bengal tests.
- Oral symptoms, dry mouth.
- Histopathology evaluation (of salivary glands). This will help differentiate the cause of dry mouth from other causes, such as infection, malignancy, stones, and sarcoidosis.
- Salivary gland involvement.

Laboratory tests include autoantibodies to ribonucleoprotein particles (Ro[SS-A] and/or La[SS-B]), which act as antigens in this disease process. Other laboratory indices are also useful in diagnosing Sjögren's syndrome. Rheumatoid factor is present in 50% to 70% of patients. ANA, circulating DNA (cDNA), anti-CCP, ACPA, and anticentromere antibody (ACA) are all potentially present in Sjögren's syndrome and in some cases may act as markers for disease activity (Molano-Gonzalez et al., 2019).

For vasculitis manifestations, a skin biopsy can yield useful information such as leukocytoclastic vasculitis found on histologic examination. If neurologic symptoms are present, nerve conduction studies, MRI, electroencephalograms, and cerebrospinal fluid testing may be used to aid in diagnosis and treatment planning.

Medical Management

There is no cure for Sjögren's syndrome, and treatment is aimed at symptom management and improving quality of life (Cornec et al., 2017; Cui et al., 2018; Hackett et al., 2017). Artificial tears, drops such as pilocarpine, and ocular ointments such as topical cyclosporine are used for dry eyes. Tears normally drain through the lacrimal puncta to the nose, which can render artificial tears ineffective. Therefore, punctum plugs may be a useful management tool. One systematic review reported that pilocarpine is highly effective in decreasing symptoms of dry mouth by increasing salivary flow (Hamad, Lodi, Porter, et al., 2018). Biotene oral rinse may also be useful for some patients. Additional suggestions include eating small frequent meals; omitting spicy, salty, and irritating food; and avoiding smoking (including ENDS), excessive alcohol use, and drugs with anticholinergic side effects. There is some evidence for the effectiveness of rituximab and interferone (Cornec et al., 2017; Hamad et al., 2018; MacIsaac et al., 2018). Patients need to be screened for depression and sleep disturbances, then appropriate referrals made when these comorbid conditions are present (Cui et al., 2018; Hackett et al., 2017).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The primary issues for the patient with Sjögren's syndrome are pain, fatigue, and inadequate knowledge of self-management techniques. The nurse is in the unique position to educate and reinforce the treatment regimen with the patient, especially involving the ocular treatments to avoid eye infections secondary to the dry eyes. The high prevalence of pain, fatigue, and depressive symptoms may interfere with the patient's ability to learn and engage in self-management techniques and should be addressed (Cui et al., 2018).

Scleroderma

Scleroderma is a rare autoimmune disease affecting the connective tissue of the skin, blood vessel walls, and internal organs. There are two general types: localized (affecting only the cutaneous system) or diffuse (routinely referred to as systemic sclerosis and affecting multiple organ systems). Similar to other autoimmune diseases, women are affected four times more than men, and the onset occurs typically between the ages of 25 and 50 years (Norris, 2019). Scleroderma has a variable course with remissions and exacerbations.

Pathophysiology

The pathogenesis is poorly understood. Scleroderma commonly begins with skin involvement. Mononuclear cells cluster on the skin and stimulate lymphokines to stimulate procollagen. Insoluble collagen is formed and accumulates excessively in the tissues (Norris, 2019). Initially, the inflammatory response causes edema, with a resulting taut, smooth, and shiny skin appearance. The skin then undergoes fibrotic changes, leading to loss of elasticity and movement. Eventually, the tissue degenerates and becomes nonfunctional. This chain of events, from inflammation to degeneration, also occurs in blood vessels, major organs, and body systems (Norris, 2019).

Clinical Manifestations

The skin and subcutaneous tissues become increasingly hard and rigid due to excess collagen and cannot be pinched up from the underlying structures. Wrinkles and lines are obliterated. The skin is dry because sweat secretion over the involved region is suppressed. The extremities stiffen and lose mobility. The condition spreads slowly; for years, these changes may remain localized in the hands and the feet. The face appears masklike, immobile, and expressionless, and the mouth becomes rigid; referred to as "stone facies" (Norris, 2019).

The changes within the body, although not visible directly, are vastly more important than the visible changes. The esophagus hardens, interfering with swallowing. The lungs become scarred, impeding respiration. Digestive disturbances occur because of sclerosing (hardening) of the intestinal mucosa. Vascular involvement of the kidneys leads to malignant hypertension and renal insufficiency. Cardiac disorders include pericarditis, heart block, and myocardial fibrosis (Norris, 2019).

The patient may manifest a variety of symptoms referred to as the CREST syndrome. *CREST* stands for *c*alcinosis (calcium deposits in the tissues), *R*aynaud's phenomenon, *e*sophageal dysmobility, *s*clerodactyly (scleroderma of the digits), and *t*elangiectasia (capillary dilation that forms a vascular lesion) (Norris, 2019).

Assessment and Diagnostic Findings

Assessment focuses on the sclerotic changes in the skin, contractures in the fingers, and color changes or lesions in the fingertips. Assessment of systemic involvement requires a systems review with special attention to gastrointestinal, pulmonary, renal, and cardiac symptoms. Limitations in mobility and self-care activities should be assessed, along with the impact the disease has had (or will have) on body image.

There is no one conclusive diagnostic test used to diagnose scleroderma. Generally, the patient is diagnosed with the CREST type of scleroderma if they have four of the five symptoms in the syndrome (Norris, 2019).

Medical Management

Treatment of scleroderma is mainly symptomatic and supportive. No medication regimen is effective in modifying the disease process in scleroderma, but various medications are used to treat organ system involvement. The use of angiotensin-converting enzyme inhibitors when there is kidney involvement has led to a substantial decrease in mortality from hypertensive kidney disease (Norris, 2019).

All patients require counseling, during which realistic individual goals may be determined. Support measures include strategies to decrease pain and limit disability. A moderate exercise program is encouraged to prevent joint contractures. Patients are advised to avoid extreme temperatures and to use lotion to minimize skin dryness.

Nursing Management

Nursing care of the patient with scleroderma is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The primary nursing

diagnoses are impaired skin integrity; self care deficits; impaired nutritional status; and disturbed body image. The patient with advanced disease may also have impaired gas exchange, impaired cardiac output, impaired swallowing, and constipation.

Providing meticulous skin care and preventing the effects of Raynaud's phenomenon are major nursing challenges. See Chapter 26 for further discussion of Raynaud's phenomenon.

Polymyositis

Polymyositis is a group of diseases that are termed *idiopathic inflammatory myopathies* (Klippel et al., 2008). They are rare chronic conditions, with an incidence estimated at 2 cases per 10,000 adults per year. Polymyositis is most commonly seen in women versus men (2:1) and usually seen between 40 and 50 years of age (Miller & Vleugels, 2019).

Pathophysiology

Polymyositis is classified as autoimmune because autoantibodies are present. However, these antibodies do not cause damage to muscle cells, indicating only an indirect role in tissue damage. The pathogenesis is multifactorial, including cellular and humoral immune mechanisms (Norris, 2019).

Clinical Manifestations

The onset may be very slow and insidious, with symptoms gradually worsening over weeks to months. Proximal muscle weakness is typically the first symptom. Muscle weakness is usually symmetric and diffuse. Common complaints include having difficulty rising from a chair, climbing steps, or holding up the head. Myalgia and muscle tenderness occur in 25% to 50% of patients. Dermatomyositis, a related condition, is most commonly identified by an erythematous smooth or scaly lesion found over the joint surface, which often occurs prior to symptoms of weakness in 50% to 60% of patients (Miller & Vleugels, 2019).

Assessment and Diagnostic Findings

A complete history and physical examination help exclude other muscle-related disorders. As with other diffuse connective tissue disorders, no single test confirms polymyositis. An electromyogram is performed to rule out degenerative muscle disease. A muscle biopsy may reveal inflammatory infiltrate in the tissue. Serum studies indicate increased muscle enzyme activity.

Medical Management

Corticosteroid therapy is the mainstay of medical management (Norris, 2019). IV immune globulin, plasmapheresis, lymphapheresis, and total-body irradiation have been used if there is no response to corticosteroids. The goal is to control inflammation and prevent long-term damage to muscles, joints, and internal organs (Norris, 2019). The antimalarial agent hydroxychloroquine may be effective for skin rashes. Physical therapy is initiated slowly, with range-of-motion exercises to maintain joint mobility, followed by gradual strengthening exercises (Klippel et al., 2008).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The primary nursing diagnoses for the patient with polymyositis are impaired mobility, fatigue, self care deficit, and lack of knowledge of self-management techniques.

Patients with polymyositis may have symptoms similar to those of other inflammatory diseases. However, proximal muscle weakness is characteristic, making activities such as combing the hair, reaching overhead, and using stairs difficult. Therefore, the use of assistive devices may be recommended, and referral to occupational or physical therapy may be warranted.

Polymyalgia Rheumatica and Giant Cell Arteritis

PMR involves stiffness of muscles and pain in the neck, shoulder, and pelvic girdle. GCA is a form of vasculitis affecting the medium-sized and large arteries of the body (Klippel et al., 2008). GCA is also sometimes referred to as temporal arteritis (Hill, Black, Nossent, et al., 2017). PMR and GCA represent a spectrum of one disease. Both primarily affect individuals older than 50 years and are associated with the same HLA haplotype genetic markers. PMR and GCA occur predominately in Caucasians and often in first-degree relatives. PMR has an annual incidence rate of 52 cases per 100,000 people older than 50 years. GCA varies by geographic location and has the highest incidence in Scandinavian countries. PMR is two to three times more common than GCA (Klippel et al., 2008).

Pathophysiology

The underlying mechanism of action involved with PMR and GCA is unknown. It is clear, however, that the immune system is abnormally activated in both disease processes with increases in circulating monocytes that produce IL-1 and IL-6. These circulating monocytes make the endothelial linings of

blood vessels more vulnerable to vasculitis (Klippel et al., 2008). Immunoglobulin deposits in the walls of inflamed temporal arteries suggest that an autoimmune process is at work.

Clinical Manifestations

PMR is characterized by severe proximal muscle discomfort with mild joint swelling. Severe aching in the neck, shoulder, and pelvic muscles is common. Stiffness is noticeable most often in the morning and after periods of inactivity. This stiffness can become so severe that patients struggle putting on a coat or combing their hair. Systemic features include low-grade fever, weight loss, malaise, anorexia, and depression. Because PMR usually occurs in people 50 years and older, it may be confused with, or dismissed as, an inevitable consequence of aging.

GCA may cause headaches, changes in vision, and jaw claudication. These symptoms should be evaluated immediately because of the potential for blindness and stroke if left untreated (Hill et al., 2017). PMR and GCA have a self-limited course, lasting several months to several years (Klippel et al., 2008).

Assessment and Diagnostic Findings

Assessment focuses on musculoskeletal tenderness, weakness, and decreased function. Careful attention should be directed toward assessing the head (for changes in vision, headaches, and jaw claudication). An MRI scan may be used in the assessment of extra-articular synovitis in patients with PMR, regardless of symptoms.

Often, diagnosis is difficult because of the lack of specificity of tests. A markedly high ESR is a screening test but is not definitive. The CRP level and platelet count also provide valuable data. In fact, simultaneous elevation in the ESR and CRP has a sensitivity of 98.6% and a specificity of 75.7% in making the diagnosis of GCA when coupled with clinical findings (Seetharaman, 2019). Diagnosis of both GCA and PMR is more likely to be made by eliminating other potential diagnoses. The dramatic and immediate response to treatment with corticosteroids is considered by some to be diagnostic.

In the case of GCA, biopsy of the temporal artery is the definitive diagnostic tool (Seetharaman, 2019). High-resolution MRI is an alternative or adjunct to the traditional temporal artery biopsy.

Medical Management

The treatment for patients with PMR (without GCA) is moderate doses of corticosteroids. Longer durations of corticosteroid treatment are required with

patients who have higher baseline inflammatory markers. Gradual tapering of the corticosteroid treatment should be monitored. NSAIDs are sometimes given in mild disease. The treatment for patients with GCA is rapid initiation of and strict adherence to a regimen of corticosteroids. This is essential to avoid the complication of blindness (Hill et al., 2017). Aspirin is an adjunctive treatment may help reduce the risk of visual loss.

Nursing Management

Nursing care of the patient with PMR is based on the fundamental plan of nursing care presented earlier (see Chart 34-3). The most common nursing diagnoses are pain and lack of knowledge of medications.

A management concern is that the patient will take the prescribed medication, frequently corticosteroids, until symptoms improve and then discontinue the medication. The decision to discontinue the medication should be based on clinical and laboratory findings and the prescription. Nursing implications are related to helping the patient prevent and monitor adverse effects of medications (e.g., infections, diabetes, gastrointestinal problems, and depression) and adjust to those side effects that cannot be prevented (e.g., increased appetite and altered body image).

Quality and Safety Nursing Alert

The nurse must emphasize to the patient the need for continued adherence to the prescribed medication regimen to avoid complications of GCA, such as blindness and stroke.

The loss of bone mass with corticosteroid use increases the risk of osteoporosis in this already at-risk population. Interventions to promote bone health, such as adequate dietary calcium and vitamin D, measurement of bone mineral density, weight-bearing exercise, smoking and ENDS cessation, and reduction of alcohol consumption if indicated, should be emphasized.

Spondyloarthropathies

The spondyloarthropathies are another category of systemic inflammatory disorders of the skeleton. The spondyloarthropathies include ankylosing spondylitis (AS), reactive arthritis (formerly known as Reiter's syndrome), and psoriatic arthritis. Spondyloarthritis is also associated with inflammatory bowel diseases such as Crohn's disease (regional enteritis) and ulcerative colitis (Norris, 2019).

These rheumatic diseases share several clinical features. The inflammation tends to occur peripherally at the sites of attachment—at tendons, joint capsules, and ligaments. Periosteal inflammation may be present. Many patients have arthritis of the sacroiliac joints. The onset tends to occur during young adulthood, with the disease affecting men more often than women. There is a strong tendency for these conditions to occur in families. Frequently, the HLA-B27 genetic marker is found. In addition, more than one of these conditions can be found simultaneously in the same person or another family member (Norris, 2019).

As with other inflammatory conditions, patients with spondyloarthropathies have an increased risk for cardiovascular disease. These findings may be related to a state of chronic systemic inflammation and an increase in traditional cardiac risk factors, such as lack of exercise due to increased pain (Norris, 2019).

Ankylosing Spondylitis

AS is a chronic inflammatory disease of the spine. It is more prevalent in males than in females and is usually diagnosed in the second or third decade of life. The disease is also more severe in males, and significant systemic involvement is likely (Norris, 2019).

AS affects the cartilaginous joints of the spine and surrounding tissues, making them rigid, decreasing mobility, and leading to kyphosis (a stooped position). This kyphosis can, in turn, lead to decreased stability and balance. Back pain is the characteristic feature. The back pain can be so severe that it may mask symptoms of a cervical fracture, which can lead to neurologic problems if left untreated. Occasionally, the large synovial joints, such as the hips, knees, or shoulders, may be involved (Norris, 2019).

AS also exhibits systemic effects as the heart and lungs become constricted in the chest cavity (Norris, 2019). Another potential complication of AS is the risk of osteoporosis, which appears to be related to the inflammatory process as well as bone turnover and low vitamin D levels. Other complications involve atrioventricular conduction defects, aortic insufficiency, and pulmonary fibrosis. As the disease progresses, ankylosis (i.e., fixation or immobility) of the entire spine may occur, leading to respiratory compromise and further complications.

Reactive Arthritis (Reiter's Syndrome)

The disease process involved in reactive arthritis is called *reactive* because the arthritis occurs after an infection, primarily gastrointestinal or genitourinary (Norris, 2019). It mostly affects young adult males and is characterized

primarily by urethritis, arthritis, and conjunctivitis. Dermatitis and ulcerations of the mouth and penis may also be present. Low back pain is common.

Psoriatic Arthritis

Psoriatic arthritis is an inflammatory arthritis associated with the skin disease psoriasis. Approximately 7% of people with psoriasis develop psoriatic arthritis (Norris, 2019). Psoriasis is the most common autoimmune disease in the United States, affecting 2% to 3% of the population. Psoriatic arthritis onset occurs between 30 and 50 years of age and affects equal numbers of men and women (Dewing, 2015). See Chapter 56 for more information on psoriasis.

Psoriatic arthritis is characterized by synovitis, polyarthritis, and spondylitis. Inflammatory back pain is a common symptom, which is differentiated from other back pain by symptoms of back pain presenting at a young age, pain improving with activity, and pain occurring at night. Radiographic evidence of asymetrical sacroilitis or spondylitis may also assist with diagnosing psoriatic arthritis (Dewing, 2015). Other sites of pain commonly seen in these patients are the Achilles tendon, plantar fascia, or tibial tuberosity areas. Pain in these areas is common from the inflammation that occurs at the entheses, where tendons and ligaments attach to the bone.

Medical Management

Medical management of spondyloarthropathies focuses on treating pain and maintaining mobility by suppressing inflammation. For the patient with AS, good body positioning and posture are essential so that if ankylosis does occur, the patient is in the most functional position. Maintaining range of motion with regular exercise and a muscle-strengthening program is especially important and has been linked with higher quality of life for patients.

Pharmacologic Management

NSAIDs are the first-line therapy for treating all spondylarthropathies. All chronic conditions (cardiac, renal, and gastrointestinal) should be taken into consideration when prescribing long-term NSAIDs. Methotrexate, sulfasalazine, and leflunomide may also be used; these drugs may help with skin and peripheral joint disease but may not prevent spinal changes. Corticosteroid injections may be used for periodic flares; however, oral and long-term use of steroids is not recommended due to the possibility of psoriatic skin flare when discontinuing use.

Disease remission is now the target for psoriatic arthritis (Mease & Coates, 2018). Anti-TNF medications that have been used effectively include etanercept, infliximab, adalimumab, golimumab, and certolizumabpegol.

Additional agents include apremilast, which is a PDE4 inhibitor, and ustekinumab, an anti-IL12/anti-IL23 agent (Mease & Coates, 2018).

Surgical Management

With advanced AS and subsequent debilitating kyphosis, an osteotomy of the spine can be done. One study showed that an average correction of 45 degrees in the cervical spine was obtained and that quality of life also improved. Surgical management may also include total joint replacement (see Chapter 36).

Nursing Management

Major nursing interventions in the spondyloarthropathies are related to symptom management and maintenance of optimal functioning. Affected patients are primarily young men. Their major concerns are often related to prognosis and job modification, especially among those who perform physical work. Patients may also express concerns about leisure and recreational activities. Focusing on physical activity and staying active and maintaining good posture will help to prevent chronic changes that may lead to deformities. It is important to address psychological changes, such as depression and emotional stress, that can occur with the diagnosis and chronic nature of the disease. If symptoms are present, the primary provider should assess for emotional stress and treat as appropriate.

Metabolic and Endocrine Diseases Associated with Rheumatic Disorders

Metabolic and endocrine diseases may be associated with rheumatic disorders. These include biochemical abnormalities (amyloidosis and scurvy), endocrine diseases (diabetes and acromegaly), immune deficiency diseases (human immune deficiency virus infection, acquired immune deficiency syndrome), and some inherited disorders (hypermobility syndromes). However, the most common conditions are the crystal-induced arthropathies, in which crystals such as monosodium urate (gout) or calcium pyrophosphate (calcium pyrophosphate dihydrate disease or pseudogout) are deposited within joints and other tissues (Norris, 2019).

Gout

Gout is the most common form of inflammatory arthritis. More than 8.3 million Americans self-report the diagnosis of gout (CDC, 2019). The prevalence is reported to be about 3.9% and appears to be on the rise. Men are

three to four times more likely to be diagnosed with gout than women. The incidence of gout increases with age, body mass index, alcohol consumption, hypertension, and diuretic use (CDC, 2019). Evidence links the consumption of fructose-rich beverages with the risk of gout for both men and women (CDC, 2019). Patients with gout have an increased risk of cardiovascular disease. Comorbid conditions such as hypertension, dyslipidemia, diabetes, osteoarthritis, kidney disease, and depression may be present in patients with gout (Lin, Zhang, & Ma, 2018; Norris, 2019).

Pathophysiology

Gout is caused by hyperuricemia (increased serum uric acid). Uric acid is a by-product of purine metabolism; purines are basic chemical compounds found in high concentrations in meat products. Urate levels are affected by diet, medications, overproduction in the body, and inadequate excretion by the kidneys. Hyperuricemia (serum concentration greater than 6.8 mg/dL) can, but does not always, cause urate crystal deposition. However, as uric acid levels increase, the risk becomes greater. The initial cause for the gout attack occurs when macrophages in the joint space phagocytize urate crystals. Through a series of immunologic steps, interleukin-1β is secreted, increasing the inflammation. This process is exacerbated by the presence of free fatty acids. Both alcohol and consumption of a large meal, especially with red meat, can lead to increases in free fatty acid concentrations; they also are implicated as triggers to acute gout attacks (Norris, 2019).

With repeated attacks, accumulations of sodium urate crystals, called tophi, are deposited in peripheral areas of the body, such as the great toe, the hands, and the ear. Renal uratelithiasis (kidney stones), with chronic kidney disease secondary to urate deposition, may develop.

Primary hyperuricemia may be caused by severe dieting or starvation, excessive intake of foods that are high in purines (shellfish, organ meats), or heredity. In secondary hyperuricemia, gout is a clinical feature secondary to any of a number of genetic or acquired processes, including conditions in which there is an increase in cell turnover (leukemia, multiple myeloma, some types of anemias, psoriasis) and an increase in cell breakdown. Altered renal tubular function, either as a major action or as an unintended side effect of certain pharmacologic agents (e.g., diuretics such as thiazides and furosemide), low-dose salicylates, or ethanol can contribute to uric acid underexcretion (Klippel et al., 2008). The finding of urate crystals in the synovial fluid of asymptomatic joints suggests that factors other than crystals may be related to the inflammatory reaction. Recovered monosodium urate crystals are coated with immunoglobulins that are mainly IgG. IgG enhances crystal phagocytosis, thereby demonstrating immunologic activity (Klippel et al., 2008).

Clinical Manifestations

Manifestations of the gout syndrome include acute gouty arthritis (recurrent attacks of severe articular and periarticular inflammation), **tophi** (crystalline deposits accumulating in articular tissue, osseous tissue, soft tissue, and cartilage), gouty nephropathy (renal impairment), and uric acid urinary calculi. Four stages of gout can be identified: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout (Neoai, Jansen, Dalbeth, et al., 2015). The subsequent development of gout is directly related to the duration and magnitude of the hyperuricemia. Therefore, the commitment to lifelong pharmacologic treatment of hyperuricemia is deferred until there is an initial attack of gout.

Acute arthritis is the most common early clinical manifestation. The metatarsophalangeal joint of the big toe is a commonly affected joint. The tarsal area, ankle, or knee may also be affected. Less commonly, the wrists, fingers, and elbows may be affected. Trauma, alcohol ingestion, dieting, medications, surgical stress, or illness may trigger the acute attack. The abrupt onset often occurs at night, awakening the patient with severe pain, redness, swelling, and warmth of the affected joint. Early attacks tend to subside spontaneously over 3 to 10 days without treatment. The attack is followed by a symptom-free period (the intercritical stage) until the next attack, which may not come for months or years. However, with time, attacks tend to occur more frequently, involve more joints, and last longer (Becker & Gaffo, 2019).

Tophi (seen in chronic tophaceous gout) are generally associated with more frequent and severe inflammatory episodes. Higher serum concentrations of uric acid are also associated with more extensive tophus formation. Tophi most commonly occur in the synovium, olecranon bursa, **subchondral bone** (bony plate that supports the articular cartilage), infrapatellar and Achilles tendons, and subcutaneous tissue on the extensor surface of the forearms and overlying joints. They have also been found in the aortic walls, heart valves, nasal and ear cartilage, eyelids, cornea, and sclera. Joint enlargement may cause a loss of joint motion. Uric acid deposits may cause renal stones and kidney damage.

Medical Management

Given that the incidence of gout increases with age, its management can be complicated by other medical conditions, medications, and age-related changes. A definitive diagnosis of gouty arthritis is established by polarized light microscopy of the synovial fluid of the involved joint. Uric acid crystals are seen within the polymorphonuclear leukocytes in the fluid during a disease flare up (CDC, 2019).

Acute attacks are managed with colchicine (oral or parenteral), an NSAID such as indomethacin, or a corticosteroid. Management of hyperuricemia,

tophi, joint destruction, and renal disorders is usually initiated after the acute inflammatory process has subsided. Once the acute attack has subsided, uric acid lowering therapy should be considered. Xanthine oxidase inhibitors, such as allopurinol and febuxostat, are the agents of choice. Given the role of IL-1 in the pathogenesis of gout, some experts suggest that there may be a role for anakinra, an IL-1 receptor antagonist in the management of acute gout (Becker & Perez-Ruiz, 2019).

Management between gout attacks needs to include lifestyle changes such as avoiding purine-rich foods, weight loss, decreasing alcohol consumption, and avoiding certain medications. Uricosuric agents, such as probenecid, may be indicated in patients with frequent acute attacks. Uricosuric medications correct hyperuricemia and dissolve deposited urate. Corticosteroids may also be used in patients who have no response to other therapy. In patients with refractory chronic gout who are not controlled with the regimens mentioned earlier, pegloticase, a newer agent, has been shown to be effective in lowering uric acid levels (Becker & Perez-Ruiz, 2019). Specific treatment is based on the serum uric acid level, 24-hour urinary uric acid excretion, and renal function (see Table 34-4).

TABLE 34-4  Common Medications Used to Treat Gout

Medication	Actions and Use	Nursing Implications
colchicine	Lowers the deposition of uric acid and interferes with leukocyte infiltration, thus reducing inflammation; does not alter serum or urine levels of uric acid; used in acute and chronic management	*Acute management:* Administer when attack begins; dosage increased until pain is relieved or diarrhea develops, then stop medication *Chronic management:* Causes gastrointestinal upset in most patients.
probenecid	Uricosuric agent; inhibits renal reabsorption of urates and increases the urinary excretion of uric acid; prevents tophi formation	Be alert for nausea and rash.
allopurinol, febuxostat	Xanthine oxidase inhibitors; interrupt the breakdown of purines before uric acid is formed; inhibit xanthinoxidase because uric acid formation is blocked	Monitor for side effects, including bone marrow depression, nausea, vomiting, diarrhea, abdominal pain, or rash. Avoid starting medication or increasing dose if active flare present.

Adapted from Comerford, K. C., & Durkin, M. T. (2020). *Nursing 2020 drug handbook*. Philadelphia, PA: Wolters Kluwer.

Nursing Management

Research indicates that providers overestimate patient knowledge of gout and that patients prefer the use of both written and verbal materials (Abhishek & Doherty, 2018). Therefore, the nurse takes every opportunity to educate and reinforce knowledge of gout verbally and in writing. Severe dietary restriction is not necessary; however, the nurse encourages the patient to restrict consumption of foods high in purines, especially organ meats, and to limit alcohol intake. Maintenance of normal body weight should be encouraged. In an acute episode of gouty arthritis, pain management with prescribed medications is essential, along with avoidance of factors that increase pain and inflammation, such as trauma, stress, and alcohol. Medication adherence is critical but poor among patients prescribed urate lowering therapies (Scheepers, van Onna, Stehouwer, et al., 2018). The nurse reinforces the importance of taking prescribed medications. Between acute episodes, the patient feels well and may abandon medications and preventive behaviors, which may result in an acute attack. Acute attacks are most effectively treated if therapy begins early.

Fibromyalgia

Fibromyalgia is a chronic pain syndrome that involves chronic fatigue, generalized muscle aching, stiffness, sleep disturbances, and functional impairment. It is estimated to affect more than 5 million Americans, representing 2% to 5% of the general population, with women affected more than men. Between 25% and 65% of patients with fibromyalgia have other rheumatic conditions such as RA, SLE, and AS (CDC, 2017).

Pathophysiology

The amplified pain experienced by patients with fibromyalgia is thought to be neurogenic in origin. The central nervous system's ascending and descending pathways that regulate and moderate pain processing function abnormally, causing amplification of pain signals. Some describe this as if the "volume control setting" for pain were abnormally high. Therefore, stimulation that may not normally elicit pain, such as touch, may do so. In addition, there are a number of predisposing factors to pain, including anxiety, depression, physical trauma, emotional stress, sleep disorder, and viral infection (CDC, 2017; Melin, Svensson, & Thulesius, 2018).

Assessment and Diagnostic Findings

Since fibromyalgia is a diffuse syndrome, standard diagnostic testing is often not useful except to rule out other conditions that may be causing the pain.

One study reported that two items, pain upon pinching the Achilles tendon using 4 kg of pressure for 4 seconds and an affirmative answer to the statement "I have a persistent deep aching all over my body," were the most useful in recognizing fibromyalgia (Jones, Aebischer, St John, et al., 2017). Positive responses to these screening items need to be followed by a comprehensive examination for confirmation of a diagnosis (Jones et al., 2017).

Medical Management

Treatment consists of attention to the specific symptoms reported by the patient. NSAIDs may be used to treat the diffuse muscle aching and stiffness. Tricyclic antidepressants such as amitriptyline and nortriptyline as well as sleep hygiene measures are used to improve or restore normal sleep patterns (CDC, 2017). Muscle relaxants such as cyclobenzaprine may also be used to help with relaxation and pain. Cognitive behavioral therapy is also useful in improving sleep and attentional dysfunction. In addition, serotonin norepinephrine reuptake inhibitors, such as duloxetine, venlafaxine, and milnacipran; selective serotonin reuptake inhibitors, including fluoxetine, paroxetine, and sertraline; as well as anticonvulsants such as gabapentin and pregabalin may be effective. Individualized programs of exercise are used to decrease muscle weakness and discomfort and to improve the general deconditioning that occurs in affected patients. There has been some promising research in complementary, alternative, and integrative health therapies, such as acupuncture (Kim, Kim, Lee, et al., 2019).

Nursing Management

Typically, patients with fibromyalgia have endured their symptoms for a long period of time. They may feel as if their symptoms have not been taken seriously. Nurses need to pay special attention to supporting these patients and providing encouragement as they begin their program of therapy. Patient support groups may be helpful (Melin et al., 2018). Careful listening to patients' descriptions of their concerns and symptoms is essential to help them make the changes that are necessary to improve their quality of life.

Miscellaneous Disorders

The last category in the classification of the rheumatic diseases is aptly labeled miscellaneous disorders because it contains a mix of disorders that are frequently associated with arthritis and other conditions. These include the direct consequences of trauma (including internal derangement and loose bodies of joints), pancreatic disease (related to avascular necrosis or

osteonecrosis), sarcoidosis (a multisystem disorder particularly of the lymph nodes and lungs), and palindromic rheumatism (an uncommon variety of recurring and acute arthritis and periarthritis that in some may progress to RA but is characterized by symptom-free periods of days to months). Other conditions include villonodular synovitis, chronic active hepatitis, and drug-related rheumatic syndromes. The nursing interventions related to these varied conditions are specific to the multisystemic problems experienced by the patient. However, the musculoskeletal components should not be neglected or overlooked. Further information about these rare disorders can be found in specialty references.

CRITICAL THINKING EXERCISES

1 pq Your patient, a 52-year-old male with RA, is being discharged from the medical surgical unit where you work. He smokes 1 pack of cigarettes a day and drinks alcohol on occasion. He is 6′0″ and weighs 240 lb. Identify the priorities, approach, and techniques you would use to provide discharge education to this patient. What lifestyle modifications are a priority for this patient?

2 ipc A 28-year-old patient who was recently diagnosed with SLE comes to the clinic where you work for a follow-up appointment. She tells you that she is planning to become pregnant soon. What additional members of the health care team should be included in the care of this patient given her childbearing plans?

3 ebp You are the nurse taking care of a woman newly diagnosed with fibromyalgia. What is the evidence for symptom management for this patient? What criteria would you use to assess the strength of the evidence? What is the evidence for complementary therapy options to improve her symptoms?

UNIT 8 Musculoskeletal Function

Case Study

IMPLEMENTING EVIDENCE-BASED PRACTICE IN PAIN MANAGEMENT

You are a nurse working on an orthopedic unit caring for a 76-year-old female with osteoporosis who had fallen at home and underwent a right hip replacement. She is 2 days postoperative,

recovering from her surgery without complications, and you are discussing plans for her transition to a skilled rehabilitation unit. However, the patient does not want to get out of bed and participate in physical or occupational therapy because she is in pain. Despite having spoken with the pain team, she states she does not want to take any medications that may cause her to become addicted. You need to develop an evidence-based plan of care that implements pharmacologic and nonpharmacologic strategies for pain management so the patient is able to participate in her physical and occupational therapies and thus help facilitate her recovery.

QSEN Competency Focus: **Evidence-Based Practice (EBP)**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Evidence-Based Practice Definition: Integrate best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal health care.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Explain the role of evidence in determining best clinical practice	Differentiate between evidence-based guidelines in managing acute postoperative pain verses chronic osteoporosis pain. Evidence-based practice guidelines include adherence to pharmacologic and nonpharmacologic interventions to promote recovery after surgery. How does managing the patient's pain reduce postoperative complications, including risk for blood clot, pneumonia, and gastric complications?
Skills	
Locate evidence reports related to clinical practice topics and guidelines	What additional strategies might you use to educate this patient on controlling acute postoperative pain? Differentiate between the various types of pain medications, including opioid and nonopioid analgesics, that are used to decrease pain. Evidence-based pain management includes the use of pain scales. Which scale would be the best to evaluate this patient's pain?
Attitudes	
Value the need for continuous improvement in clinical practice based on new knowledge	Reflect on your attitudes toward patients who are prescribed opioid medications postoperatively for pain control. Because this patient may have chronic pain due to her osteoporosis, how can your approach regarding acute and chronic pain management reflect evidence-based practice guidelines?

35 Assessment of Musculoskeletal Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the basic structure and function of the musculoskeletal system.
2. Discuss the significance of the health history to the assessment of musculoskeletal health.
3. Recognize and evaluate the major manifestations of musculoskeletal dysfunction by applying concepts from the patient's health history and physical assessment findings.
4. Explain clinical indications, patient preparation, and other related nursing implications for common tests and procedures used to assess musculoskeletal function.

NURSING CONCEPTS

Assessment
Mobility

GLOSSARY

atonic: without tone; denervated muscle that atrophies

atrophy: decrease in the size of a muscle

bursa: fluid-filled sac found in connective tissue, usually in the area of joints

callus: cartilaginous/fibrous tissue at fracture site

cancellous bone: latticelike bone structure; trabecular bone

cartilage: tough, elastic, avascular tissue at ends of bone

clonus: rhythmic contractions of a muscle

contracture: abnormal shortening of muscle, joint, or both; fibrosis

cortical bone: compact bone

crepitus: grating or crackling sound or sensation; may occur with movement of ends of a broken bone or irregular joint surface

diaphysis: shaft of long bone

effusion: excess fluid in joint

endosteum: a thin, vascular membrane covering the marrow cavity of long bones and the spaces in cancellous bone

epiphysis: end of long bone

fascia: fibrous tissue that covers, supports, and separates muscles (*synonym:* epimysium)

fasciculation: involuntary twitch of muscle fibers

flaccid: limp; without muscle tone

hypertrophy: enlargement; increase in the size of a muscle

isometric contraction: muscle tension is increased without changing its length; there is no associated joint motion

isotonic contraction: muscle is shortened without a change in its tension; a joint is moved as a result

joint: area where bone ends meet; provides for motion and flexibility

joint capsule: fibrous tissue that encloses bone ends and other joint surfaces

kyphosis: increase in the convex curvature of the thoracic spine

lamellae: mature compact bone structures that form concentric rings of bone matrix; lamellar bone

ligament: ropelike bundles of collagen fibrils connecting bones

lordosis: increase in concave curvature of the lumbar spine

ossification: process in which minerals (calcium) are deposited in bone matrix

osteoblast: bone-forming cell

osteoclast: bone resorption cell

osteocyte: mature bone cell

osteogenesis: bone formation
osteon: microscopic functional bone unit
osteopenic: refers to a reduction in bone mass to below-normal levels
paresthesia: abnormal sensation (e.g., burning, tingling, numbness)
periosteum: fibrous connective tissue covering bone
remodeling: process that ensures bone maintenance through simultaneous bone resorption and formation
resorption: removal/destruction of tissue, such as bone
scoliosis: lateral curving of the spine
spastic: having greater-than-normal muscle tone
synovium: membrane in joint that secretes lubricating fluid
tendon: cord of fibrous tissue connecting muscle to bone
tone: normal tension (resistance to stretch) in resting muscle (*synonym:* tonus)
trabeculae: latticelike bone structure; cancellous bone

The musculoskeletal system is composed of the bones, joints, muscles, tendons, ligaments, and bursae of the body. The major functions of this system are to support and protect the body and foster movement of the extremities. The components of this system are highly integrated; therefore, disease in or injury to one component adversely affects the others. For instance, an infection in a joint (e.g., septic arthritis) causes degeneration of the articular surfaces of the bones within the joint and local muscle atrophy.

Musculoskeletal disorders and injuries directly affect the quality of life of individuals and are a leading cause of disability in the United States. The annual cost to treat these conditions is estimated to be over $980 billion for direct costs as well as indirect costs, such as lost wages from loss of work time (United States Bone and Joint Initiative [USBJI], 2018). Arthritis is the chief cause of musculoskeletal-related disability in the United States, with an estimated 54.4 million adults diagnosed with this disorder. Because the incidence of arthritis increases with age, the number of adults with arthritis is expected to increase to 78 million by 2040 (Centers for Disease Control and Prevention [CDC], 2019). Nurses in all practice areas may encounter patients with complaints about or impairment of the musculoskeletal system.

Anatomic and Physiologic Overview

The musculoskeletal system provides protection for vital organs, including the brain, heart, and lungs; serves as a framework to support body structures; and makes mobility possible. Muscles and tendons hold the bones together, and joints allow the body to move. They also move to produce heat that helps

maintain body temperature. Movement facilitates the return of deoxygenated blood to the right side of the heart by massaging the venous vasculature. The musculoskeletal system serves as a reservoir for immature blood cells and essential minerals, including calcium, phosphorus, magnesium, and fluoride (Norris, 2019). More than 98% of total-body calcium is present in bone (National Institutes of Health [NIH], 2019a).

Structure and Function of the Skeletal System

There are 206 bones in the human body, divided into four categories classified by their shape: long, short, flat, and irregular. The long bones are found in the upper and lower extremities (e.g., the femur). Long bones are shaped like rods or shafts with rounded ends (Fig. 35-1). The shaft, known as the **diaphysis**, is primarily **cortical bone** (compact bone). The ends of the long bones, called **epiphyses**, are primarily **cancellous bone** (trabecular bone). During childhood and adolescence, there is a layer of cartilage known as the epiphyseal plate, or growth plate, that separates the epiphysis from the diaphysis. The epiphyseal plate nurtures and facilitates longitudinal growth. The epiphyseal plate is calcified in adults. The ends of long bones are covered at the joints by articular **cartilage**, which is tough, elastic, and avascular tissue (Norris, 2019).

The short bones are the irregularly shaped bones located in the ankle and hand (e.g., metacarpals). The flat bones are located where extensive protection of underlying structures is needed (e.g., the sternum or skull). Finally, because of their shape, the irregular bones cannot be categorized in any other group and include bones such as the vertebrae and bones of the jaw.

The shape and construction of a specific bone are determined by its function and the forces exerted on it. Bones are constructed of cortical or cancellous bone tissue. Cortical bone exists in areas where support is needed, and cancellous bone is found where hematopoiesis and bone formation occur. For example, long bones are designed for weight bearing and movement and tend to be composed primarily of cortical bone, whereas flat bones, which are important sites of hematopoiesis and frequently protect vital organs, are made of cancellous bone layered between compact bone. Short bones consist of cancellous bone covered by a layer of cortical bone. Irregular bones have unique shapes related to their function. Generally, irregular bone structure is similar to that of flat bones (Norris, 2019).

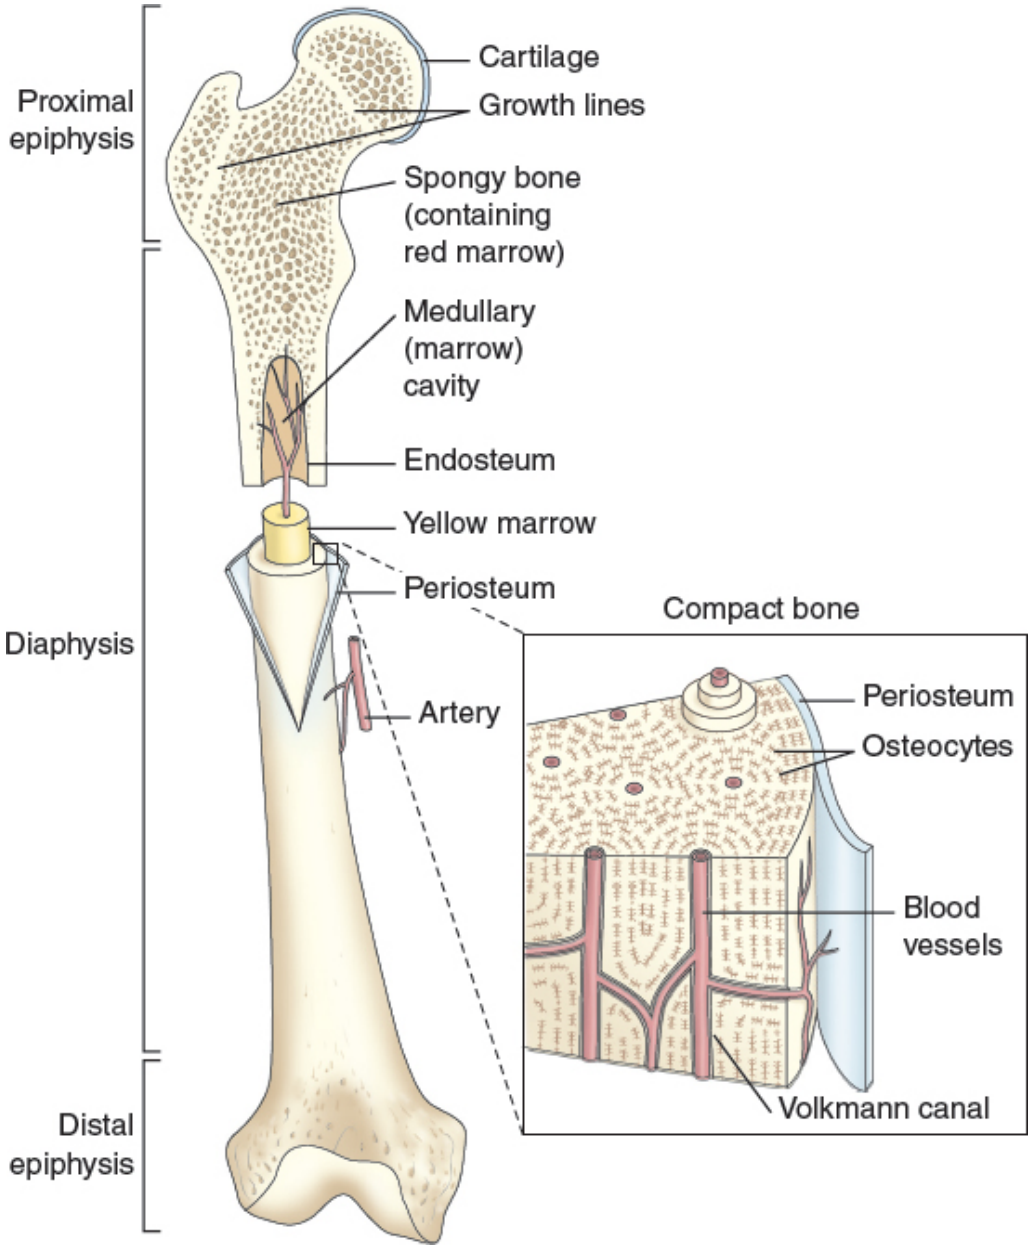

Figure 35-1 • Structure of a long bone; composition of compact bone.

Bone is composed of cells, protein matrix, and mineral deposits. The cells are of three basic types—osteoblasts, osteocytes, and osteoclasts. **Osteoblasts** function in bone formation by secreting bone matrix. The matrix consists of collagen and ground substances (glycoproteins and proteoglycans) that provide a framework in which inorganic mineral salts are deposited. These minerals are primarily composed of calcium and phosphorus. **Osteocytes** are mature bone cells involved in bone maintenance; they are located in lacunae (bone matrix units). **Osteoclasts**, located in shallow Howship's lacunae (small pits in bones), are multinuclear cells involved in dissolving and resorbing bone. The microscopic functioning unit of mature cortical bone is the **osteon**, or

haversian system. The center of the osteon—the haversian canal—contains a capillary. Around the capillary are circles of mineralized bone matrix called **lamellae**. Within the lamellae are lacunae that contain osteocytes. These are nourished through tiny structures called *canaliculi* (canals), which communicate with adjacent blood vessels within the haversian system. Lacunae in cancellous bone are layered in an irregular lattice network known as **trabeculae**. Red bone marrow fills the lattice network. Capillaries nourish the osteocytes located in the lacunae (Norris, 2019).

Covering the bone is a dense, fibrous membrane known as the **periosteum**. This membranous structure nourishes bone and facilitates its growth. The periosteum contains nerves, blood vessels, and lymphatics. It also provides for the attachment of tendons and ligaments (Norris, 2019).

The **endosteum** is a thin, vascular membrane that covers the marrow cavity of long bones and the spaces in cancellous bone. Osteoclasts, which dissolve bone matrix to maintain the marrow cavity, are located near the endosteum in Howship's lacunae (Norris, 2019).

Bone marrow is a vascular tissue located in the medullary cavity (shaft) of long bones and in flat bones. Red bone marrow, located mainly in the sternum, ilium, vertebrae, and ribs in adults, is responsible for producing red blood cells, white blood cells, and platelets through a process called *hematopoiesis.* In adults, the long bone is filled with fatty, yellow marrow (Norris, 2019).

Bone tissue is well vascularized. Cancellous bone receives a rich blood supply through metaphyseal and epiphyseal vessels. Periosteal vessels carry blood to compact bone through minute Volkmann canals. In addition, nutrient arteries penetrate the periosteum and enter the medullary cavity through foramina (small openings). Arteries supply blood to the marrow and bone. The venous system may accompany arteries or may exit independently (Norris, 2019).

Bone Formation

Osteogenesis (bone formation) begins before birth. **Ossification** is the process by which the bone matrix is formed and hard mineral crystals composed of calcium and phosphorus (e.g., hydroxyapatite) are bound to the collagen fibers. These mineral components give bone its characteristic strength, whereas the proteinaceous collagen gives bone its resilience (Norris, 2019).

Bone Maintenance

Bone is a dynamic tissue in a constant state of turnover. Throughout the lifespan, a process known as bone **remodeling** occurs, in which old bone is removed and new bone is added to the skeleton (formation). During childhood and the teenage years, new bone is added faster than old bone is removed; therefore, bones become larger, heavier, and denser. This continues until peak

bone mass is reached, typically by age 20 years. Remodeling maintains bone structure and function through simultaneous resorption and osteogenesis, and as a result, complete skeletal turnover occurs every 10 years (Norris, 2019).

The balance between bone **resorption** (removal or destruction) and formation is influenced by the following factors: physical activity; dietary intake of certain nutrients, especially calcium; and several hormones, including calcitriol (i.e., activated vitamin D), parathyroid hormone (PTH), calcitonin, thyroid hormone, cortisol, growth hormone, and the sex hormones estrogen and testosterone (Norris, 2019).

Physical activity, particularly weight-bearing activity, acts to stimulate bone formation and remodeling. Bones subjected to continued weight bearing tend to be thick and strong. Conversely, people who are unable to engage in regular weight-bearing activities, such as those on prolonged bed rest or those with some physical disabilities, have increased bone resorption from calcium loss, and their bones become **osteopenic** (reduced in terms of mass) and weak. These weakened bones may fracture easily (Meiner & Yeager, 2019).

Good dietary habits are integral to bone health. Daily intake of approximately 1000 to 1200 mg of calcium is essential to maintaining adult bone mass. Quality sources of calcium include low-fat milk, yogurt, and cheese. Foods with added calcium such as orange juice, cereals, and bread are also beneficial (NIH, 2019a). Vitamin D also plays a major role in calcium absorption and bone health. Young adults need a daily vitamin D intake of 600 IU, whereas adults 50 years and older require a daily intake of 800 to 1000 IU to ensure good bone health (NIH, 2019b). Dietary sources of vitamin D include vitamin D–fortified milk and cereals, egg yolks, saltwater fish, and liver.

Several hormones are vital in ensuring that calcium is properly absorbed and available for bone mineralization and matrix formation. Calcitriol functions to increase the amount of calcium in the blood by promoting absorption of calcium from the gastrointestinal tract. It also facilitates mineralization of osteoid tissue. A deficiency of vitamin D results in bone mineralization deficit, deformity, and fracture (Norris, 2019).

PTH and calcitonin are the major hormonal regulators of calcium homeostasis. PTH regulates the concentration of calcium in the blood, in part by promoting movement of calcium from the bone. In response to low calcium levels in the blood, increased levels of PTH prompt the mobilization of calcium, the demineralization of bone, and the formation of bone cysts. Calcitonin, secreted by the thyroid gland in response to elevated blood calcium levels, inhibits bone resorption and increases the deposit of calcium in bone (Norris, 2019).

Both thyroid hormone and cortisol have multiple systemic effects with specific effects on bones. Excessive thyroid hormone production in adults (e.g., Graves' disease) can result in increased bone resorption and decreased

bone formation. Increased levels of cortisol have these same effects. Patients receiving long-term synthetic cortisol or corticosteroids (e.g., prednisone) are at increased risk for steroid-induced osteopenia and fractures.

Growth hormone has direct and indirect effects on skeletal growth and remodeling. It stimulates the liver and, to a lesser degree, the bones to produce insulinlike growth factor 1 (IGF-I), which accelerates bone modeling in children and adolescents. Growth hormone also directly stimulates skeletal growth in children and adolescents. It is believed that the low levels of both growth hormone and IGF-I that occur with aging may be partly responsible for decreased bone formation and resultant osteopenia (Norris, 2019).

The sex hormones testosterone and estrogen have important effects on bone remodeling. Estrogen stimulates osteoblasts and inhibits osteoclasts; therefore, bone formation is enhanced and resorption is inhibited. Testosterone has both direct and indirect effects on bone growth and formation. It directly causes skeletal growth in adolescence and has continued effects on skeletal muscle growth throughout the lifespan. Increased muscle mass results in greater weight-bearing stress on bones, resulting in increased bone formation. In addition, testosterone converts to estrogen in adipose tissue, providing an additional source of bone-preserving estrogen for aging men (Kennedy-Malone, Martin-Plank, & Duffy, 2019).

During the process of bone remodeling, osteoblasts produce a receptor for activated nuclear factor-kappa B ligand (RANKL) that binds to the receptor for activated nuclear factor-kappa B (RANK) present on the cell membranes of osteoclast precursors, causing them to differentiate and mature into osteoclasts, which causes bone resorption. Conversely, osteoblasts may produce osteoprotegerin (OPG), which blocks the effects of RANKL, thereby turning off the process of bone resorption. T cells that may become activated as a result of the inflammatory process may also produce RANKL, overriding the effects of OPG and causing continued bone resorption during times of stress and injury, which can lead to loss of bone matrix and fractures (Takeno, Kanazawa, Notsu, et al., 2018).

Blood supply to the bone also affects bone formation. With diminished blood supply or hyperemia (congestion), osteogenesis, and bone density decrease. Bone necrosis occurs when the bone is deprived of blood (Norris, 2019).

Bone Healing

Most fractures heal through a combination of intramembranous and endochondral ossification processes. When a bone is fractured, the bone begins a healing process to reestablish continuity and strength. The bone fragments are not patched together with scar tissue; instead, the bone regenerates itself.

Fracture healing occurs in the bone marrow, where endothelial cells rapidly differentiate into osteoblasts; in the bone cortex, where new osteons are

formed; in the periosteum, where a hard **callus** (fibrous tissue) is formed through intramembranous ossification peripheral to the fracture, and where cartilage is formed through endochondral ossification adjacent to the fracture site; and in adjacent soft tissue, where a bridging callus forms that provides stability to the fractured bones (Norris, 2019).

When a fracture occurs, the body's response is similar to that after injury elsewhere in the body. The repair of a simple fracture occurs in essentially four stages. These include the following (Norris, 2019):

Stage I: Hematoma formation occurs during the first 1 to 2 days of the fracture. Bleeding into the injured tissue and local vasoconstriction occur, and a hematoma forms at the site of the fracture. Cytokines are released, initiating the fracture healing processes by causing replicating cells known as fibroblasts to proliferate, which in turn causes angiogenesis to occur (i.e., the growth of new blood vessels). Granulation tissue begins to form within the clot and becomes dense. At the same time, degranulated platelets and inflammatory cells release growth factor, which stimulates the generation of osteoclasts and osteoblasts.

Stage II: Inflammatory phase occurs with the formation of granulation tissue. Fibroblasts and osteoblasts migrate into the fractured site and begin the reconstruction of bone. The fibroblasts produce a fibrocartilaginous soft callus bridge that connects the bone fragments. Although tissue repair may reach maximum girth by the end of the second or third week, it is still not strong enough for weight bearing.

Stage III: Reparative phase usually begins during the third or fourth week of fracture healing and continues until a firm bony union is formed. During this stage, mature bone gradually replaces the fibrocartilaginous callus and the excess callus is gradually reabsorbed by the osteoclasts. During this stage, the fracture site feels immovable and appears aligned on x-ray. At this time, it is usually safe to remove a cast, if one is present.

Stage IV: Remodeling occurs as necrotic bone is removed by the osteoclasts. Compact bone replaces spongy bone around the periphery of the fracture. Although the final structure of the remodeled bone resembles the original unbroken bone, a thickened area on the surface of the bone may remain after healing. Remodeling may take months to years, depending on the extent of bone modification needed, the function of the bone, and the functional stresses on the bone.

Serial x-rays are used to monitor the progress of bone healing. The type of bone fractured, the adequacy of blood supply, the condition of the fracture fragments, the immobility of the fracture site, and the age and general health of the person influence the rate of fracture healing. Adequate immobilization is essential until there is x-ray evidence of bone formation with ossification (Norris, 2019).

When fractures are treated with internal or external fixation techniques, the bony fragments can be placed in direct contact. Primary bone healing occurs through cortical bone (haversian) remodeling. Little or no cartilaginous callus develops. Immature bone develops from the endosteum. There is an intensive regeneration of new osteons, which develop in the fracture line by a process similar to normal bone maintenance. Fracture strength is obtained when the new osteons have become established (Norris, 2019).

Structure and Function of the Articular System

The junction of two or more bones is called a **joint,** or articulation. There are three basic kinds of joints: synarthrosis, amphiarthrosis, and diarthrosis joints. Synarthrosis joints, also referred to as fibrous joints, are immovable because of fibrous tissue banding (e.g., the skull sutures). Amphiarthrosis joints, also referred to as cartilaginous joints, allow limited motion (e.g., the vertebral joints and the symphysis pubis). Diarthrosis joints, also referred to as synovial joints, are freely movable joints (Fig. 35-2).

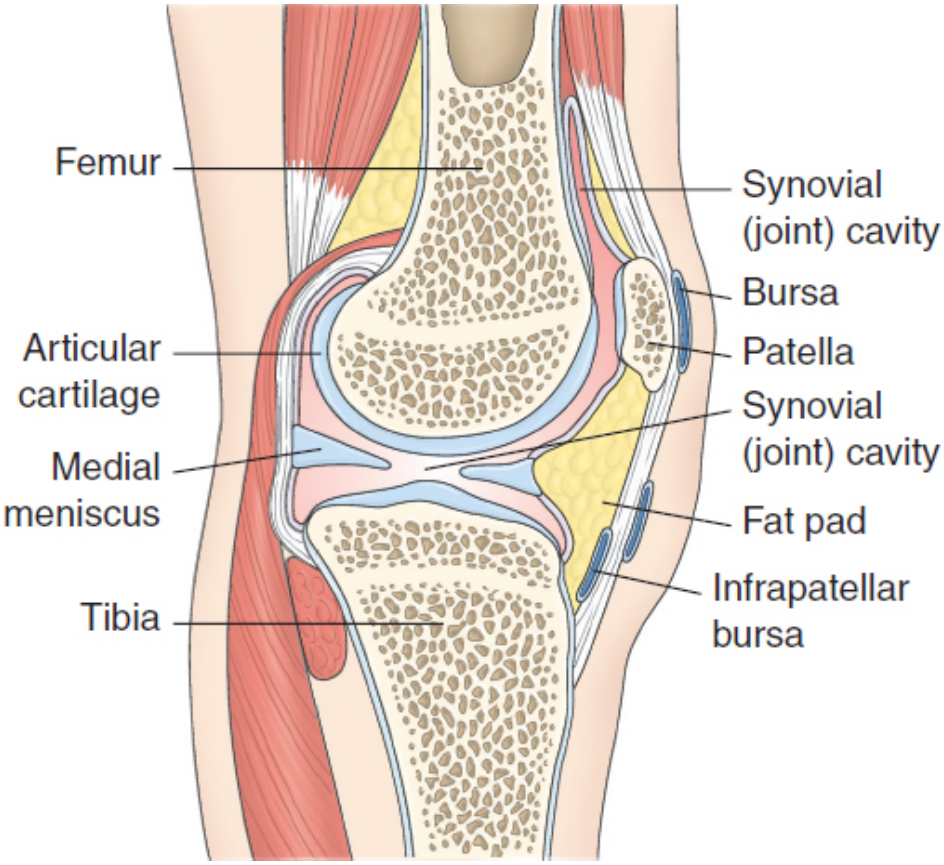

Figure 35-2 • Hinge joint of the knee.

There are several types of diarthrosis joints:

- *Ball-and-socket joints* (e.g., the hip and the shoulder) permit full freedom of movement.
- *Hinge joints* permit bending in only one direction, either flexion or extension (e.g., the elbow and the knee).
- *Saddle joints* allow movement in two planes at right angles to each other. The joint at the base of the thumb is a saddle, biaxial joint.
- *Pivot joints* allow one bone to move around a central axis without displacement. An example of a pivot joint is the articulation between the radius and the ulna. They permit rotation for such activities as turning a doorknob.
- *Gliding joints* allow for limited movement in all directions and are represented by the joints of the carpal bones in the wrist.

The ends of the articulating bones of a typical movable joint are covered with smooth hyaline cartilage. A tough, fibrous sheath called the **joint capsule** surrounds the articulating bones. The capsule is lined with a membrane, the **synovium**, which secretes the lubricating and shock-absorbing synovial fluid into the joint capsule. Therefore, the bone surfaces are not in direct contact. In some synovial joints (e.g., the knee), fibrocartilage discs (e.g., medial meniscus) are located between the articular cartilage surfaces. These discs provide shock absorption (Bickley, 2017).

Ligaments (ropelike bundles of collagen fibrils) bind the articulating bones together. **Tendons** are cords of fibrous tissue that connect muscle to bone. Ligaments and tendons, which pass over the joint, provide joint stability. In some joints, interosseous ligaments (e.g., the cruciate ligaments of the knee) are found within the capsule and add anterior and posterior stability to the joint. Ligaments are pliable enough to allow movement of the joints; however, they can tear rather than stretch if they are subjected to excess stress (Norris, 2019).

A **bursa** is a sac filled with synovial fluid that cushions the movement of tendons, ligaments, and bones over bones or other joint structures. Bursae can be found in the joints of the elbow, shoulder, hip, and knee. They may become inflamed, causing discomfort, swelling, and limited movement in that area.

Structure and Function of the Skeletal Muscle System

Muscles are attached by tendons to bones, connective tissue, other muscles, soft tissue, or skin. The muscles of the body are composed of parallel groups of muscle cells (fasciculi) encased in fibrous tissue called **fascia** (epimysium). The more fasciculi contained in a muscle, the more precise the movements. Muscles vary in shape and size according to the activities for which they are responsible. Skeletal (striated) muscles are involved in body movement,

posture, and heat-production functions. Muscles contract to bring the two points of attachment closer together, resulting in movement (Norris, 2019).

Skeletal Muscle Contraction

Each muscle cell (also referred to as a muscle fiber) contains myofibrils, which in turn are composed of a series of sarcomeres—the actual contractile units of skeletal muscle. Sarcomeres contain thick myosin and thin actin filaments.

Muscle cells contract in response to electrical stimulation delivered by an effector nerve cell at the motor end-plate. When stimulated, the muscle cell depolarizes and generates an action potential in a manner similar to that described for nerve cells. These action potentials propagate along the muscle cell membrane and lead to the release of calcium ions that are stored in a specialized organelle called *sarcoplasmic reticulum*. When there is a local increase in calcium ion concentration, the myosin and actin filaments slide across one another. Shortly after the muscle cell membrane is depolarized, it recovers its resting membrane voltage. Calcium is rapidly removed from the sarcomeres by active reaccumulation in the sarcoplasmic reticulum. When the calcium concentration in the sarcomere decreases, the myosin and actin filaments cease to interact, and the sarcomere returns to its original resting length (relaxation). Actin and myosin do not interact in the absence of calcium (Norris, 2019).

The contraction of muscle fibers can result in either isotonic or isometric contraction of the muscle. In **isometric contraction**, the length of the muscles remains constant but the force generated by the muscles is increased; an example of this is pushing against an immovable wall. **Isotonic contraction** is characterized by the shortening of the muscle without an increase in tension within the muscle; an example of this is flexing the forearm. In normal activities, many muscle movements are a combination of isometric and isotonic contraction. For example, during walking, isotonic contraction results in shortening of the leg, and isometric contraction causes the stiff leg to push against the floor.

Energy is consumed during muscle contraction and relaxation. The main source of energy for the muscle cells is adenosine triphosphate (ATP), which is generated through cellular oxidative metabolism. At low levels of activity (i.e., sedentary activity), the skeletal muscle synthesizes ATP from the oxidation of glucose to water and carbon dioxide. During periods of strenuous activity, when sufficient oxygen may not be available, glucose is metabolized primarily to lactic acid, an inefficient process compared with that of oxidative pathways. Stored muscle glycogen is used to supply glucose during periods of activity. Muscle fatigue is thought to be caused by depletion of glycogen and accumulation of lactic acid. As a result, the cycle of muscle contraction and relaxation cannot continue (Norris, 2019).

During muscle contraction, the energy released from ATP is not completely used. The excess energy is dissipated in the form of heat. During isometric contraction, almost all of the energy is released in the form of heat; during isotonic contraction, some of the energy is expended in mechanical work. In some situations (i.e., shivering), the need to generate heat is the main stimulus for muscle contraction.

The speed of the muscle contraction is variable. Myoglobulin is a hemoglobinlike protein pigment present in striated muscle cells that transports oxygen. Muscles containing large quantities of myoglobulin (red muscles) have been observed to contract slowly and powerfully (e.g., respiratory and postural muscles). Muscles containing little myoglobulin (white muscles) contract quickly (e.g., extraocular eye muscles). Most muscles contain both red and white muscle fibers (Norris, 2019).

Muscle Tone

Muscle **tone** (tonus) is produced by the maintenance of some of the muscle fibers in a contracted state. Muscle spindles, which are sense organs in the muscles, monitor muscle tone. Muscle tone is minimal during sleep and is increased when the person is anxious. A muscle that is limp and without tone is described as **flaccid**; a muscle with greater-than-normal tone is described as **spastic**. Typically, upper motor neuron lesions produce increased tone, whereas lower motor neuron lesions produce decreased tone. For example, in conditions characterized by upper motor neuron destruction (e.g., cerebral palsy), muscle becomes hypertonic and reflexes become hyperactive. In contrast, conditions characterized by lower motor neuron destruction (e.g., muscular dystrophy), denervated muscle becomes **atonic** (soft and flabby) and atrophies (Norris, 2019). See Chapter 60, Table 60-4, for a comparison of upper and lower motor function.

Muscle Actions

Muscle contraction produces movement. The body is able to perform a wide variety of movements as a result of the coordination of muscle groups (Fig. 35-3). The prime mover is the muscle that causes a particular motion. The muscles assisting the prime mover are known as synergists. The muscles causing movement opposite to that of the prime mover are known as antagonists. An antagonist must relax to allow the prime mover to contract, producing motion. For example, when contraction of the biceps causes flexion of the elbow joint, the biceps are the prime movers and the triceps are the antagonists. A person with muscle paralysis (i.e., loss of movement) may be able to retrain functioning muscles within the synergistic group to produce the needed movement. Muscles of the synergistic group then become the prime movers (Norris, 2019).

Exercise, Disuse, and Repair

Muscles need exercise to maintain function and strength. When a muscle repeatedly develops maximum or close to maximum tension over a long time, as in regular exercise with weights, the cross-sectional area of the muscle increases. This enlargement, known as **hypertrophy**, results from an increase in the size of individual muscle fibers without an increase in their number. Hypertrophy persists only if the exercise is continued. The opposite phenomenon occurs with disuse of muscle over a long period of time. Age and disuse cause loss of muscular function as fibrotic tissue replaces the contractile muscle tissue. The decrease in the size of a muscle is called **atrophy**. Bed rest and immobility cause loss of muscle mass and strength. When immobility is the result of a treatment modality (e.g., casting, traction, or bed rest), the patient can decrease the effects of immobility by isometric exercise of the muscles of the immobilized part. Quadriceps contraction exercises (tightening the muscles of the thigh) and gluteal setting exercises (tightening of the muscles of the buttocks) help maintain the larger muscle groups that are important in ambulation. Active and weight-resistance exercises of uninjured parts of the body maintain muscle strength. When muscles are injured, they need rest and immobilization until tissue repair occurs. The healed muscle then needs progressive exercise to resume its pre-injury strength and functional ability.

Gerontologic Considerations

Multiple changes in the musculoskeletal system occur with aging (Table 35-1) and bring complaints of pain and joint limitations. There is a loss of height due to osteoporosis (abnormal excessive bone loss), kyphosis (forward curvature of the thoracic spine), thinned intervertebral discs, compressed vertebral bodies, and flexion of the knees and hips. Numerous metabolic changes, including menopausal withdrawal of estrogen and decreased activity, contribute to osteoporosis (National Osteoporosis Foundation [NOF], 2019). Women lose more bone mass than men. In addition, bones change in shape and have reduced strength. Fractures are common. Collagen structures are less able to absorb energy. Increased inactivity, diminished neuron stimulation, and nutritional deficiencies contribute to the loss of muscle strength. In addition, remote musculoskeletal problems for which the patient has compensated may become new problems with age-related changes. For example, people who have had polio and who have been able to function normally by using synergistic muscle groups may discover increasing incapacity because of a reduced compensatory ability. Older adults may suffer from chronic musculoskeletal disorders that limit mobility and interfere with their ability to perform self-care. This may lead older adults to depend on others for

completion of their activities of daily living (ADLs); in turn, they may grieve over the loss of independence. In particular, musculoskeletal disorders of the hand and wrist are prevalent among older adults; and, the incidence of these disorders increases with increasing age (Leow, Teo, Low, et al., 2019) (see Nursing Research Profile: Hand Assessment of Older Adults in Chart 35-1). Despite a multitude of age-related musculoskeletal changes, the many effects of aging can be slowed if the body is kept healthy and active through positive lifestyle behaviors (Eliopoulos, 2018).

Assessment

The nursing assessment of the patient with musculoskeletal dysfunction includes a health history and physical examination that evaluate the effects of the musculoskeletal disorder on the patient.

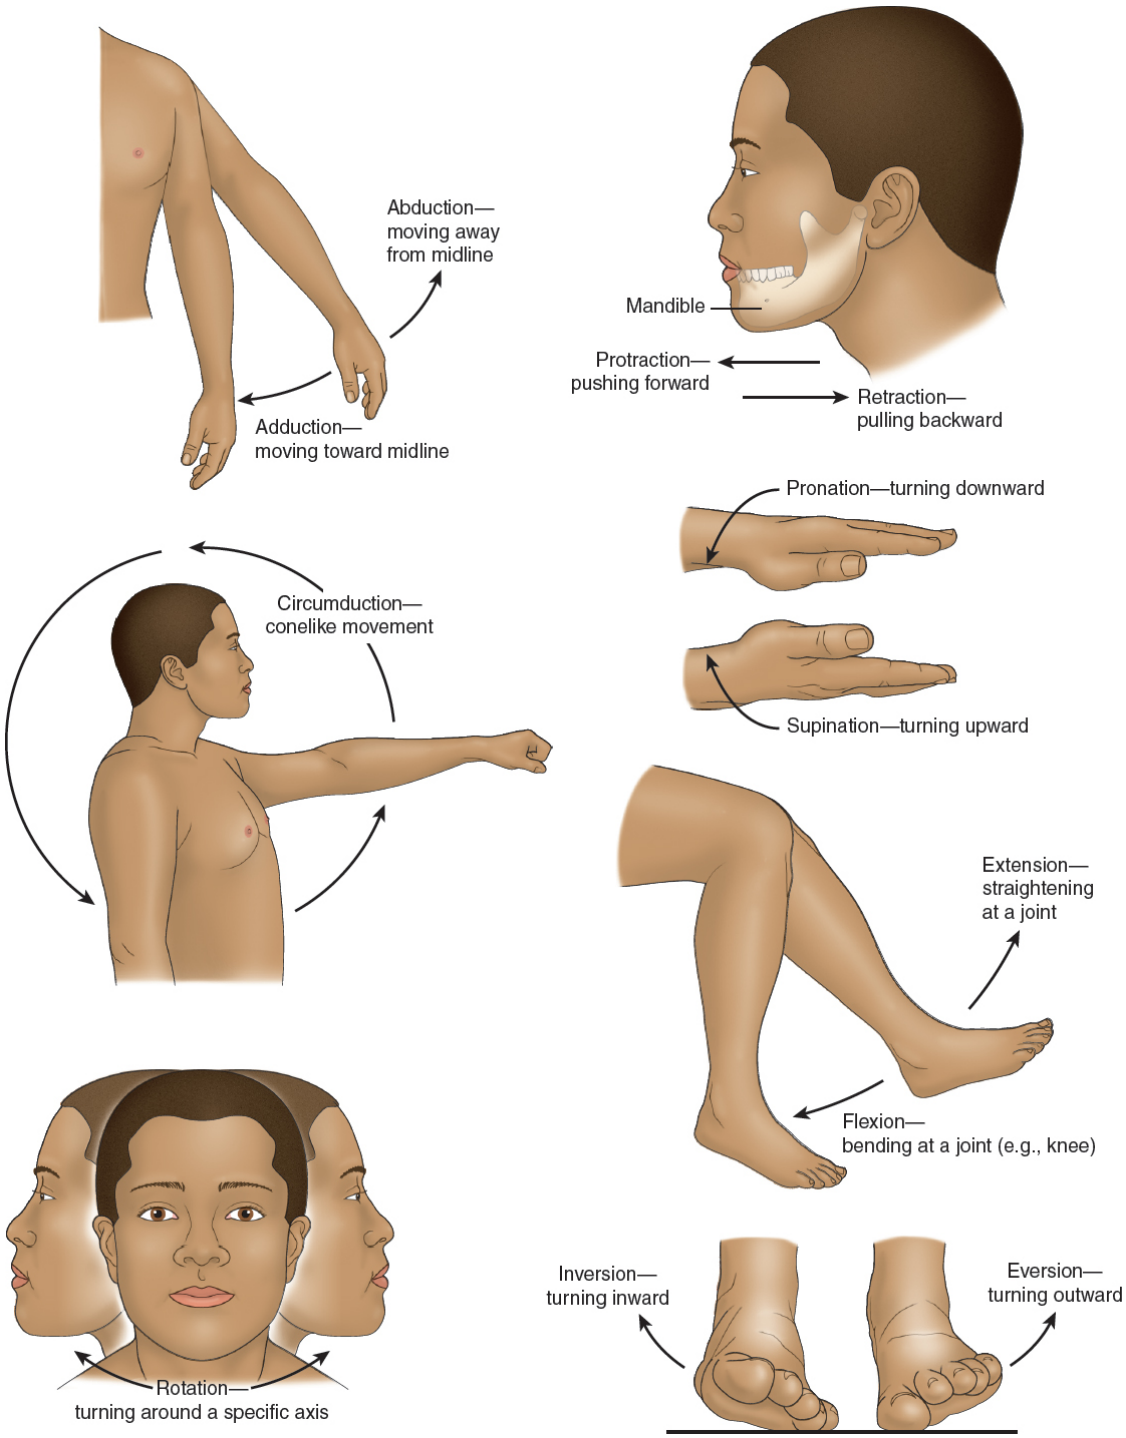

Figure 35-3 • Body movements produced by muscle contraction.

TABLE 35-1 Age-Related Changes of the Musculoskeletal System

Musculoskeletal System	Structural Changes	Functional Changes	History and Physical Findings
Bones	Gradual, progressive loss of bone mass after 30 y of age Vertebral collapse	Bones fragile and prone to fracture—vertebrae, hip, wrist	Loss of height Postural changes Kyphosis Loss of flexibility Flexion of hips and knees Back pain Osteoporosis Fracture
Muscles	Increase in collagen and resultant fibrosis Muscles atrophy (diminish in size); wasting Tendons less elastic	Loss of strength and flexibility Weakness Fatigue Stumbling Falls	Loss of strength Diminished agility Decreased endurance Prolonged response time (diminished reaction time) Diminished tone Broad base of support History of falls
Joints	Cartilage—progressive deterioration Thinning of intervertebral discs	Stiffness, reduced flexibility, and pain interfere with activities of daily living	Diminished range of motion Stiffness Loss of height
Ligaments	Lax ligaments (less-than-normal strength; weakness)	Postural joint abnormality Weakness	Joint pain on motion; resolves with rest Crepitus Joint swelling/enlargement Osteoarthritis (degenerative joint disease)

Chart 35-1 **NURSING RESEARCH PROFILE**

Hand Assessment of Older Adults

Leow, M. Q., Teo, W., Low, T. L., et al. (2019). Hand assessment for elderly people in the community. *Orthopaedic Nursing*, *38*(1), 25–30.

Purpose

Hand and wrist disorders are common, particularly among older adults. These disorders typically include osteoarthritis, trigger finger, and carpal tunnel syndrome. These conditions can cause significant pain, stiffness, numbness, and decreased range of motion in the affected extremity. Early treatment may mitigate the detrimental effects of these disorders; yet, treatment is uncommon until later, when there is a disruption in the patient's activities of daily living (ADLs). The purpose of this study was to evaluate the prevalence of these hand disorders among older adults in a community setting.

Design

This descriptive study solicited participation from older adults who frequented a neighborhood day center in Singapore. All eligible participants were independent in completing their ADLs. Demographic information, a brief health history, hand and wrist assessments, and grip and pinch strength were obtained from all participants. Questionnaires completed by participants included the 11-item QuickDASH questionnaire, a psychometrically validated tool for assessing functional ability of the upper extremities, and a numeric pain intensity scale score that assessed hand and wrist pain. Assessments were conducted specifically for participants who were experiencing symptoms associated with osteoarthritis, trigger finger, and carpal tunnel syndrome. Fifty-five older adults participated in this study.

Findings

Participants (N = 55) ranged in age from 60 to 90 years with a mean age of 74 years. The majority of participants were female (n = 41). Nearly one third of participants presented with a hand condition (n = 17); 11 had osteoarthritis, one had trigger finger, three had carpal tunnel syndrome, and two had both trigger finger and carpal tunnel. Hand disorders were more prevalent in female participants than in males (39% in females, 7% in males). Of those with hand disorders, 34.5% reported difficulty in doing household chores, 21.8% had difficulty opening jars, and 21.8% reported difficulty participating in recreational activities that required arm, shoulder, or hand strength. This study found that participants who had an abnormal hand assessment finding did not seek medical attention until these conditions impacted their ADLs.

Nursing Implications

Findings from this study suggest that hand and wrist disorders are indeed commonplace among community-dwelling older adults; yet most study

participants had not previously sought medical treatment for their disorders. Nurses may develop screening programs for hand and wrist disorders in older adults with the tools used in this study. Screening older adults for early-stage hand and wrist disorders can lead to timely and effective treatment that can preserve function and assist the older adult to maintain independence in ADLs.

Health History

An important aspect of a musculoskeletal assessment is the history of the present illness. Musculoskeletal disorders may be stable or progressive, characterized by symptom-free periods as well as fluctuations in symptoms. The health history therefore includes details about the onset, character, severity, location, duration, and frequency of symptoms and signs; associated complaints; precipitating, aggravating, and relieving factors; progression, remission, and exacerbation; and the presence or absence of similar symptoms among family members.

Common Symptoms

During the interview and physical assessment, the patient with a musculoskeletal disorder may report pain, tenderness, and altered sensations (Weber & Kelley, 2018).

Pain

Most patients with diseases and traumatic conditions or disorders of the muscles, bones, and joints experience pain. Bone pain is typically described as a dull, deep ache that is "boring" in nature. This pain is not typically related to movement and may interfere with sleep. Muscular pain is described as soreness or aching and is referred to as "muscle cramps." Fracture pain is sharp and piercing and is relieved by immobilization. Sharp pain may also result from bone infection with muscle spasm or pressure on a sensory nerve. Joint pain is felt around or in the joint and typically worsens with movement (Kennedy-Malone et al., 2019).

Rest relieves most musculoskeletal pain. Pain that increases with activity may indicate joint sprain, muscle strain, or compartment syndrome, whereas steadily increasing pain points to the progression of an infectious process (osteomyelitis), a malignant tumor, or neurovascular complications. Radiating pain occurs in conditions in which pressure is exerted on a nerve root (Kennedy-Malone et al., 2019).

The time of day that the pain occurs may be important to evaluate. Those experiencing pain with an inflammatory rheumatic disorder experience pain that is worse in the morning, especially upon waking. Tendonitis worsens during the early morning and eases by midday, whereas osteoarthritis worsens

as the day progresses (Kennedy-Malone et al., 2019). Pain is variable, and its assessment and nursing management must be individualized.

The nurse assesses the patient's pain as described in Chapter 9. Specific assessments that the nurse should make regarding the pain include the following:

- Is the body in proper alignment?
- Are the joints symmetrical or are bony deformities present?
- Is there any inflammation or arthritis, swelling, warmth, tenderness, or redness?
- Is there pressure from traction, bed linens, a cast, or other appliances?
- Is there tension on the skin at a pin site?

The patient's pain and discomfort must be managed successfully. Not only is pain exhausting, but also, if prolonged, it can force the patient to become increasingly withdrawn and dependent on others as the musculoskeletal disorder continues.

Altered Sensations

Sensory disturbances are frequently associated with musculoskeletal problems. The patient may describe **paresthesias,** which are sensations of burning, tingling, or numbness. These sensations may be caused by pressure on nerves or by circulatory impairment. Soft tissue swelling or direct trauma to these structures can impair their function. The nurse assesses the neurovascular status of the involved musculoskeletal area.

Questions that the nurse should ask regarding altered sensations include the following:

- Is the patient experiencing abnormal sensations, such as burning, tingling, or numbness?
- If the abnormal sensation involves an extremity, how does this feeling compare to sensation in the unaffected extremity?
- When did the condition begin? Is it getting worse?
- Does the patient also have pain? (If the patient has pain, then the questions and assessments for pain discussed previously should be followed.)

Past Health, Social, and Family History

When assessing the musculoskeletal system, the nurse should gather pertinent data to include in the patient's health history, such as occupation (e.g., does the patient's work require physical activity or heavy lifting?), exercise patterns, alcohol consumption, tobacco use, and dietary intake (e.g., calcium, vitamin D). Concurrent health conditions (e.g., diabetes, heart disease, chronic obstructive pulmonary disease, infection, preexisting disability) and related problems (e.g., familial or genetic abnormalities; see Chart 35-2) need to be

considered when developing and implementing the plan of care. Any previous history of trauma or injury to the musculoskeletal system or a history of falls should be included as well (Weber & Kelley, 2018).

The Fracture Risk Assessment Tool (FRAX®)

The Fracture Risk Assessment Tool (FRAX®) was developed in 2008 by a task force convened by the World Health Organization (WHO). It is a tool that predicts a patient's 10-year risk of fracturing a hip or other major bone, which includes the spine, forearm, or shoulder (NOF, 2019). The tool may be accessed online, where it automatically calculates a patient's odds of fracture. Data entered are validated risks for fracture, and include:

- age (risk increases with increasing age)
- gender (risk is higher in females)
- body mass index (risk is higher with lower body mass indices)
- history of a previous fracture
- parental history of hip fracture
- current cigarette smoker
- current use of a corticosteroid (e.g., prednisone)
- history of rheumatoid arthritis
- alcohol intake of 3 or more drinks per day
- history of secondary causes/risks for osteoporosis, which include any of the following:
  - type 1 diabetes
  - osteogenesis imperfecta
  - untreated long-standing hyperthyroidism
  - hypogonadism or premature menopause
  - chronic malnutrition or malabsorption syndromes
  - chronic liver disease

Chart 35-2  **GENETICS IN NURSING PRACTICE**

Musculoskeletal Disorders

Genetic musculoskeletal disorders vary in presentation and can tend to present at different points in time across the lifespan. Consideration must be given to other genetic disorders that will impact the musculoskeletal system. Some examples of inherited genetic musculoskeletal disorders include:
Autosomal Dominant:

- Achondroplasia
- Nail–Patella syndrome
- Osteogenesis imperfecta
- Polydactyly
- van der Woude syndrome

Autosomal Recessive:

- Tay-Sachs

Forms of Muscular Dystrophy:

- Becker muscular dystrophy
- Congenital muscular dystrophy
- Distal muscular dystrophy
- Duchenne muscular dystrophy (X-linked)
- Emery–Dreifuss muscular dystrophy (X-linked)
- Facioscapulohumeral muscular dystrophy (autosomal dominant)
- Limb–girdle muscular dystrophy (autosomal dominant and autosomal recessive forms)

Other genetic disorders that impact the musculoskeletal system:

- Amyotrophic lateral sclerosis (neurologic disorder)
- Ehlers–Danlos syndrome (connective tissue disorder)
- Marfan syndrome (connective tissue disorder)
- Spina bifida (neurologic disorder)
- Stickler syndrome (connective tissue disorder)

Nursing Assessments

See Chapter 4, Chart 4-2 for Genetics in Nursing Practice: Genetic Aspects of Health Assessment.

Family History Assessment Related to Genetic Musculoskeletal Disorders

- Assess for other similarly affected family members in the past three generations.
- Assess for the presence of other related genetic conditions (e.g., hematologic, cardiac, integumentary conditions).
- Determine the age at onset (e.g., fractures present at birth such as osteogenesis imperfecta, hip dislocation present at birth in DDH, or

early-onset osteoporosis).

Patient Assessment Specific to Genetic Musculoskeletal Disorders

- Assess stature for general screening purposes (unusually short stature may be related to achondroplasia; unusually tall stature may be related to Marfan syndrome).
- Assess for disease-specific skeletal findings (e.g., pectus excavatum, scoliosis, long fingers [Marfan syndrome], osteoarthritis of the hip or waddling gait).
- Assessment findings that could indicate a genetic musculoskeletal disorder include:
  - Bone pain
  - Enlarged hands or feet
  - Excessive height, short stature, or decrease in height
  - Flat feet or highly arched feet
  - Frequency of bone-related injuries or unexplained fractures
  - Hypermobility of joints
  - Large or small head circumference
  - Protruding jaw or forehead
  - Unexplained changes in muscle tone (hypotonia)

Genetic Resources

The National Osteoporosis Foundation, www.nof.org
NIH Osteoporosis and Related Bone Diseases National Resource Center, www.niams.nih.gov/Health_Info/Bone
See Chapter 6, Chart 6-7 for components of genetic counseling.
DDH, developmental dysplasia of the hip(s)

An additional validated risk factor that may be entered into the FRAX® is the patient's bone mineral density (BMD), based on bone densitometry results, if those results are hip based (see later discussion). However, while entering BMD results in the FRAX® provides a more accurate fracture risk calculation, it is not necessary (Bickley, 2017). Thus, the FRAX® provides a good estimate of fracture risk in patients who may not have submitted to BMD testing. Patients who should be assessed for hip or major bone fracture risk include men and postmenopausal women over the age of 50, patients with known low BMD, and patients with known secondary causes/risks for osteoporosis. See Chapter 36 for further discussion of osteoporosis.

Physical Assessment

An examination of the musculoskeletal system ranges from a basic assessment of functional capabilities to sophisticated physical examination maneuvers that

facilitate diagnosis of specific bone, muscle, and joint disorders. The extent of assessment depends on the patient's physical complaints, health history, and physical clues that warrant further exploration. The nursing assessment is primarily a functional evaluation, focusing on the patient's ability to perform ADLs.

Techniques of inspection and palpation are used to evaluate the patient's posture, gait, bone integrity, joint function, and muscle strength and size. In addition, assessing the skin and neurovascular status is an important part of a complete musculoskeletal assessment. The nurse should also understand and be able to perform correct assessment techniques on patients with musculoskeletal trauma. When specific symptoms or physical findings of musculoskeletal dysfunction are apparent, the nurse carefully documents the examination findings and shares the information with the primary provider, who may decide that a more extensive examination and a diagnostic evaluation are necessary.

Posture

The normal curvature of the spine is convex through the thoracic portion and concave through the cervical and lumbar portions. Common deformities of the spine include **kyphosis**, which is an increased forward curvature of the thoracic spine that causes a bowing or rounding of the back, leading to a hunchback or slouching posture. The second deformity of the spine is referred to as **lordosis**, or swayback, an exaggerated curvature of the lumbar spine. A third deformity is **scoliosis**, which is a lateral curving deviation of the spine (Fig. 35-4). Kyphosis can occur at any age and may be caused by degenerative diseases of the spine (e.g., arthritis or disc degeneration), fractures related to osteoporosis, and injury or trauma (Meiner & Yeager, 2019). It may also be seen in patients with other neuromuscular disease. Lordosis can affect people of any age. Common causes of lordosis include tight low back muscles, excessive visceral fat, and pregnancy as the woman adjusts her posture in response to changes in her center of gravity. Scoliosis may be congenital, idiopathic (without an identifiable cause), or the result of damage to the paraspinal muscles (e.g., muscular dystrophy).

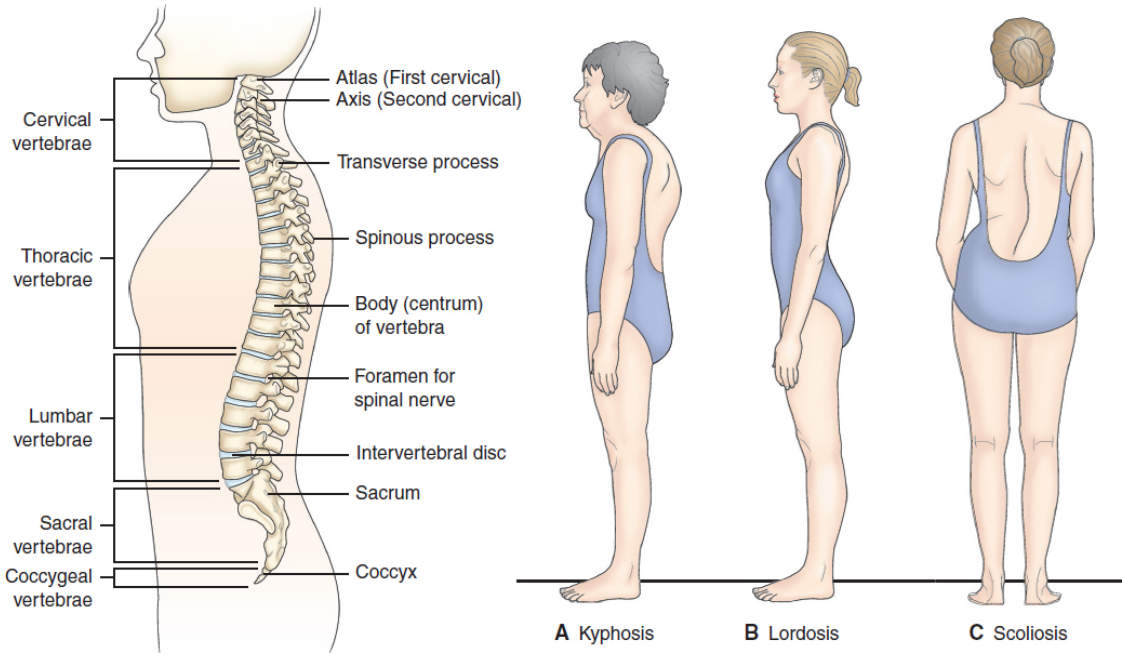

Figure 35-4 • A normal spine and three abnormalities. **A.** Kyphosis: an increased convexity or roundness of the spine's thoracic curve. **B.** Lordosis: swayback; exaggeration of the lumbar spine curve. **C.** Scoliosis: a lateral curvature of the spine.

During inspection of the spine, the entire back, buttocks, and legs are exposed. The examiner inspects the spinal curves and trunk symmetry from posterior and lateral views. Standing behind the patient, the examiner notes any differences in the height of the shoulders or iliac crests. Shoulder and hip symmetry, as well as the line of the vertebral column, is inspected with the patient erect and with the patient bending forward (flexion). Scoliosis is evidenced by an abnormal lateral curve in the spine; shoulders that are not level; an asymmetric waistline; and a prominent scapula, which is accentuated by bending forward. The examiner should then instruct the patient to bend backward (extension) with the examiner supporting the patient by placing hands on the posterior iliac spine (Weber & Kelley, 2018). Older adults experience a loss in height due to the loss of vertebral cartilage and osteoporosis-related vertebral compression fractures. Therefore, an adult's height should be measured during each health screening.

Gait

Gait is assessed by having the patient walk away from the examiner for a short distance. The examiner observes the patient's gait for smoothness and rhythm. Any unsteadiness or irregular movements (frequently noted in older adult patients) are considered abnormal. A limping motion is most frequently caused by painful weight bearing. In such instances, the patient can usually pinpoint the area of discomfort, thus guiding further examination. If one extremity is

shorter than another, a limp may also be observed as the patient's pelvis drops downward on the affected side with each step. The knee should be flexed during normal gait; therefore, limited joint motion may interrupt the smooth pattern of gait. Evaluation of the knee involves the joints, bones, ligaments, tendons, and cartilage, and may include tests for the anterior and collateral ligaments, medial and lateral ligaments, and medial meniscus (Weber & Kelley, 2018). In addition, a variety of neurologic conditions are associated with abnormal gait, such as a spastic hemiparesis gait (stroke), steppage gait (lower motor neuron disease), and shuffling gait (Parkinson's disease).

Bone Integrity

The bony skeleton is assessed for deformities and alignment. Symmetric parts of the body, such as extremities, are compared. Abnormal bony growths due to bone tumors may be observed. Shortened extremities, amputations, and body parts that are not in anatomic alignment are noted. Fracture findings may include abnormal angulation of long bones, motion at points other than joints, and **crepitus** (a grating or crackling sound or sensation) at the point of abnormal motion. Movement of fracture fragments must be minimized to avoid additional injury. The nurse should include the following observations (Weber & Kelley, 2018):

- If the affected part is an extremity, how does its overall appearance compare to the unaffected extremity?
- Can the patient move the affected part? If an extremity is involved, does each toe or finger have normal sensation and motion (flexion and extension), and is the skin warm or cool?
- What is the color of the part distal to the affected area? Is it pale? Dusky? Mottled? Cyanotic?
- Does rapid capillary refill occur? (The nurse can gently squeeze a nail until it blanches, then release the pressure. The amount of time for the color under the nail to return to normal is noted. Color normally returns within 3 seconds. The return of color is evidence of capillary refill.)
- Is a pulse distal to the affected area palpable? If the affected area is an extremity, how does the pulse compare to the pulse of the unaffected extremity?
- Is edema present?
- Is any constrictive device or clothing causing nerve or vascular compression?
- Does elevating the affected part or modifying its position affect the symptoms?

Joint Function

The articular system is evaluated by noting range of motion, deformity, stability, tenderness, and nodular formation. Range of motion is evaluated both actively (the joint is moved by the muscles surrounding the joint) and passively (the joint is moved by the examiner). The examiner is familiar with the normal range of motion of major joints. Precise measurement of range of motion can be made by a goniometer (a protractor designed for evaluating joint motion) (Bickley, 2017). Limited range of motion may be the result of skeletal deformity, joint pathology, or **contracture** (shortening of surrounding joint structures) of the surrounding muscles, tendons, and joint capsule. In older adult patients, limitations of range of motion associated with osteoarthritis may reduce their ability to perform ADLs (Eliopoulos, 2018).

If joint motion is compromised or the joint is painful, the joint is examined for **effusion** (excessive fluid within the capsule), swelling, and increased temperature that may reflect active inflammation. An effusion is suspected if the joint is swollen and the normal bony landmarks are obscured. The most common site for joint effusion is the knee. If large amounts of fluid are present in the joint spaces beneath the patella, it may be identified by assessing for the balloon sign and for ballottement of the knee (Fig. 35-5). If inflammation or fluid is suspected in a joint, consultation with a specialist (e.g., orthopedic surgeon or rheumatologist) is indicated.

Joint deformity may be caused by contracture, dislocation (complete separation of joint surfaces), subluxation (partial separation of articular surfaces), or disruption of structures surrounding the joint. Weakness or disruption of joint-supporting structures may result in a weak joint that requires an external supporting appliance (e.g., brace).

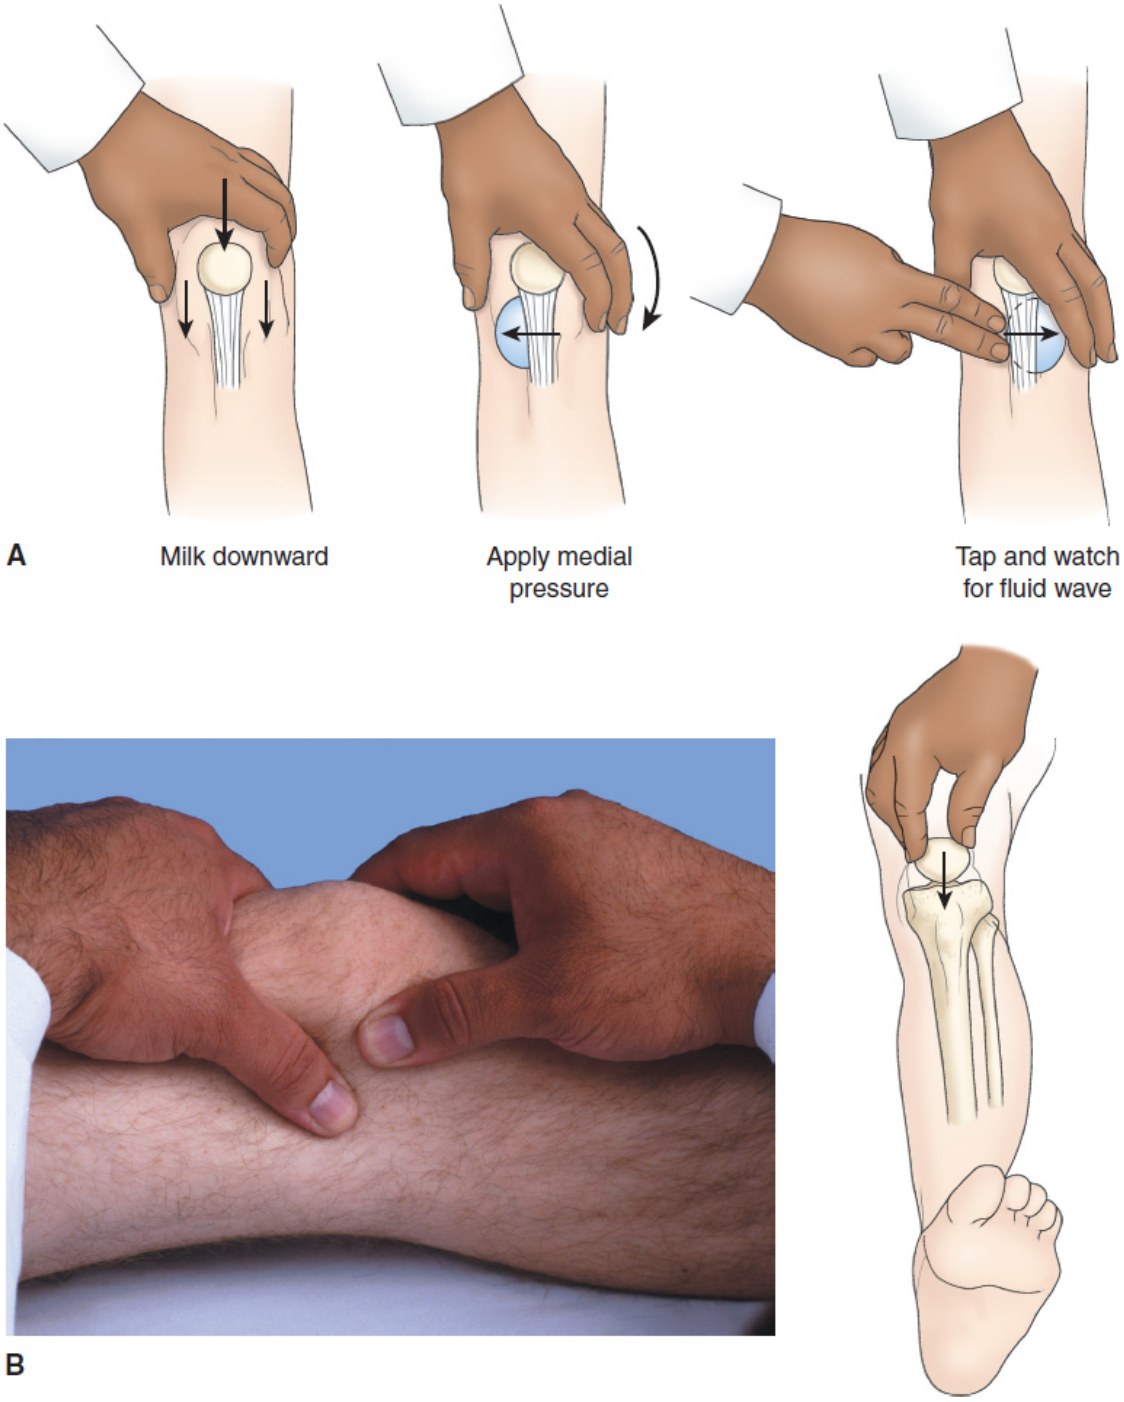

Figure 35-5 • Tests for detecting fluid in the knee. **A.** Technique for balloon sign. The medial and lateral aspects of the extended knee are milked firmly in a downward motion, which displaces any fluid downward. The examiner feels for any fluid entering the space directly inferior to the patella. When larger amounts of fluid are present, the subpatellar region feels as if it is "ballooning," and the balloon sign test is positive. **B.** Technique for ballottement sign. The medial and lateral aspects of the extended knee are milked firmly in a downward motion. The examiner pushes the patella toward the femur and observes for fluid return to the region superior to the patella. When larger amounts of fluid are present, the patella

elevates, there is visible return of fluid to the region directly superior to the patella, and the ballottement test is positive. Photograph used with permission from Bickley, L. S. (2017). *Bates' guide to physical examination and history taking* (12th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Palpation of the joint while it is moved passively provides information about the integrity of the joint. Normally, the joint moves smoothly. A snap or crack may indicate that a ligament is slipping over a bony prominence. Slightly roughened surfaces, as in arthritic conditions, result in crepitus as the irregular joint surfaces move across one another (Bickley, 2017).

The tissues surrounding joints are examined for nodule formation. Rheumatoid arthritis, gout, and osteoarthritis may produce characteristic nodules. The subcutaneous nodules of rheumatoid arthritis are soft and occur within and along tendons that provide extensor function to the joints. The nodules of gout are hard and lie within and immediately adjacent to the joint capsule itself. They may rupture, exuding white uric acid crystals onto the skin surface. Osteoarthritic nodules are hard and painless and represent bony overgrowth that has resulted from the destruction of the cartilaginous surface of bone within the joint capsule. They are frequently seen in older adults (Bickley, 2017).

Often, the size of the joint is exaggerated by atrophy of the muscles proximal and distal to that joint. This is seen in rheumatoid arthritis of the knees, in which the quadriceps muscle may atrophy dramatically. In rheumatoid arthritis, joint involvement assumes a symmetric pattern (Fig. 35-6). See Chapter 34 for further information about rheumatoid arthritis.

Muscle Strength and Size

The muscular system is assessed by noting muscular strength and coordination, the size of individual muscles, and the patient's ability to change position. Weakness of a group of muscles may indicate a variety of conditions, such as polyneuropathy, electrolyte disturbances (particularly potassium and calcium), myasthenia gravis, poliomyelitis, and muscular dystrophy. By palpating the muscle while passively moving the relaxed extremity, the nurse can determine the muscle tone (Bickley, 2017). Muscle strength is assessed by having the patient perform certain maneuvers with and without added resistance. For example, when the biceps are tested, the patient is asked to extend the arm fully and then to flex it against resistance applied by the nurse. A simple handshake may provide an indication of grasp strength.

Figure 35-6 • Rheumatoid arthritis joint deformity with ulnar deviation of fingers and "swan neck" deformity of fingers (i.e., hyperextension of proximal interphalangeal joints with flexion of distal interphalangeal joints).

The nurse may elicit muscle **clonus** (rhythmic contractions of a muscle) in the ankle or wrist by sudden, forceful, sustained dorsiflexion of the foot or extension of the wrist. **Fasciculation** (involuntary twitching of muscle fiber groups) may be observed.

The nurse measures the girth of an extremity to monitor increased size due to exercise, edema, or bleeding into the muscle. Girth may decrease due to muscle atrophy. The unaffected extremity is measured and used as the reference standard for the affected extremity. Measurements are taken at the maximum circumference of the extremity. It is important that the measurements be taken at the same location on the extremity, and with the extremity in the same position, with the muscle at rest. Distance from a specific anatomic landmark (e.g., 10 cm below the medial aspect of the knee for measurement of the calf muscle) should be indicated in the patient's record so that subsequent measurements can be made at the same point. For ease of serial assessment, the nurse may indicate the point of measurement by marking the skin. Variations in size greater than 1 cm are considered significant (Bickley, 2017).

Skin

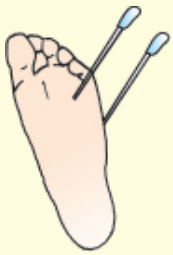
In addition to assessing the musculoskeletal system, the nurse inspects the skin for edema, temperature, and color. Palpation of the skin may reveal whether any areas are warmer, suggesting increased perfusion or inflammation, or

cooler, suggesting decreased perfusion, and whether edema is present. Cuts, bruises, skin color, and evidence of decreased circulation or inflammation can influence nursing management of musculoskeletal conditions.

Neurovascular Status

The nurse must perform frequent neurovascular assessments of patients with musculoskeletal disorders (especially of those with fractures) because of the risk of tissue and nerve damage. Chart 35-3 describes methods the nurse may use to evaluate peripheral nerve function. The nurse needs to be particularly aware of signs and symptoms of compartment syndrome (which is described in detail later in this unit) when assessing the patient with a musculoskeletal injury. This neurovascular problem is caused by pressure within a muscle compartment that increases to such an extent that microcirculation diminishes, leading to nerve and muscle anoxia and necrosis. Function can be permanently lost if the anoxic situation continues for longer than 6 hours. Assessment of neurovascular status (Chart 35-4) is frequently referred to as assessment of CMS (circulation, motion, and sensation).

Diagnostic Evaluation



X-Ray Studies

Bone x-rays determine bone density, texture, erosion, and changes in bone relationships. X-ray study of the cortex of the bone reveals any widening, narrowing, or signs of irregularity. Joint x-rays reveal fluid, irregularity, spur formation, narrowing, and changes in the joint structure. Multiple x-rays, with multiple views (e.g., anterior, posterior, lateral), are needed for full assessment of the structure being examined. Serial x-rays may be indicated to determine the status of the healing process (Kennedy-Malone et al., 2019).

Chart 35-3  **ASSESSMENT**

Assessing for Peripheral Nerve Function

Assessment of peripheral nerve function has two key elements: evaluation of sensation and evaluation of motion. The nurse may perform one or all of the following during a musculoskeletal assessment.

Nerve	Test of Sensation	Test of Movement
Peroneal	Prick the skin midway between the great and second toe. 	Ask the patient to dorsiflex the foot and extend the toes. 
Tibial	Prick the medial and lateral surface of the sole. 	Ask the patient to plantar flex toes and foot. 
Radial	Prick the skin midway between the thumb and second finger. 	Ask the patient to stretch out the thumb, then the wrist, and then the fingers at the metacarpal joints. 
Ulnar	Prick the distal fat pad of the small finger. 	Ask the patient to abduct all fingers. 
Median	Prick the top or distal surface of the index	Ask the patient to touch the thumb to the little finger. In addition, observe whether the patient

finger.

can flex the wrist.

Computed Tomography

A computed tomography (CT) scan, which may be performed with or without the use of oral or intravenous (IV) contrast agents, shows a more detailed cross-sectional image of the body. It may be used to visualize and assess

tumors; injury to the soft tissue, ligaments, or tendons; and severe trauma to the chest, abdomen, pelvis, head, or spinal cord. It is also used to identify the location and extent of fractures in areas that are difficult to evaluate (e.g., acetabulum) and not visible on x-ray (Van Leeuwen & Bladh, 2019).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive imaging technique that uses magnetic fields and radio waves to create high-resolution pictures of bones and soft tissues. It can be used to visualize and assess torn muscles, ligaments, and cartilage; herniated discs; and a variety of hip or pelvic conditions. The patient does not experience any pain during the procedure. The MRI scanner is noisy, and it may take 30 to 90 minutes to complete the test. Because an electromagnet is used, patients with most metal implants (i.e., cochlear implants) or clips are not candidates for MRI (Van Leeuwen & Bladh, 2019).

Quality and Safety Nursing Alert

Jewelry, hair clips, hearing aids, credit cards with magnetic strips, and other metal-containing objects must be removed before the MRI is performed; otherwise, they can become dangerous projectile objects or cause burns. Credit cards with magnetic strips may be erased, and nonremovable cochlear devices can become inoperable; therefore, their presence is a contraindication for MRI. In addition, transdermal patches (e.g., nicotine patch, nitroglycerin transdermal, scopolamine transdermal, clonidine transdermal) that have a thin layer of aluminized backing must be removed before MRI because they can cause burns. The primary provider should be notified before the patches are removed.

To enhance visualization of anatomic structures, an IV contrast agent may be used. Patients who experience claustrophobia may be unable to tolerate the confinement of closed MRI equipment without sedation. Open MRI systems are available, but they use lower-intensity magnetic fields, which produce lower-quality images. Advantages of open MRI include increased patient comfort, reduced problems with claustrophobic reactions, and reduced noise.

Arthrography

Arthrography is used to identify the cause of any unexplained joint pain and progression of joint disease. A radiopaque contrast agent or air is injected into

the joint cavity to visualize the joint structures, such as the ligaments, cartilage, tendons, and joint capsule. The joint is put through its range of motion to distribute the contrast agent while a series of x-rays are obtained. If a tear is present, the contrast agent leaks out of the joint and is evident on the x-ray image (Van Leeuwen & Bladh, 2019).

Bone Densitometry

Bone densitometry is used to evaluate BMD. This can be performed through the use of x-rays or ultrasound. The most common modalities used include dual-energy x-ray absorptiometry (DXA or DEXA), quantitative computed tomography (QCT), and quantitative ultrasound (QUS). DXA measures BMD and predicts fracture risk through accurate monitoring of bone density changes in patients with osteoporosis who are undergoing treatment. The density of bones in the spine, hip, and wrist may be calculated, as well as the total body. Peripheral dual-energy x-ray absorptiometry (pDXA) may be an alternative test that measures BMD of the forearm, finger, or heel, although its ability to project hip or spine fracture risk is less accurate than DXA (Felicilda-Reynaldo & Kenneally, 2019).

Bone density may vary among different skeletal areas; therefore, BMD results may be normal at one site but low at another. Because these tests only measure density at specific sites, they may miss abnormal findings in other skeletal areas. Thus, although the BMD of the heel can be used to diagnose and monitor osteoporosis, predicting bone fracture risk related to osteoporosis is best achieved through DXA of the hip and spine. Hence, DXA is the most commonly prescribed diagnostic test for determining BMD (Bickley, 2017; Van Leeuwen & Bladh, 2019). See Chapter 36 for a further discussion of osteoporosis risks.

Nursing Interventions

Before any of the imaging studies described previously (i.e., x-rays, CT scans, MRIs, arthrography, bone densitometry) are performed, the nurse prepares the patient. For all of these studies, the patient must lie still. During an MRI study, the patient may hear a knocking sound. In addition, the nurse assesses for conditions that may require special consideration during the study or that may be contraindications to the study (e.g., pregnancy; claustrophobia; inability to tolerate required positioning due to age, debility, or disability; metal implants). If contrast agents will be used for the CT scan, MRI, or arthrography, the patient is assessed for possible allergies (Van Leeuwen & Bladh, 2019).

The patient having an arthrogram may feel some discomfort or tingling during the procedure. After the arthrogram, a compression elastic bandage may be applied if prescribed, and the joint is usually rested for 12 hours. Strenuous activity should be avoided until approved by the primary provider. The nurse

provides additional comfort measures (e.g., mild analgesia, ice) as appropriate and explains to the patient that it is normal to experience clicking or crackling in the joint for 24 to 48 hours after the procedure until the contrast agent or air is absorbed.

Bone Scan

A bone scan is performed to detect metastatic and primary bone tumors, osteomyelitis, some fractures, and aseptic necrosis, and to monitor the progression of degenerative bone diseases. A bone scan may accurately identify bone disease before it can be detected on x-ray; as such, it may diagnose a stress fracture in a patient who continues to experience pain after x-ray findings are negative (Van Leeuwen & Bladh, 2019). A bone scan requires the injection of a radioisotope through an IV line; the scan is performed 2 to 3 hours afterward. At this point, distribution and concentration of the isotope in the bone are measured. The degree of nuclide uptake is related to the metabolism of the bone; areas of abnormal bone formation will appear brighter. An increased uptake of the isotope is seen in primary skeletal disease (osteosarcoma), metastatic bone disease, inflammatory skeletal disease (osteomyelitis), and fractures that do not heal as expected.

Nursing Interventions

Prior to the bone scan, the nurse inquires about possible allergies to the radioisotope and assesses for any condition that would contraindicate performing the procedure (e.g., pregnancy, breast-feeding). The patient is educated about why the bone scan may be indicated and how it can assist in the identification of bone disease before it can be detected on an x-ray. The nurse should explain that the patient may experience moments of discomfort from the isotope (e.g., flushing, warmth) but provide reassurance that the radionuclide poses no radioactive hazard (Van Leeuwen & Bladh, 2019). In addition, the patient is encouraged to drink plenty of fluids to help distribute and eliminate the isotope. Before the scan, the patient should empty the bladder, because a full bladder interferes with accurate scanning of the pelvic bones.

Arthroscopy

Arthroscopy allows direct visualization of a joint through the use of a fiberoptic endoscope. Thus, it is a useful adjunct to diagnosing joint disorders. Biopsy and treatment of tears, defects, and disease processes may be performed through the arthroscope. The procedure takes place in the operating room under sterile conditions with either injection of a local anesthetic agent into the joint or general anesthesia. A large-bore needle is inserted, and the

joint is distended with saline. The arthroscope is introduced, and joint structures, synovium, and articular surfaces are visualized. After the procedure, the puncture wound is closed with adhesive strips or sutures and covered with a sterile dressing. Complications are rare but may include infection, hemarthrosis, neurovascular compromise, thrombophlebitis, stiffness, effusion, adhesions, and delayed wound healing (Van Leeuwen & Bladh, 2019).

Nursing Interventions

After the arthroscopic procedure, the joint is wrapped with a compression dressing to control swelling. In addition, ice may be applied to control edema and enhance comfort. Frequently, the joint is kept extended and elevated to reduce swelling. The nurse monitors and documents the neurovascular status (see Chart 35-4). Analgesic agents are given as needed. The patient is instructed to avoid strenuous activity of the joint, and exercises must be approved by the primary provider. The patient and family are instructed to monitor for signs and symptoms of complications (e.g., fever, excessive bleeding, swelling, numbness, cool skin) and the importance of notifying the primary provider should any of these occur (Van Leeuwen & Bladh, 2019).

Arthrocentesis

Arthrocentesis (joint aspiration) is carried out to obtain synovial fluid for purposes of examination or to relieve pain due to effusion. Examination of synovial fluid is helpful in the diagnosis of septic arthritis and other inflammatory arthropathies and reveals the presence of hemarthrosis (bleeding into the joint cavity), which suggests trauma or a bleeding disorder. Normally, synovial fluid is clear, pale, straw colored, and scanty in volume. Using aseptic technique, the primary provider inserts a needle into the joint and aspirates fluid. Anti-inflammatory medications may be injected into the joint. A sterile dressing is applied after aspiration. There is a risk of infection after this procedure (Van Leeuwen & Bladh, 2019).

Nursing Interventions

The nurse should review the procedure with the patient and its indications. Hair may need to be removed from the site before the procedure. Pain may be a concern; telling the patient that antispasmodic agents may be given to alleviate discomfort during the procedure may help decrease anxiety. Ice may be prescribed for the first 24 to 48 hours postprocedure; the patient should be educated about why ice may be indicated (i.e., to diminish edema formation and pain). If antibiotics are prescribed postprocedure, the patient must be educated about their use and reminded to take medications as prescribed. The

patient and family are educated about the possible signs and symptoms of complications, particularly infection and bleeding (e.g., fever, excessive bleeding, swelling, numbness, cool skin) and the importance of promptly notifying the primary provider if any of these occur (Van Leeuwen & Bladh, 2019).

Electromyography

Electromyography (EMG) provides information about the electrical potential of the muscles and the nerves leading to them. The test is performed to evaluate muscle weakness, pain, and disability. The purpose of the procedure is to determine any abnormality of function and to differentiate muscle and nerve problems. An EMG can be used to identify the extent of damage if nerve function does not return within 4 months of an injury. Needle electrodes are inserted into selected muscles, and responses to electrical stimuli are recorded on an oscilloscope. Warm compresses may relieve residual discomfort after the study.

Nursing Interventions

Before the patient undergoes an EMG, the nurse inquires if the patient is taking any anticoagulant medications and assesses for any active skin infection. If the patient is found to be taking an anticoagulant or has a skin infection, the primary provider is notified. An EMG is usually contraindicated in patients receiving anticoagulant therapy (e.g., warfarin) because the needle electrodes may cause bleeding within the muscle. EMG also may be contraindicated in patients with extensive skin infections due to the risk of spreading infection from the skin to the muscle. The nurse instructs the patient to avoid using any lotions or creams on the day of the test (Van Leeuwen & Bladh, 2019).

Biopsy

Biopsy may be performed to determine the structure and composition of bone marrow, bone, muscle, or synovium to help diagnose specific diseases. It involves excising a sample of tissue that can be analyzed microscopically to determine cell morphology and tissue abnormalities.

Nursing Interventions

The nurse educates the patient about the procedure and offers assurance that analgesic agents will be provided. The biopsy site is monitored for edema, bleeding, pain, hematoma formation, and infection. Ice is applied as prescribed to control bleeding and edema. In addition, antibiotics and analgesic agents are

given as prescribed. The patient is instructed to report signs of redness, bleeding, or pain at the biopsy site as well as fever or chills to the primary provider (Van Leeuwen & Bladh, 2019).

Laboratory Studies

Examination of the patient's blood and urine is used to identify the presence and amount of chemicals and other substances. The results may indicate a primary musculoskeletal problem (e.g., Paget's disease of the bone), a developing complication (e.g., infection), the baseline for instituting therapy (e.g., anticoagulant therapy), or the response to therapy, as well as possible causes of bone loss. Before surgery, coagulation studies are performed to detect bleeding tendencies (because bone is vascular tissue).

Serum calcium levels are altered in patients with osteomalacia, parathyroid dysfunction, Paget's disease, metastatic bone tumors, or prolonged immobilization. Serum phosphorus levels are inversely related to calcium levels and are diminished in osteomalacia associated with malabsorption syndrome. Acid phosphatase is elevated in Paget's disease and metastatic cancer. Alkaline phosphatase (ALP) is elevated during early fracture healing and in diseases with increased osteoblastic activity (e.g., metastatic bone tumors). Bone metabolism may be evaluated through thyroid studies and determination of calcitonin, PTH, and vitamin D levels. Serum enzyme levels of creatine kinase and aspartate aminotransferase become elevated with muscle damage. Serum osteocalcin indicates the rate of bone turnover. Urine calcium levels increase with bone destruction (e.g., parathyroid dysfunction, metastatic bone tumors, multiple myeloma) (Van Leeuwen & Bladh, 2019).

Specific urine and serum biochemical markers can be used to provide information about the speed of bone resorption or bone formation, as well as to document the effects of therapeutic interventions prescribed for patients diagnosed with musculoskeletal disorders. These include urinary *N*-telopeptide of type 1 collagen (NTx) and deoxypyridinoline (Dpd), both of which reflect increased osteoclast activity and increased bone resorption. Conversely, elevated serum levels of bone-specific ALP, osteocalcin, and intact *N*-terminal propeptide of type 1 collagen (P1NP) reflect increased activity of osteoblasts and enhanced bone remodeling activity (NOF, 2019).

CRITICAL THINKING EXERCISES

1 pq You are a nurse working in an urgent care facility and are assigned to care for a 35-year-old man who fell while hiking. He is holding his left arm. You note a small laceration and a few abrasions to the arm as well as swelling and deformity. What are the priority interventions for this patient? What diagnostic test would most likely be indicated? What comfort measure should be provided until a diagnosis is confirmed?

2 ebp You are a faith community nurse and your parish has many older adult parishioners. You want to develop an educational program regarding healthy lifestyle choices and bone health. What are the current evidence-based recommendations to maintain bone health for older adults? What is the level of evidence that supports each of the recommendations and strategies for reducing musculoskeletal risk for the aging adult?

36 Management of Patients with Musculoskeletal Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the pathophysiology, clinical manifestations, and medical and nursing management of low back pain.
2. Discuss common musculoskeletal disorders of the hand, wrist, shoulder, and foot, and nursing management of the patient undergoing surgery to correct these disorders.
3. Identify the pathophysiology, clinical manifestations, and medical, surgical, and nursing management of osteoarthritis.
4. Explain the pathophysiology, clinical manifestations, and medical and nursing management of metabolic bone disorders, including osteoporosis, osteomalacia, and Paget disease.
5. Articulate the pathophysiology, clinical manifestations, and medical and nursing management of musculoskeletal infections, including osteomyelitis and septic arthritis, and of bone tumors.
6. Use the nursing process as a framework for care of the patient undergoing total hip arthroplasty, with select complications of osteoporosis, or with osteomyelitis.

NURSING CONCEPTS

Comfort
Inflammation
Mobility

GLOSSARY

abduction: movement away from the center or median line of the body
adduction: movement toward the center or median line of the body
arthroplasty: surgical replacement of a joint
avascular necrosis: death of tissue due to insufficient blood supply
bursitis: inflammation of a fluid-filled sac in a joint
contracture: abnormal shortening of muscle or fibrosis of joint structures
heterotopic ossification: misplaced formation of bone
involucrum: new bone growth around a sequestrum
osteolysis: lysis of bone from inflammatory reaction against polyethylene particulate debris
osteopenia: low bone mineral density
osteophyte: a bony outgrowth or protuberance; bone spur
osteoporosis: degenerative disease of the bone characterized by reduced mass, deterioration of matrix, and diminished architectural strength
osteotomy: surgical cutting of bone
radiculopathy: disease of a spinal nerve root, often resulting in pain and extreme sensitivity to touch
sciatica: inflammation of the sciatic nerve, resulting in pain and tenderness along the nerve through the thigh and leg
sequestrum: dead bone in abscess cavity
subchondral bone: bony plate that supports the articular cartilage
tendonitis: inflammation of muscle tendons

Musculoskeletal disorders, particularly impairment of the back, joints, and spine, are leading health problems and causes of disability. The functional and psychological limitations for the patient may be severe. Nurses should be cognizant of these limitations and the effects these disorders may have on these patients when providing care in inpatient and outpatient settings.

Low Back Pain

Most low back pain is caused by one of many musculoskeletal problems, including acute lumbosacral strain, unstable lumbosacral ligaments and weak muscles, intervertebral disc problems, and unequal leg length. Depression, smoking, alcohol abuse, obesity, and stress are frequent comorbidities (Ramanathan, Hibbert, Wiles, et al., 2018). Generally, back pain due to musculoskeletal disorders is aggravated by activity, whereas pain due to other conditions is not. Higher numbers of areas of pain are associated with a higher level of disability. Other nonmusculoskeletal causes of back pain, beyond the scope of this chapter, include kidney disorders, pelvic problems, retroperitoneal tumors, and abdominal aortic aneurysms.

Gerontologic Considerations

Older patients may experience back pain associated with osteoporotic vertebral fractures (see later discussion), osteoarthritis of the spine, and spinal stenosis. In addition, inactivity can have grave consequences on quality of life, progression of medical disease, energy level, and morbidity in older adults (Simon & Hicks, 2018).

Pathophysiology

The spinal column can be considered a rod constructed of rigid units (vertebrae) and flexible units (intervertebral discs) held together by complex facet joints, multiple ligaments, and paravertebral muscles. Its unique construction allows for flexibility while providing maximum protection for the spinal cord. The spinal curves absorb vertical shocks from running and jumping. The abdominal and thoracic muscles are important in lifting activities, working together to minimize stress on the spinal units. Disuse weakens these supporting muscular structures. Obesity, postural problems, structural problems, and overstretching of the spinal supports may result in back pain (McCance & Huether, 2019).

The intervertebral discs change in character as a person ages. A young person's discs are mainly fibrocartilage with a gelatinous matrix. Over time, the fibrocartilage becomes dense and irregularly shaped. Disc degeneration is a common cause of back pain. The lower lumbar discs, L4–5 and L5–S1, are subject to the greatest mechanical stress and the greatest degenerative changes. Disc protrusion or facet joint changes can cause pressure on nerve roots as they leave the spinal canal, which results in pain that radiates along the nerve (McCance & Huether, 2019). See Chapter 65 for discussion of the management of intervertebral disc disease.

Clinical Manifestations

The typical patient reports either acute back pain (lasting fewer than 3 months) or chronic back pain (3 months or longer without improvement) and fatigue. The patient may report pain radiating down the leg, which is known as **radiculopathy** (i.e., pain radiating from a diseased spinal nerve root) or **sciatica** (i.e., pain radiating from an inflamed sciatic nerve); presence of this symptom suggests nerve root involvement. The patient's gait, spinal mobility, reflexes, leg length, leg motor strength, and sensory perception may be affected. Physical examination may disclose paravertebral muscle spasm (greatly increased muscle tone of the back postural muscles) with a loss of the normal lumbar curve and possible spinal deformity.

Assessment and Diagnostic Findings

The initial evaluation of acute low back pain includes a focused history and physical examination, including observation of the patient, gait evaluation, and neurologic testing (see Chapter 35). The findings suggest either nonspecific lumbar strain or potentially serious problems, such as a spinal fracture, cancer, infection, or rapidly progressing neurologic deficits. The presence of bruising, older age, and prolonged use of corticosteroid medications increases the risk of a fracture posttraumatic injury (Gironda, Nguyen, & Mosqueda, 2016). In addition, the nurse should be alert to the potential for older adult abuse.

Another potential cause of low back pain is *cauda equina syndrome,* which results from compression of the cauda equina, the bundle of spinal nerves that arise from the lower portion of the spinal cord. When these nerves become compressed, the patient will have signs and symptoms that include severe or progressive neurologic deficit, recent bowel or bladder dysfunction, and saddle anesthesia which is characterized by paresthesias in the perineal, inner thigh, or buttock region that may be asymmetrical (Qaseem, Wilt, McLean, et al., 2017). Cauda equina syndrome is a medical emergency requiring immediate referral to an emergency department so that the patient may receive expeditious treatment to relieve the underlying cause before nerve damage occurs (e.g., treatment can consist of surgical removal of vertebral fragments, decompression of a tumor mass).

The diagnostic procedures described in Chart 36-1 may be indicated for the patient with potentially serious or prolonged low back pain. Red flags that trigger prescribing these studies include suspected spinal infection, severe neurologic weakness, urinary or fecal incontinence, and a new onset of back pain in a patient with cancer (Qaseem et al., 2017). The nurse

prepares the patient for these studies, provides the necessary support during the testing period, and monitors the patient for any adverse responses to the procedures.

Medical Management

Most back pain is self-limited and resolves within 4 to 6 weeks with analgesics, rest, and avoidance of strain. Based on initial assessment findings indicating nonspecific back symptoms, the patient is reassured that the pain is not due to a serious condition and x-rays or other imaging modalities are not necessary (Qaseem et al., 2017). Management focuses on relief of discomfort, activity modification, and patient education. The presence of other medical problems and fear of pain complicates the picture and has higher cost, less favorable outcomes, and more long-term disability (Karasawa, Yamadada, Iseki, et al., 2019).

Chart 36-1

Diagnostic Procedures for Low Back Pain

X-ray of the spine: may demonstrate a fracture, dislocation, infection, osteoarthritis, or scoliosis

Bone scan and blood studies: may disclose infections, tumors, and bone marrow abnormalities

Computed tomography (CT) scan: useful in identifying underlying problems, such as obscure soft tissue lesions adjacent to the vertebral column and problems of vertebral discs

Magnetic resonance imaging (MRI) scan: permits visualization of the nature and location of spinal pathology

Electromyogram (EMG) and nerve conduction studies: used to evaluate spinal nerve root disorders (radiculopathies)

Myelogram: permits visualization of segments of the spinal cord that may have herniated or may be compressed (infrequently performed; indicated when MRI scan is contraindicated)

Ultrasound: useful in detecting tears in ligaments, muscles, tendons, and soft tissues in the back

Adapted from Fischbach, F. T., & Fischbach, M. A. (2018). *A manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Wolters Kluwer; Wheeler, S. G., Wipf, J. E., Staiger, T. O., et al. (2019). Evaluation of low back pain in adults. *UpToDate*. Retrieved on 3/9/2020 at: www.uptodate.com/contents/evaluation-of-low-back-pain-in-adults

Nonprescription analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) and short-term prescription muscle relaxants (e.g., cyclobenzaprine) are effective in relieving acute low back pain, but no one medication is considered superior to another (Michigan Quality Improvement Consortium [MQIC], 2018). Tricyclic antidepressants (e.g., amitriptyline) and the dual-action serotonin-norepinephrine reuptake inhibitors (e.g., duloxetine) or atypical anticonvulsant medications (e.g., gabapentin, which is prescribed for pain from radiculopathy) are used effectively in chronic low back pain. Opioid medications are indicated only short term (1 to 2 weeks) for acute moderate to severe cases of low back pain, except in older adults, those with kidney disease, or those who must avoid chronic NSAID exposure because of its adverse gastric effects. Systemic corticosteroids and acetaminophen are not effective in fully alleviating acute low back pain (Krebs, Gravely, Nugent, et al., 2018). For chronic pain, a reduction of pain by 30% less than baseline is the goal (Dupuis & Duff, 2019).

Effective nonpharmacologic interventions include thermal applications (hot or cold) and spinal manipulation (e.g., chiropractic therapy). Lumbar support belts are not recommended to treat acute low back pain but may be marginally effective devices for preventing low back pain in occupational health settings (MQIC, 2018). Orthopedic shoe inserts are not recommended for prevention but may help correct an underlying issue contributing to the problem (e.g., unequal leg length). Cognitive-behavioral therapy (e.g., biofeedback), exercise regimens, spinal manipulation, physical therapy, acupuncture, massage, and yoga are all effective nonpharmacologic interventions for treating chronic low back pain (Qaseem et al., 2017).

Most patients need to alter their activity patterns to avoid aggravating the pain. They should avoid twisting, bending, lifting, and reaching—all of which stress the back. The patient is taught to change position frequently. Sitting should be limited to 20 to 50 minutes based on level of comfort. Absolute bed rest is no longer recommended; typical activities of daily living (ADLs) should be resumed as soon as possible. A quick return to normal activities and a program of low-stress aerobic exercise are recommended (MQIC, 2018). Conditioning exercises for both back and trunk muscles are begun after about 2 weeks to help prevent recurrence of pain. Active motion activities such as walking have a beneficial impact on outcomes (Dupuis & Duff, 2019).

Nursing Management

The nurse asks the patient to describe the discomfort (e.g., location, severity, duration, characteristics, radiation, and weakness in the legs). Descriptions

of how the pain occurred, such as with a specific action (e.g., opening a garage door) or with an activity in which weak muscles were overused (e.g., weekend gardening), and how the patient has dealt with the pain often suggest areas for intervention and patient education.

If back pain is a recurring problem, assessment about previous successful pain control methods helps in planning current management. Information about work and recreational activities helps identify areas for back health education. Because stress and anxiety can evoke muscle spasms and pain (Feinstein, Khalsa, Yeh, et al., 2018), the nurse assesses environmental variables, work situations, and family relationships. In addition, the nurse assesses the effect of chronic pain on the emotional well-being of the patient. Referral to a mental health professional for assessment and management of stressors contributing to the low back pain and related depression may be appropriate.

During the interview, the nurse observes the patient's posture, position changes, and gait. Often, the patient's movements are guarded, with the back kept as still as possible. The patient should be directed to a chair of standard seat height with arms for support. The patient may sit and stand in an unusual position, leaning away from the most painful side, and may need assistance when undressing for the physical examination.

On physical examination, the nurse assesses the spinal curve, any leg length discrepancy, and pelvic crest and shoulder symmetry. The nurse palpates the paraspinal muscles and notes spasm and tenderness. When the patient is in a prone position, the paraspinal muscles relax and any deformity caused by spasm can subside. The nurse asks the patient to bend forward and then laterally, noting any discomfort or limitations in movement. It is important to determine the effect of these limitations on ADLs. The nurse evaluates nerve involvement by assessing deep tendon reflexes, sensations (e.g., paresthesia), and muscle strength. Back and leg pain on straight-leg raising (with the patient supine, the patient's leg is lifted upward with the knee extended) suggests nerve root involvement.

The major nursing goals for patient management include relief of pain, improved physical mobility, the use of back-conserving techniques of body mechanics, improved self-esteem, and weight reduction (as necessary) (see Chart 36-2).

The nurse assesses the patient's response to analgesic agents. As the acute pain subsides, medication dosages are reduced. The nurse evaluates and notes the patient's response to various pain management modalities (see Chapter 9). The nurse cautions the patient with severe pain not to remain on bed rest because extended periods of inactivity are not effective and result in deconditioning. A medium to firm, nonsagging mattress (a bed board may be used) is recommended; there is no evidence to support the use of a firm

mattress (Radwan, Fess, James, et al., 2015). Lumbar flexion is increased by elevating the head and thorax 30 degrees by using pillows or a foam wedge and slightly flexing the knees supported on a pillow. Alternatively, the patient can assume a lateral position with knees and hips flexed (curled position) with a pillow between the knees and legs and a pillow supporting the head (see Fig. 36-1). A prone position should be avoided because it accentuates lordosis. The nurse instructs the patient to get out of bed by rolling to one side and placing the legs down while pushing the torso up, keeping the back straight.

Chart 36-2 HEALTH PROMOTION

Strategies for Preventing Acute Low Back Pain

Prevention

- Weight reduction as needed
- Stress reduction
- Avoid high heels
- Walk daily and gradually increase the distance and pace of walking
- Avoid jumping and jarring activities
- Stretch to enhance flexibility. Do strengthening exercises

Body Mechanics

- Practice good posture
- Avoid twisting, lifting above waist level, and reaching up for any length of time
- Push objects rather than pull them
- Keep load close to your body when lifting
- Lift with the large leg muscles, not the back muscles
- Squat while keeping the back straight when it is necessary to pick something up off the floor
- Bend your knees and tighten abdominal muscles when lifting
- Avoid overreaching or a forward flexion position
- Use a wide base of support

Work Modifications

- Adjust height of chair using a footstool to position knees higher than hips
- Adjust height of work area to avoid stress on back
- Avoid bending, twisting, and lifting heavy objects
- Avoid prolonged standing and repetitive tasks
- Avoid work involving continuous vibrations
- Use lumbar support in straight back chair with arm rests
- When standing for any length of time, rest one foot on a small stool or box to relieve lumbar lordosis

As the patient achieves comfort, an exercise program is gradually initiated with low-stress aerobic exercises, such as short walks or swimming. The physical therapist designs an exercise program for the patient to reduce lordosis, increase flexibility, and reduce strain on the back. It may include hyperextension exercises to strengthen the paravertebral muscles, flexion exercises to increase back movement and strength, and

isometric flexion exercises to strengthen trunk muscles. Each 30-minute daily exercise period begins and ends with muscle stretching and relaxation.

Figure 36-1 • Positioning to promote lumbar flexion. Photo by B. Proud.

The nurse encourages the patient to adhere to the prescribed exercise program. Some patients may find it difficult to do so for a long period. In these instances, alternating activities may help facilitate adherence to the regimen. Activities should not cause excessive lumbar strain or twisting, with avoidance of activities such as horseback riding and weight lifting.

Good body mechanics and posture are essential to avoid recurrence of back pain. The patient must be taught how to stand, sit, lie, and lift properly (see Fig. 36-2). Providing the patient with a list of suggestions helps in making these long-term changes (see Chart 36-2). The patient who wears high heels is encouraged to change to low heels with good arch support. The patient who is required to stand for long periods should shift weight frequently and rest one foot on a low stool, which decreases lumbar lordosis. Standing on a foot cushion made of foam or rubber can be helpful. The proper posture can be verified by looking in a mirror to see whether the chest is up, the abdomen is tucked in, and the shoulders are down and relaxed. Locking the knees when standing is avoided as well as bending forward for long periods.

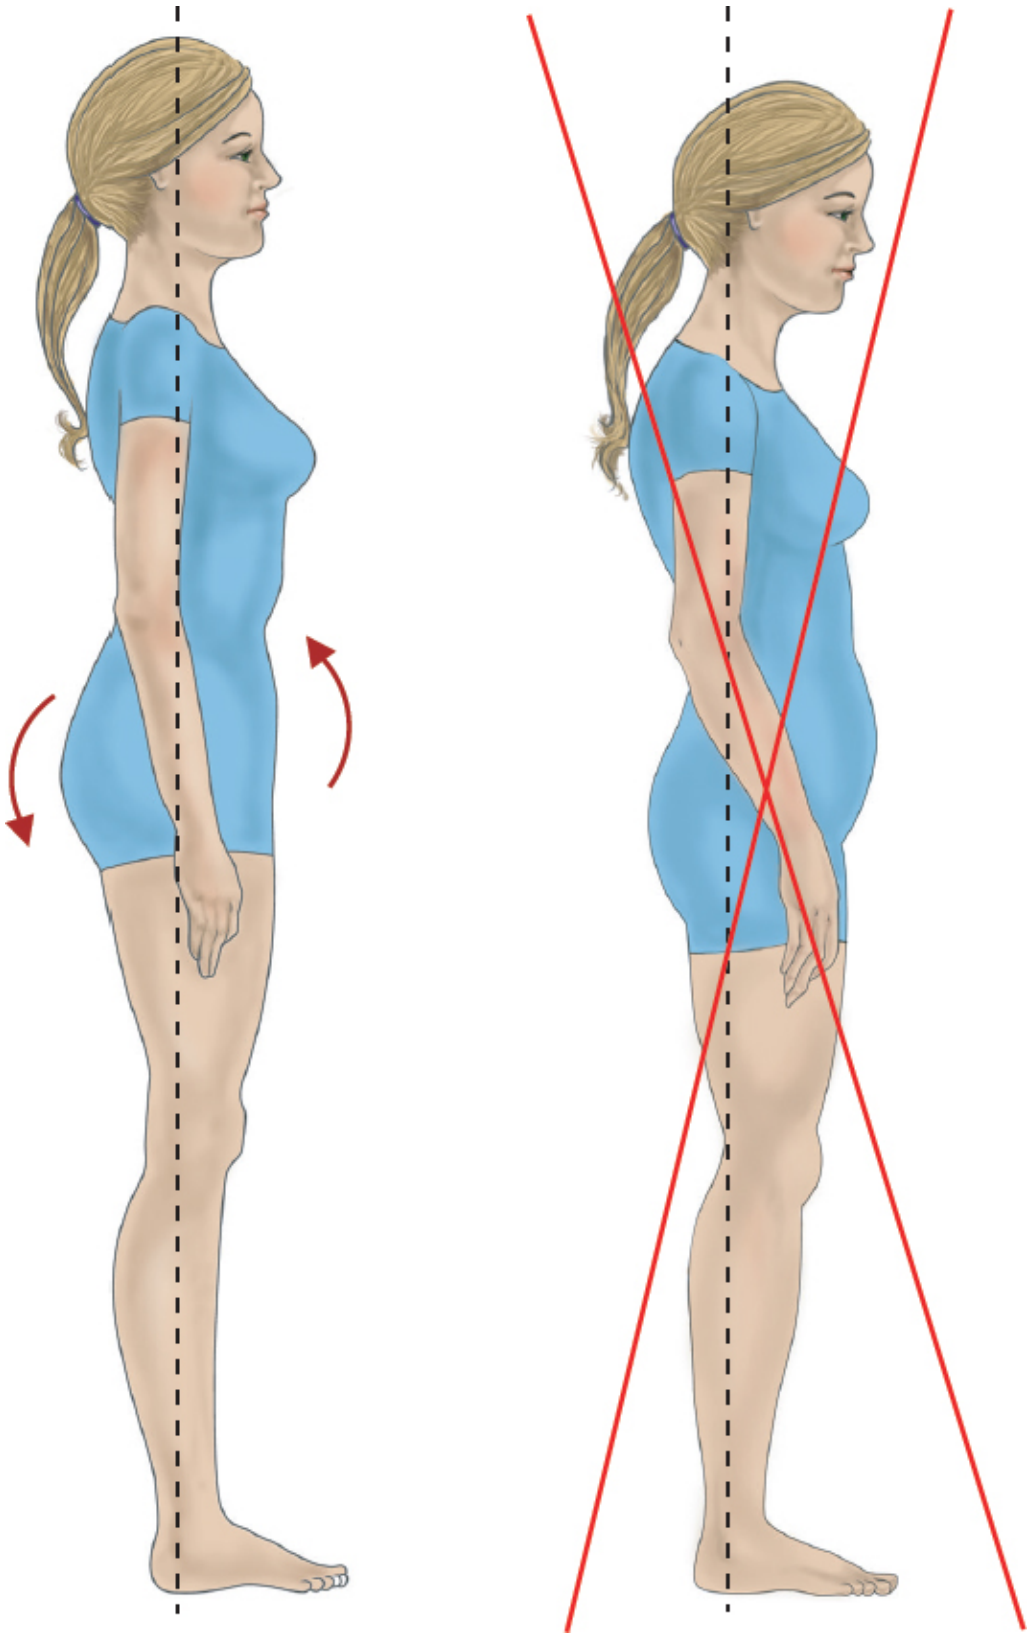

Figure 36-2 • Proper and improper standing postures. (*Left*) Abdominal muscles contracted, giving a feeling of upward pull, and gluteal muscles contracted, giving a downward pull. (*Right*) Slouch position, showing abdominal muscles relaxed and body out of proper alignment.

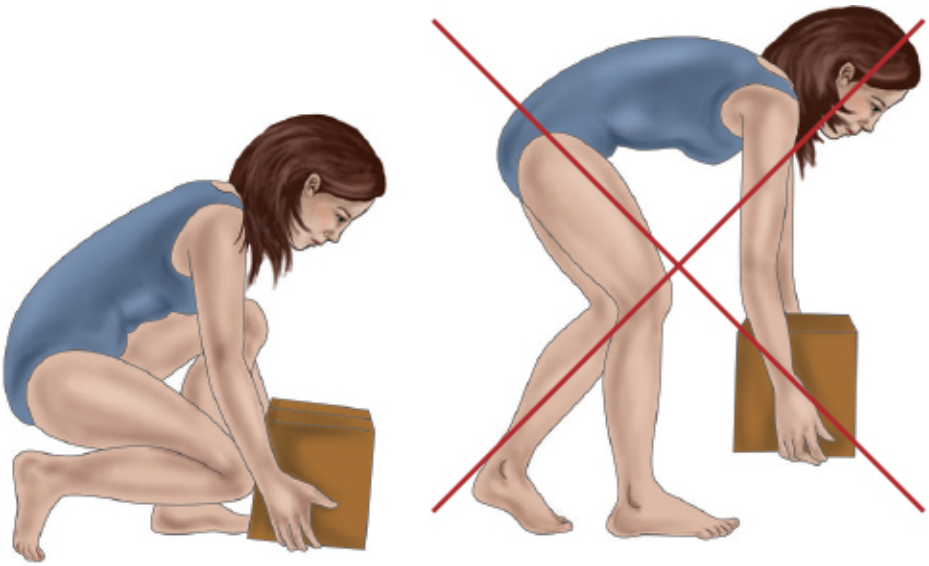

Figure 36-3 • Proper and improper lifting techniques. (***Left***) Correct position for lifting. This person is using the long and strong muscles of the arms and legs and holding the object so that the line of gravity falls within the base of support. (***Right***) Incorrect position for lifting. In this position, pull is exerted on the back muscles, and leaning causes the line of gravity to fall outside the base.

When sitting, the knees and hips should be flexed, with the knees in level with the hips or higher to minimize lordosis. The feet should be flat on the floor or supported on a raised surface. Patients should avoid sitting on stools or chairs that do not provide firm back support.

The nurse instructs the patient in the safe and correct way to lift objects —using the strong quadriceps muscles of the thighs, with minimal use of weak back muscles (see Fig. 36-3). With feet placed hip-width apart to provide a wide base of support, the patient should bend the knees, tighten the abdominal muscles, and lift the object close to the body with a smooth motion, avoiding twisting and jarring motions. The patient should avoid lifting more than one third of their ideal weight without help to prevent injury.

Role-related responsibilities may have to be modified with the onset of low back pain (e.g., carrying children). As recovery progresses, the patient may resume them. However, if these activities contributed to the development of low back pain, resuming them may lead to the development of chronic low back pain, with associated disability. If the patient experiences secondary gains associated with low back disability (e.g., workers' compensation, easier lifestyle or workload, increased emotional support), there is a risk that the patient will not fully resume work and

family roles. Earlier return to work and lifestyle, even at a reduced level, have better outcomes than waiting for full recovery (Qaseem et al., 2017). Antidepressants and counseling may be needed to assist the person in resuming a full, productive life. Specialized back clinics use multidisciplinary approaches to help the patient with chronic pain resume role-related responsibilities; these approaches are especially beneficial for patients who experience fear and depression associated with chronic pain (Karasawa et al., 2019).

Obesity contributes to back strain by overtaxing the relatively weak back muscles in the absence of abdominal muscle support. Exercises are less effective and more difficult to perform when the patient is overweight. Weight reduction through diet modification is important to minimize recurrence of back pain. A sound nutritional plan that includes a change in eating habits and low-impact activities is vital. Noting achievement of weight reduction and providing positive reinforcement facilitate adherence. Back problems may or may not fully resolve as optimal weight is achieved (MQIC, 2018).

Common Upper Extremity Disorders

The structures in the upper extremities are frequently the sites of painful syndromes. This is especially true in occupational health settings, where many patient visits involve the shoulder, wrist, and hand.

Bursitis and Tendonitis

Bursitis and tendonitis are inflammatory conditions that commonly occur in the shoulder. Bursae are fluid-filled sacs that prevent friction between joint structures during joint activity and are painful when inflamed; **bursitis** is the consequence when these sacs become inflamed. Muscle tendon sheaths also become inflamed with repetitive stretching, causing **tendonitis**. The inflammation causes proliferation of synovial membrane and pannus formation, which restricts joint movement. Conservative treatment includes rest of the extremity, intermittent ice and heat to the joint, and NSAIDs to control the inflammation and pain. Newer therapies that include extracorporeal shock waves, pulsed magnetic fields, laser phototherapy, radiofrequency ablation, and stem cell therapies are touted to accelerate tendon healing, although further research is needed to determine their overall effectiveness (Cook & Young, 2020). There are no non–research-based sites for injection of cellular therapies that are registered with the Centers for Disease Control and Prevention (CDC) in the United States

(Cook & Yong, 2020). The World Anti-Doping Agency (WADA) for sports allows autologous (self-donated) localized injections for soft tissue injuries, but IV infusions are prohibited (WADA, 2020). Arthroscopic synovectomy may be considered if shoulder pain and weakness persist. Corticosteroid injections remain more evidence based than most other interventions for short-term, rapid improvement, but are not always helpful in the long term (McAlindon, LaValley, Harvey, et al., 2017). Most tendon and bursal inflammatory problems are self-limiting; they go away on their own with or without therapy. The treatments are primarily aimed at pain relief, not cure.

Loose Bodies

Loose bodies ("joint mice") may occur in a joint space as a result of articular cartilage wear and bone erosion. These fragments can interfere with joint movement ("locking the joint"). Loose bodies are removed by arthroscopic surgery if they cause pain or mobility issues.

Impingement Syndrome

Impingement syndrome is a general term that describes impaired movement of the rotator cuff of the shoulder. Impingement usually occurs from repetitive overhead movement of the arm or from acute trauma resulting in irritation and eventual inflammation of the rotator cuff tendons or the subacromial bursa as they grate against the coracoacromial arch. Early manifestations of this syndrome are characterized by edema from hemorrhage of these structures, pain, shoulder tenderness, limited movement, muscle spasm, and eventual disuse atrophy. The process may progress to a partial or complete rotator cuff tear (see Chapter 37).

Chart 36-3  **PATIENT EDUCATION**

Measures to Promote Shoulder Healing of Impingement Syndrome

The nurse instructs the patient to:

- Rest the joint in a position that minimizes stress on the joint structures to prevent further damage and the development of adhesions.
- Support the affected arm on pillows while sleeping to keep from turning onto the shoulder.
- Gradually resume motion and use of the joint. Assistance with dressing and other activities of daily living may be needed.
- Avoid working and lifting above shoulder level or pushing an object against a "locked" shoulder.
- Perform the prescribed daily range-of-motion and strengthening exercises.

Medications used to treat early impingement syndrome include oral NSAIDs or intra-articular injections of corticosteroids. Application of superficial cold or heat may subjectively improve patients' symptoms; however, a therapeutic exercise program (see Chapter 37) is required to improve outcomes, including reduction of pain and improved shoulder function (see Chart 36-3).

Carpal Tunnel Syndrome

Carpal tunnel syndrome is an entrapment neuropathy that occurs when the median nerve at the wrist is compressed by a thickened flexor tendon sheath, skeletal encroachment, edema, or a soft tissue mass. It frequently occurs in women between 30 and 60 years of age. Women going through menopause or who are taking estrogen or birth control pills have the highest risk (Calandruccio & Thompson, 2018). While carpal tunnel syndrome is commonly caused by repetitive hand and wrist movements, it is also associated with rheumatoid arthritis (RA), diabetes, acromegaly, hyperthyroidism, or trauma (McCance & Huether, 2019). People employed in occupations that require frequent repetitive hand movements or flexing of the wrist, such as assembly line workers and hairdressers, and those exposed to vibration when doing tasks, such as construction workers and machinists, may be at increased risk for carpal tunnel syndrome (Calandruccio & Thompson, 2018).

The patient experiences pain, numbness, paresthesia, and, possibly, weakness along the median nerve distribution (thumb, index, and middle fingers). Night pain and/or fist clenching upon awakening is common. A

positive Tinel sign helps identify patients requiring intervention (see Fig. 36-4).

Evidence-based treatment of acute carpal tunnel syndrome includes oral or intra-articular injections of corticosteroids, use of NSAIDs and acupuncture with and without electrical stimulation (attached to the needles). Application of splints to prevent hyperextension and prolonged flexion of the wrist is also effective; however, laser and ultrasound therapies are ineffective, as are prolotherapies, or the injection of substances (e.g., dextrose, lidocaine) purported to stimulate healing, diuretics, and vitamin B_6 (Calandruccio & Thompson, 2018). The risks of inhibiting the synthesis of reparative substrates like collagen can potentiate an increased risk for tendon rupture; therefore, long-term use of corticosteroids is not supported (McAlindon et al., 2017).

Figure 36-4 • Tinel sign may be elicited in patients with carpal tunnel syndrome by percussing lightly over the median nerve, located on the inner aspect of the wrist. If the patient reports tingling, numbness, and pain, the test for Tinel sign is considered positive. Reprinted with permission from Weber, J. W., & Kelley, J. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer. Photo by B. Proud.

Traditional open nerve release or endoscopic laser surgery are the two most common surgical management options when nonsurgical treatments fail. Both of these procedures are performed under local anesthesia and

involve making incisions into the affected wrist and cutting the carpal ligament so that the carpal tunnel is widened. Smaller incisions are made with the endoscopic laser procedure, resulting in less scar formation and a shorter recovery time than with the open method. Following either procedure, the patient wears a hand splint and limits hand use during healing. The patient may need assistance with personal care. Full recovery of motor and sensory function after either type of nerve release surgery may take several weeks or months.

Ganglion

A ganglion—a collection of neurologic gelatinous material near the tendon sheaths and joints—appears as a round, firm, cystic swelling, usually on the dorsum of the wrist. It frequently occurs in women younger than 50 years (McCance & Huether, 2019). The swelling is locally tender and may cause an aching pain. When a tendon sheath is involved, weakness of the finger occurs. Treatment may include aspiration, corticosteroid injection, or surgical excision. After treatment, a compression dressing and immobilization splint are used; however, a ganglion may recur after medical intervention (De Keyser, 2019).

Dupuytren Disease

Dupuytren disease results in a slowly progressive **contracture** (i.e., an abnormal shortening) of the palmar fascia that causes flexion of the fourth, fifth, and, sometimes, middle finger, rendering these fingers more or less useless (see Fig. 36-5). It is linked to an inherited autosomal dominant trait and occurs most frequently in men of Scandinavian or Celtic heritage who are older than 50 years (McCance & Huether, 2019). Dupuytren disease is also associated with arthritis, diabetes, gout, cigarette smoking, and alcoholism (Ball, Izadi, Verjee, et al., 2016). Starting as a nodule, it may or may not progress, producing a contracture of the fingers and palmar skin changes. The patient may experience dull and aching discomfort, morning numbness, and stiffness in the affected fingers. This condition starts in one hand, but eventually both are affected. Finger-stretching exercises in early disease or intranodular injections of corticosteroids or collagenases may prevent contractures (Ball et al., 2016). With loss of movement, palmar and digital fasciotomies are performed to improve function.

Figure 36-5 • Dupuytren contracture, a flexion deformity caused by an inherited trait, is a slowly progressive contracture of the palmar fascia, which severely impairs the function of the fourth, fifth, and, sometimes, middle finger.

Nursing Management of the Patient Undergoing Surgery of the Hand or Wrist

Surgery of the hand or wrist, unless related to major trauma, is generally an ambulatory procedure. Before surgery, the nurse assesses the patient's level and type of discomfort, as well as limitations in function, caused by the condition.

Hourly neurovascular assessment of the exposed fingers for the first 24 hours following surgery is essential for monitoring function of the nerves and perfusion. This is especially important if an intraoperative tourniquet technique was used, which is implicated in neurovascular deficits. The nurse compares the affected extremity with the unaffected extremity and the postoperative status with the documented preoperative status. The nurse asks the patient to describe sensations in the digits and has the patient demonstrate mobility, while enforcing limitations in movement prescribed by the patient's surgeon. With tendon repairs and nerve, vascular, or skin grafts, more extensive function is tested (see Chapter 35, Chart 35-3). Percutaneous pins may be used to hold bones in position. These pins serve as potential sites of infection. Patient education concerning aseptic wound and pin care may be necessary.

Dressings provide support but should be nonconstrictive. Intermittent use of ice packs to the surgical area during the first 24 to 48 hours may be prescribed to control edema. Unless contraindicated, active extension and flexion of the fingers to promote circulation are encouraged, even though movement is limited by the bulky dressing.

Generally, pain and discomfort can be controlled by the use of oral analgesic agents. Patient education concerning the risk of falls and impaired

cognition is important. Pain out of proportion to what is expected, particularly if it is accompanied with compromised neurovascular functioning, needs to be evaluated as an indication of compartment syndrome (see Chapter 37). Pain may be related to surgery, edema, hematoma formation, or restrictive bandages. To control swelling that may increase the patient's discomfort, the nurse instructs the patient to elevate the hand to heart level with pillows. If the patient is ambulatory, the arm is supported in a conventional sling with the hand elevated at heart level (see Chapter 37, Fig. 37-15).

During the first few days after surgery, independent self-care is impaired. The patient may need to arrange for assistance with feeding, bathing, dressing, and toileting. Within a few days, the patient develops skills in one-handed ADLs and is usually able to function with minimal help and assistive devices. The nurse encourages the patient to use the involved hand, unless contraindicated, within the limits of discomfort. As rehabilitation progresses, the patient resumes use of the limb. Physical or occupational therapy–directed exercises may be prescribed.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

After the patient has undergone surgery, the nurse instructs the patient how to monitor neurovascular status and the signs of complications that need to be reported to the surgeon (e.g., paresthesia, paralysis, uncontrolled pain, coolness of fingers, extreme swelling, excessive bleeding, purulent drainage, foul odor, fever). The nurse discusses prescribed medications and their side effects with the patient. In addition, the nurse instructs the patient how to elevate the extremity and to apply ice (if prescribed) to control swelling. The use of assistive devices is demonstrated if such devices would be helpful in promoting accomplishment of ADLs. For bathing, the nurse instructs the patient to keep the dressing dry by covering it with a secured plastic bag. Generally, the wound is not redressed until the patient's follow-up visit with the surgeon (see Chart 36-4). The nurse identifies any perceived barriers to being able to attend to this plan (such as childcare needs). The patient is referred to community-based resources as appropriate.

Common Foot Problems

Disorders of the foot may be caused by poorly fitting shoes, which distort normal anatomy while inducing deformity and pain. Dermatologic problems commonly affect the feet in the form of fungal infections and plantar warts. Several systemic diseases affect the feet. Patients with diabetes are prone to develop corns and peripheral neuropathies with diminished sensation, leading to diabetic ulcers at pressure points of the foot. Patients with peripheral vascular disease and arteriosclerosis complain of burning and itching feet, resulting in scratching and skin breakdown. Foot deformities may occur with RA. Obesity can cause a host of foot anomalies, including adult-onset pes planus (i.e., "fallen arches") and plantar fasciitis.

The discomforts of foot strain are treated with rest, elevation, physiotherapy, supportive taping, and orthotic devices (Luffy, Grosel, Thomas, et al., 2018). The patient must inspect the foot and skin under pads and orthotic devices for pressure and skin breakdown daily. If a "window" is cut into shoes to relieve pressure over a bony deformity, the skin must be monitored daily for breakdown from pressure exerted at the window area. Active foot exercises promote circulation and help strengthen the feet. Walking in properly fitting shoes is considered the ideal exercise.

Chart 36-4  HOME CARE CHECKLIST

Hand or Foot Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., durable medical equipment, adaptive equipment) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., immobilization) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Describe methods to prevent wound infection (e.g., keeping dressing clean and dry during activities of daily living).
  - Demonstrate how to assess neurovascular status.
  - Demonstrate control of edema by elevating extremity and applying ice intermittently if prescribed.
  - Observe prescribed weight-bearing, activity and exercise limits.
  - Demonstrate safe use of assistive devices, if appropriate.
  - Consume a healthy diet to promote healing.
- State the name, dose, side effects, frequency, and schedule for all prescribed therapeutic and prophylactic medications (e.g., antibiotics and analgesic agents).
- State indicators of wound infections (e.g., redness, swelling, tenderness, purulent drainage, fever, signs of systemic infection) to report promptly to the provider.
- State indicators of other potential complications to report promptly to the provider (e.g., uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of deep vein thrombosis or pulmonary embolism).
- Relate how to reach the providers with questions or complications.
- Verbalize the need to keep appointment with surgeon for initial dressing change.
  - State time and date of follow-up appointments and testing.
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention and screening activities.

Resources

See Chapter 2, Chart 2-6 for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Callus

A callus is a thickened area of the skin that has been exposed to persistent pressure or friction. Faulty foot mechanics usually precede the formation of a callus. Treatment consists of eliminating the underlying causes and having a painful callus treated by a podiatrist. A keratolytic ointment may be applied and a thin plastic cup worn over the heel if the callus is on this area. Felt padding with an adhesive backing is also used to prevent and relieve pressure. Prevention of the callus is best, with attention to well-fitting socks and shoes. Orthotic devices can be made to remove the pressure from bony protuberances, or the protuberance may be excised (van Netten, Sacco, Lavery, et al., 2020).

Corn

A corn is an area of hyperkeratosis (overgrowth of a horny layer of epidermis) produced by internal pressure (the underlying bone is prominent because of a congenital or acquired abnormality, commonly arthritis) or external pressure (ill-fitting shoes). The fifth toe is most frequently involved, but any toe may be involved.

Corns are treated by a podiatrist by soaking and scraping off the horny layer, by application of a protective shield or pad, or by surgical modification of the underlying offending osseous structure. Early intervention is required for patients with diabetes.

Soft corns are located between the toes and are kept soft by moisture. Treatment consists of drying the affected spaces and separating the affected toes with lamb's wool or gauze. A wider shoe and toe box may be helpful (Malhotra, Davda, & Singh, 2017).

Hammer Toe

Hammer toe is a flexion deformity of the interphalangeal joint, which may involve several toes (see Fig. 36-6**A**). Tight socks or shoes may push an overlying toe back into the line of the other toes. The toes usually are pulled upward, forcing the metatarsal joints (ball of the foot) downward. Corns develop on top of the toes, and tender calluses develop under the metatarsal area. Treatment consists of conservative measures: wearing open-toed

sandals (unless the patient has diabetes) or shoes that conform to the shape of the foot with a round toe box, carrying out manipulative exercises, and protecting the protruding joints with pads. **Osteotomy** (surgical cutting of the bone) may be used to correct a resulting deformity. There is little evidence to support treatment of hammer toe when the patient does not report pain or other symptoms (Malhotra et al., 2017). Orthotics may help prevent hammer toe in people with high arches. Attention is required for patients with diabetes who may develop friction points, causing wounds.

Onychocryptosis

Onychocryptosis (ingrown toenail) is a condition in which the free edge of a nail plate penetrates the surrounding skin. A secondary infection or granulation tissue may develop. This painful condition is caused by improper self-treatment, external pressure (tight shoes or stockings), internal pressure (deformed toes, growth under the nail), trauma, or infection. Trimming the nails properly (clipping them straight across and filing the corners consistent with the contour of the toe) can prevent this problem. Active treatment consists of washing the foot twice a day and relieving the pain by decreasing the pressure of the nail plate on the surrounding soft tissue. Warm, wet soaks help drain an infection. A toenail may need to be excised by the podiatrist or primary provider if there are recurrent infections (Malhotra et al., 2017).

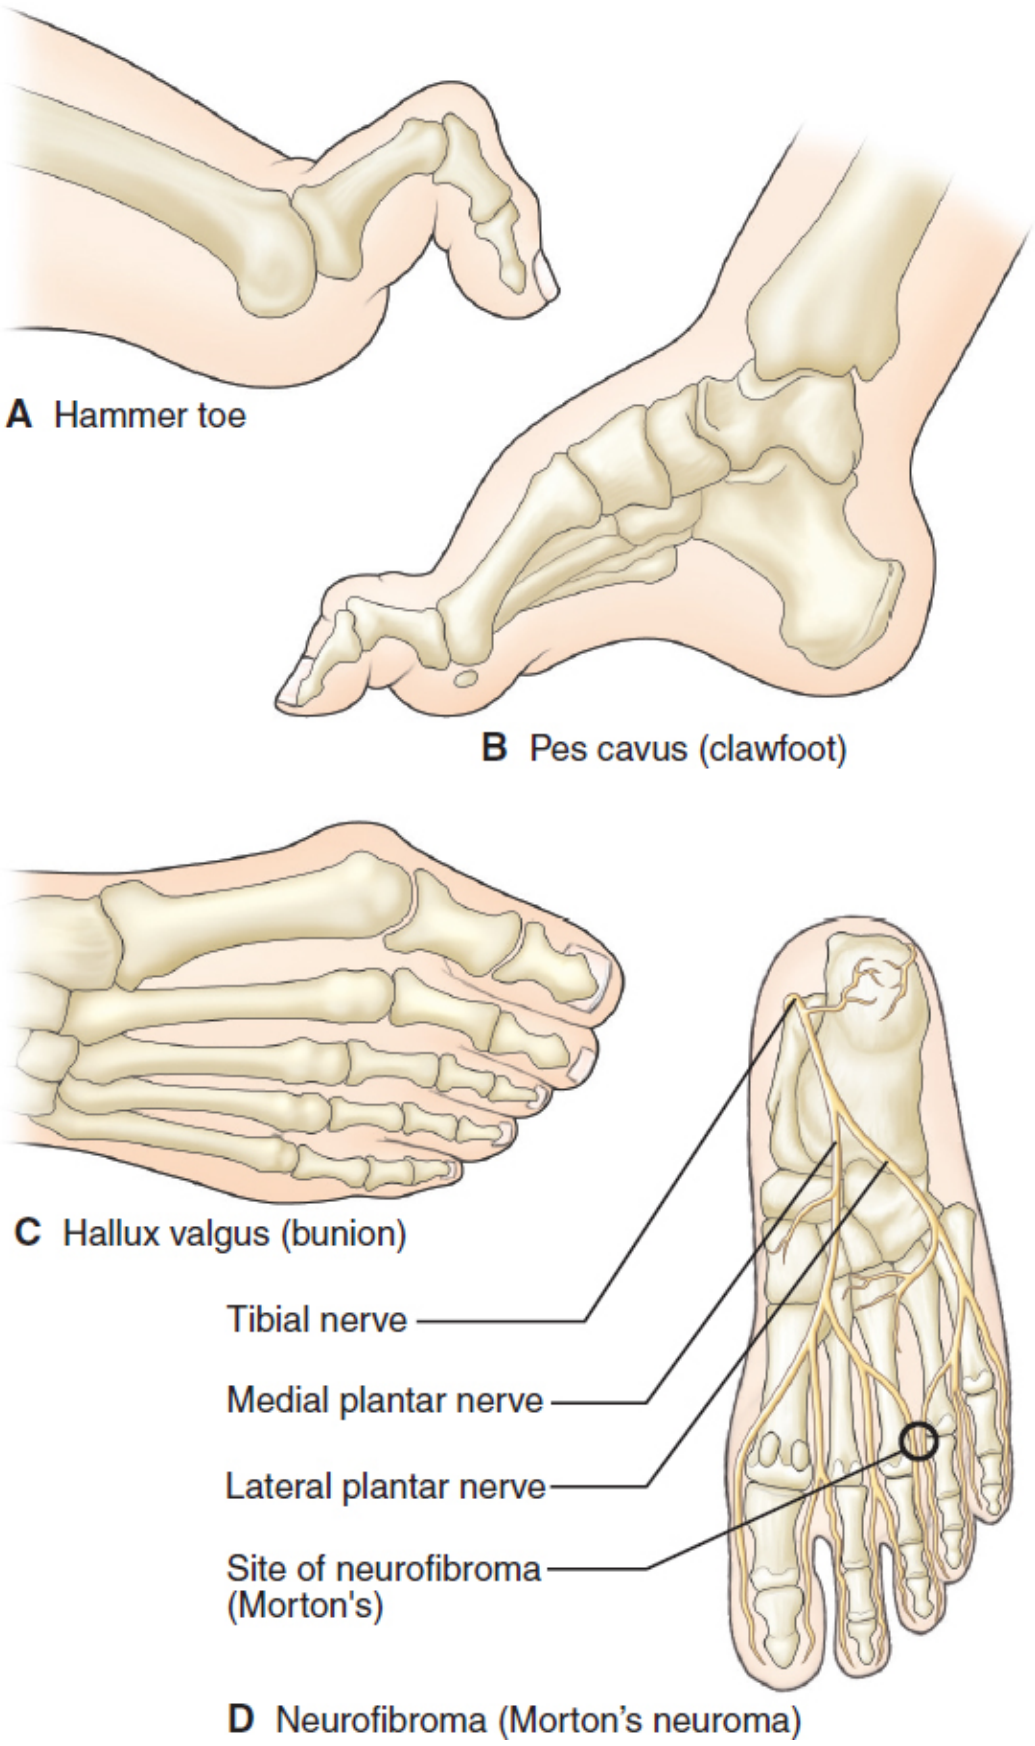

Figure 36-6 • Common foot deformities.

Pes Cavus

Pes cavus (clawfoot) refers to a foot with an abnormally high arch and a fixed equines deformity of the forefoot (see Fig. 36-6**B**). The shortening of the foot and increased pressure produce calluses on the metatarsal area and on the dorsum of the foot. Charcot–Marie–Tooth disease (a peripheral neuromuscular disease associated with a familial degenerative disorder), diabetes, and progressive neurologic disorders are common causes (Alderson & Ghosh, 2019). Exercises are prescribed to manipulate the forefoot into dorsiflexion and relax the toes. Orthotic devices alleviate pain and can protect the foot. In severe cases, arthrodesis (fusion) is performed to reshape and stabilize the foot.

Hallux Valgus

Hallux valgus (bunion) is a deformity in which the great toe deviates laterally (see Fig. 36-6**C**). There is a marked prominence of the medial aspect of the first metatarsophalangeal joint. There is also osseous enlargement (exostosis) of the medial side of the first metatarsal head, over which a bursa may form (secondary to pressure and inflammation). Acute bursitis symptoms include a reddened area, edema, and tenderness.

Factors contributing to bunion formation include heredity, ill-fitting shoes, osteoarthritis, and the gradual lengthening and widening of the foot associated with aging. Treatment depends on the patient's age, the degree of deformity, and the severity of symptoms. In uncomplicated cases, wearing a shoe that conforms to the shape of the foot, or that is molded to the foot to prevent pressure on the protruding portions, may be the only treatment needed. Corticosteroid injections control acute inflammation. In advanced cases, surgical removal of the exostosis and toe realignment may be required to improve function, appearance, and symptoms. If surgery is required in an athlete, at least 3 months of rest is required before returning to play (Fournier, Saxena, & Maffuli, 2019).

Morton Neuroma

Morton neuroma (plantar digital neuroma, neurofibroma) is a swelling near the third (lateral) branch of the median plantar nerve (see Fig. 36-6**D**). Microscopically, digital artery changes cause an ischemia within the third intermetatarsal (web) space. The result is a throbbing, burning pain in the foot that is usually relieved with rest and massage.

Conservative treatment consists of inserting innersoles and metatarsal pads designed to spread the metatarsal heads and balance the foot posture.

Local injections of a corticosteroid and a local anesthetic may provide relief. If these fail, surgical excision of the neuroma is necessary. Pain relief and loss of sensation are immediate and permanent with surgery. The risk of falls is increased because of the loss of all sensation (Matthews, Hum, Harding, et al., 2019).

Pes Planus

Pes planus (flatfoot) is a common disorder in which the longitudinal arch of the foot is diminished. It may be caused by congenital abnormalities or associated with bone or ligament injury, excessive weight, muscle fatigue, poorly fitting shoes, or arthritis. Signs and symptoms include a burning sensation, fatigue, clumsy gait, edema, and pain. Exercises to strengthen the muscles and to improve posture and walking habits are helpful (Unver, Erdem, & Akbas, 2019). Foot orthoses can give the foot additional support.

Plantar Fasciitis

Plantar fasciitis, an inflammation of the foot-supporting fascia, presents as an acute onset of heel pain experienced with the first steps in the morning. The pain is localized to the anterior medial aspect of the heel and diminishes with gentle stretching of the foot and Achilles tendon. Management includes stretching exercises, wearing shoes with support and cushioning to relieve pain, orthotic devices (e.g., heel cups, arch supports, night splints), and corticosteroid injections. Unresolved plantar fasciitis may progress to fascial tears at the heel and eventual development of heel spurs (Luffy et al., 2018).

Nursing Management of the Patient Undergoing Foot Surgery

Surgery of the foot may be necessary because of various conditions, including neuromas and foot deformities (bunion, hammer toe, clawfoot). Generally, foot surgery is performed on an outpatient basis. Before surgery, the nurse assesses the patient's gait and balance, as well as the neurovascular status of the foot. Additionally, the nurse considers the availability of assistance at home and the structural characteristics of the home in planning for care during the days after surgery.

Postoperative and home care follows the same principles as discussed earlier for hand surgery (see Chart 36-4). After surgery, neurovascular assessment of the exposed toes (every 1 to 2 hours for the first 24 hours) is essential to monitor the function of the nerves and the perfusion of the tissues. The nurse educates the patient and family about how to assess for

edema and neurovascular status at home (circulation, motion, sensation). The affected foot is compared to the unaffected foot to determine differences in neurovascular function. Compromised neurovascular function can increase the patient's pain (see Chapter 35, Chart 35-4).

Pain experienced by patients who undergo foot surgery is related to inflammation and edema. Formation of a hematoma may contribute to the discomfort. To control the anticipated edema, the foot should be elevated on several pillows when the patient is sitting or lying. Support of the entire limb under the knee is preferable. Ice packs applied intermittently to the surgical area during the first 24 to 48 hours may be prescribed to control edema and provide some pain relief. As activity increases, the patient may find that dependent positioning of the foot is uncomfortable. Simply elevating the foot often relieves the discomfort. Oral analgesic agents may be used to control the pain. The nurse instructs the patient and family about appropriate use of these medications.

After surgery, the patient will have a bulky dressing on the foot, protected by a light cast or a special protective boot. Limits for weight bearing on the foot will be prescribed by the surgeon (Malhotra et al., 2017). Some patients are allowed to walk on the heel and progress to weight bearing as tolerated; other patients are restricted to non–weight-bearing activities. Assistive devices (e.g., crutches, walker) may be needed. The choice of the devices depends on the patient's general condition and balance and on the weight-bearing prescription. Safe use of the assistive devices must be ensured through adequate patient education and practice before discharge (see Chapter 2). Strategies to move around the house safely while using assistive devices are also discussed with the patient. As healing progresses, the patient gradually resumes ambulation within prescribed limits. The nurse emphasizes adherence to the therapeutic regimen.

The immobility of lower extremity surgery increases the risk of venous thromboembolism (VTE) development. See Chapter 26 for VTE risk assessment and treatment. Other postoperative complications may include limited range of motion, paresthesia, tendon injury, and recurrence of deformity. In addition, if percutaneous pins were used to hold bones in position, these pins may serve as potential sites of infection. Patient education concerning aseptic wound care and pin care may be necessary. See Chapter 37 for further discussion on pin care and infection prophylaxis. Care must be taken to protect the surgical wound from dirt and moisture. When bathing, the patient can secure a plastic bag over the dressing to prevent it from getting wet.

Osteoarthritis (Degenerative Joint Disease)

Osteoarthritis (OA) is a noninflammatory degenerative disorder of the joints. It is the most common form of joint disease and is sometimes also called degenerative joint disease. OA is classified as either primary (idiopathic), with no prior event or disease related to the OA, or secondary, resulting from previous joint injury or inflammatory disease, similar to RA (see Chapter 34). The pathophysiology of primary OA does not involve autoimmunity or inflammation. It can occur as an end result of an autoimmune disorder where joint destruction occurs. Another distinguishing characteristic of OA is that it is limited to the affected joints; there are no systemic symptoms associated with it (McCance & Huether, 2019).

OA often begins in the third decade of life and peaks between the fifth and sixth decades. By 40 years of age, 90% of the population has degenerative joint changes in their weight-bearing joints, even though clinical symptoms are usually absent (CDC, 2018). Women, especially those who are Hispanic or African American, are more commonly affected. The incidence of OA increases with age. It is estimated that over 85% of the general population over 65 years of age has radiographic changes indicating OA. Although OA is usually thought of as a disease of aging, it can affect younger patients resulting in significant loss of work-related productivity (CDC, 2018).

Pathophysiology

All joints consist of bone, particularly **subchondral bone** or the bony plate to which the articular cartilage is attached. This articular cartilage is a lubricated, smooth tissue that protects the bone from damage with physical activity. Between the articular cartilage of the bones forming the joint is a space (called the *joint space*) that allows for movement. To aid in fluidity, each joint contains synovial fluid to help lubricate and protect the joint's movement. With OA, the articular cartilage breaks down, leading to progressive damage to the underlying bone and eventual formation of **osteophytes** (bone spurs) that protrude into the joint space. The result is that the joint space is narrowed, leading to decreased joint movement and the potential for more damage. Consequently, the joint can progressively degenerate (see Fig. 36-7). Understanding of OA pathophysiology has been greatly expanded beyond what was previously thought of as simply "wear and tear" related to aging. The basic degenerative process in the joint exemplified in OA is presented in Figure 36-8. In addition to the

degeneration, an infectious arthritis can occur. See later discussion of septic (infectious) arthritis.

Risk factors for the disease and its progression include older age, female gender, and obesity. In addition, certain occupations (e.g., those requiring laborious tasks); engaging in sport activities; and a history of previous injuries, muscle weakness, genetic predisposition, and certain diseases can also place patients at risk for joint destruction. The most prominent modifiable risk factor for OA is obesity. In fact, both quality and quantity of life are reduced with OA, especially when obesity and OA are combined. A program of diet and exercise can help minimize symptoms of OA in patients with obesity (CDC, 2018).

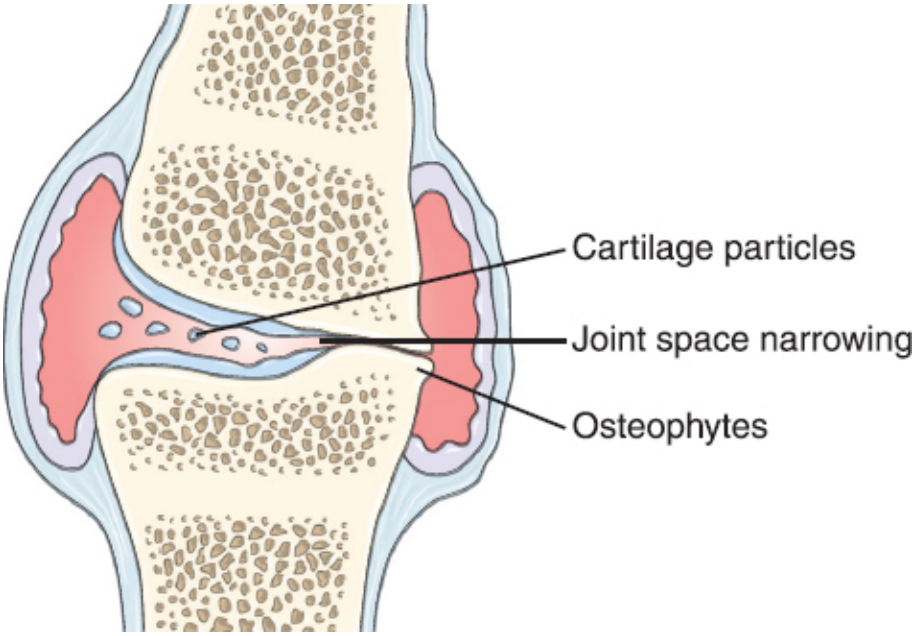

Figure 36-7 • Joint space narrowing and osteophytes (bone spurs) are characteristic of degenerative changes in joints.

Clinical Manifestations

The main clinical manifestations of OA are pain, stiffness, and functional impairment. The joint pain is usually aggravated by movement or exercise and relieved by rest. If morning stiffness is present, it is usually brief, lasting less than 30 minutes. The onset is routinely insidious, progressing over multiple years.

On physical examination, the affected joint may be enlarged with a decreased range of motion. Although OA occurs most often in weight-bearing joints (hips, knees, cervical and lumbar spine), the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints are also often involved causing bony enlargements of the DIP (Heberden's nodes) and PIP

(Bouchard's nodes) joints. Crepitus may be palpated, especially over the knee. Joint effusion, a sign of inflammation, is usually mild. No systemic manifestations are found.

Physiology/Pathophysiology

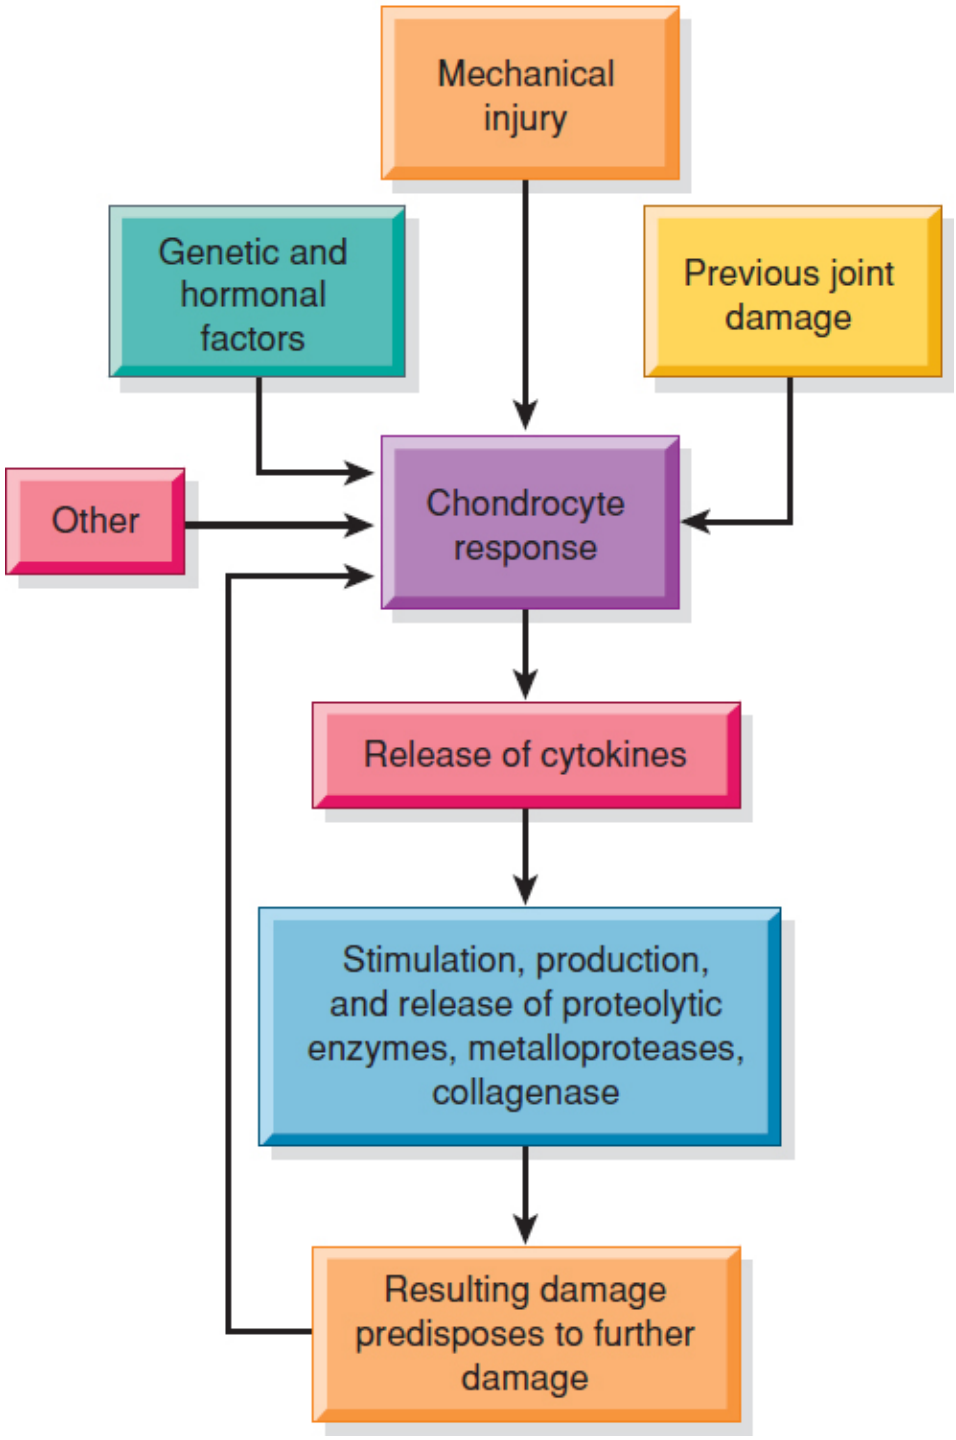

Figure 36-8 • Pathophysiology of osteoarthritis.

Assessment and Diagnostic Findings

Blood tests and examination of joint fluid are not useful in the diagnosis of OA but are occasionally indicated to rule out an autoimmune cause for the joint pain, such as RA. X-rays may show a narrowing of the joint space; osteophyte formation; and dense, thickened subchondral bone (O'Neill & Felson, 2018).

Medical Management

The goals of management are to decrease pain and stiffness and to maintain or, when possible, improve joint mobility. Exercise, especially in the form of cardiovascular aerobic exercise and lower extremity strength training, has been found to prevent OA progression and decrease symptoms of OA. Along with exercise, weight loss, which in turn decreases excess load on the joint, can also be extremely beneficial. Occupational and physical therapy can help the patient adopt self-management strategies (Schmidt, 2018).

Wedged insoles, knee braces, and other modalities are being evaluated as possible therapies aimed at treating the abnormalities in biomechanics found in OA. The use of orthotic devices (e.g., splints, braces) and walking aids (e.g., canes) can improve pain and function by decreasing force on the affected joint (Schmidt, 2018). Patients with arthritis often use complementary, alternative, and integrative health therapies, such as massage, yoga, pulsed electromagnetic fields, transcutaneous electrical nerve stimulation (TENS), and music therapy. These therapies may also include herbal and dietary supplements, other special diets, acupuncture, acupressure, wearing copper bracelets or magnets, and participation in T'ai chi. Research is under way to determine the effectiveness of many of these treatments. To date, there is no definitive evidence showing their superiority to standard care; the American College of Rheumatology (ACR) has encouraged the use of these therapies only if they do not interfere with medications and are found to increase comfort, mobility, and function for patients (Kolasinski, Neogi, Hochberg, et al., 2020).

Pharmacologic Therapy

Pharmacologic management of OA is directed toward symptom management and pain control. Selection of medication is based on the patient's needs, the stage of disease, and the risk of side effects. Medications are used in conjunction with nonpharmacologic strategies. In most patients with OA, the initial analgesic therapy is acetaminophen. Some patients respond to the nonselective NSAIDs and COX-2 enzyme blockers; however, COX-2 enzyme blockers must be used with caution because of the

associated risk of cardiovascular disease and little to no decrease in GI upset. Other medications that may be considered are nonopioids, such as tramadol, opioids in severe cases, and intra-articular corticosteroids (Cooper, Chapurlat, Al-Daghri, et al., 2019; Kolasinski et al., 2020). Topical analgesic agents such as capsaicin and methylsalicylate are also used. Topical diclofenac sodium gel has been FDA approved for the use of osteoarthritic joint pain in the hands and knees (Cooper et al., 2019; Kolasinski et al., 2020). Methotrexate and colchicine, typically prescribed for treating RA and gout, respectively, may also be considered for some patients with OA who are refractory to other treatments. The pathophysiologic antecedents of these diseases are similar to those in OA, and it is believed that may explain the effectiveness of these medications in some select patients with OA (Kolasinski et al., 2020; Raman, FitzGerald, & Murphy, 2018).

Other therapeutic approaches include glucosamine and chondroitin. Although it has been suggested that these substances modify cartilage structure, studies have not shown them to be effective (Kolasinski et al., 2020; Runhaar, Rozendaal, Middlekoop, et al., 2017). Viscosupplementation, the injection of gel-like substances (hyaluronates) into a joint (intra-articular), is thought to supplement the viscous properties of synovial fluid. These viscosupplements aim to prevent the loss of cartilage and repair chondral defects but lack strong evidence that support their use (Kolasinski et al., 2020; Raman, Henrontin, Chevalier, et al., 2018).

Nursing Management

Pain management and optimal functional ability are the major goals of nursing interventions. With those goals in mind, nursing management of the patient with OA includes pharmacologic and nonpharmacologic approaches as well as education. The patient's understanding of the disease process and symptom pattern is critical to the plan of care. Because patients with OA usually are older, they may have other health problems. Commonly they are overweight, and they may have a sedentary lifestyle. Weight loss and exercise are important approaches to lessen pain and disability. Canes or other assistive devices for ambulation should be considered, and any stigma about the use of these devices should be explored. Exercises such as walking should be begun in moderation and increased gradually. Patients should plan their daily exercise for a time when the pain is least severe or plan to use an analgesic agent, if appropriate, before exercising. Adequate pain management is important for the success of an exercise program. Open discussion regarding the use of complementary, alternative, and integrative

health therapies is important to maintain safe and effective practices for patients looking for relief.

The Patient Undergoing Arthroplasty

In moderate to severe OA, when pain is severe or because of loss of function, surgical intervention may be used. The procedures most commonly used are osteotomy (to alter the distribution of weight within the joint) and arthroplasty. Joint **arthroplasty** refers to the surgical removal of an unhealthy joint and replacement of joint surfaces with metal or synthetic materials.

Patients with OA and with severe joint pain and disability may undergo arthroplasty. Other conditions contributing to joint degeneration that might require arthroplasty include RA, trauma, and congenital deformity. Some fractures (e.g., femoral neck fracture) may cause disruption of the blood supply and subsequent **avascular necrosis** (death of tissue due to insufficient blood supply); management with joint replacement may be elected over open reduction internal fixation (ORIF) (see Chapter 37). Joints frequently replaced include the hip, knee (see Fig. 36-9), and finger joints. More complex joints (shoulder, elbow, wrist, ankle) are replaced less frequently.

Total joint arthroplasty, also known as total joint replacement, involves the replacement of all components of an articulating joint. Most joint replacements consist of metal (e.g., stainless steel, cobalt-chromium, titanium) and high-density polyethylene components. In order to achieve fixation of components, the material can be cemented, cementless, or a hybrid of both of these materials. Cemented fixation uses a fast-curing bone cement (polymethylmethacrylate [PMMA]) to hold implants in place. Cementless fixation relies on new bone growing into the surface of the implant by using a press-fit, porous-coated prosthesis. There is also a hybrid fixation technique for total knee arthroplasty (TKA) where the femoral component is inserted without cement, and the tibial and patellar components are inserted with cement. Use of each of these materials and techniques have different benefits and risks. Current research evidence supports the use of either component fixation methods (cemented or cementless) because postoperative functional outcomes, rates of complications, and rates of reoperations are similar (Quinn, Murray, Pezold, et al., 2018). Identifying patient-specific factors that may inform the decision to utilize a particular fixation technique is important. Considerations include gender, age, diagnosis, weight and activity level as

well as the presence of healthy bone with adequate blood supply. Issues of cost and cost-effectiveness should also be considered (Quinn et al., 2018).

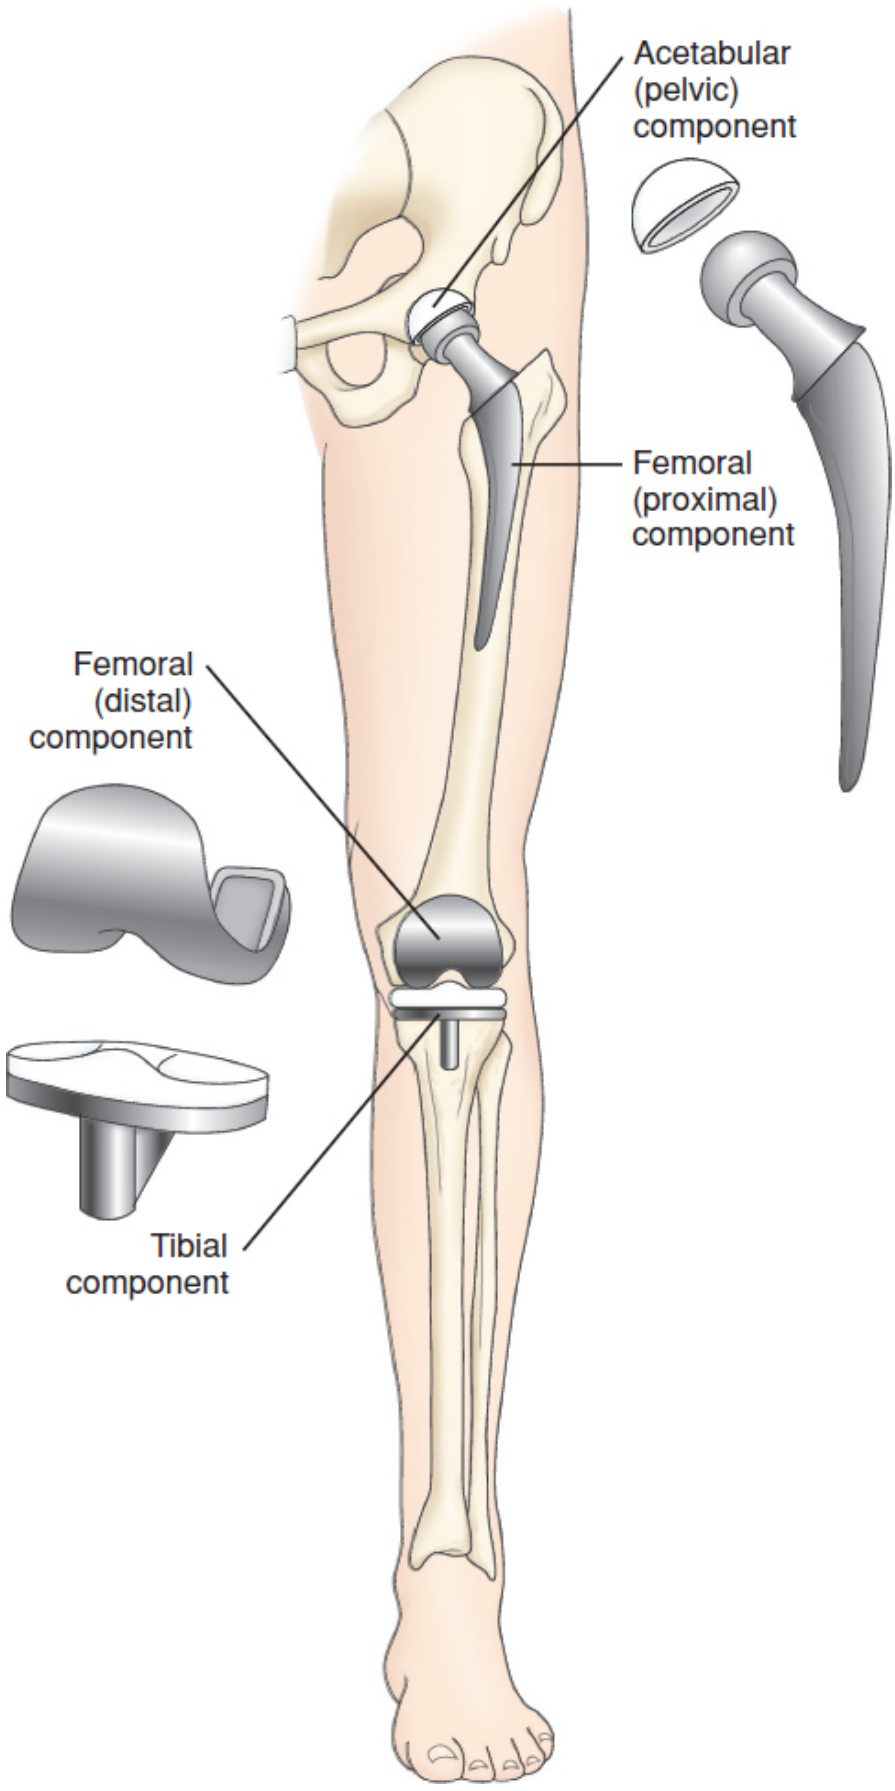

Figure 36-9 • Examples of Hip and Knee Replacement.

With joint replacement, patients may expect pain relief, return of joint motion, and improved functional status and quality of life. The scope of these improvements depends in part on patients' preoperative soft tissue condition and general muscle strength. Serious complications seldom occur, and recent innovations in total joint replacement surgery have made this a safer and more routinely performed surgery. Rehabilitation with physical therapy that is initiated within the first 24 hours is associated with decreased hospital length of stay and improved balance and gait function (Quinn et al., 2018). In addition, minimally invasive surgical techniques, biomaterials, postoperative rehabilitation protocols, and multimodal analgesia strategies have led to earlier hospital discharge and quicker recovery (Lee, 2016). The American Joint Replacement Registry (AJRR) monitors the performance of devices and evaluates the cost-effectiveness of procedures. The data generated from the AJRR and other registries provide orthopedic researchers and practitioners with the information necessary to improve the quality of health care among patients in need of knee and hip replacement procedures (Dy, Bumpass, Makhni, et al., 2016). Annual reports are provided to hospital system members to facilitate quality improvement programs (American Academy of Orthopaedic Surgeons [AAOS], 2020).

Preoperative and Intraoperative Nursing Management

Preoperative and intraoperative assessment and management of the patient having arthroplasty are aimed at having the patient in optimal health for surgery (see Chapters 14 and 15). Risks for bleeding, VTE, infection, and pain are managed proactively.

Preventing and Managing Blood Loss

Until recently, acute postoperative anemia due to perioperative blood loss was a common occurrence in patients having total hip arthroplasty (THA) and TKA; allogeneic blood transfusions (i.e., blood transfused from a donor) were required in up to 50% of patients who had THA and TKA (Rasouli, Maltenfort, Erkocak, et al., 2016). Recent research findings suggest that rate has dropped significantly, to approximately 9% of patients who have THA and 4% for patients who have TKA (Bedard, Pugely, Lux, et al., 2017). This diminished demand for allogeneic blood transfusions is attributable to the following interventions (Alexander & Frew, 2017; Loftus, Spratling, Stone, et al., 2016; Martin & Harris, 2020; Stalenhag & Sterner, 2019):

- Appropriate preoperative assessment and treatment of patients with anemia (i.e., low red blood cell counts) with pharmacologic agents, such as epoetin alfa or iron supplements
- Application of pneumatic tourniquets during orthopedic limb surgery (e.g., TKA), which not only minimizes bleeding but also helps maintain a clean surgical field
- Employment of intraoperative red blood cell salvage systems, as appropriate, during procedures when a large volume of blood is lost. This is effectively a type of autologous transfusion; that is, the patient's own blood is salvaged during the operative procedure and re-transfused back to the patient.
- Intraoperative administration of the antifibrinolytic agent tranexamic acid, which is thought to have significantly reduced overall blood loss and the need for blood transfusions in patients having THA or TKA.

Preventing Venous Thromboembolism

Patients having orthopedic surgery are particularly at risk for VTE, including deep vein thrombosis (DVT) and pulmonary embolism (PE). Therefore, factors that compound or further increase this risk are assessed preoperatively. Increasing age (older than age 40), obesity, taking prescription hormonal medications, preoperative leg edema, previous history of any VTE, and varicose veins increase the risk for postoperative DVT and PE (Menaka & Douketis, 2019). The use of medications that increase the risk of clotting, such as certain hormones and NSAIDs, may be discontinued a week before surgery. Prophylactic low-molecular-weight heparin (LMWH) or another anticoagulant agent may be prescribed prior to or after surgery (Quinn et al., 2018).

Assessing the neurovascular status of the extremity undergoing joint replacement is important, because postoperative assessment data are compared with preoperative assessment data to identify changes and any arterial impairment to the affected extremity. For example, an absent pulse postoperatively is of concern unless the pulse was also absent preoperatively. Nerve palsy could occur as a result of surgery.

Preventing Infection

Preoperative assessment of the patient for recent or active infections, including urinary tract infection, is necessary because of the risk for postoperative infection. Any infection presenting 2 to 4 weeks before planned surgery may result in postponement of surgery. Preoperative skin preparations, such as showers with antiseptic soap, are recommended the

evening before and the morning of surgery. Scrubbing of the surgical site with a prescribed antiseptic soap the night before or on the morning of surgery decreases bacterial count on the skin and helps lower the chance of infection (Berrios-Torres, Umscheid, Bratzler, et al., 2017; Papas, Conguista, Scuderi, et al., 2018).

Research findings suggest that prophylactic broad-spectrum antibiotics given 60 minutes prior to skin incision and discontinued within 24 hours postoperatively are effective in preventing surgical site infections (De Francesco, Fu, Kalenberg, et al., 2019).

The use of antibiotic-loaded bone cement and preoperative nasal swabbing to screen for patients who are carriers of methicillin-resistant *Staphylococcus aureus* (MRSA) or methicillin-sensitive *Staphylococcus aureus* (MSSA) may help in further reducing postoperative infections; the effectiveness of these modalities is under research as is the use of dual antibiotic therapy (Villa, Pannu, Riesgo, et al., 2020). Culture of the joint during surgery may be important in identifying and treating subsequent infections.

Managing Pain

Assessment of the patient's pain preoperatively and any cultural and personal preferences are important components related to the control of pain following joint surgery. Assessing the patient's level of understanding of the surgery and explaining what to expect in the postoperative period (e.g., incentive spirometry, pain control methods, activity limits) can improve outcomes. Research findings suggest that patients who are supported and educated telephonically in the preoperative period report better quality of life and well-being postoperatively (Allsop, Fairhall, & Morphet, 2019) (see Nursing Research Profile in Chart 36-5). However, high anxiety and severe pain prior to surgery may have an impact on these outcomes (Jones, Al-Naseer, Bodger, et al., 2018) (see Chapter 9).

Total Hip Arthroplasty

THA is the replacement of a severely damaged hip with an artificial joint. Indications for this surgery include OA, as well as RA, femoral neck fractures (i.e., hip fracture; see Chapter 37), failure of previous reconstructive surgeries, such as a failed prosthesis with osteotomy, and conditions resulting from developmental dysplasia or Legg–Calvé–Perthes disease (avascular necrosis of the hip in childhood). A variety of total hip prostheses are available. Most consist of a metal femoral component topped

by a spherical ball made of metal, ceramic, or plastic that is fitted into a plastic or metal acetabular socket (see Fig. 36-9).

The surgeon selects the prosthesis that is best suited to the individual patient, considering various factors including skeletal structure and activity level. The patient has irreversibly damaged hip joints, and the potential benefits, including improved quality of life, outweigh the surgical risks. With the advent of improved prosthetic materials and operative techniques, the life of the prosthesis has been extended, and today younger patients with severely damaged and painful hip joints are undergoing total hip replacement.

Nursing Management

The nurse must be aware of and monitor for specific potential complications associated with THA (Gabbert, Filson, Bodden, et al., 2019). Complications that may occur include dislocation of the hip prosthesis, excessive wound drainage, VTE, infection, and heel pressure injury (see Chart 36-6). The nurse also monitors for complications associated with immobility. Long-term complications include **heterotopic ossification** (formation of bone in the periprosthetic space), avascular necrosis, and loosening of the prosthesis.

Chart 36-5  **NURSING RESEARCH PROFILE**

Preoperative Telephone Support for Patients Having Total Knee Arthroplasty

Allsop, S., Fairhill, R., & Morphet, J. (2019). The impact of pre-operative telephone support and education on symptoms of anxiety, depression, pain and quality of life post total knee replacement. *International Journal of Orthopaedic and Trauma Nursing*, *34*, 21–27.

Purpose

Patients scheduled to have elective total knee arthroplasty (TKA) can experience anxiety and depression during the preoperative waiting period which may negatively impact postoperative outcomes. The purpose of this study was to determine whether preoperative patient support and education delivered via telephone would impact postoperative reports of quality of life (QOL), depression, anxiety and pain among patients having total knee replacement surgery.

Design

This mixed methods study explored the effects of a support intervention in a sample of participants (N = 18) who underwent unilateral total knee replacements. Pre-tests were administered up to 6 weeks prior to elective surgery in the clinic setting. Those with infections, malignancy, or repeat interventions were excluded. Baseline data included demographics and Patient Reported Outcomes Measures (PROMS) which assessed QOL, psychological distress, and pain; using scales previously validated in this population.

Two phone calls were made by the same researcher to address open- and closed-ended questions based on information considered essential for patients to understand before surgery. The researcher individualized content that was delivered to the participants in response to their unique questions and concerns. A thematic analysis was undertaken to identify patterns in responses. The PROMS scales were readministered 6 weeks after surgery, either during a clinic visit or by telephone.

Findings

Of the 18 enrolled participants, 16 completed the study. One third were men; 19% lived alone; half of the participants were under 65 years of age and 69% of them were not actively employed. Depression and anxiety (rated as high or very high) were reported by 31% of the patients preoperatively.

Participants' concerns related to the administrative processes of admission and discharge and the psychological processing of having a major surgery; some expressed fears of being awake with spinal anesthetic approaches. Participants voiced concerns about their caregivers, the potential for infection, and the wish to return home quickly.

Many favorable comments were made concerning the positive impact of the program.

Fewer participants experienced anxiety and depression post-surgery; however, this change was not significant. There were significant improvements in QOL scores ($p = 0.008$) and pain scores ($p < 0.001$). However, compared to previous studies (most of which had longer duration of interventions and follow-up), the improvement in QOL, anxiety, and pain scores was not as substantial.

Nursing Implications

Findings from this study suggest that preoperative telephone support and education of patients scheduled for TKA can improve QOL and pain postoperatively. This study only spanned a 6-week postoperative period, potentially limiting the ability to capture change in study outcomes. This was a single site study which warrants replication in a greater number of facilities with greater attention to the optimal time period required to assess outcomes in this population. In addition, greater attention to more comprehensive psychological interventions preoperatively may also be required for better success in the long term.

Chart 36-6  PLAN OF NURSING CARE

The Patient with a Total Hip Arthroplasty

NURSING DIAGNOSIS: Acute pain associated with total hip arthroplasty
GOAL: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient for pain using a standard pain intensity scale. 2. Ask patient to describe discomfort. 3. Acknowledge existence of pain; inform patient of available analgesic agents or muscle relaxants. a. Use pain-modifying techniques. Administer analgesic agents as prescribed. b. Change position within prescribed limits. c. Modify environment. d. Notify primary provider about	1. Pain is expected after a surgical procedure because of the surgical trauma and tissue response. Muscle spasms occur after total hip replacements. Immobility causes discomfort at pressure points. 2. Pain characteristics may help to determine the cause of discomfort. Pain may be due to complications (hematoma, infection, dislocation). Pain is an individual experience—it means different things to different people. 3. The nurse can reduce the stress experienced by patient by communicating concern and availability of assistance to help the patient deal with the pain. a. Patient will require parenteral opioids during the first 24–48 hours and then will progress to	• Describes discomfort • Expresses confidence in efforts to control pain • States pain is reduced; pain intensity scores are decreasing • Appears comfortable and relaxed • Uses physical, psychological, and pharmacologic measures to reduce pain and discomfort

persistent pain. 4. Evaluate and record discomfort and effectiveness of pain-modifying techniques.	oral analgesic agents. b. The use of pillows to provide adequate support and relief of pressure on bony prominences assists in minimizing pain. c. Interactions with others, distractions, and sensory overload or deprivation may affect pain experience. d. Surgical intervention may be necessary if pain is due to hematoma or excessive edema. 4. Effectiveness of action is based on experience; data provide a baseline about pain experiences, pain management, and pain relief.	

Nursing Diagnosis: Impaired mobility associated with positioning, weight bearing, and activity restrictions after total hip arthroplasty
Goal: Achieves pain-free, functional, stable hip joint

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain proper positioning of hip joint (abduction, neutral rotation, limited flexion).	1. Prevents dislocation of hip prosthesis.	• Maintains prescribed position
2. Keep pressure off heel.	2. Prevents pressure injury on heel.	• No heel pressure
3. Instruct and assist in position changes and transfers.	3. Encourages patient's active participation while preventing dislocation.	• Assists in position changes
4. Instruct and supervise isometric quadriceps and gluteal setting exercises.	4. Strengthens muscles needed for walking.	• Shows increased independence in transfers
5. In consultation with physical therapist, instruct and supervise progressive safe ambulation within limitations of weight-bearing prescription.	5. Amount of weight bearing depends on patient's condition and prosthesis; ambulatory aids are used to assist the patient with non–weight-bearing and partial weight-bearing ambulation.	• Exercises hourly while awake • Participates in progressive ambulation program
6. Offer encouragement and support exercise regimen.	6. Reconditioning exercises can be uncomfortable and fatiguing; encouragement helps patient comply with exercise program.	• Actively participates in exercise regimen
	7. Prevents injury from unsafe use and prevents falls.	• Uses ambulatory aids correctly and safely

7. Instruct and supervise safe use of ambulatory aids.

Collaborative Problems: Hemorrhage; neurovascular compromise; dislocation of prosthesis; venous thromboembolism; infection associated with surgery

Goal: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Hemorrhage		
1. Monitor vital signs, observing for shock. 2. Note character and amount of drainage. 3. Notify primary provider if patient develops shock or excessive bleeding, and prepare for administration of fluids, blood component therapy, and medications. 4. Monitor hemoglobin and hematocrit values.	1. Changes in pulse, blood pressure, and respirations may indicate development of shock. Blood loss and stress of surgery may contribute to development of shock. 2. Within 48 hours, bloody drainage collected in portable suction device, if in use, should decrease to 25–30 mL per 8 hours. Excessive drainage (>250 mL in first 8 hours after surgery) and bright-red drainage may indicate active bleeding. 3. Corrective measures need to be instituted.	• Vital signs stabilize within normal limits • Amount of drainage decreases • No bright-red bloody drainage • Hematology values are within normal limits

	4. Anemia due to blood loss may develop. Blood replacement or iron supplementation may be needed.	
Neurovascular Dysfunction		
1. Assess affected extremity for color and temperature. 2. Assess toes for capillary refill response. 3. Assess extremity for edema and swelling. Report patient complaints of leg tightness. 4. Elevate lower extremity. Keep elevated extremity lower than hip when in chair. 5. Assess for deep, throbbing, unrelenting pain. 6. Assess for pain on passive flexion of foot.	1. The skin becomes pale and feels cool with decreased tissue perfusion. Venous congestion may produce cyanosis. 2. After compression of the nail, rapid return of pink color indicates good capillary perfusion. 3. The trauma of surgery will cause edema. Excessive swelling and hematoma formation can compromise circulation and function. 4. Minimizes dependent edema. Hip is never flexed more than 90 degrees to prevent dislocation. 5. Surgical pain can be controlled with pharmacologic and nonpharmacologic interventions; pain due to neurovascular	• Color normal • Extremity warm • Normal capillary refill • Moderate edema and swelling; tissue not palpably tense • Pain controllable • No pain with passive dorsiflexion • Normal sensations • No paresthesia • Normal motor abilities • No paresis or paralysis • Pulses strong and equal

7. Assess for change in sensations and numbness. 8. Assess ability to move foot and toes. 9. Assess pedal pulses in both feet. 10. Notify surgeon if altered neurovascular status is noted.	compromise typically does not respond to traditional postoperative pain management strategies. 6. With nerve ischemia, there will be pain on passive stretch. Additionally, pain or tenderness may indicate deep vein thrombosis. 7. Diminished pain and sensory function may indicate nerve damage. Sensation in web between great and second toe–peroneal nerve; sensation on sole of foot–tibial nerve. 8. Dorsiflexion of ankle and extension of toes indicate function of peroneal nerve. Plantar flexion of ankle and flexion of toes indicate function of tibial nerve. 9. Indicator of extremity circulation. 10. Function of extremity needs to be preserved.

Dislocation of Prosthesis

1. Position patient as prescribed. 2. Use abductor splint or pillows to maintain position and to support extremity. 3. Support leg and place pillows between legs when patient is turning and side-lying; turn to the unaffected side. 4. Avoid acute flexion of hip (head of bed ≤90 degrees). 5. Avoid crossing legs. 6. Assess for dislocation of prosthesis (extremity shortens, internally or externally rotated, severe hip pain, patient unable to move extremity). 7. Notify surgeon of possible dislocation.	1. Hip component positioning (femoral component in acetabular component) needs to be maintained. 2. Keeps hip in abduction and in a neutral rotation to prevent dislocation. 3. Prevent dislocation. 4. Findings may indicate dislocation of prosthesis. 5. Joint dislocations compromise neurovascular status and future function of extremity.	• Prosthesis not dislocated • Adheres to recommendations to prevent dislocation
Venous Thromboembolism		
1. Use anti-	1. Aids in venous	• Wears anti-

embolism stocking and sequential compression device as prescribed. 2. Remove stocking for 20 minutes twice a day and provide skin care. 3. Assess popliteal, dorsalis pedis, and posterior tibial pulses. 4. Assess skin temperature of legs. 5. Assess for unilateral calf pain or tenderness every 8 hours. 6. Avoid pressure on popliteal blood vessels from equipment (e.g., abductor splint straps, sequential compression stockings) or pillows. 7. Change position and increase activity as prescribed. 8. Supervise ankle exercises hourly.	blood return and prevents stasis. 2. Aids in venous blood return and prevents stasis. 3. Skin care is necessary to avoid breakdown. Extended removal of stocking defeats purpose of stocking. 4. Pulses indicate arterial perfusion of extremity. 5. Local inflammation will increase local skin temperature. 6. Pain or tenderness may indicate deep vein thrombosis. 7. Compression of blood vessels diminishes blood flow. 8. Activity promotes circulation and diminishes venous stasis. 9. Muscle exercise promotes circulation. 10. Body temperature increases with inflammation. 11. Dehydration increases blood viscosity.	embolism stocking; uses compression device • No skin breakdown • Pulses equal and strong • Skin temperature normal • No calf pain or tenderness • Changes position with assistance and supervision • Participates in exercise regimen • Well hydrated • No chest pain; lungs clear to auscultation; no evidence of pulmonary emboli

9. Monitor body temperature. 10. Encourage fluids.			
Infection			
1. Monitor vital signs. 2. Use aseptic technique for dressing changes and emptying of portable drainage. 3. Assess wound appearance and character of drainage. 4. Assess complaints of pain. 5. Administer prophylactic antibiotics if prescribed, and observe for side effects.	1. Temperature, pulse, and respirations increase in response to infection. (Magnitude of response may be minimal in older adults.) 2. Avoids introducing organisms. 3. Red, swollen, draining incision is indicative of infection. 4. Pain may be due to wound hematoma–a possible locus of infection–that needs to be surgically evacuated. 5. Infected prosthesis is avoided.	• Vital signs normal • Well-approximated incision without drainage or excessive inflammatory response • Minimal discomfort; no hematoma • Tolerates antibiotics	

Figure 36-10 • An abduction pillow may be used after a total hip arthroplasty to prevent dislocation of the prosthesis.

Preventing Dislocation of the Hip Prosthesis

For patients undergoing a posterior or posterolateral approach for THA, maintenance of the femoral head component in the acetabular cup is essential. The risk for dislocation is more common with this approach and may occur when the hip is in full flexion, adducted (legs together), and internally rotated. Therefore, correct positioning is maintained at all times. The patient should be in a supine position with the head slightly elevated and the affected leg in a neutral position. The use of an abduction splint, a wedge pillow (see Fig. 36-10), or two or three pillows placed between the legs prevent adduction beyond the midline of the body. A cradle boot may be used to prevent leg rotation and to support the heel off the bed, preventing development of a pressure injury. When the nurse turns the patient in bed to the unaffected side, it is important to keep the operative hip in **abduction** (movement away from the center or median line of the body) (Gabbert et al., 2019). The patient should not be turned to the operative side, which could cause dislocation, unless specified by the surgeon.

The patient's hip is never flexed more than 90 degrees. When using a fracture bedpan, the nurse instructs the patient to flex the unaffected hip and to use the trapeze to lift the pelvis onto the pan. The patient is also reminded not to flex the affected hip.

Limited flexion is maintained during transfers and when sitting. When the patient is initially assisted out of bed, an abduction splint or pillows are

kept between the legs. The nurse encourages the patient to keep the affected hip in extension, instructing the patient to pivot on the unaffected leg with assistance by the nurse, who protects the affected hip from **adduction** (movement toward the center or median line of the body), flexion, internal or external rotation, and excessive weight bearing.

High-seat (orthopedic) chairs with arm rests, semi-reclining chairs, and raised toilet seats are used to minimize hip joint flexion. When sitting, the patient's hips should be higher than the knees. The patient's affected leg should not be elevated when sitting. The patient may flex the knee.

The nurse educates the patient about protective positioning, which includes maintaining abduction and avoiding internal and external rotation, hyperextension, and acute flexion, as described previously. At no time should the patient cross the legs or bend at the waist past 90 degrees (e.g., to put on shoes and socks). Occupational therapists can provide the patient with devices to assist with dressing below the waist. Hip precautions for patients who had a posterior or posterolateral approach for THA should be enforced for 4 months or longer after surgery (see Chart 36-7). A patient who has had an anterior surgical approach may not need these precautions. Several studies have reported an anterolateral approach to THA results in a lower rate of dislocation than a posterior approach owing to its ease of access, superior visualization, and a predictable healing pattern. Using a less restrictive mobility protocol in these patients can lead to earlier and better resumption of ADL, earlier return to work, a shorter length of hospital stay, and improved patient satisfaction (Morris, Fornit, Marchoni, et al., 2018).

Dislocation may occur with positioning that exceeds the limits of the prosthesis. The nurse must monitor for signs and symptoms of dislocation of the prosthesis, which include:

- Increased pain at the surgical site, swelling, and immobilization
- Acute groin pain in the affected hip or increased discomfort
- Shortening of the affected extremity
- Abnormal external or internal rotation of the affected extremity
- Restricted ability or inability to move the leg
- Reported "popping" sensation in the hip

If any of these clinical manifestations occur, the nurse (or the patient, if at home) immediately notifies the surgeon, because the hip must be reduced and stabilized promptly so that the leg does not sustain circulatory and nerve damage. After closed reduction, the hip may be stabilized with Buck's traction or a brace to prevent recurrent dislocation (see Chapter 37, Fig. 37-11). As the muscles and joint capsule heal, the chance of dislocation diminishes. Stresses to the new hip joint should be avoided for the first 8 to 12 weeks, when the risk of dislocation is greatest (Gabbert et al., 2019).

Promoting Ambulation

Patients begin ambulation with the assistance of a walker or crutches within a day after surgery. The nurse and the physical therapist assist the patient in achieving the goal of independent ambulation. At first, the patient may be able to stand for only a brief period because of orthostatic hypotension. Specific weight-bearing limits on the prosthesis are based on the patient's condition, the procedure, and the fixation method. Weight bearing immediately after surgery may be limited to minimize micromotion of the prosthesis in the bone. As the patient is able to tolerate more activity, the nurse encourages transferring to a chair several times a day for short periods and walking for progressively greater distances.

Monitoring Wound Drainage

Fluid and blood accumulating at the surgical site, which could contribute to discomfort and provide a source for infection, may be drained with a closed suction portable suction device. The efficacy of using a wound drainage system is controversial, especially since the system can be a potential source for infection (Keeney, Austin, & Jevsevar, 2019; Mujagic, Hoffmann, Soysal, et al., 2019). In particular, drains that remain in place for longer than 24 hours create an increased risk for contamination and infection (Keeney et al., 2019; Mujagic et al., 2019). The nurse should monitor the amount of drainage and measure output each shift; the surgeon must be promptly notified of excessive or foul-smelling drainage. After the drain is removed, the drain tube site is cleaned with an antiseptic solution and a small gauze dressing is applied if there is oozing at the site (Gabbert et al., 2019).

Chart 36-7  **PATIENT EDUCATION**

Avoiding Hip Dislocation After Arthroplasty with Posterior or Posterolateral Approach

The nurse instructs the patient to:
Until the hip prosthesis stabilizes after hip replacement surgery, it is necessary to follow instructions for proper positioning so that the prosthesis remains in place. Dislocation of the hip is a serious complication of surgery that causes pain and loss of function and necessitates reduction under anesthesia to correct the dislocation. Desirable positions include abduction, neutral rotation, and flexion of less than 90 degrees. When you are seated, the knees should be lower than the hip.

The nurse notes the following methods for avoiding displacement:

- Keep the knees apart at all times.
- Put a pillow between the legs when sleeping.
- Never cross the legs when seated.
- Avoid bending forward when seated in a chair.
- Avoid bending forward to pick up an object on the floor.
- Use a high-seated chair and a raised toilet seat.
- Do not flex the hip to put on clothing such as pants, stockings, socks, or shoes. Positions to avoid after total hip replacement are shown in the illustrations.

Affected leg should not cross the center of the body

Hip should not bend more than 90 degrees

Affected leg should not turn inward

Preventing Venous Thromboembolism

Without prophylaxis, DVT formation can develop within 7 to 14 days following surgery and lead to PE, which can be fatal. Early identification of the patient's VTE risk, ensuring that the patient receives the appropriate

prophylaxis, instituting preventive measures, and monitoring the patient closely for clinical signs of the development of DVT and PE are key. However, the nurse should also be aware that VTE prevention may increase the postoperative risk for bleeding and stay alert for this potential complication (Erens & Walter, 2019).

Physical signs of DVT include pain and tenderness at or below the area of the clot, swelling or tightness of the affected leg, possibly with pitting edema, with either warmth or cooling, and skin discoloration; PE symptoms may include acute onset of dyspnea, tachycardia, confusion, and pleuritic chest pain (McCance & Huether, 2019).

Intermittent compression devices are applied either intraoperatively or immediately postoperatively; these devices must remain on the legs at all times, even when the patient is out of bed. Patients should be instructed to dorsi- and plantar flex the ankles and the toes 10 to 20 times every half hour while awake. In addition, patients who are post-THA should be mobilized as soon as possible to assist with decreasing venous stasis; even patients with epidural catheters should stand and ambulate when they are physically able (Erens & Walter, 2019).

Aspirin, LMWH and synthetic pentasaccharides (fondaparinux) can be used as prophylaxis for VTE. They typically are continued for up to 35 days following surgery based on surgeon preference and patient risk level (Menaka & Douketis, 2019) (see Chapter 26 for further discussion of VTE and VTE prophylaxis).

Preventing Infection

Infection—a serious complication of THA—may necessitate removal of the prosthesis. Patients who are older, poorly nourished, smoke cigarettes, or use corticosteroid medications and patients who have obesity, diabetes, RA, concurrent infections (e.g., urinary tract infection, dental abscess), carry MRSA, or have hematomas are at high risk for infection (Beam & Osmon, 2018). Use of two types of antibiotics is being investigated as a method to decrease MRSA infections both in THA and TKA (Villa et al., 2020).

Over time, one in five patients with THA will undergo revision of the prosthesis, most commonly because of aseptic loosening, infection, instability, or a mechanical complication. Because these joint infections are difficult to treat, strategies for preventing infections should be implemented at various steps of the process of care. Strict hand hygiene and utilization of appropriate infection control practices can prevent transmission of infectious organisms. Appropriate antibiotic administration and discontinuation, as well as thorough patient education regarding subsequent antibiotic use are important.

Chart 36-8

Providing Home Care After Total Hip Arthroplasty

Considerations

- Pain management
- Wound care
- Mobility
- Self-care (activities of daily living)
- Potential complications

Nursing Interventions

Discuss with patient the following methods to reduce pain:

- Periodic rest
- Distraction and relaxation techniques
- Medication therapy (e.g., nonsteroidal anti-inflammatory drugs, opioid analgesic agents): actions of medications, administration, schedule, side effects

Instruct patient in the following:

- Keeping incision clean and dry
- Cleansing incision daily with soap and water and changing the dressing
- Recognizing signs of wound infection (e.g., pain, increased redness, swelling, purulent drainage, fever)

Explain that sutures or staples will be removed 10 to 14 days after surgery.

Educate patient about the following:

- Safe use of assistive devices
- Weight-bearing limits
- How to change positions frequently
- Limitations on hip flexion and adduction (e.g., avoid acute flexion and crossing legs)
- How to stand without flexing hip acutely
- Avoidance of low-seated chairs and toilets
- Sleeping with pillow between legs to prevent adduction
- Gradual increase in activities and participation in prescribed exercise regimen
- Use of important medications such as warfarin and aspirin

Assess home environment for physical barriers.

Instruct patient to use elevated toilet seat and to use reachers to aid in dressing.

Encourage patient to accept assistance with activities of daily living during early convalescence until mobility and strength improve.

Arrange services and accommodations to address the patient's disability or illness, as appropriate.

Assess patient for development of potential problems, and instruct patient to report signs of potential complications:

- Dislocation of prosthesis (e.g., increased pain, shortening of leg, inability to move leg, popping sensation in hip, abnormal rotation)
- Deep vein thrombosis (e.g., calf pain, swelling, redness)
- Wound infection (e.g., pain, increased redness, swelling, purulent drainage, fever)
- Pulmonary emboli (e.g., shortness of breath, tachypnea, pleuritic chest pain)

Discuss with patient the need to continue regular health care (routine physical examinations) and screenings.

Adapted from Erens, G. A., Walter, B., & Crowley, M. (2020). Total hip arthroplasty. *UpToDate*. Retrieved on 3/16/2020 at: www.uptodate.com/contents/total-hip-arthroplasty

Acute infections may occur within 3 months after surgery and are associated with progressive superficial infections or hematomas. Delayed surgical infections may appear 4 to 24 months after surgery and may cause return of discomfort in the hip. Routine use of antibiotic prophylaxis prior to dental procedures for patients with total joint prostheses remains controversial and is not recommended (Goff, Mangino, Glassman, et al., 2019). Antibiotic prophylaxis can still be prescribed for patients who are immunosuppressed.

Infections occurring more than 2 years after surgery are attributed to the spread of infection through the bloodstream from another site in the body. If an infection occurs, antibiotics are prescribed. Severe infections may require surgical débridement or removal of the prosthesis. (See sections on Septic Arthritis and Osteomyelitis later in this chapter.)

Promoting Home, Community-Based, and Transitional Care

Educating the Patient About Self-Care

Before the patient leaves the acute care setting, the nurse provides thorough education to promote continuity of the therapeutic regimen and active participation in the rehabilitation process (see Chart 36-8). The patient may be discharged to the home, a rehabilitation unit, a transitional care unit, or a

long-term care facility. The nurse advises the patient of the importance of a daily exercise program in maintaining the functional motion of the hip joint and strengthening the abductor muscles of the hip, and reminds the patient that it will take time to strengthen and retrain the muscles.

Most patients benefit from physical therapy to regain mobility. Assistive devices (crutches, walker, or cane) may be used for a time. After sufficient muscle tone has developed to permit a normal gait without discomfort, these devices are not necessary. In general, by 3 months, the patient can resume routine ADLs. Stair climbing typically may resume within 3 to 6 weeks following surgery. Some discomfort with activity and at night is common for several weeks. Frequent walks, swimming, and the use of a high rocking chair are excellent for hip exercises.

Restrictions must be kept in mind when resuming sexual activity. Patients should be questioned about concerns and counseled on physical and functional aspects of sexual activity. Sexual activity can be resumed based upon the surgeon's recommendation (typically 3 to 6 months postoperatively). Attention to positioning and comfort may enhance the intimacy of the experience.

At no time during the first 4 months should the patient cross the legs or flex the hip more than 90 degrees. Assistive devices should be used for dressing, such as long-handled shoehorns or dressing sticks for putting on shoes and socks. The patient should avoid low chairs and sitting for longer than 45 minutes at a time. These precautions minimize hip flexion and the risks of prosthetic dislocation, hip stiffness, and flexion contracture. Driving requires sufficient range of motion and muscle strength; most patients are given permission to drive 4 to 6 weeks postoperatively. Traveling long distances should be avoided unless frequent position changes are possible. Other activities to avoid include tub baths, jogging, lifting heavy loads, and excessive bending and twisting (e.g., lifting, shoveling snow, forceful turning). The surgeon may give the patient a card indicating that they have had a joint replacement; this card may be used to alert security personnel who use screening devices at airports or malls.

Continuing and Transitional Care

A nurse may assess the patient's home for potential problems and monitor wound healing (see Chart 36-9). The nurse, physical therapist, or occupational therapist assesses the home environment for physical barriers that may impede the patient's rehabilitation. In addition, the nurse or therapist may need to assist the patient in acquiring devices such as reachers and long-handled shoehorns or tongs to help with dressing, or a toilet seat extender to elevate the toilet seat. The home rehabilitation program came be done via telehealth (Eichler, Salzwedel, Rabe, et al., 2019). After successful

surgery and rehabilitation, the patient can expect a hip joint that is free or almost free of pain, has good motion, is stable, and permits normal or near-normal ambulation and function.

Gerontologic Considerations

The older adult patient who has had THA merits special postoperative care considerations. Early THA surgery for hip fractures (within 24 to 36 hours) is recommended for most patients once a medical assessment has been made and the patient's condition has been stabilized appropriately. If there are no contraindications (e.g., history of a bleeding disorder), these patients should receive LMWH for VTE prophylaxis; mechanical devices should be used for patients in whom anticoagulants and antiplatelet agents are contraindicated. Providing an appropriate postoperative analgesic regimen for older adults can be challenging in the presence of impaired cognition, medical comorbidities, and possible drug interactions. Consulting with a pain management specialist to specifically tailor the analgesic type and dose may be helpful (see Chapter 9).

All older adult patients who are post-THA should be placed on a higher-specification, foam pressure-relieving mattress rather than an air-bed hospital mattress (Morris et al., 2018). A major goal following surgery in this patient population is early mobilization, in an effort to prevent the complications associated with prolonged immobility and to return the patient to functional activity (Gabbert et al., 2019). Early assisted mobilization and ambulation on the day of surgery can decrease hospital length of stay, complications, and hospital costs and can prepare patients to care for themselves at home with a higher level of independent functioning. Patients who are assigned to restricted hip precautions have slower rehabilitation and return to usual ADLs (Morris et al., 2018) (see Chapter 37 for general discussion of the Postoperative Care of the Patient Undergoing Orthopedic Surgery). Research suggests that use of a telehealth connection to provide rehabilitation remotely has the same level of outcomes as traditional home physical therapy programs (Eichler et al., 2019). Patients who are assigned to restricted hip precautions have slower rehabilitation and return to usual ADLs (Morris et al., 2018).

Chart 36-9 HOME CARE CHECKLIST

The Patient Who Has Had Orthopedic Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., durable medical equipment, adaptive equipment) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports)
  - Consume a healthy diet to promote wound and bone healing.
  - Observe prescribed weight-bearing and activity limits.
  - Participate in prescribed exercise regimen to promote circulation and mobility.
  - Demonstrate safe use of mobility aid.
- State the name, dose, side effects, frequency, and schedule for all prescribed therapeutic and prophylactic medications (e.g., antibiotics, anticoagulants, analgesic agents).
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- State indicators of wound infections (e.g., redness, swelling, tenderness, purulent drainage, fever).
- State indicators of complications to report promptly to primary provider (e.g., uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of systemic infection; signs of deep vein thrombosis or pulmonary embolism).
- State time and date of follow-up appointments and testing.
- Relate how to reach primary provider with questions or complications.
- State understanding of community resources and referrals as appropriate.
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention, and screening activities.

Resources

See Chapter 2, Chart 2-6 for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Total Knee Arthroplasty

A TKA is considered for patients whose joint pain cannot be managed by nonsurgical treatment and who have severe pain and functional disability related to destruction of joint surfaces by OA, RA, or posttraumatic (osteonecrotic) arthritis. When activity and mobility severely prevent patients from participating in ADLs, TKA is a successful, cost-effective, low-risk therapy that offers significant pain relief and restores quality of life and function (Quinn et al., 2018). If the patient's ligaments have weakened, a fully constrained (hinged) or semi-constrained prosthesis may be used to provide joint stability. Selection of a nonconstrained prosthesis, characterized by components that are not linked, is dependent upon the patient having healthy and functional ligaments to provide joint stability (Quinn et al., 2018).

Nursing Management

Postoperatively, the knee is dressed with a compression bandage. Ice or cold packs may be applied to reduce postoperative swelling and bleeding. The nurse assesses the neurovascular status (movement, sensation, color, pulse, capillary refill) of the surgical extremity and compares it with the contralateral extremity every 2 to 4 hours. It is important to encourage active flexion of the foot every hour when the patient is awake. Postoperative efforts are directed at preventing complications (VTE, peroneal nerve palsy, infection, bleeding, limited range of motion).

Similar to hip surgery, a wound suction drain may be used to remove fluid accumulating in the joint. It is more likely to be used in patients with a body mass index (BMI) over 35 kg/m^2 (Keeney et al., 2019). If a drain is used, it is usually left in place for only 24 to 48 hours to reduce the risk of infection (Keeney et al., 2019). Antibiotics are given prophylactically and continued for 24 hours postoperatively. The color, type, and amount of drainage are documented, and any excessive drainage or change in characteristics of the drainage is promptly reported to the provider.

Research findings suggest that continuous passive motion devices (CPMs) have no influence on functional recovery, drainage, pain, or decreasing adverse outcomes in patient's post-TKA. However, they still may be used by some surgeons.

The physical therapist supervises exercises for strength and range of motion and educates the patient about how to use assistive devices based on

weight-bearing restrictions. The goal is eventual flexion around 125 degrees to allow normal motion at the end of rehabilitation. If satisfactory flexion is not achieved, gentle manipulation of the knee joint under general anesthesia may be necessary about 2 weeks after surgery (Newman, Herschmiller, Attarian, et al., 2018).

Patients who are postoperative for TKA should mobilize and ambulate by the first postoperative day (Quinn et al., 2018). The patient's weight-bearing status is determined by the surgeon. The knee is usually protected with a knee immobilizer and is elevated when the patient sits in a chair. The typical requirements for discharge to home may include evidence of wound stability (e.g., no erythema, discharge, or redness), appropriate anticoagulation status by laboratory results (i.e., international normalized ratio [INR] between 1.5 and 2), progress toward physical therapy goals (e.g., appropriate use of walker), and satisfactory pain control with oral medications.

Acute rehabilitation usually takes about 1 to 2 weeks; length of time and discharge destination (e.g., home, acute rehabilitation unit) depend on the age and tolerance of the patient. If discharge is to home, the patient may undergo physical therapy on an outpatient basis. Total recovery takes 6 weeks or longer, especially for those older than 75 years. Late complications that may occur include **osteolysis** (polyethylene-induced breakdown infection), periprosthetic joint infections, and aseptic loosening of prosthetic components (Mar, Tan, Song, et al., 2019).

More than 82% of patients who have TKA will still have a functioning prosthesis 25 years after surgery (Evans, Walker, Evans, et al., 2019). TKA is a viable option for improving both disease-specific and generic health-related quality of life, especially pain and function, leading to positive patient satisfaction. Patients usually can achieve a pain-free, functional joint and participate more fully in life activities than before the surgery (Quinn et al., 2018). The nurse provides ongoing education and psychosocial support throughout the perioperative period to help facilitate these positive outcomes (see Chart 36-5).

Metabolic Bone Disorders

Osteoporosis

Osteoporosis is the most prevalent bone disease in the world. More than 1.5 million osteoporotic fractures occur every year. Fractures requiring hospitalization have risen significantly over the past two decades (International Osteoporosis Foundation [IOF], 2017). More than 10 million

Americans have osteoporosis, and an additional 33.6 million have **osteopenia** (i.e., low bone mineral density [BMD])—the precursor to osteoporosis (IOF, 2017). The consequence of osteoporosis is bone fracture. It is projected that one of every three women and one of every five men over the age of 50 will have an osteoporosis-related fracture at some point in their lives (IOF, 2017).

Prevention

Peak adult bone mass is achieved between the ages of 18 and 25 years in both women and men and is affected by genetic factors, nutrition, physical activity, medications, endocrine status, and general health (IOF, 2017). Men typically develop larger, heavier bones than women; therefore, they manifest osteoporosis at more advanced ages.

Primary osteoporosis occurs in women after menopause (usually by age 51) but it is not merely a consequence of aging. Failure to develop optimal peak bone mass and low vitamin D levels contribute to the development of osteopenia without associated bone loss (Drezner, 2019). Early identification of at-risk teenagers and young adults, increased calcium and vitamin D intake, participation in regular weight-bearing exercise, and modification of lifestyle (e.g., reduced use of caffeine, tobacco products, carbonated soft drinks, and alcohol) are interventions that decrease the risk of fractures and associated disability later in life (Black, Cauley, Wagman, et al., 2017) (see Chart 36-10).

Secondary osteoporosis is the result of medications or diseases that affect bone metabolism. Men are more likely than women to have secondary causes of osteoporosis, including the use of corticosteroids (especially if they receive doses in excess of 5 mg of prednisone daily for more than 3 months) and excessive alcohol intake. Specific disease states (e.g., celiac disease, hypogonadism) and medications such as anticonvulsants (e.g., phenytoin), thyroid replacement agents (e.g., levothyroxine), antiestrogens (e.g., medroxyprogesterone), androgen inhibitors (e.g., leuprolide), selective serotonin receptor inhibitors (SSRIs; e.g., fluoxetine) and proton pump inhibitors (e.g., esomeprazole) place patients at risk; these diseases and medications need to be identified and therapies instituted to halt the development of osteoporosis (Robinson, 2020). The degree of bone loss is related to the duration of medication therapy. When the drugs are discontinued or the metabolic problem is corrected, the progression is halted but restoration of lost bone mass may not occur.

Chart 36-10 HEALTH PROMOTION

Strategies for Preventing Osteoporosis

Adolescents and Young Adults

- Educate so that they can:
  - Characterize risk factors for osteoporosis.
  - Consume diet with adequate calcium (1000–1300 mg/day) and vitamin D.
  - Engage in weight-bearing exercise daily.
  - Identify calcium- and vitamin D–rich foods.
  - Modify lifestyle choices—avoid smoking, alcohol, caffeine, and carbonated beverages.

Women Who Are Menopausal and Postmenopausal (in addition to above)

- Educate so that they can:
  - Assess home environment for hazards contributing to falls.
  - Demonstrate good body mechanics.
  - Describe appropriate calcium supplements and pharmacologic agents to maintain and enhance bone mass.
  - Engage in exercise that improves balance to reduce risk of falls.
  - Review concurrent medical conditions and medications with primary provider to identify factors that contribute to bone mass loss.

Men (in addition to above)

- Educate so that they can:
  - Characterize risk factors associated with osteoporosis in men, including medications (e.g., corticosteroids, anticonvulsants, aluminum-containing antacids), chronic diseases (e.g., kidney, lung, gastrointestinal), and undiagnosed low testosterone levels.
  - Participate in screening for osteoporosis.
  - Talk with primary provider about the use of medications (e.g., alendronate) to enhance bone mass or to correct testosterone deficiency.

COVID-19 Considerations

An important source of vitamin D is through direct sunlight exposure. The National Osteoporosis Foundation (NOF) and IOF, in collaboration with other relevant stakeholders, have raised concerns that government initiated stay-at-home orders enacted in response to the coronavirus disease 2019

(COVID-19) pandemic may have reduced the amount of time adults were spending outside, potentially limiting exposure to sunlight (American Society for Bone and Mineral Research [ASBMR], 2020). Subsequently, a joint statement was published to reinforce the importance of vitamin D to bone health and highlight current recommendations for vitamin D intake; these include that adults should obtain 15 to 30 minutes of direct skin exposure to sunlight daily, and, when they cannot meet this recommendation, they should consume between 400 to 1000 IU of vitamin D daily through diet or supplements (ASBMR, 2020). Research is ongoing to better understand the relationship between vitamin D and COVID-19 (ASBMR, 2020).

Gerontologic Considerations

The prevalence of osteoporosis in women older than 80 years is 50%. The average 75-year-old woman has lost 25% of her cortical bone and 40% of her trabecular bone. Most residents of long-term care facilities have a low BMD and are at risk for bone fracture. One third of all hip fractures occur among men, and men have a higher mortality rate than women after sustaining a hip fracture (Rapp, Büchele, Dreinhőfer, et al., 2019). It is estimated that the number of hip fractures and their associated costs will at least double by the year 2040 because of the projected aging of the U.S. population.

A fragility fracture is defined as one that occurs when a person falls from their natural height (or less) or with low velocity. Frequently, an underlying disease or metabolic alteration makes the bone more likely to fracture. Osteoporosis and osteopenia are the most frequently cited risks of fragility fractures. The aging of the population, the increased use of medications that contribute to falls risk, and a lack of caregivers contribute to the rising risk of fragility fractures. Inadequate staffing related to a worsening nursing shortage may result in gaps in care that increase the incidence of fragility fractures; decreased staffing may delay nursing assessments and follow-up and increase the likelihood that patients try to get up unsupervised, resulting in falls (Brent, Hommel, Maher, et al., 2018).

Routine vertebral fracture screenings are not recommended for older adults. However, 80% to 90% of these fractures can be seen incidentally on chest x-rays taken for other purposes. It is estimated that only one third of vertebral fractures are diagnosed. Vertebral fracture risk is five times higher among patients who have had prior fractures. Furthermore, 20% of women who are postmenopausal and have a vertebral fracture will have another one within 1 year (Pouresmaeili, Kamalidehghan, Kamerehei, et al., 2018).

Nurses are the team members who frequently are first to uncover vertebral fractures by identifying a change in a patient's height during routine exams conducted in office or clinic settings.

Older adults absorb dietary calcium less efficiently and excrete it more readily through their kidneys. Women who are postmenopausal and older adults need to consume approximately 1200 mg of daily calcium. Quantities larger than this may place patients at heightened risk of renal calculi or cardiovascular disease (United States Preventive Services Task Force [USPSTF], 2018). Though bone density increases with calcium intake, the rate of fractures does not decrease in women who are postmenopausal and who routinely take calcium supplements (Bailey, Zou, Wallace, et al., 2020).

Pathophysiology

Osteoporosis is characterized by reduced bone mass, deterioration of bone matrix, and diminished bone architectural strength. Normal homeostatic bone turnover is altered; the rate of bone resorption that is maintained by osteoclasts is greater than the rate of bone formation that is maintained by osteoblasts, resulting in a reduced total bone mass. The bones become progressively porous, brittle, and fragile. They fracture easily under stresses that would not break normal bone. This occurs most commonly as compression fractures (see Fig. 36-11) of the thoracic and lumbar spine, hip fractures, and Colles fractures of the wrist. These fractures may be the first clinical manifestation of osteoporosis (Black et al., 2017).

Figure 36-11 • Progressive osteoporotic bone loss and compression fractures. Reprinted with permission from Rubin, E., Gorstein, F., Schwarting, R., et al. (2004). *Pathology* (4th ed.). Philadelphia, PA: Wolters Kluwer.

The gradual collapse of a vertebra may be asymptomatic. With the development of kyphosis (i.e., Dowager hump), there is an associated loss of height (see Fig. 36-12). The postural changes result in relaxation of the abdominal muscles and a protruding abdomen. The deformity may also produce pulmonary insufficiency and increase the risk for falls related to balance issues.

Age-related loss begins soon after the peak bone mass is achieved (i.e., in the fourth decade). Calcitonin, which inhibits bone resorption and promotes bone formation, is decreased. Estrogen, which inhibits bone breakdown, also decreases with aging. On the other hand, parathyroid hormone (PTH) increases with aging, thus increasing bone turnover and resorption. The consequence of these changes is net loss of bone mass over time.

The withdrawal of estrogens at menopause or with oophorectomy causes an accelerated bone resorption within the first 5 years after cessation of menses. Most women lose 10% of their bone mass. More than half of all women older than 50 years show evidence of osteopenia (Black et al., 2017; MQIC, 2020).

Risk Factors

Small-framed women are at greatest risk for osteoporosis. In terms of ethnicity, Asian and Caucasian women are at highest risk. Although African American women tend to have higher mineral mass when younger, they are still at risk due to the prevalence of sickle cell and autoimmune diseases in this population. In addition, many African American women also have poor calcium intake due to lactose intolerance (National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMSD], 2018). The use of aromatase inhibitors is an additional risk for women with breast cancer (Robinson, 2020).

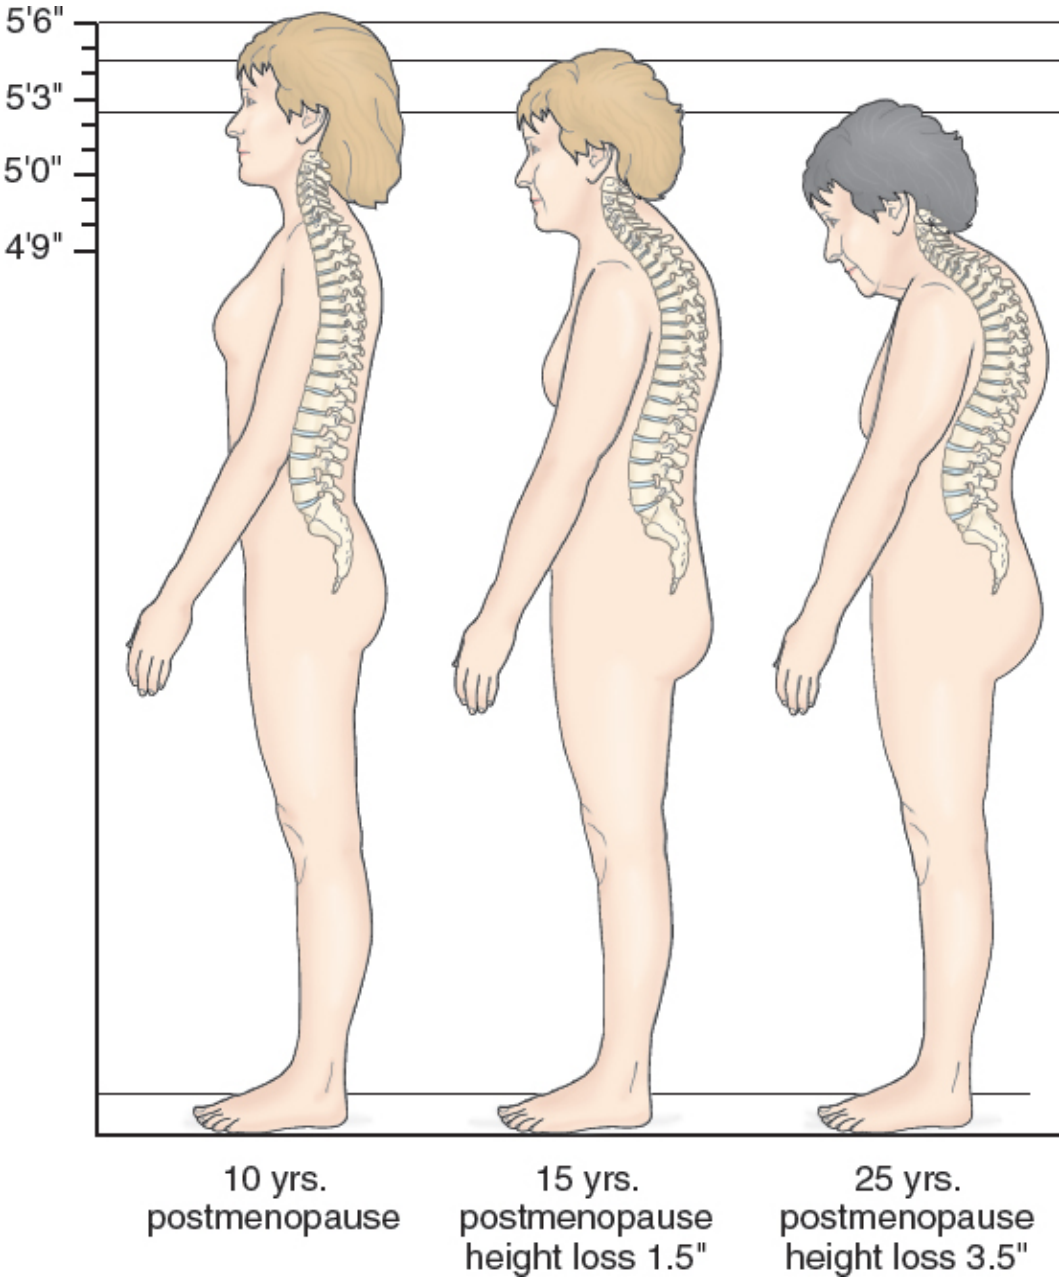

Figure 36-12 • Typical loss of height associated with osteoporosis and aging.

Men have a greater peak bone mass and do not experience a sudden midlife estrogen reduction. As a result, osteoporosis occurs about one decade later, but one in four men still sustain an osteopenic fracture (Pouresmaeili et al., 2018). It is believed that both testosterone and estrogen are important in achieving and maintaining bone mass in men, although the risk profile for men is not as well established as it is for women (Pouresmaeili et al., 2018) (see Chart 36-11).

Nutritional factors contribute to the development of osteoporosis. A diet that includes adequate calories and nutrients needed to maintain

bone, calcium, and vitamin D must be consumed. Patients who have had bariatric surgery are at increased risk for osteoporosis as the duodenum is bypassed, which is the primary site for absorption of calcium. Patients who have gastrointestinal (GI) diseases that cause malabsorption (e.g., celiac disease, alcoholism) may benefit from additional magnesium supplements (Rondanelli, Faliva, Gasparri, et al., 2019). However, in adults who follow a strict gluten free diet, magnesium supplements are currently not recommended.

Autoimmune diseases also contribute to poor bone health. Many of them are associated with nutritional deficiencies (e.g., celiac, autoimmune liver disease). Furthermore, many patients with autoimmune diseases are prescribed corticosteroid medications and, as a consequence of their disease processes, are relatively sedentary. These factors also can cause weak bones (Arase, Tsuruya, Hirose, et al., 2020).

Chart 36-11  **RISK FACTORS**

Osteoporosis

- Alcohol intake of 3 or more drinks daily
- Corticosteroid prescription (e.g., prednisone) for longer than 3 months
- Current use of tobacco products
- Family history
- History of bone fracture during adulthood
- History of impaired glucose tolerance and diabetes
- History of rheumatoid disease
- Inactive or sedentary lifestyle
- Inadequate calcium and vitamin D intake
- Low body mass index
- Malabsorption disorders (e.g., eating disorder, celiac disease, bariatric surgery)
- Men older than 60 years of age
- Women who are postmenopausal

A pilot study to identify modifiable and non-modifiable variables associated with osteopenia and osteoporosis in men. *Orthopaedic Nursing 34*(5), 289–293; International Osteoporosis Foundation. (2017). Retrieved on 3/7/2020 at: www.iofbonehealth.org/facts-statistics; Robinson, M. (2020). Drugs affecting the bones and joints. In T. Woo & M. Robinson (Eds.). *Pharmacotherapeutics for advanced practice prescribers* (5th ed.). Philadelphia, PA: F. A. Davis.

Bone formation is enhanced by the stress of weight and muscle activity. When immobilized by casts, general inactivity, paralysis, or other disability, the bone is resorbed faster than it is formed, and osteoporosis results (McCance & Huether, 2019). Immobility contributes to the development of osteoporosis. Resistance and impact exercises are most beneficial in developing and maintaining bone mass.

Assessment and Diagnostic Findings

Osteoporosis may be undetectable on routine x-rays until there has been significant demineralization, resulting in radiolucency of the bones (Black et al., 2017). When the vertebrae collapse, causing compression fractures, the thoracic vertebrae become wedge shaped and the lumbar vertebrae become biconcave. Osteoporosis is diagnosed by dual-energy x-ray absorptiometry (DEXA), which provides information about BMD at the spine and hip (see Chapter 35). The DEXA scan data are analyzed and

reported as T-scores (the number of standard deviations above or below the average BMD value for a 30-year-old healthy adult of the same sex).

Baseline DEXA testing is recommended for all women older than 65 years, for women who are postmenopausal older than 50 years with osteoporosis risk factors, and for all people who have had a fracture thought to occur as a consequence of osteoporosis (Black et al., 2017). BMD studies are also useful in assessing response to therapy and are recommended 3 months post any osteoporotic fracture. There is no evidence to support basic screening of men younger than 70 years of age or to determine the optimal time interval to repeat studies in either gender following a normal baseline report (USPSTF, 2019).

Female fracture risk can be estimated using the World Health Organization (WHO) Fracture Risk Assessment Tool (FRAX) (Cass, Shepard, Asirot, et al., 2016). These FRAX tables typically underestimate the bone loss risk in men. The Male Osteoporosis Risk Estimation Score (MORES) generates a more gender-specific evaluation than the standard FRAX score in men. Treatment for both genders is now reserved for those with a 10-year risk of more than 3% for hip fracture or 20% risk for other major fractures. Risk scores are based on BMD, personal and family history of fractures, BMI, gender, age, and secondary factors such as medication use, smoking, and history of rheumatoid disease. Impaired glucose tolerance and diabetes are now also recognized as additional risk factors (Robinson, 2020).

Laboratory studies (e.g., serum calcium, serum phosphate, serum alkaline phosphatase [ALP], urine calcium excretion, urinary hydroxyproline excretion, hematocrit, erythrocyte sedimentation rate [ESR]), and x-ray studies are used to exclude other possible disorders (e.g., multiple myeloma, osteomalacia, hyperparathyroidism, malignancy) that contribute to bone loss. In men, low testosterone levels may be part of the cause.

Medical Management

A diet rich in calcium and vitamin D throughout life, with an increased calcium intake during adolescence and the middle years, protects against skeletal demineralization. Such a diet includes three glasses of skimmed vitamin D–enriched milk or other foods high in calcium (e.g., cheese and other dairy products, steamed broccoli, canned salmon with bones) daily. A cup of milk or calcium-fortified orange juice contains about 300 mg of calcium. The recommended adequate intake level of calcium for men 50 to 70 years is 1000 mg daily, and for women aged 51 and older and men aged 71 and older is 1200 mg daily (USPSTF, 2018). Some researchers are challenging these levels as too low for patients with low baseline values,

while others express concern of administering higher dosages, noting that they are associated with adverse events (e.g., renal calculi). The recommended vitamin D intake for most adults, which can be acquired from food or supplements, is between 400 and 1000 IU daily; however optimal vitamin D intake is influenced by a patient's age and sex (ASBMR, 2020).

Regular weight-bearing exercise promotes bone formation. Recommendations include 20 to 30 minutes of aerobic, bone-stressing exercise daily (e.g., not swimming). Weight training stimulates an increase in BMD. In addition, exercise improves balance, reducing the incidence of falls and fractures. Women who are postmenopausal and men aged 50 and older should be advised to avoid excessive intake of alcohol. Those who use tobacco products should be advised to quit. However, additional research is needed to better understand the relationship between smoking and bone health (Strozyk, Gress, & Brietling, 2018). Current guidelines recommend that hormone therapy with estrogen not be used for primary prevention of bone loss in women who are postmenopausal (USPSTF, 2017).

Pharmacologic Therapy

To ensure adequate calcium intake, a calcium supplement with vitamin D may be prescribed and taken with meals or with a beverage high in vitamin C to promote absorption. The recommended daily dose should be split and not taken as a single dose (Drezner, 2019). Common side effects of calcium supplements are abdominal distention and constipation. Calcium from foods is better absorbed, but calcium supplements may be necessary for patients who are lactose intolerant. Meta-analysis findings demonstrate that vitamin D taken alone is not effective in primary prevention of fractures. However, vitamin D plus calcium does reduce the risk of fractures in patients who are found to be vitamin D deficient by laboratory testing (USPSTF, 2018). Calcium and vitamin D should be taken as supplements to drugs prescribed to treat osteoporosis. These types of drugs include bisphosphonates, estrogen agonist/antagonists, and receptor activator of nuclear factor kappa-B ligand (RANKL) inhibitors (see Table 36-1). Salmon egg based PTH is no longer a therapy, but synthetic human PTH analogues are used in patients with advanced osteoporosis or who are treatment resistant (Robinson, 2020).

TABLE 36-1  Select Osteoporosis Medications

Medication	Therapeutic Effects and Indications	Key Nursing Considerations
Bisphosphonates	Inhibit osteoclasts, causing decreased bone loss and increased bone mass	Adequate calcium and vitamin D intake is needed to assure maximum effect; however, these supplements should not be taken at the same time as the bisphosphonates Side effects include gastrointestinal symptoms, including dyspepsia, nausea, flatulence, diarrhea, and constipation Adverse effects may include esophageal or gastric ulcers, osteonecrosis of the jaw, and atypical femur fractures; these effects may be mitigated by instituting a 1–2 yr drug-free holiday in patients with mild osteoporosis after 4–5 yrs of treatment, and in patients with higher fracture risk after 10 yrs of treatment
Alendronate Risedronate	• Treatment of osteoporosis in women who are postmenopausal • Treatment of osteoporosis in men, and in women and men taking corticosteroids	Administer PO, either daily or weekly Advise patient to take in AM on empty stomach with 250 mL of water while sitting upright and to remain upright for at least 30 min Effects of alendronate may be diminished in older adult patients who take proton pump inhibitors
Ibandronate	• Treatment of osteoporosis in women who are postmenopausal • IV dosing may be good option for patients either intolerant of PO bisphosphonates or nonadherent to prescribed therapy	May be given PO monthly or IV every 3 mo
Zoledronic acid		Administer IV once yearly for

	• Treatment of osteoporosis in women who are postmenopausal • Treatment of osteoporosis in men and in both men and women taking corticosteroids for at least 12 mo	osteoporosis treatment or once every 2 yrs for osteoporosis prevention This is the most potent bisphosphonate and is associated with acute kidney injury; therefore it is contraindicated in patients with creatinine clearances less than 35 mL/min or in patients with chronic kidney disease
Estrogen Agonist/Antagonist (formerly called selective estrogen receptor modulator [SERM]) Raloxifene	Promotes estrogenic effects on bone, preserving BMD, with concomitant antiestrogenic effects on the uterus and breasts • Prevention and treatment of osteoporosis in women who are postmenopausal, particularly those with breast cancer • May also reduce the risk of breast cancer in patients at risk	Administer PO once daily. May be given in tandem with calcium and vitamin D Side effects include hot flashes and leg cramps Adverse effects include VTE formation
RANKL Inhibitor Denosumab	Monoclonal antibody that increases BMD and reduces the porosity of cortical bone by inhibiting the effects of TNF on osteoclasts, inhibiting their activity • Treatment of osteoporosis in men and women who are postmenopausal at high risk of fracture; also indicated for women with osteoporosis and breast cancer receiving aromatase inhibitors and for men with osteoporosis and prostate cancer receiving	Given once every 6 mo SQ Side effects include skin rashes Adverse effects include hypocalcemia, cellulitis, osteonecrosis of the jaw, and atypical femur fracture Note: when treatment with denosumab is stopped, loss of BMD can be rapid; other drugs should be started to mitigate this response

	gonadotropin-reducing hormones	
PTH Analogue Teriparatide	Synthetic parathyroid hormone which increases bone strength and density • Treatment of osteoporosis in men and women who are postmenopausal at high risk of fracture	Must be refrigerated Daily self-administered SQ injections for up to 2 yrs

BMD, bone mineral density; IV, intravenously; PO, orally; PTH, parathyroid hormone; SQ, subcutaneous; TNF, tissue necrosis factor; VTE, venous thromboembolism.
Adapted from International Osteoporosis Foundation. (2017). Retrieved on 3/7/2020 at: www.iofbonehealth.org/facts-statistics; Robinson, M. (2020). Drugs affecting the bones and joints. In T. Woo, & M. Robinson (Eds.). *Pharmacotherapeutics for advanced practice prescribers* (5th ed.). Philadelphia, PA: F. A. Davis.

Bisphosphonate therapy is no longer recommended for patients who only have evidence of osteopenia without reaching the precise DEXA scores that define osteoporosis. These medications must be given on an empty stomach, only with water, and the person must sit upright for at least 30 minutes after ingestion. There are many gastric and esophageal risks, including gastritis, ulceration, and GI bleeding. Contradictions include previously known Barrett esophagus (see Chapter 39), low serum calcium levels, and pregnancy (Robinson, 2020). Atrial fibrillation has been reported after chronic use of these medications. Two rare side effects include osteonecrosis of the jaw (more likely with intravenous [IV] preparations of these medications) and subtrochanteric fractures. Concerns about these rare adverse effects must be addressed to ensure the patient will adhere to the therapeutic plan and take the medication (Robinson, 2020).

Fracture Management

Fractures of the hip that occur as a consequence of osteoporosis are managed surgically by joint replacement or by closed or open reduction with internal fixation (e.g., hip pinning) as described in Chapter 37. Management of Colles fractures is also described in Chapter 37.

Osteoporotic compression fractures of the vertebrae are managed conservatively. Patients with these findings should be referred to an osteoporosis specialist. Most patients who experience these fractures are asymptomatic and do not require acute care management; for those who experience pain, acute care management is indicated as outlined in the following Nursing Process section. Percutaneous vertebroplasty or kyphoplasty (injection of polymethylmethacrylate [PMMA] bone cement

into the fractured vertebra, followed by inflation of a pressurized balloon to restore the shape of the affected vertebra) can provide rapid relief of acute pain and improve quality of life, but might contribute to other complications resulting from alterations in spinal mechanics. These procedures are contraindicated in the presence of infection, multiple old fractures, and certain coagulopathies. The use of vertebroplasty is highly contested in the medical literature (De Leacy, Chandra, Barr, et al., 2020).

NURSING PROCESS

The Patient with a Spontaneous Vertebral Fracture Related to Osteoporosis

Assessment

Recognition of risks and problems associated with osteoporosis form the basis for nursing assessment. The health history focuses on family history, previous fractures, dietary consumption of calcium, exercise patterns, onset of menopause, and the use of certain medications (e.g., corticosteroids), as well as alcohol, smoking, and caffeine intake. Any symptoms the patient is experiencing, such as back pain, constipation, or altered body image, are explored.

Physical examination may disclose localized pain, kyphosis of the thoracic spine, or shortened stature. Problems in mobility and breathing may exist as a result of changes in posture and weakened muscles.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Lack of knowledge about the osteoporotic process and treatment regimen
- Acute pain associated with fracture and muscle spasm
- Risk for constipation associated with immobility or development of ileus (intestinal obstruction)
- Risk for injury: additional fractures associated with osteoporosis

Planning and Goals

The major goals for the patient may include knowledge about osteoporosis and the treatment regimen, relief of pain, improved bowel elimination, and absence of additional fractures.

Nursing Interventions

Promoting Understanding of Osteoporosis and the Treatment Regimen

Patient education focuses on factors influencing the development of osteoporosis, interventions to arrest or slow the process, and measures to relieve symptoms. The nurse emphasizes that people of any age need sufficient calcium, vitamin D, and weight-bearing exercise to slow the progression of osteoporosis (Drezner, 2019). Patient education related to medication therapy as described previously is important. Patients must

understand that having one fracture increases the probability of sustaining another.

Relieving Pain

Relief of back pain resulting from compression fracture may be accomplished by short periods of resting in bed in a supine or side-lying position. The mattress should be supportive. Knee flexion increases comfort by relaxing back muscles. Intermittent local heat and backrubs promote muscle relaxation. The nurse instructs the patient to move the trunk as a unit and to avoid twisting. When the patient is assisted out of bed, a trunk orthosis (e.g., lumbosacral corset) may be worn for temporary support and immobilization, although such a device is frequently uncomfortable and is poorly tolerated by many older adults. The patient gradually resumes activities as pain diminishes.

Improving Bowel Elimination

Constipation is a problem related to immobility and medications. Early institution of a high-fiber diet, increased fluids, and the use of prescribed stool softeners help prevent or minimize constipation. If the vertebral collapse involves the T10–L2 vertebrae, the patient may develop a paralytic ileus. The nurse therefore monitors the patient's intake, bowel sounds, and bowel activity.

Preventing Injury

Physical activity is essential to strengthen muscles, improve balance, prevent disuse atrophy, and retard progressive bone demineralization. Isometric exercises can strengthen trunk muscles. The nurse encourages walking, good body mechanics, and good posture. Daily weight-bearing activity, preferably outdoors in the sunshine to enhance the body's ability to produce vitamin D, is encouraged. Sudden bending, jarring, and strenuous lifting are avoided.

 Gerontologic Considerations. Older adults fall frequently as a result of environmental hazards, diminished senses and cardiovascular responses, and responses to medications. The patient and family need to be included in planning for care and preventive management regimens. For example, the home environment should be assessed for elimination of potential hazards (e.g., scatter rugs, cluttered rooms and stairwells, toys on the floor, pets underfoot). A safe environment can then be created (e.g., well-lighted staircases with secure handrails, grab bars in the bathroom, properly fitting footwear). Adequate nurse–patient ratios are also critical for fall prevention in inpatient settings (Brent et al., 2018).

Evaluation

Expected patient outcomes may include:

1. Acquires knowledge about osteoporosis and the treatment regimen
    a. States relationship of calcium and vitamin D intake and exercise to bone mass
    b. Consumes adequate dietary calcium and vitamin D
    c. Takes prescribed medications, following instructions for administration
    d. Increases level of exercise
    e. Adheres to prescribed screening and monitoring procedures
2. Achieves pain relief
    a. Experiences pain relief at rest
    b. Experiences minimal discomfort during ADLs
    c. Demonstrates diminished tenderness at fracture site
3. Demonstrates usual pattern of bowel elimination
    a. Has active bowel sounds
    b. Reports regular pattern of bowel movements
4. Experiences no new fractures
    a. Maintains good posture
    b. Uses good body mechanics
    c. Engages in weight-bearing exercises (walks daily)
    d. Creates a safe home environment
    e. Accepts assistance and supervision as needed

Osteomalacia

Osteomalacia is a metabolic bone disease characterized by inadequate mineralization of bone. As a result, the skeleton softens and weakens, causing pain, tenderness to touch, bowing of the bones, and pathologic fractures. On physical examination, skeletal deformities (spinal kyphosis and bowed legs) give patients an unusual appearance and a waddling gait. These patients may be uncomfortable with their appearance and are at risk for falls and pathologic fractures, particularly of the distal radius and the proximal femur (McCance & Huether, 2019).

Pathophysiology

The major defect in osteomalacia is a deficiency of activated vitamin D, which promotes calcium absorption from the GI tract and facilitates

mineralization of bone. The supply of calcium and phosphate in the extracellular fluid is low and does not move to calcification sites in bones.

Osteomalacia may result from failed calcium absorption or from excessive loss of calcium from the body (e.g., kidney failure). GI disorders (e.g., celiac disease, chronic biliary tract obstruction, chronic pancreatitis, small bowel resection) in which fats are inadequately absorbed are likely to produce osteomalacia through loss of vitamin D (along with other fat-soluble vitamins) and calcium, the latter being excreted in the feces with fatty acids. In addition, liver and kidney diseases can produce a lack of vitamin D because these are the organs that convert vitamin D to its active form.

Severe renal insufficiency results in acidosis. The body uses available calcium to combat the acidosis, and PTH stimulates the release of skeletal calcium in an attempt to reestablish a physiologic pH. During this continual drain of skeletal calcium, bony fibrosis occurs, and bony cysts form. Chronic glomerulonephritis, obstructive uropathies, and heavy metal poisoning result in a reduced serum phosphate level and demineralization of bone.

Hyperparathyroidism leads to skeletal decalcification and thus to osteomalacia by increasing phosphate excretion in the urine. Prolonged use of anticonvulsant medication (e.g., phenytoin, phenobarbital) poses a risk of osteomalacia, as does insufficient vitamin D (dietary, sunlight).

Osteomalacia that results from malnutrition (deficiency in vitamin D often associated with poor intake of calcium) is a result of poverty, poor dietary habits, and lack of knowledge about nutrition. It occurs most frequently in parts of the world where vitamin D is not added to food, where dietary deficiencies exist, and where sunlight is rare (McCance & Huether, 2019).

Gerontologic Considerations

A nutritious diet is particularly important in older adults. Adequate intake of calcium and vitamin D is promoted. Because sunlight is necessary for synthesizing vitamin D, patients should be encouraged to spend 15 to 30 minutes each day in the sun, if not contraindicated and while avoiding sunburn (ASBMR, 2020). Prevention, identification, and management of osteomalacia in older adults are essential to reduce the incidence of fractures. When osteomalacia is combined with osteoporosis, the risk of fracture increases.

Assessment and Diagnostic Findings

On x-ray studies, generalized demineralization of bone is evident. Studies of the vertebrae may show a compression fracture with indistinct vertebral end plates. Laboratory studies show low serum calcium and phosphorus levels and a moderately elevated ALP. Urine excretion of calcium and creatinine is low. Bone biopsy demonstrates an increased amount of osteoid, a demineralized, cartilaginous bone matrix that is sometimes referred to as prebone.

Medical Management

Physical, psychological, and pharmaceutical measures are used to reduce the patient's discomfort and pain. If the underlying cause of osteomalacia is corrected, the disorder may resolve. If kidney disease prevents activation of absorbed vitamin D, then supplementation requires the activated form (calcitriol). If osteomalacia is caused by malabsorption, increased doses of vitamin D, along with supplemental calcium, are usually prescribed. Exposure to sunlight may be recommended; ultraviolet radiation transforms a cholesterol substance (7-dehydrocholesterol) present in the skin into vitamin D (McCance & Huether, 2019).

If osteomalacia is dietary in origin, the interventions are akin to those discussed previously in the discussion on osteoporosis. Long-term monitoring of the patient is appropriate to ensure stabilization or reversal of osteomalacia. Some persistent orthopedic deformities may need to be treated with braces or surgery (e.g., osteotomy may be performed to correct long bone deformity).

Paget Disease of the Bone

Paget disease (osteitis deformans) is a disorder of localized rapid bone turnover, most commonly affecting the skull, femur, tibia, pelvic bones, and vertebrae. The disease occurs in about 2% to 3% of the population older than 50 years. The incidence is slightly greater in aging men than in women. A family history has been noted, with siblings often developing the disease. The cause of Paget disease is not known (Ralston, Corral-Gudino, Cooper, et al., 2019).

Pathophysiology

In Paget disease, a primary proliferation of osteoclasts occurs, which induces bone resorption. This is followed by a compensatory increase in osteoblastic activity that replaces the bone. As bone turnover continues, a classic mosaic (disorganized) pattern of bone develops. Because the

diseased bone is highly vascularized and structurally weak, pathologic fractures occur. Structural bowing of the legs causes malalignment of the hip, knee, and ankle joints, which contributes to the development of arthritis and back and joint pain (Cundy, 2017).

Clinical Manifestations

Paget disease is insidious. Some patients do not experience symptoms but only have skeletal deformity. The condition is most frequently identified on x-ray studies performed during a workup for another problem. Sclerotic changes and cortical thickening of the long bones occur.

In most patients, skeletal deformity involves the skull. The skull may thicken, and the patient may report that a hat no longer fits. In some cases, the cranium, but not the face, is enlarged. This gives the face a small, triangular appearance. Most patients with skull involvement have impaired hearing from cranial nerve compression and dysfunction. Other cranial nerves may also be similarly affected.

The femurs and tibiae tend to bow, producing a waddling gait. The spine is bent forward and is rigid; the chin rests on the chest. The thorax becomes immobile during respiration. The trunk is flexed on the legs to maintain balance and the arms are bent outward and forward, appearing long in relation to the shortened trunk (McCance & Huether, 2019).

Tenderness and warmth over bones may be noted due to increased bone vascularity. Patients with large, highly vascular lesions may develop high-output cardiac failure due to the increased vascular bed and metabolic demands (McCance & Huether, 2019). The pain is mild to moderate, deep, and aching. It increases with weight bearing. Pain and discomfort may precede skeletal deformities of Paget disease by years and are often wrongly attributed by the patient to old age or arthritis (Cundy, 2017).

Assessment and Diagnostic Findings

Elevated serum ALP concentration and urinary hydroxyproline excretion reflect increased osteoblastic activity. Higher values suggest more active disease. Patients with Paget disease have normal blood calcium levels. X-rays confirm the diagnosis of Paget disease by revealing local areas of demineralization and bone overgrowth in the characteristic mosaic patterns. Bone scans demonstrate the extent of the disease. Bone biopsy may aid in the differential diagnosis with other bone diseases (Cundy, 2017).

Medical Management

Pain usually responds to NSAIDs. Gait problems from bowing of the legs are managed with walking aids, shoe lifts, and physical therapy. Weight is controlled to reduce stress on weakened bones and misaligned joints. Patients who are asymptomatic may be managed with diets adequate in calcium and vitamin D and periodic monitoring.

Fractures, arthritis, and hearing loss are complications of Paget disease. Fractures are managed according to location. Healing occurs if fracture reduction, immobilization, and stability are adequate. Severe degenerative arthritis may require total joint replacement; however, the afflicted "soft" bones do not make ideal surgical sites and are thus prone to complications. Loss of hearing is managed with hearing aids and communication techniques used with people who have hearing impairments (e.g., speech reading, body language) (see Chapter 59).

Pharmacologic Therapy

Patients with moderate to severe disease may benefit from specific antiosteoclastic therapy. These medications reduce bone turnover, reverse the course of the disease, relieve pain, and improve mobility.

Bisphosphonates are the cornerstone of Paget therapy in that they stabilize the rapid bone turnover (Ralston et al., 2019). Their use may not suppress all Paget symptoms, but they reduce serum ALP and urinary hydroxyproline levels. See earlier discussion on bisphosphonates.

Plicamycin, a cytotoxic antibiotic, may be used to control the disease. This medication is reserved for severely affected patients with neurologic compromise and for those whose disease is resistant to other therapy. This medication has dramatic effects on pain reduction and on serum calcium, ALP, and urinary hydroxyproline levels; however, there are significant side effects. It is given by IV infusion; hepatic, kidney, and bone marrow function must be monitored during therapy. Clinical remissions may continue for months after the medication is discontinued.

Gerontologic Considerations

Because Paget disease tends to affect older adults, patients and their families and caregivers should be educated about how to compensate for altered musculoskeletal functioning with an emphasis on the risk of falls. The home environment is assessed for safety to prevent falls and to reduce the risk of fracture. Strategies for coping with a chronic health problem and its effect on quality of life need to be developed. If age-related hearing loss is exacerbated by Paget disease, alternative communication devices (e.g., text

telephone, telecommunication device for the deaf) and home safety alarms may be indicated.

Musculoskeletal Infections

Osteomyelitis

Osteomyelitis is an infection of the bone that results in inflammation, necrosis, and formation of new bone. Osteomyelitis is classified as follows (McCance & Huether, 2019):

- Hematogenous osteomyelitis (i.e., due to bloodborne spread of infection)
- Contiguous-focus osteomyelitis, from contamination from bone surgery (especially with hardware insertion), open fracture, or traumatic injury (e.g., gunshot wound)
- Osteomyelitis with vascular insufficiency, seen most commonly among patients with diabetes and peripheral vascular disease, most commonly affecting the feet

Patients who are at high risk for osteomyelitis include older adults and those who are poorly nourished or obese. Other patients at risk include those with impaired immune systems, those with chronic illnesses (e.g., diabetes, RA), those receiving long-term corticosteroid therapy or immunosuppressive agents, and those who use illicit IV drugs (Lalani & Schmidt, 2019).

Postoperative surgical wound infections typically occur within 30 days after surgery. They are classified as incisional (superficial, located above the deep fascia layer) or deep (involving tissue beneath the deep fascia). If an implant has been used, deep postoperative infections may occur within a year. Osteomyelitis may become chronic and may affect the patient's quality of life.

Pathophysiology

More than 50% of bone infections are caused by *Staphylococcus aureus* and increasingly of the variety that is methicillin resistant (i.e., MRSA) (Lalani & Schmidt, 2019). Surgical site ink markers have been linked to infections by cross contamination between preoperative patients who use their markers; therefore, these items are now considered one patient or one-time use items (Driessche, 2012). Other pathogens include the gram-positive

organisms *streptococci* and *enterococci,* followed by gram-negative bacteria, including *pseudomonas* (Lalani & Schmidt, 2019).

The initial response to infection is inflammation, increased vascularity, and edema. After 2 or 3 days, thrombosis of the local blood vessels occurs, resulting in ischemia with bone necrosis. The infection extends into the medullary cavity and under the periosteum and may spread into adjacent soft tissues and joints. Unless the infective process is treated promptly, a bone abscess forms. The resulting abscess cavity contains **sequestrum** (i.e., dead bone tissue), which does not easily liquefy and drain. Therefore, the cavity cannot collapse and heal, as it does in soft tissue abscesses. New bone growth, the **involucrum**, forms and surrounds the sequestrum. Although healing appears to take place, a chronically infected sequestrum remains and produces recurring abscesses throughout the patient's life. This is referred to as chronic osteomyelitis.

Clinical Manifestations

When the infection is bloodborne, the onset is usually sudden, occurring often with the clinical and laboratory manifestations of sepsis (e.g., chills, high fever, rapid pulse, general malaise). The systemic symptoms at first may overshadow the local signs. As the infection extends through the cortex of the bone, it involves the periosteum and the soft tissues. The infected area becomes painful, swollen, and extremely tender. The patient may describe a constant, pulsating pain that intensifies with movement as a result of the pressure of the collecting purulent material (i.e., pus). When osteomyelitis occurs from spread of adjacent infection or from direct contamination, there are no manifestations of sepsis. The surface area that lies over the infected bone is swollen, warm, painful, and tender to touch. The patient with chronic osteomyelitis presents with a nonhealing ulcer that overlies the infected bone with a connecting sinus that will intermittently and spontaneously drain pus (Lalani & Schmidt, 2019).

Diabetic osteomyelitis can occur without any external wounds. It may present as a nonhealing fracture. Microvascular and macrovascular pathophysiologic changes, along with an impaired immune response by patients with diabetes who have poor glycemic control can exacerbate the spread of infection from other sources. Any foot ulcer more than 2 cm in diameter is highly suspicious for osteomyelitis (Lalani & Schmidt, 2019).

Assessment and Diagnostic Findings

In acute osteomyelitis, early x-ray findings demonstrate soft tissue edema. In about 2 to 3 weeks, areas of periosteal elevation and bone necrosis are

evident. Radioisotope bone scans and MRI help with early definitive diagnosis. Blood studies reveal leukocytosis and an elevated ESR. Wound and blood culture studies are performed, although they are only positive in 50% of cases. Therefore, treatment with antibiotics may be prescribed without isolating the organism and then refined after results are obtained. IV antibiotics and bone biopsies are preferably done prior to starting the antibiotics (Osmon & Tande, 2019).

With chronic osteomyelitis, large, irregular cavities, raised periosteum, sequestrum, or dense bone formations are seen on x-ray. Bone scans may be performed to identify areas of infection. The ESR and the WBC count are usually normal. Anemia, associated with chronic infection, may be evident. Cultures of blood specimens and drainage from the sinus tract are frequently unreliable for isolating the organisms involved. Bone cultures are aspirated through uninfected skin (Lalani & Schmidt, 2019).

Prevention

Prevention of osteomyelitis is the goal. Elective orthopedic surgery should be postponed if the patient has a current infection (e.g., urinary tract infection, sore throat that may suggest a *Streptococcal* infection). During surgery, careful attention is paid to the surgical environment. Prophylactic antibiotics, given to achieve adequate tissue levels at the time of surgery and for 24 hours after surgery, are helpful. Urinary catheters and drains are removed as soon as possible to decrease the incidence of hematogenous spread of infection.

Aseptic postoperative wound care reduces the incidence of superficial infections and osteomyelitis. Prompt management of soft tissue infections reduces extension of infection to the bone or hematogenous spread.

Medical Management

The initial goal of therapy is to control and halt the infective process. General supportive measures (e.g., hydration, diet high in vitamins and protein, correction of anemia) are instituted. The area affected with osteomyelitis is immobilized to decrease discomfort and to prevent pathologic fracture of the weakened bone.

Pharmacologic Therapy

Bone infections are more difficult to eradicate than soft tissue infections because bone is mostly avascular and less accessible to the body's natural immune response. Because there is decreased penetration by medications,

antibiotic therapy is longer term than with other infections; typically, it continues for 6 to 12 weeks. After the infection appears to be controlled, the antibiotic may be given orally. However, there is little evidence to support optimal length of therapy (Li, Romach, Zabellas, et al., 2019).

Surgical Management

If the infection is chronic and does not respond to antibiotic therapy, surgical débridement is indicated. The infected bone is surgically exposed, the purulent and necrotic material is removed, and the area is irrigated with sterile saline solution. A sequestrectomy (removal of enough involucrum to enable the surgeon to remove the sequestrum) is performed. In many cases, sufficient bone is removed to convert a deep cavity into a shallow saucer (saucerization). All dead, infected bone and cartilage must be removed before permanent healing can occur. A closed suction irrigation system may be used to remove debris. Wound irrigation using sterile physiologic saline solution may be performed for extended periods if the debris remains. Typically, irrigation does not need to extend beyond a week.

The wound is either closed tightly to obliterate the dead space or packed and closed later by granulation or possibly by grafting. The débrided cavity may be packed with cancellous bone graft to stimulate healing. With a large defect, the cavity may be filled with a vascularized bone transfer or muscle flap (in which a muscle is moved from an adjacent area with blood supply intact). These microsurgery techniques enhance the blood supply. The improved blood supply facilitates bone healing and eradication of the infection. These surgical procedures may be staged over time to ensure healing. Because surgical débridement weakens the bone, internal fixation or external supportive devices may be needed to stabilize or support the bone to prevent pathologic fracture (Rüschenschmidt, Glombitza, Dahmen, et al., 2019). Original orthopedic hardware may need to be removed.

NURSING PROCESS

The Patient with Osteomyelitis

Assessment

The patient reports an acute onset of signs and symptoms (e.g., localized pain, edema, erythema, fever) or recurrent drainage of an infected sinus with associated pain, edema, and low-grade fever. The nurse assesses the patient for risk factors (e.g., older age, diabetes, long-term corticosteroid therapy) and for a history of previous injury, infection, or orthopedic surgery. The gait may be altered as the patient avoids pressure and movement of the area. In acute hematogenous osteomyelitis, the patient exhibits generalized weakness due to the systemic reaction to the infection.

Physical examination reveals an inflamed, markedly edematous, warm area that is tender. Purulent drainage may be noted. The patient has an elevated temperature. With chronic osteomyelitis, the temperature elevation may be minimal, occurring in the afternoon or evening.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Acute pain associated with inflammation and edema
- Impaired mobility associated with pain, use of immobilization devices, and weight-bearing limitations
- Risk for infection: bone abscess formation
- Lack of knowledge associated with the treatment regimen

Planning and Goals

The patient's goals may include relief of pain, improved physical mobility within therapeutic limitations, control and eradication of infection, and knowledge of the treatment regimen.

Nursing Interventions

Relieving Pain

The affected part may be immobilized with a splint to decrease pain and muscle spasm. The nurse monitors the skin and neurovascular status of the affected extremity. The wounds are frequently very painful, and the extremity must be handled with great care and gentleness. Elevation reduces swelling and associated discomfort. Pain is controlled with prescribed analgesic agents and other pain-reducing techniques.

Improving Physical Mobility

Treatment regimens restrict weight-bearing activity. The bone is weakened by the infective process and must be protected by avoidance of stress on the bone. The patient must understand the rationale for the activity restrictions. The joints above and below the affected part should be gently moved through their range of motion. The nurse encourages full participation in ADLs within the prescribed physical limitations to promote general well-being. Caution around external fixation devices is required (see Chapter 37 for discussion of external fixation devices).

Controlling the Infectious Process

The nurse monitors the patient's response to antibiotic therapy and observes the IV access site for evidence of phlebitis, infection, or infiltration. With long-term, intensive antibiotic therapy, the patient is monitored for signs of superinfection (e.g., oral or vaginal candidiasis, loose or foul-smelling stools). The nurse carefully monitors for the development of additional sites that are painful or for sudden increases in body temperature.

If surgery is necessary, the nurse takes measures to ensure adequate circulation to the affected area (wound suction to prevent fluid accumulation, elevation of the area to promote venous drainage, avoidance of pressure on the grafted area), to maintain needed immobility, and to ensure the patient's adherence to weight-bearing restrictions. Dressings are changed using aseptic technique to promote healing and to prevent cross contamination.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient and family are educated about the importance of strictly adhering to the therapeutic regimen of antibiotics. Patients and families often need to learn to maintain and manage the IV access and IV administration equipment in the home. Education includes the medication name, dosage, frequency, administration rate, safe storage and handling, adverse reactions, and necessary laboratory monitoring. In addition, the nurse provides education on aseptic dressing and warm compression techniques.

Continuing and Transitional Care. The patient must be medically stable and physically able and motivated to adhere strictly to the therapeutic regimen of antibiotic therapy. The transitional care environment needs to be conducive to the promotion of health and to the requirements of the therapeutic regimen.

If warranted, the nurse completes a home assessment to determine the patient's and family's abilities regarding continuation of the therapeutic

regimen. If the patient's support system is questionable or if the patient lives alone, a home health nurse may be needed to assist with IV administration of the antibiotics, monitoring for response to the treatment and evaluation of signs and symptoms of superinfections, and adverse drug reactions. This can also be done via telehealth (Eichler et al., 2019). The nurse stresses the importance of follow-up health care appointments (see Chart 36-12).

Evaluation

Expected patient outcomes may include:

1. Experiences pain relief
    a. Reports decreased pain at rest
    b. Experiences no tenderness at site of previous infection
    c. Experiences minimal discomfort with movement
2. Increases in safe physical mobility
    a. Participates in self-care activities within restrictions
    b. Maintains full function of unimpaired extremities
    c. Demonstrates safe use of immobilizing and assistive devices
    d. Modifies environment to promote safety and to avoid falls
3. Shows absence of infection
    a. Takes antibiotic as prescribed
    b. Reports normal temperature
    c. Exhibits no edema
    d. Reports absence of drainage
    e. Laboratory results indicate normal WBC count and ESR
    f. Wound cultures are negative
4. Adheres to therapeutic plan
    a. Takes medications as prescribed
    b. Protects weakened bones
    c. Demonstrates proper wound care
    d. Reports signs and symptoms of complications promptly
    e. Consumes a healthy diet
    f. Keeps follow-up health care appointments

Chart 36-12 HOME CARE CHECKLIST

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of osteomyelitis on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., durable medical equipment, adaptive equipment) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Consume a healthy diet to promote wound and bone healing.
  - Observe prescribed weight-bearing and activity limits.
  - Demonstrate proper wound care.
  - Demonstrate safe use of ambulatory aids and assistive devices.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Demonstrate accurate and safe administration of medications.
- When indicated, identify the benefits and expected outcomes of intravenous antibiotic therapy and IV access management.
  - Demonstrate how to prepare, infuse, maintain, and clean IV access and equipment.
  - Identify adverse effects of antibiotic therapy and actions to take for adverse effects.
  - Describe to whom, how, and when to report adverse effects.
- Relieve pain with pharmacologic and nonpharmacologic interventions.
- State indicators of wound infections (e.g., redness, swelling, tenderness, purulent drainage, fever) and systemic infection (e.g., fever, chills, rapid pulse, general malaise) to report promptly to primary provider.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up appointments and testing.
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention,

and screening activities.

Resources

See Chapter 2, Chart 2-6 for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living; IV, intravenous.

Septic (Infectious) Arthritis

Joints can become infected through spread of pathogens from other parts of the body (hematogenous spread) or directly through trauma, injection, or surgical instrumentation, causing septic arthritis. People at greatest risk include older adults, particularly those older than 80 years; people with comorbid conditions such as diabetes, RA, skin infection, or alcoholism; and people with a history of a joint replacement or other joint surgery or IV drug abuse. *S. aureus* is the most common cause of joint infections in all age groups, followed by other gram-positive bacteria, including streptococci. Gonococcal infection may cause septic arthritis through hematogenous spread. *Pseudomonas aeruginosa* is a commonly implicated pathogen in those who use illicit IV drugs (Goldenberg & Sexton, 2019).

Single knee or hip joints are most commonly infected in patients with septic arthritis, although up to 20% of cases involve more than one joint (i.e., polyarticular disease). Prompt recognition and treatment of an infected joint are important because accumulating purulent material may result in chondrolysis (destruction of hyaline cartilage), and continued hematogenous spread may lead to sepsis and death. See Chapter 11 for further discussion of sepsis. The overall mortality rate for single joint infections is about 11%, but it approaches 50% in patients with polyarticular disease or in those who are immunocompromised (Oh, Wurcel, Tybor, et al., 2018).

Clinical Manifestations

The patient with acute septic arthritis presents with a warm, painful, swollen joint with decreased range of motion. Systemic chills, fever, and leukocytosis are sometimes present. Fever may not occur in older patients. Although any joint may be infected, approximately half of all cases involve a knee (Goldenberg & Sexton, 2019).

Assessment and Diagnostic Findings

An assessment for the source and cause of infection is performed. Diagnostic studies include aspiration, examination, and culture of the synovial fluid. Computed tomography (CT) and MRI scans may reveal damage to the joint lining. Radioisotope scanning may be useful in localizing the infectious process. There may not be any external wound or reported recent trauma.

Medical Management

Prompt treatment is essential and may save the prosthesis for patients who have had joint replacement surgery or may prevent sepsis. Broad-spectrum IV antibiotics are started promptly and then changed to organism-specific antibiotics after culture results are available (Goldenberg & Sexton, 2019). The IV antibiotics are continued until symptoms resolve. The synovial fluid is aspirated and analyzed periodically for sterility and decrease in WBCs.

Aspiration of the joint with a needle to remove excessive joint fluid, exudate, and debris promotes comfort and decreases joint destruction caused by the action of proteolytic enzymes in the purulent fluid. Arthrotomy or arthroscopy is used to drain the joint and remove dead tissue (Oh et al., 2018).

The inflamed joint is supported and immobilized in a functional position by a splint that increases the patient's comfort. Analgesic agents are prescribed to relieve pain. The patient's nutrition and fluid status is monitored. Progressive range-of-motion exercises are prescribed as soon as the patient can begin movement without exacerbating symptoms of acute pain. If septic joints are treated promptly, recovery of normal function is expected. If the articular cartilage was damaged during the inflammatory reaction, joint fibrosis and diminished function may result. The patient is assessed periodically for recurrence over the next year.

Nursing Management

The nurse educates the patient and family about the septic arthritis physiologic process and explains the importance of supporting the affected joint, adhering to the prescribed antibiotic regimen, inspecting the skin under any splints that may be prescribed, and observing weight-bearing and activity restrictions. The patient must understand that recurrence of infection in the near and far future is possible and is educated about signs and symptoms to observe and report to the primary provider. The same

interventions used for the patient with osteomyelitis are planned for the patient with septic arthritis. See previous discussion.

Bone Tumors

Neoplasms of the musculoskeletal system are of various types, including osteogenic, chondrogenic, fibrogenic, muscle (rhabdomyogenic), and marrow (reticulum) cell tumors as well as nerve, vascular and fatty cell tumors. They may be primary tumors or metastatic tumors from cancers elsewhere in the body (e.g., breast, lung, prostate, kidney).

Benign Bone Tumors

Benign tumors of the bone and soft tissue are more common than malignant primary bone tumors. Benign bone tumors generally are slow growing, well circumscribed, and encapsulated; present few symptoms; and are not a cause of death. Benign masses include osteochondroma, enchondroma, bone cysts, osteoid osteoma, rhabdomyoma, and fibroma. Some benign tumors have the potential to become malignant.

Osteochondroma is the most common benign bone tumor. It usually occurs as a large projection of bone at the end of long bones (at the knee or shoulder), developing during growth. It then becomes a static bony mass. In fewer than 1% of patients, the cartilage cap of the osteochondroma may undergo malignant transformation after trauma, and a chondrosarcoma or osteosarcoma may develop (Czerniak, 2016).

Bone cysts are expanding lesions within the bone. Aneurysmal (widening) bone cysts are seen in young adults, who present with a painful, palpable mass of the long bones, vertebrae, or flat bone. Unicameral (single cavity) bone cysts occur more often in the first two decades of life and cause mild discomfort and possible pathologic fractures of the upper humerus and femur, which may heal spontaneously.

An osteoid osteoma is a painful tumor that occurs in children and young adults. The neoplastic tissue is surrounded by reactive bone formation that can be identified by x-ray. Enchondroma is a common tumor of the hyaline cartilage that develops in the hand, femur, tibia, or humerus. Usually, the only symptom is a mild ache. Pathologic fractures may occur in both types of tumors.

Giant cell tumors (osteoclastomas) are benign for long periods but may invade local tissue and cause destruction. They occur in young adults and are soft and hemorrhagic. Eventually, giant cell tumors may undergo malignant transformation and metastasize (Czerniak, 2016).

Malignant Bone Tumors

Primary malignant musculoskeletal tumors are relatively rare and arise from connective and supportive tissue cells (sarcomas) or bone marrow elements (multiple myeloma; see Chapter 30). Malignant primary musculoskeletal tumors include osteosarcoma, chondrosarcoma, Ewing sarcoma, and fibrosarcoma. Soft tissue sarcomas include liposarcoma, fibrosarcoma of soft tissue, and rhabdomyosarcoma. Bone tumor metastasis to the lungs is common (Davis, James, & Saifuddin, 2015).

Osteosarcoma is the most common and most often fatal primary malignant bone tumor. Prognosis depends on whether the tumor has metastasized to the lungs at the time the patient seeks health care. It appears most frequently in children, adolescents and young adults (in bones that grow rapidly), in older adults with Paget disease of the bone, and in people with a prior history of radiation exposure. Clinical manifestations typically include localized bone pain that may be accompanied by a tender, palpable soft tissue mass. The primary lesion may involve any bone, but the most common sites are the distal femur, the proximal tibia, and the proximal humerus.

Malignant tumors of the hyaline cartilage are called *chondrosarcomas.* These tumors are the second most common primary malignant bone tumors affecting middle aged and older adults (Hornicek, 2019). They may grow and metastasize slowly or very fast, depending on the characteristics of the tumor cells involved (i.e., grade). Patients with low-grade chondrosarcomas tend to have a much better prognosis than those with high-grade chondrosarcomas. See Chapter 12 for a discussion of tumor grades. The usual tumor sites include the pelvis, femur, humerus, spine, scapula, and tibia. Metastasis to the lungs occurs in fewer than half of patients. These tumors may recur after excision.

Metastatic Bone Disease

Metastatic bone disease (secondary bone tumor) is more common than primary bone tumors (Mu, Shen, Liang, et al., 2018). Tumors arising from tissues elsewhere in the body may invade the bone and produce localized bone destruction (lytic lesions) or bone overgrowth (blastic lesions). The most common primary sites of tumors that metastasize to bone are the kidney, prostate, lung, breast, ovary, and thyroid (Mu et al., 2018). Metastatic tumors are most frequently found in the skull, spine, pelvis, femur, and humerus and often involve more than one bone (polyostotic).

Pathophysiology

A tumor in the bone causes the normal bone tissue to react by osteolytic response (bone destruction) or osteoblastic response (bone formation). Adjacent normal bone responds to the tumor by altering its normal pattern of remodeling. The bone's surface changes, and the contours enlarge in the tumor area.

Malignant bone tumors invade and destroy adjacent bone tissue (Mu et al., 2018). Benign bone tumors, in contrast, have a symmetric, controlled growth pattern and place pressure on adjacent bone tissue. Malignant bone tumors invade and weaken the structure of the bone until it can no longer withstand the stress of ordinary use; pathologic fracture commonly results.

Clinical Manifestations

Patients with metastatic bone tumor may have a wide range of associated clinical manifestations. They may be symptom free or have pain that ranges from mild and occasional to constant and severe, varying degrees of disability, and, at times, obvious bone growth. Weight loss, malaise, and fever may be present. The tumor may be diagnosed only after pathologic fractures occur or as an incidental finding.

With spinal metastasis, spinal cord compression may occur. It can progress rapidly or slowly. Neurologic deficits (e.g., progressive pain, weakness, gait abnormality, paresthesia, paraplegia, urinary retention, loss of bowel or bladder control) must be identified early and treated with decompression laminectomy to prevent permanent spinal cord injury.

Assessment and Diagnostic Findings

The differential diagnosis is based on the history, physical examination, and diagnostic studies, including CT, myelography, arteriography, MRI, biopsy, and biochemical assays of the blood and urine. General bone scans lack specificity. Positron emission tomography (PET) scans, although more expensive than other diagnostic tests, are assuming a larger role in whole body surveys after the initial diagnosis (Hornicek, 2019). PET scans generate images of the metabolic activity of cells and highlight metastatic bone disease when an increase uptake of radioactive substances is noted. A surgical or core needle biopsy is performed for histologic identification. Extreme care is taken during the biopsy to prevent seeding and resultant recurrence after excision of the tumor. Chest x-rays are performed to determine the presence of lung metastasis. Surgical staging of musculoskeletal tumors is based on tumor grade and site (intra- or extracompartmental), as well as on metastasis. Staging is used for planning treatment (see Chapter 12).

Serum ALP levels are frequently elevated with osteogenic sarcoma or bone metastasis. Hypercalcemia is also present with bone metastases from breast, lung, or kidney cancer. Symptoms of hypercalcemia include muscle weakness, fatigue, anorexia, nausea, vomiting, polyuria, cardiac arrhythmias, seizures, and coma. Hypercalcemia must be identified and treated promptly.

During the diagnostic period, the nurse explains the diagnostic tests and provides psychological and emotional support to the patient and family. The nurse assesses coping behaviors and encourages the use of support systems. Because the terminology associated with benign and malignant growths sound similar, the nurse can clarify the meaning of these in terms of treatment and prognosis and may allay fears.

Medical Management

Primary Bone Tumors

The goal of primary bone tumor treatment is to destroy or remove the tumor rapidly. This may be accomplished by surgical excision, radiation therapy if the tumor is radiosensitive, and chemotherapy for possible micrometastases. Survival and quality of life are important considerations in procedures that attempt to save the involved extremity; however, surgical removal of the tumor may require amputation of the affected extremity, with the amputation extending well above the tumor to achieve local control of the primary lesion (see Chapter 37).

If possible, limb-sparing (salvage) procedures are used to remove the tumor and adjacent tissue. A customized prosthesis, total joint arthroplasty, or bone tissue from the patient (autograft) or from a cadaver donor (allograft) replaces the resected tissue. Soft tissue and blood vessels may need grafting because of the extent of the excision. Complications may include infection, loosening or dislocation of the prosthesis, allograft nonunion, fracture, devitalization of the skin and soft tissues, joint fibrosis, and recurrence of the tumor.

Because of the danger of metastasis with malignant bone tumors, chemotherapy is started before and continued after surgery in an effort to eradicate micrometastatic lesions. The goal of combined chemotherapy is greater therapeutic effect at a lower toxicity rate with reduced resistance to the medications. Soft tissue sarcomas are treated with radiation, limb-sparing excision, and adjuvant chemotherapy (see Chapter 12).

Secondary Bone Tumors

The treatment of advanced metastatic bone cancer is palliative. The therapeutic goal is to relieve the patient's pain and discomfort while promoting quality of life. If the bone is weakened, structural support and stabilization are needed to prevent pathologic fracture. Bones are strengthened by prophylactic internal fixation, arthroplasty, or PMMA (bone cement) reconstruction. Patients with metastatic disease are at higher risk than other patients for postoperative pulmonary congestion, hypoxemia, VTE, and hemorrhage.

Hematopoiesis is frequently disrupted by tumor invasion of the bone marrow or by treatment (chemotherapy, surgery, or radiation). Blood component therapy restores hematologic factors. Additional therapies may be used to treat the original cancer. Radiation, chemotherapy, and hormonal therapy may also be effective in promoting healing of osteolytic lesions (see Chapter 12). Bisphosphonates are effective in stabilizing bone and may prevent cancer spread, as are the RANKL drugs (see Table 36-1).

Nursing Management

The nurse asks the patient about the onset and course of symptoms. During the interview, the nurse assesses the patient's understanding of the disease process, how the patient and the family have been coping, and how the patient has managed the pain. Palpation of the mass is limited to decrease any potential seeding process. The mass size and associated soft tissue swelling, pain, and tenderness are noted. Assessment of the neurovascular status and range of motion of the extremity provides baseline data for future comparisons. Evaluation of the patient's mobility and ability to perform ADLs is also documented.

The nursing care of a patient who has undergone excision of a bone tumor is similar to that of other patients who have had skeletal surgery. Explanation of diagnostic tests, treatments (e.g., wound care), and expected results (e.g., decreased range of motion, numbness, change of body contours) helps the patient deal with the procedures and changes and adhere to the therapeutic regimen. The nurse can most effectively reinforce and clarify information provided by the surgeon by being present during these discussions.

Pain can result from multiple factors. Oncology-associated bone pain is recognized as difficult to control. Pain must be assessed accurately and managed with adequate interventions. External-beam radiation to involved metastatic sites may be used. Patients with multiple bony metastases may achieve pain control with systemically given "bone-seeking" isotopes (e.g., strontium 89). (See Chapter 9 for more information about pain management.)

Bone tumors weaken the bone to a point at which normal activities or even position changes can result in fracture. During nursing care, the affected extremities must be supported and handled gently. External supports (e.g., splints) may be used for additional protection. Surgery (e.g., open reduction with internal fixation, joint replacement) may be done in an attempt to prevent pathologic fracture. Prescribed weight-bearing restrictions must be followed. The nurse and physical therapist must educate the patient about using assistive devices safely and strengthening unaffected extremities.

The nurse encourages the patient and family to verbalize their fears, concerns, and feelings. They need to be supported as they deal with the impact of the malignant bone tumor. Referral to a psychiatric advanced practice nurse, psychologist, counselor, or spiritual advisor may be indicated for specific psychological help and emotional support.

Monitoring and Managing Potential Complications

Delayed Wound Healing

Wound healing may be delayed because of tissue trauma from surgery, previous radiation therapy, inadequate nutrition, or infection. The nurse minimizes pressure on the wound site to promote circulation to the tissues. An aseptic, nontraumatic wound dressing promotes healing. Monitoring and reporting of laboratory findings facilitate initiation of interventions to promote homeostasis and wound healing.

Repositioning the patient at frequent intervals reduces the incidence of skin breakdown and pressure injuries. Special therapeutic beds or mattresses may be needed to prevent skin breakdown and to promote wound healing after extensive surgical reconstruction and skin grafting.

Inadequate nutrition impairs healing as well. Antiemetic agents and relaxation techniques reduce the adverse GI effects of chemotherapy. Stomatitis is controlled with anesthetic or antifungal mouthwash (see Chapter 12). Adequate hydration is essential. Nutritional supplements or parenteral nutrition may be prescribed to achieve adequate nutrition.

Osteomyelitis and Wound Infections

Prophylactic antibiotics and strict aseptic dressing techniques are used to diminish the occurrence of osteomyelitis and wound infections. During healing, other infections (e.g., upper respiratory infections) need to be prevented so that healing efforts are not divided between the cancer and the new, acute process. If the patient is receiving chemotherapy, the nurse monitors the WBC count and instructs the patient to avoid contact with people who have colds or other infections.

Hypercalcemia

Hypercalcemia is a dangerous complication of bone cancer or any process involved with breakdown of bone. Symptoms include muscular weakness, incoordination, anorexia, nausea and vomiting, constipation, electrocardiographic changes (e.g., shortened QT interval and ST segment, bradycardia, heart blocks), and altered mental states (e.g., confusion, lethargy, psychotic behavior). Treatment includes hydration with IV administration of normal saline solution, diuresis, mobilization, and medications such as IV bisphosphonates (e.g., zoledronic acid). Because inactivity leads to additional loss of bone mass and increased calcium in the blood, the nurse assists the patient to increase activity and ambulation. Denosumab may be prescribed if the calcium levels are not responsive to the IV bisphosphonates (see Table 36-1). See Chapters 10 and 12 for further discussion of hypercalcemia and its management.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Preparation for and coordination of continuing health care are begun early as a multidisciplinary effort. Patient education addresses medication, dressing changes, treatment regimens, and the importance of physical and occupational therapy programs. The nurse educates the patient about weight-bearing limitations and special handling to prevent pathologic fractures. The patient and family must be educated about the signs and symptoms of possible complications as well as resources available for continuing care (see Chart 36-13).

Continuing and Transitional Care

Arrangements may be made for home, community-based, or transitional care. A home visit allows the nurse to assess the patient's and family's abilities to meet the patient's needs and determine whether other services are needed. The nurse advises the patient to have telephone numbers readily available so that providers can be contacted in case concerns arise.

The nurse emphasizes the need for long-term health monitoring to ensure cure or to detect tumor recurrence or metastasis and the need for recommended health screening. If the patient has metastatic disease, end-of-life issues may need to be explored. Referrals for hospice and palliative care are made if appropriate.

Chart 36-13  HOME CARE CHECKLIST

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the bone tumor growth process and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., durable medical equipment, wound care/dressings, adaptive equipment, ADL assistance) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Describe ongoing therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Consume a healthy diet to promote healing and health.
  - State weight-bearing and activity restrictions.
  - Support affected musculoskeletal area, position to decrease risk of skin breakdown.
  - Demonstrate safe use of ambulatory aids and assistive devices.
  - Engage in exercise that improves balance to reduce risk of falls.
- State the name, dose, side effects, frequency, and schedule for all prescribed therapeutic and prophylactic medications (e.g., antibiotics, analgesic agents).
- Control pain with pharmacologic and nonpharmacologic interventions.
- State indicators of complications to report promptly to the provider such as:
  - Wound infection/delayed wound healing (e.g., redness, swelling, tenderness, purulent drainage, fever).
  - Osteomyelitis (e.g., localized pain, edema, erythema, fever).
  - Hypercalcemia (e.g., muscular weakness, anorexia, decreased coordination, nausea, vomiting, constipation).
- Relate how to reach the primary provider with questions or complications.
- State time and date of follow-up appointments, therapy, and testing.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify the contact details for support services for patients and their caregivers/families.

- Identify the need for health promotion, disease prevention, and screening activities.

Resources

See Chapter 2, Chart 2-6 for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

CRITICAL THINKING EXERCISES

1 ebp A patient is being scheduled for a total knee arthroplasty. He shares with you that many years ago his mother had a total hip arthroplasty and experienced ongoing issues related to pain and infection. He is concerned that he may also experience postoperative complications. He asks you to explain to him common complications and how they can be prevented. What evidence-based practice guidelines support your patient education? Explain the strength of the evidence that supports various nursing interventions to prevent infection and venous thromboembolism and to promote improved physical mobility.

2 pq You work as a nurse at a college's student health center. A student presents to the health center after a very busy final exam schedule and end of semester paper writing session. She is a varsity basketball player and is having issues with grabbing the ball. In the past, she has had episodes where she "jammed" a finger playing basketball, but this has not occurred recently. She is complaining of severe wrist pain and numbness in her fingers. Describe the priority assessment process that you would follow when you examine her hands. What is the expected care for a possible carpel tunnel disorder and how would you prioritize nursing interventions?

3 ipc A patient with a history of profound deafness, poor nutritional habits, and a significantly increased body mass index is status post total knee arthroplasty. The patient lives on the second floor of an apartment building. Develop an interprofessional plan of care that addresses the patient's care needs, both during hospitalization and upon discharge.

37 Management of Patients with Musculoskeletal Trauma

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Differentiate between contusions, strains, sprains, dislocations, and subluxations.
2. Identify the clinical manifestations, common treatment modalities, complications, and rehabilitation needs of patients with common types of fractures.
3. Describe the nursing management including the health education needs of the patient with a cast, splint, or brace, or who is in traction.
4. Use the nursing process as a framework for care of the older adult patient with a fracture of the hip.
5. Recognize sports- and occupation-related musculoskeletal disorders and their signs, symptoms, and treatments.
6. Apply the nursing process as a framework for care of the patient with an amputation.

NURSING CONCEPTS

Mobility
Tissue Integrity

GLOSSARY

allograft: tissue harvested from a donor for use in another person

amputation: removal of a body part, usually a limb or part of a limb

arthroscope: surgical scope inserted into a joint to examine or repair

autograft: tissue harvested from one area of the body and used for transplantation to another area of the same body

avascular necrosis (AVN): death of tissue secondary to a decrease or lack of perfusion; also called osteonecrosis

brace: externally applied device to support the body or a body part, control movement, and prevent injury

cast: rigid external immobilizing device molded to contours of body part

contusion: blunt force injury to soft tissue (*synonym:* bruise)

crepitus: a grating sound or sensation made by rubbing bony fragments together

débridement: surgical removal of contaminated and devitalized tissues and foreign material

delayed union: prolongation of expected healing time for a fracture

disarticulation: amputation through a joint

dislocation: complete separation of joint surfaces

external fixator: external metal frame attached to bone fragments to stabilize them

fracture: a break in the continuity of a bone

fracture reduction: restoration of fracture fragments into anatomic alignment

heterotopic ossification: misplaced formation of bone

malunion: healing of a fractured bone in a malaligned position

neurovascular status: assessment of the neurologic (motor and sensory components) and circulatory functioning of a body part

nonunion: failure of fractured bones to heal together

osteomyelitis: infection of the bone

paresthesia: an abnormal sensation of tingling or numbness or burning

phantom limb pain: pain perceived in an amputated section

RICE: acronym for *r*est, *i*ce, *c*ompression, *e*levation

sling: bandage used to support an arm

splint: device designed specifically to support and immobilize a body part in a desired position

sprain: an injury to ligaments and muscles and other soft tissues at a joint

strain: a musculotendinous stress injury

subluxation: partial separation of joint surfaces

traction: application of a pulling force to a part of the body
trapeze: overhead assistive device to promote patient mobility in bed

Unintentional injury is the third leading cause of death in the United States (Kochanek, Murphy, Xu, et al., 2019). Unintentional injuries are commonly called *accidents;* however, this term is considered inaccurate by trauma professionals. The term *accident* infers that there is no potential for prevention; yet, health care professionals understand that prevention plays a major role in decreasing the rate of unintentional injuries. The implementation of evidence-based primary prevention policies (e.g., mandatory use of seat belts for drivers and passengers in motor vehicles) may prevent many unintentional injuries from occurring.

Trauma is a frequent cause of musculoskeletal injury and is among the most common reasons for people to seek medical attention (Centers for Disease Control and Prevention [CDC], National Center for Health Statistics, 2017). Therefore, nurses who work in emergency departments (EDs), critical care units, and inpatient medical-surgical units frequently encounter patients who have experienced musculoskeletal trauma. The management of musculoskeletal injuries frequently includes the use of casts, splints, braces, traction, surgery, or a combination of these. Nursing care is planned to maximize the effectiveness of these treatment modalities and to prevent potential complications associated with each of the interventions. However, upon discharge from the hospital, many of these patients require extensive periods of rehabilitation and follow-up. Thus, nurses who work in rehabilitation centers, long-term care facilities, ambulatory surgery centers, occupational health settings, and primary care clinics may all care for patients with musculoskeletal injuries.

Contusions, Strains, and Sprains

A **contusion** is a soft tissue injury produced by blunt force, such as a blow, kick, or fall, causing small blood vessels to rupture and bleed into soft tissues (ecchymosis or bruising). A hematoma develops from bleeding at the site of impact, leaving a characteristic "black and blue" appearance. Contusions can be minor or severe, isolated or in conjunction with additional injuries (e.g., fracture). Local symptoms include pain, swelling, and discoloration. Contusions can limit joint range of motion (ROM) near the injury, and the injured muscle may feel weak and stiff (American Academy of Orthopedic Surgeons [AAOS], 2019a). Most contusions resolve in 1 to 2 weeks; severe contusions may take longer to heal.

A **strain** is an injury to a muscle or tendon from overuse, overstretching, or excessive stress; it is commonly known as a muscle pull (Babarinde, Ismail, &

Schellack, 2018). Tendons are fibrous cords that attach muscle to a bone; strains often occur in tendons of the foot, leg (e.g., hamstring), and back. Strains can be categorized as acute or chronic and are graded along a continuum based on postinjury symptoms and loss of function. Acute strains can result from a single injurious incident; whereas, chronic strains result from repetitive injuries. Chronic strains can result from improper management of acute strains. Depending on the severity of muscle fiber damage, three degrees of strains can be classified (Babarinde et al., 2018):

- **A first-degree** strain is mild stretching of the muscle or tendon with no loss of ROM. Signs and symptoms may include the gradual onset of palpation-induced tenderness and mild muscle spasm.
- **A second-degree** strain involves moderate stretching and/or partial tearing of the muscle or tendon. Signs and symptoms include acute pain during the precipitating event, followed by tenderness at the site with increased pain with passive ROM (PROM), edema, significant muscle spasm, and ecchymosis.
- **A third-degree** strain is severe muscle or tendon stretching with rupturing and complete tearing of the involved tissue. Signs and symptoms include immediate pain described as tearing, snapping, or burning, muscle spasm, ecchymosis, edema, and loss of function. An x-ray should be obtained to rule out bone injury, because an avulsion fracture (in which a bone fragment is pulled away from the bone by a tendon) may be associated with a third-degree strain. X-rays do not reveal injuries to soft tissue or muscles, tendons, or ligaments, but magnetic resonance imaging (MRI) and ultrasound can identify tendon injury.

A **sprain** is an injury to the ligaments and tendons that surround a joint. It is caused by a twisting motion or hyperextension (forcible) of a joint (Babarinde et al., 2018). While tendons connect muscle to bone, ligaments connect bone to bone. The function of a ligament is to stabilize and support the body's joints while permitting mobility. An injured ligament causes joint instability, with the most vulnerable areas of the body being the ankles, knees, and wrists. The severity of a sprain is graded according to how badly the ligament has been damaged and whether or not the joint has been made unstable (Maughan, 2019):

- A Grade I sprain is stretching or slight tearing in some fibers of the ligament and mild, localized hematoma formation. Manifestations include mild pain, edema, and local tenderness.
- A Grade II sprain is more severe and involves partial tearing of the ligament. Manifestations include increased pain with motion, edema, tenderness, joint instability, ecchymosis, and partial loss of normal joint function.

- A Grade III sprain is a complete tear or rupture of the ligament. A Grade III sprain may also cause an avulsion of the bone. Symptoms include severe pain, edema, tenderness, ecchymosis, and abnormal joint motion.

Management

The treatment for contusions, strains, and sprains is guided by the severity of injury and the goal of protecting from further injury. Protection from further injury is accomplished through support of the affected area (e.g., sling, brace) and/or splinting, taping, or compression bandages. To control pain, bleeding, and inflammation, most contusions, strains, and sprains are managed with the **RICE** method, an acronym that refers to ***r***est, ***i***ce, ***c***ompression, and ***e***levation (AAOS, 2019a). Rest prevents additional injury and promotes healing. Intermittent application of cold or ice packs during the first 24 to 72 hours after injury produces vasoconstriction, which decreases bleeding, edema, and discomfort. Cold packs should not be in place for longer than 20 minutes at a time, and care must be taken to avoid skin and tissue damage from excessive cold (AAOS, 2019a). An elastic compression bandage controls bleeding, reduces edema, and provides support for the injured tissues. Elevation at or just above the level of the heart controls the swelling (AAOS, 2019a). If the sprain or strain is the most severe grade or degree, immobilization by a splint, brace, or cast may be necessary so that the joint will not lose its stability (see later discussions). Nonsteroidal anti-inflammatory drugs (NSAIDs) may be prescribed for pain management (AAOS, 2019a). The **neurovascular status**, a type of focused assessment of the neurologic (motor and sensory) and vascular function of the injured extremity, is monitored at frequent intervals (e.g., every 15 minutes for the first 1 to 2 hours after injury) and then at lesser intervals (e.g., every 30 minutes) until stable. Decreases in sensation or motion and increases in pain level should be documented and reported to the patient's primary provider immediately so that acute compartment syndrome can be prevented (see later discussion).

Joint Dislocations

A **dislocation** of a joint is a condition in which the articular surfaces of the distal and proximal bones that form the joint are no longer in anatomic alignment. A **subluxation** is a partial or incomplete dislocation and does not cause as much deformity as a complete dislocation. In complete dislocation, the bones are literally "out of joint." Acute traumatic dislocations are orthopedic emergencies because the associated joint structures, blood supply, and nerves are displaced and may be entrapped with extensive pressure on

them. If a dislocation or subluxation is not reduced immediately, **avascular necrosis (AVN)** may develop. AVN of bone is caused by ischemia, which leads to necrosis or death of the bone cells.

Signs and symptoms of a traumatic dislocation include acute pain, change in or awkward positioning of the joint, and decreased ROM. Bilateral assessment will usually make apparent the abnormality in the affected joint. X-rays are usually taken to confirm the diagnosis and reveal any associated fracture (DeBerardino, 2018).

Medical Management

When a joint is dislocated, the main treatment priorities are to avoid neurovascular complications and reduce the joint as atraumatically as possible (DeBerardino, 2018). The affected joint needs to be immobilized at the scene and during transport to the hospital. Informed consent for the procedure is obtained and the dislocation is promptly reduced so that displaced parts are placed back in proper anatomic position to preserve joint function (see Chart 37-1). Analgesia, muscle relaxants, and possibly anesthesia are used to facilitate closed reduction. The joint is immobilized by splints, casts, or traction and is maintained in a stable position. Neurovascular status is assessed at a minimum of every 15 minutes until stable. After reduction, if the joint is stable, gentle, progressive, active and passive movement is begun to preserve ROM and restore strength. The joint is supported between exercise sessions.

Nursing Management

The focus of nursing care is on frequent assessment and evaluation of the injury, including complete neurovascular assessment with proper documentation and communication with the primary provider. The patient and family members are educated regarding proper exercises and activities as well as danger signs and symptoms to look for, such as increasing pain (even with analgesic agents), numbness or tingling, and increased edema in the extremity. These signs and symptoms may indicate acute compartment syndrome; if acute compartment syndrome is not identified and communicated to the primary provider, it may lead to disability or loss of the extremity (see later discussion).

Injuries to the Tendons, Ligaments, and Menisci

Rotator Cuff Tears

A rotator cuff tear is a rip in a tendon that connects one of the rotator muscles to the humeral head. The rotator cuff stabilizes the humeral head and keeps the

arm in the shoulder socket. The rotator cuff is composed of four muscles that come together as tendons (supraspinatus, infraspinatus, teres minor, and subscapularis) that cover the head of the humerus, helping to raise and rotate the arm (AAOS, 2019b).

Rotator cuff tears may result from acute or chronic stresses on the joint and from intrinsic (e.g., age-related) or extrinsic (e.g., overuse, fracture, etc.) factors. Physical examination should include bilateral evaluation of the joint. The patient complains of aching pain that is typically insidious in nature (unless related to an acute injury) and worsens with use. The patient will complain of tenderness to palpation and difficulty sleeping on the affected side and will exhibit decreased ROM and decreased strength. A thorough physical examination and imaging studies, including x-ray, MRI scan and musculoskeletal ultrasound, aid in confirming diagnosis and extent of injury (AAOS, 2019b; Simons, Dixon, & Kruse, 2019). Arthrography with MRI or computed tomography (CT) scan may be more sensitive for certain tears but is usually reserved for cases when a labral injury is suspected (Simons et al., 2019).

Treatment options depend upon several factors, including the duration of symptoms, hand dominance, the type of tear, and patient characteristics such as age, general health, and activity level. Initial conservative management consists primarily of physical therapy, injury surveillance, NSAIDs, rest with modification of activities, and corticosteroid injections into the shoulder joint (Simons et al., 2019). If conservative methods fail, surgical management is warranted. Multiple surgical approaches (e.g., open, mini-open, and arthroscopic) can be employed. Selection of surgical modality is based upon the factors discussed above and the surgeon's preference as there is limited evidence whether surgery provides clinically important benefits (Karjalainen, Jain, Heikkinen, et al., 2019). Postoperatively, the shoulder is immobilized with a **sling**, a supportive arm bandage, for 4 to 6 weeks; length of time of immobilization depends on the severity of injury. Physical therapy with shoulder exercises is begun as prescribed, and the patient is educated on how to perform the exercises at home. The course of rehabilitation is lengthy (e.g., 3 to 6 months); functionality post rehabilitation depends on the patient's commitment to the rehabilitation regimen (AAOS, 2019b).

Lateral and Medial Epicondylitis

Epicondylitis is a chronic, painful condition that is caused by excessive, repetitive extension, flexion, pronation, and supination motions of the forearm. These motions result in inflammation (tendonitis) and minor tears in the tendons at the origin of the muscles on the lateral or medial epicondyles. Lateral epicondylitis (e.g., tennis elbow) is frequently identified in someone who repeatedly extends the wrist with supination of the forearm. Patients

complain of pain and tenderness over the lateral epicondyle and in the proximal wrist extensor muscles (Cutts, Gangoo, Modi, et al., 2020). Medial epicondylitis (e.g., golfer's elbow) is consistent with repetitive wrist flexion and pronation of the forearm. Extreme tenderness occurs at the medial epicondyle and in the proximal wrist flexor muscles (Neeru, 2020). Lateral epicondylitis is seven times more common than its medial counterpart (Cutts et al., 2020).

Chart 37-1 ETHICAL DILEMMA

Does Informed Consent Always Uphold Autonomy?

Case Scenario

D.N. is a 27-year-old man brought by ambulance to the emergency department (ED) where you work as a staff nurse. You are his admitting nurse. Paramedics bring him to the trauma bay by stretcher; he is sitting upright, alert and fully oriented, breathing room air, and gripping his right elbow in flexion with his left hand, holding his right arm slightly away from his torso. The right arm has had a sling applied. As you approach him, you can hear him groaning and see that his forehead is diaphoretic. You see an obvious deformity at his right shoulder, which is slumped, and observe a bulge below his right clavicle, which is likely his dislocated right humeral head. The ED physician meets you and D.N. in the trauma bay and tells D.N. that he could send him to x-ray to confirm that his right shoulder is dislocated and to ensure he does not have any associated fractures; however, that will delay his treatment and fractures are very uncommon occurrences when shoulders dislocate in young men. The ED physician asks D.N. if he can attempt to correct his dislocation manually first, and that if that does not work, he will send him to x-ray. D.N. agrees that the ED physician may correct his dislocation; the physician begins to quickly note the risks associated with this manual procedure and procures an informed consent for D.N. to sign. D.N. blurts out “Oh for heaven’s sakes just fix my shoulder!” as he scribbles a jumbled signature on the form with his nondominant left hand. The ED physician quickly and efficiently reduces the dislocated shoulder, and D.N. immediately sighs with relief and says “Oh thank you, doctor! You are a miracle worker!” After you send D.N. to radiology for a follow-up x-ray, the physician turns to you and says “What a crock about these consents. Was that patient really going to not consent to have me try to fix his shoulder? It is just useless paperwork that takes additional time, and that poor guy had to needlessly suffer those extra minutes while we got that paperwork signed!”

Discussion

Obtaining informed consent from a patient prior to any procedure that incurs any risk is a legal requirement. The informed consent must clearly identify what is going to be done and what adverse consequences may ensue from the procedure. The informed consent must meet a *professional standard* so that it includes information that most other health care professionals would disclose during the informed consent process. Furthermore, the informed consent must also meet the *reasonable patient standard,* meaning that information is shared that the patient needs to know in order to make a decision whether or not to have the procedure performed. The informed consent process is considered central to ensuring patient autonomy.

However, some bioethicists have asserted that patients who have had a traumatic injury many times do not remember information shared during the informed consent process. They counter that because of pain, fear, and anxiety, patients with trauma are not focused on the actual risks associated

with treatments. Therefore, these bioethicists note that the informed consent process with patients with trauma is actually a sham process and fundamentally does little to preserve patient self-determination.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). In most instances, the principle of autonomy is considered preeminent. In this case, are the principles of beneficence or nonmaleficence of more importance?
- Think about what the ED physician said about the informed consent process for D.N. Were there any benefits to D.N. by upholding the informed consent process? What risks could D.N. have incurred if there had not been an informed consent process?
- What if D.N. does indeed have a fracture associated with his dislocated shoulder? What risks are there to the ED physician or to you had you not ensured an informed consent occurs?
- What resources might be mobilized to be of assistance to you, the ED physician, and to D.N. so that D.N.'s autonomy is upheld and he can be assured the best treatment options?

Resources

See Chapter 1, Chart 1-10, for Steps of an Ethical Analysis and Ethics Resources.

To date, there is no universally accepted regimen of treatment (Cutts et al., 2020); however, some general principles can be considered. Rest and cessation of aggravating actions is the first-line treatment. Intermittent application of ice and administration of NSAIDs usually relieve the pain and inflammation. In some instances, the arm is immobilized in a molded splint for support and pain relief. Local injection of corticosteroids may be used for symptom management, but because of its degenerative effects on tendons, this treatment is traditionally reserved for patients with severe pain who do not respond to first-line treatment methods (Lenoir, Mares, & Carlier, 2019). Physical therapy and rehabilitation exercises are also considered first-line, nonsurgical treatments (Lai, Erickson, Mlynarek, et al., 2018). Multiple electrophysical modalities, such as transcutaneous electrical nerve stimulation (TENS), ultrasound, extracorporeal shock wave therapy (ESWT), and laser therapy,

may provide limited benefit; however, more research is needed to validate their efficacy (Cutts et al., 2020). Surgical interventions are typically a last resort and can be considered in patients who have no response to nonoperative management, want faster symptom management, or have severe pain (Lenoir et al., 2019).

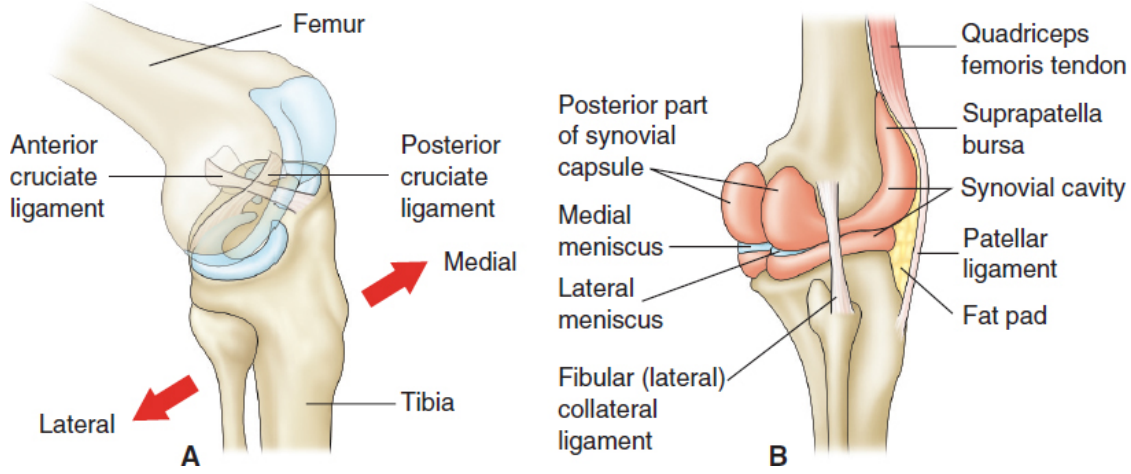

Figure 37-1 • Knee ligaments, tendons, and menisci. **A.** Anterolateral view. **B.** Posterolateral view.

Lateral and Medial Collateral Ligament Injury

Lateral and medial collateral ligaments (MCLs) of the knee (see Fig. 37-1) provide stability to the knee. Injury to these ligaments occurs when the foot is firmly planted and the knee is struck—either medially, causing stretching and tearing injury to the lateral collateral ligament (LCL), or laterally, causing stretching and tearing injury to the MCL. The patient experiences an acute onset of pain, joint tenderness, joint instability, and inability to walk without assistance.

Medical Management

Early management includes the RICE method, use of analgesics, and protection of the joint from further injury (Dexter, 2019). The joint is evaluated for fracture. Hemarthrosis (bleeding into the joint) may develop, contributing to the pain; should this occur, the joint fluid may be aspirated to relieve pressure.

Treatment depends on the severity of the injury. Conservative management includes weight bearing as tolerated and the use of a hinged-brace for support. Crutches may be indicated to assist ambulation until weight bearing can be tolerated. Exercises to strengthen the supportive muscles to the knee without straining the ligaments are beneficial. Severe MCL injuries are initially treated

with non–weight-bearing status with progression to weight bearing as tolerated in a hinged-brace for a lengthy timeframe; the healing process may take 8 to 12 weeks. Severe LCL injuries with knee instability usually require surgical intervention, followed by bracing and physical therapy (Agranoff, 2019). A progressive rehabilitation program helps restore the function and strength of the knee. Rehabilitation occurs over many months, and the patient may need to wear a derotational brace while engaging in sports to prevent recurrence of injury.

Nursing Management

The nurse educates the patient about proper use of ambulatory devices, the healing process, and activity limitation to promote healing. Education addresses pain management, the use of analgesic agents, the use of a brace, wound care, cold therapy, signs and symptoms of possible complications (e.g., altered neurovascular status, infection, skin breakdown, venous thromboembolism [VTE]), and self-care (Dexter, 2019).

Cruciate Ligament Injury

The anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL) of the knee stabilize anterior and posterior motion of the tibia articulating with the femur (see Fig. 37-1A). These ligaments cross each other in the center of the knee. Injury occurs when the foot is firmly planted and the leg sustains direct force, either forward or backward. If the force is forward, the ACL suffers the impact from the force, whereas backward force places force on the PCL. The injured person may report feeling and hearing a "pop" in the knee with this injury. If the patient exhibits significant swelling of the joint within 2 hours after the injury, the ACL or PCL may be torn. A torn cruciate ligament produces pain, joint instability, and pain with weight bearing. Immediate postinjury management includes the RICE protocol, use of NSAIDs, and stabilization of the joint until it is evaluated for a fracture (Graham, 2019). Severe joint effusion and hemarthrosis may require joint aspiration and wrapping with an elastic compression dressing. Crutches may be needed to avoid weight bearing, especially if the knee is unstable (Friedberg, 2019).

Treatment depends on the severity of the injury, patient characteristics, and the effect of the injury on daily activities. Ligament injuries can be managed operatively or nonoperatively; most active, younger patients and high performing athletes opt for surgery due to the risk for reinjury and osteoarthritis (Friedberg, 2019). Older and less active patients, whose physical activity is community ambulation, tend to benefit from nonsurgical therapy (Graham, 2019). Surgical ACL or PCL reconstruction may be scheduled after

near-normal joint ROM is achieved and includes tendon repair using a graft (e.g., autograft, allograft, or synthetic ligament; see later discussions). This is typically performed as ambulatory arthroscopic surgery, a procedure in which the surgeon uses an **arthroscope** to visualize and repair the damage. After surgery, the patient is instructed to control pain with oral analgesic medications and cryotherapy (e.g., a cooling pad incorporated in a dressing). The patient and family are educated about monitoring the neurovascular status of the leg, wound care, and signs of complications (e.g., infection, VTE) that need to be reported promptly to the surgeon (Cox, 2017). Exercises (ankle pumps, quadriceps sets, and hamstring sets) are encouraged during the early postoperative period. The patient must protect the graft by adhering to exercise restrictions. The physical therapist supervises progressive ROM and weight bearing (as permitted).

Meniscal Injuries

Within the knee are two semilunar (crescent-shaped) pads of fibrocartilages, called *menisci,* located on the right and left side of the proximal tibia, between the tibia and the femur (see Fig. 37-1B). These structures act as shock absorbers in the knee. Normally, little twisting movement is permitted in the knee joint. Forceful twisting of the knee or repetitive squatting and impact may result in either tearing or detachment of the cartilage from its attachment to the head of the tibia. The peripheral third of the menisci have a small amount of blood flow, which allows that portion to heal if torn.

These injuries leave loose cartilage in the knee joint that may slip between the femur and the tibia, preventing full extension of the leg. If this happens during walking or running, the patient often describes the leg as "giving way." The patient may hear or feel a click in the knee when walking, especially when extending the leg that is bearing weight. When the cartilage is attached to the front and back of the knee but torn loose laterally (bucket-handle tear), it may slide between the bones to lie between the condyles and prevent full flexion or extension. As a result, the knee "locks."

When a meniscus is torn, the synovial membrane secretes additional synovial fluid due to the irritation, and the knee becomes very edematous. Initial conservative management includes rest and immobilization of the knee, ice to the knee for 15 minutes every 4 to 6 hours, the use of crutches for support, anti-inflammatory agents, analgesic agents, and modification of activities to avoid those that cause the symptoms. Home exercises and physical therapy may be prescribed to increase strength in supporting muscles (e.g., quadriceps, hamstrings). Diagnosis is confirmed through MRI or arthroscopy; the approach to treatment depends on the patient's age, type of tear, associated mechanical symptoms (e.g., knee is locked, or motion is severely impaired) and the presence of persistent knee effusions (Cardone & Jacobs, 2019).

Surgical options include a partial or total meniscectomy to repair the meniscal tissue. Open or arthroscopic surgery can be performed (Baker, Wolf, & Lubowitz, 2018). The most common complication is an effusion into the knee joint, which produces pain. To ensure independent home performance, the patient is instructed to continue quadriceps strengthening and progressive ROM exercises; neuromuscular electrical stimulation/biofeedback is also recommended (Logerstedt, Snyder-Mackler, Ritter, et al., 2018). There is a lack of consensus regarding the optimal postoperative time to return to activity; therefore, prescribed weight-bearing status can range from non–weight bearing for 4 to 6 weeks to full weight bearing in a "locked" (extension) knee brace (Spang, Nasr, Mohamadi, et al., 2018).

Rupture of the Achilles Tendon

The Achilles tendon is a tough band of fibrous tissue that attaches the soleus and gastrocnemius (e.g., calf) muscles to the calcaneus (e.g., heel bone). Injury to the Achilles tendon is often multifactorial; despite being the strongest and thickest tendon in the body, it is vulnerable to injury due to its limited blood supply and the high tensions placed upon it (Egger & Berkowitz, 2017). Rupture of the Achilles tendon most commonly occurs in active young to middle-aged adults with a predilection among males. The traumatic rupture of the Achilles tendon occurs with the "pushing off" or unexpected dorsiflexion of the foot and ankle (Karlsson Westin, Carmont, et al., 2019). Patients usually describe a "popping" sound or a "giving way" sensation in their posterior heel. Immediate pain is usually experienced but gradually subsides, leaving a patient with difficulty performing plantar flexion, and the inability to fully bear weight on the affected leg (Egger & Berkowitz, 2017).

Clinical examination is paramount in diagnosis; the ability to plantar flex is decreased and to dorsiflex is improved. MRI or ultrasound is indicated to determine the extent of the injury. The decision of surgical or nonsurgical treatment for Achilles tendon rupture is much debated and depends on the patient's comorbidities, goals, and preferences (Karlsson et al., 2019). Nonoperative modalities include cast immobilization for 2 to 8 weeks; there is some controversy regarding optimal time. After immobilization with the cast, a boot and functional brace with a heel lift is worn with increasing weight-bearing status. Progressive physical therapy to promote ankle ROM and strength is implemented as well. Operative treatment has typically been reserved for young, healthy athletes, because surgery was associated with fewer cases of re-rupture. After surgery, a cast may be initially used to immobilize the ankle joint; however, early functional rehabilitation has been shown to be superior to cast immobilization in terms of patient satisfaction and the time to return to prior employment and sporting activity (Zhao, Meng, Liu,

et al., 2017). The total rehabilitation is approximately 6 weeks (Karlsson et al., 2019).

Fractures

A **fracture** is a complete or incomplete disruption in the continuity of bone structure and is defined according to its type and extent. Fractures occur when the bone is subjected to stress greater than it can absorb (Buckley & Page, 2018). Fractures may be caused by direct blows, crushing forces, sudden twisting motions, and extreme muscle contractions. When the bone is broken, adjacent structures are also affected, which may result in soft tissue edema, hemorrhage into the muscles and joints, joint dislocations, ruptured tendons, severed nerves, and damaged blood vessels. Body organs may be injured by the force that caused the fracture or by fracture fragments.

Types of Fractures

Fractures types are identified by the name of the injured bone and location (e.g., proximal, midshaft, distal) (Beutler & Titus, 2019). Fractures are also described according to the degree of break (e.g., a *greenstick fracture* refers to a partial break) or the character of any fractured bone fragments (e.g., a *comminuted fracture* has more than two fragments). Select specific types of fractures are displayed in Figure 37-2.

A *closed fracture* (simple fracture) is one that does not cause a break in the skin. An *open fracture* (compound, or complex, fracture) is one in which the skin or mucous membrane wound extends to the fractured bone. Open fractures are often classified using a modified system by Gustilo-Anderson which classifies the severity into three categories based on the extent of soft-tissue injury and the size of the corresponding skin wounds (Elniel & Giannoudis, 2018):

- Type I is a clean wound less than 1 cm long and simple fracture pattern.
- Type II is a larger wound with minimal soft tissue damage and no flaps or avulsions.
- Type III (A, B, and C subtypes) is considered the most severe, highly contaminated, and has extensive soft tissue damage; it involves vascular injury or traumatic amputation.

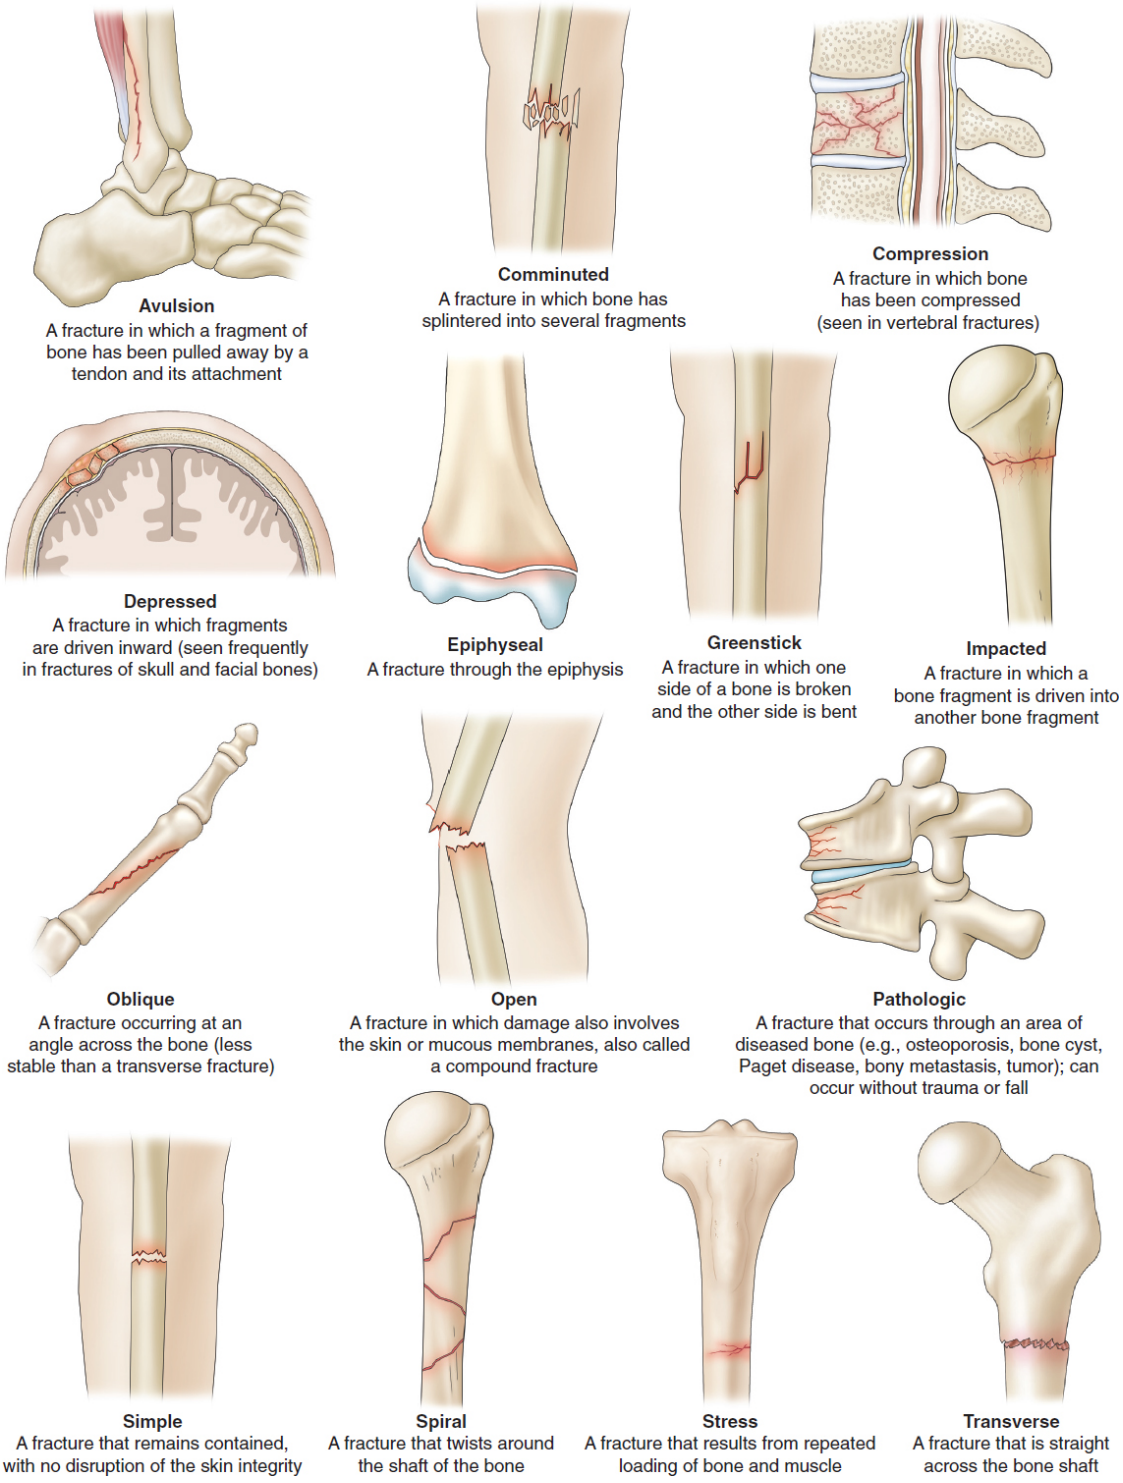

Figure 37-2 • Specific types of fractures.

An *intra-articular fracture* extends into the joint surface of a bone. Because each end of a long bone is cartilaginous, if the fracture is nondisplaced, x-rays will not always reveal the fracture because cartilage is nonradiopaque. MRI or arthroscopy will identify the fracture and confirm the diagnosis. The joint is stabilized and immobilized with a splint or cast, and no weight bearing is allowed until the fracture has healed. Because of the damage to articular

cartilage, intra-articular fractures often lead to early posttraumatic osteoarthritis (Mittal & Mittal, 2019).

Clinical Manifestations

The clinical signs and symptoms of a fracture vary according to which bone is affected, the patient's health and age, and the severity of the injury (Whittle, 2017a). However, they often include acute pain, loss of function, deformity, shortening of the extremity, crepitus, localized edema and ecchymosis, muscle spasm, and tenderness (Iyer, 2019).

Pain

The pain is continuous and increases in severity until the bone fragments are immobilized. Immediately after a fracture, the injured area becomes numb and the surrounding muscles flaccid. The muscle spasms that accompany a fracture begin shortly thereafter, within a few to 30 minutes, and result in more intense pain than the patient reports at the time of injury. The muscle spasms can minimize further movement of the fracture fragments or can result in further bony fragmentation or malalignment (Norris, 2020).

Loss of Function

After a fracture, the extremity cannot function properly because normal function of the muscles depends on the integrity of the bones to which they are attached. Pain contributes to the loss of function. In addition, abnormal movement (false motion) may be present.

Deformity

Displacement, angulation, or rotation of the fragments in a fracture of the arm or leg causes a deformity that is detectable when the limb is compared with the uninjured extremity.

Shortening

In fractures of long bones, there is actual shortening of the extremity because of the compression of the fractured bone. Sometimes, muscle spasms can cause the distal and proximal site of the fracture to overlap, causing the extremity to shorten (Norris, 2020).

Crepitus

When the extremity is gently palpated, a crumbling sensation, called **crepitus,** can be felt or may be heard. It is caused by the rubbing of the bone fragments against each other.

Localized Edema and Ecchymosis

After a fracture, localized edema and ecchymosis occur as a result of trauma and bleeding into the tissues. These signs may not develop for several hours after the injury or may develop within an hour, depending on the severity of the fracture.

Emergency Management

Immediately after injury, if a fracture is suspected, the body part must be immobilized before the patient is moved. Adequate splinting is essential. Joints proximal and distal to the fracture also must be immobilized to prevent movement of fracture fragments. Immobilization of the long bones of the lower extremities may be accomplished by bandaging the legs together, with the unaffected extremity serving as a splint for the injured one. In an upper extremity injury, the arm may be bandaged to the chest, or an injured forearm may be placed in a sling. The neurovascular status distal to the injury should be assessed both before and after splinting to determine the adequacy of peripheral tissue perfusion and nerve function (Derby & Beutler, 2018).

With an open fracture, the wound is covered with a sterile dressing to achieve homeostasis as rapidly as possible at the injury site and to prevent contamination of deeper tissues (Buckley & Page, 2018). No attempt is made to reduce the fracture, even if one of the bone fragments is protruding through the wound. Splints are applied for immobilization.

In the ED, the patient is evaluated completely. The clothes are gently removed, first from the uninjured side of the body and then from the injured side. The patient's clothing may be cut away. The fractured extremity is moved as little as possible to avoid more damage.

Medical Management

Reduction

Fracture reduction refers to restoration of bone fragments to anatomic realignment and positioning with immobilization (Iyer, 2019). Either closed reduction or open reduction may be used to reduce a fracture. The specific method selected depends on the nature of the fracture; however, the underlying principles are the same. Usually, the primary provider reduces a fracture as soon as possible to prevent loss of elasticity from the tissues through infiltration by edema or hemorrhage. In most cases, fracture reduction becomes more difficult as the injury begins to heal (Buckley & Page, 2018).

Before fracture reduction and immobilization, the patient is prepared for the procedure; consent for the procedure is obtained, and an analgesic agent is given as prescribed. Regional anesthesia can also be very useful for pain

control with fractures and dislocation reduction (Eiff, Hatch, & Higgins, 2020a). The injured extremity must be handled gently to avoid additional damage.

Closed Reduction

In most instances, closed reduction is accomplished by bringing the bone fragments into anatomic alignment through manipulation and manual traction. The extremity is held in the aligned position while a cast, splint, or other device is applied (see later discussion). Reduction under anesthesia with percutaneous pinning may also be used. The immobilizing device maintains the reduction and stabilizes the extremity for bone healing. X-rays are obtained after reduction to verify that the bone fragments are correctly aligned (Buckley & Page, 2018).

Traction (skin or skeletal) may be used until the patient is physiologically stable to undergo surgical fixation (see later discussion).

Open Reduction

Some fractures require open reduction. Through a surgical approach, the bone fragments are anatomically aligned. Internal fixation devices (e.g., metallic pins, wires, screws, plates, nails, or rods) may be used to hold the bone fragments in position until solid bone healing occurs (Iyer, 2019). These devices may be attached to the sides of bone, or they may be inserted through the bony fragments or directly into the medullary cavity of the bone (see Fig. 37-3). Internal fixation devices ensure firm approximation and fixation of the bony fragments (Buckley & Page, 2018). Open reduction internal fixation (ORIF) is a common orthopedic surgical procedure used to treat severe fractures.

Immobilization

After the fracture has been reduced, the bone fragments must be immobilized and maintained in proper position and alignment until union occurs. Immobilization may be accomplished by external or internal fixation. Methods of external fixation include bandages, casts, splints, continuous traction, and external fixators.

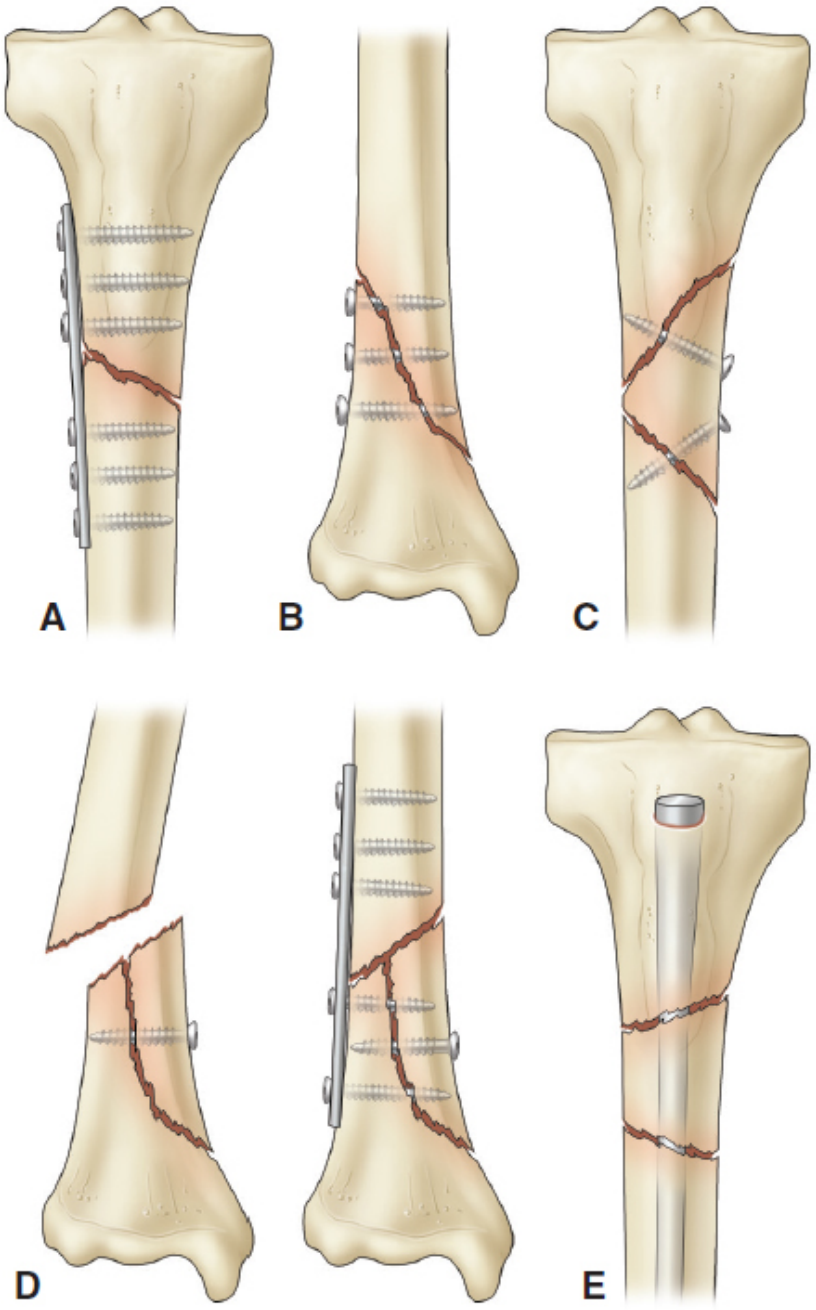

Figure 37-3 • Techniques of internal fixation. **A.** Plate and six screws for a transverse or short oblique fracture. **B.** Screws for a long oblique or spiral fracture. **C.** Screws for a long butterfly fragment. **D.** Plate and six screws for a short butterfly fragment. **E.** Medullary nail for a segmental fracture.

Maintaining and Restoring Function

Reduction and immobilization are maintained as prescribed to promote bone and soft tissue healing. Edema is controlled by elevating the injured extremity and applying ice as prescribed. Neurovascular status is monitored routinely, and the primary provider is notified immediately if signs of neurovascular

compromise develop. Restlessness, anxiety, and discomfort are controlled with a variety of approaches, such as reassurance, position changes, and pain-relief strategies, including the use of analgesic medications. Isometric and muscle setting exercises are encouraged to minimize atrophy and to promote circulation. Participation in activities of daily living (ADLs) is encouraged to promote independent functioning and self-esteem. Gradual resumption of activities is promoted as prescribed. With internal fixation, the surgeon determines the amount of movement and weight-bearing stress the extremity can sustain and prescribes the level of activity (Buckley & Page, 2018). See later discussion for more information about caring for patients who have casts, are in traction, or are undergoing surgery for fractures.

Nursing Management

Patients with Closed Fractures

The patient with a closed fracture has no opening in the skin at the fracture site. The fractured bones may be nondisplaced or slightly displaced, but the skin is intact. The nurse educates the patient regarding the proper methods to control edema and pain (see Chart 37-2). It is important to educate about exercises to maintain the health of unaffected muscles and to increase the strength of muscles needed for transferring and for using assistive devices such as crutches, walkers, and special utensils. The patient is also educated to use assistive devices safely. Plans are made to help patients modify the home environment as needed and to ensure safety, such as removing floor rugs or anything that obstructs walking paths throughout the house. Patient education includes self-care, medication information, monitoring for potential complications, and the need for continuing health care supervision. Fracture healing and restoration of strength and mobility may take an average of 6 to 8 weeks, depending on the quality of the patient's bone tissue (Iyer, 2019).

Patients with Open Fractures

In an open fracture, there is a risk for **osteomyelitis** (i.e., infection of the bone), tetanus, and gas gangrene (see Chapter 36 for discussion of osteomyelitis). The objectives of management are to prevent infection of the wound, soft tissue, and bone, and to promote healing of bone and soft tissue. Intravenous (IV) antibiotics are given upon the patient's arrival in the hospital along with intramuscular (IM) tetanus toxoid as indicated (Howe, 2018).

Wound irrigation using a sterile isotonic saline solution and **débridement** (removal of tissues and foreign material) are initiated in the operating room as soon as possible. The wound is cultured, and bone grafting may be performed to fill in areas of bone defects. The fracture is carefully reduced and stabilized by external fixation (see later discussion), and the wound is usually left open.

If there is any damage to blood vessels, soft tissue, muscles, nerves, or tendons, appropriate treatment is implemented.

Chart 37-2  HOME CARE CHECKLIST

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., durable medical equipment, adaptive equipment) used in safely promoting effective recovery and rehabilitation.
- Describe ongoing therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Describe approaches to control swelling (e.g., elevate extremity to heart level).
  - Consume a healthy diet to promote bone healing.
  - Observe prescribed weight-bearing and activity limits.
  - Participate in prescribed exercise regimen to maintain the health of unaffected muscles and those muscles now needed for safe transfer, mobility, etc.
  - If indicated, demonstrate safe use of mobility aid, assistive device, immobilizing device and transfer technique.
- State the name, dose, side effects, frequency, and schedule for all prescribed therapeutic and prophylactic medications (e.g., antibiotics, analgesic agents).
- Control pain with pharmacologic and nonpharmacologic interventions.
- Report pain uncontrolled by elevation and analgesics (may be an indicator of impaired tissue perfusion or compartment syndrome).
- State indicators of complications to report promptly to primary provider (e.g., uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; signs of local and systemic infection; signs of venous thromboembolism; problems with immobilization device).
- State possible complications of fractures (e.g., delayed union; nonunion; avascular necrosis; complex regional pain syndrome, formerly called *reflex sympathetic dystrophy syndrome;* heterotopic ossification).
- Describe gradual resumption of normal activities when medically cleared and discuss how to protect fracture site from undue stresses.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, therapy, and testing.
- Identify the need for health promotion, disease prevention, and screening activities.

Resources

See Chapter 2, Chart 2-6, for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

With open fractures, primary wound closure is usually delayed, particularly with higher-grade fractures. Heavily contaminated wounds are left unsutured and treated with vacuum-assisted closures (VACs) to facilitate wound drainage. Wound irrigation and débridement may be repeated, removing infected and devitalized tissue and increasing vascularity in the region (Dunbar & Cannada, 2017).

The extremity is elevated to minimize edema. Neurovascular status must be assessed frequently. Temperature is monitored at regular intervals, and the patient is monitored for signs of infection. Bone grafting may be necessary to bridge bone defects and to stimulate bone healing (Dunbar & Cannada, 2017).

Unfolding Patient Stories: Marilyn Hughes • Part 1

Marilyn Hughes, a 45-year-old female, was brought to the emergency department by her husband after a fall down icy stairs. She is complaining of severe left lower leg pain. She is wearing long pants and boots. What are priority assessments and interventions that the nurse should implement for a suspected lower leg fracture? (Marilyn Hughes' story continues in Chapter 60.)

Care for Marilyn and other patients in a realistic virtual environment: ***vSim*** *for Nursing* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Fracture Healing and Complications

Weeks to months are required for most fractures to heal. Many factors influence the timeframe of the healing process (see Chart 37-3). With a comminuted fracture, bone fragments must be properly aligned to attain the best healing possible. It is essential for the fractured bone to have blood supply to the area to facilitate the healing process. In general, fractures of flat bones (pelvis, sternum, and scapula) heal rapidly. A complex, comminuted fracture may heal slowly. Fractures at the ends of long bones, where the bone is more vascular and cancellous, heal more quickly than do fractures in areas where the

bone is dense and less vascular (midshaft). Fractures typically heal more quickly in younger patients (Howe, 2018).

If fracture healing is disrupted, bone union may be delayed or stopped completely. Factors that can impair fracture healing include inadequate fracture immobilization, inadequate blood supply to the fracture site or adjacent tissue, multiple trauma, extensive bone loss, infection, poor adherence to prescribed restrictions (e.g., cigarette smoking and excessive alcohol use), malignancy, certain medications (e.g., corticosteroids), older age, and some disease processes (e.g., rheumatoid arthritis) (Howe, 2018).

Complications of fractures may be either acute or delayed. Early complications include shock, fat embolism, acute compartment syndrome, VTE (deep vein thrombosis [DVT], pulmonary embolism [PE]), disseminated intravascular coagulation (DIC) and infection (Iyer, 2019). Late complications include delayed union, malunion, nonunion, AVN of bone, complex regional pain syndrome (CRPS), and heterotopic ossification.

Chart 37-3

Factors That Inhibit Fracture Healing

- Age >40 years
- Avascular necrosis
- Bone loss
- Cigarette smoking
- Comorbidities (e.g., diabetes, rheumatoid arthritis)
- Corticosteroids, nonsteroidal anti-inflammatory drugs
- Extensive local trauma
- Inadequate immobilization
- Infection
- Local malignancy
- Malalignment of the fracture fragments
- Space or tissue between bone fragments
- Weight bearing prior to approval

Adapted from Buckley, R., & Page, J. L. (2018). General principles of fracture care. *Medscape*. Retrieved on 1/7/2020 at: emedicine.medscape.com/article/1270717-overview#a6; Norris, T. L. (2020). *Porth's essentials of pathophysiology* (5th ed.). Philadelphia, PA: Wolters Kluwer.

Early Complications

Shock

Hypovolemic or traumatic shock resulting from hemorrhage is more frequently noted in trauma patients with pelvic fractures and in patients with a displaced or open femoral fracture in which the femoral artery is torn by bone fragments. Treatment for shock consists of stabilizing the fracture to prevent further hemorrhage, restoring blood volume and circulation, relieving the patient's pain, providing proper immobilization, and protecting the patient from further injury and other complications (Iyer, 2019). See Chapter 11 for a discussion of shock.

Fat Embolism Syndrome

Fat embolism syndrome (FES) describes the clinical manifestations that occur when fat emboli enter circulation following orthopedic trauma, especially long bone (e.g., femur) and pelvic fractures. FES is more frequent in closed fractures than in open fractures (Weinhouse, 2019). At the time of fracture, fat globules may diffuse from the marrow into the vascular compartment. The fat globules (e.g., emboli) may occlude the small blood vessels that supply the lungs, brain, kidneys, and other organs. The onset of symptoms is rapid, typically within 24 to 72 hours of injury, but may occur up to a week after injury (Iyer, 2019). FES occurs more frequently in males than in females, with its highest incidence in those between the ages of 10 and 40 years.

Clinical Manifestations

The classic triad of clinical manifestations of FES includes hypoxemia, neurologic compromise, and a petechial rash (Weinhouse, 2019). The typical first manifestations are pulmonary and include hypoxia, tachypnea, and dyspnea accompanied by tachycardia, substernal chest pain, low-grade fever, crackles, and additional manifestations of respiratory failure. Chest x-ray may show evidence of acute respiratory distress syndrome (ARDS) or it may be normal. Petechial rash may develop 2 to 3 days after the onset of symptoms. This rash is secondary to dysfunction in the microcirculation and/or thrombocytopenia and is typically located in nondependent regions (e.g., chest, mucous membranes) of the body. There may be varying degrees of neurologic deficits that can include restlessness, agitation, seizures, focal deficits, and encephalopathy (Fukumoto & Fukumoto, 2018). There are no universal criteria for diagnosis of FES; diagnosis relies on clinical suspicion based upon the classic triad of symptoms and imaging findings (Uranslip, Muengtaweepongsa, Chanalithichai, et al., 2018).

Quality and Safety Nursing Alert

Subtle personality changes, restlessness, irritability, or confusion in a patient who has sustained a fracture are indications for immediate arterial blood gas studies.

Prevention and Management

Prevention is the most important aspect of treatment; immediate immobilization of fractures, including early surgical fixation, minimal fracture manipulation, and adequate support for fractured bones during turning and positioning, and maintenance of fluid and electrolyte balance are measures that may reduce the incidence of fat emboli. There is no specific treatment for FES; the treatment is supportive. Fluid resuscitation, oxygenation, vasopressors, mechanical ventilation, and sometimes corticosteroids are used as supportive therapy (Weinhouse, 2019).

Acute Compartment Syndrome

An anatomic compartment is an area of the body encased by bone or fascia (e.g., the fibrous membrane that covers and separates muscles) that contains muscles, nerves, and blood vessels. The human body has 46 anatomic compartments, and 36 of these are located in the extremities (see Fig. 37-4). Acute compartment syndrome, a time-sensitive surgical emergency, is characterized by the elevation of pressure within an anatomic compartment that is above normal perfusion pressure. Acute compartment syndrome arises from an increase in compartment volume (e.g., from edema or bleeding), a decrease in compartment size (e.g., from a restrictive cast), or aspects of both. When the pressure within an affected compartment rises above normal, perfusion to the tissues is impaired, causing cell death, which may lead to tissue necrosis and permanent dysfunction (Papachristos & Giannoudis, 2018). The most common cause is fractures, with tibial fractures having the highest risk (Long, Koyfman, & Gottlieb, 2019). Acute compartment syndrome is most common among young adults, and although it may take up to 48 hours for symptoms to present, it typically has a rapid progression of symptoms and signs over a few hours after the initial injury or fracture repair (Stracciolini & Hammerberg, 2019).

Assessment and Diagnostic Findings

Frequent assessment of neurovascular function after a fracture is essential and focuses on the "five Ps": ***p***ain, ***p***allor, ***p***ulselessness, ***p***aresthesia, and ***p***aralysis (Papachristos & Giannoudis, 2018). The patient with acute compartment syndrome typically presents with severe pain that is out of proportion to the injury, which is considered the cardinal symptom (Stracciolini & Hammerberg, 2019). Additionally, patients often describe this pain as deep and burning, and that it is unrelieved by medications. Exacerbation of pain on passive stretching

of the muscles within the involved compartment is highly predictive (McMillan, Gardner, Schmidt, et al., 2019). With continued nerve ischemia and edema, the patient experiences diminished sensation followed by complete numbness. Motor weakness may occur as a late sign of nerve ischemia. Motion is evaluated by asking the patient to flex and extend the wrist or plantar flex and dorsiflex the foot. Paralysis (no movement) is a late finding after prolonged ischemia and is associated with neurovascular injury (McMillan et al., 2019).

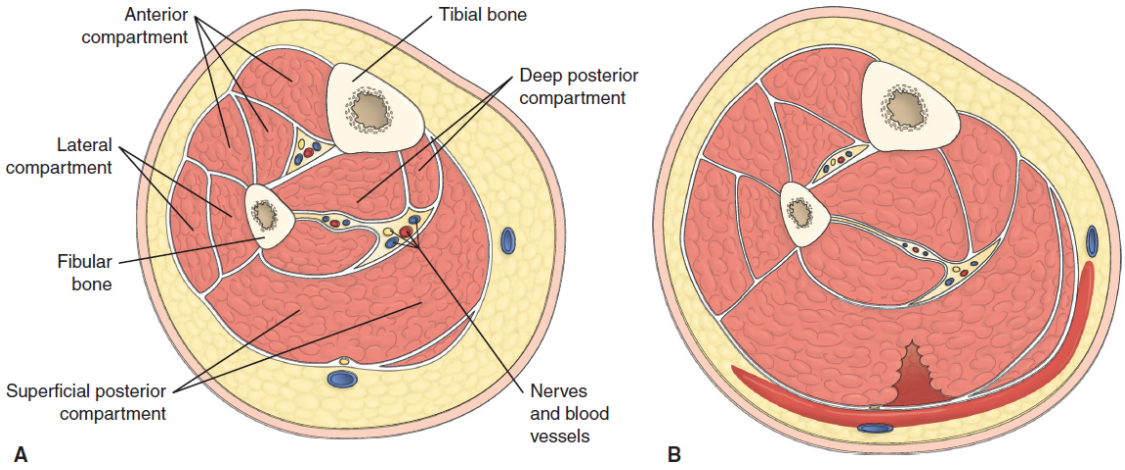

Figure 37-4 • **A.** Cross-section of normal lower leg with muscle compartments. **B.** Cross-section of lower leg with compartment syndrome.

Peripheral circulation is evaluated by assessing color, temperature, capillary refill time, edema, and pulses. Cyanotic nail beds suggest venous congestion. Pallor or dusky and cold digits, prolonged capillary refill time, and diminished pulses suggest impaired arterial perfusion. Edema may obscure the function of arterial pulsation, and Doppler ultrasonography may be used to verify a pulse. Pulselessness is a late sign (McMillan et al., 2019).

A prompt diagnosis of acute compartment syndrome is based on clinical suspicion and repeated clinical examinations of the "five Ps"; however, it is important to keep in mind that pain is a subjective measure and may only be detected in patients who are conscious (AAOS, 2018). As well, some of the clinical signs and symptoms may only present in the late stages of acute compartment syndrome (Stracciolini & Hammerberg, 2019). Palpation of the muscle, if possible, reveals it to be swollen and hard with the skin taut and shiny. The orthopedic surgeon may measure tissue pressure by inserting a tissue pressure-monitoring device, such as a handheld direct injection device (e.g., Stryker Intra-Compartmental Pressure Monitor), into the muscle compartment (normal pressure is 8 mm Hg or less) (see Fig. 37-5). Nerve and muscle tissues deteriorate as compartment pressure increases. Prolonged

pressure of more than 30 mm Hg can result in irreversible changes (Long et al., 2019).

Medical Management

Prompt management of acute compartment syndrome is essential and includes relieving all external pressure on the compartment. The orthopedic surgeon needs to be notified immediately if neurovascular compromise is suspected. Delay in treatment may result in permanent nerve and muscle damage, necrosis, infection, rhabdomyolysis with acute kidney injury, and amputation (Stracciolini & Hammerberg, 2019).

If conservative measures do not restore tissue perfusion and relieve pain, a fasciotomy (surgical decompression with excision of the fascia) is considered the definitive treatment to relieve the constrictive muscle fascia (AAOS, 2018). After fasciotomy, the wound is not sutured but is left open to allow the muscle tissues to expand; it is covered with moist, sterile saline dressings or with artificial skin. Negative-pressure wound therapy using a vacuum dressing has been shown to be effective to remove fluids and decrease times to primary closure (Modrall, 2019). The affected arm or leg is splinted in a functional position and elevated to heart level and prescribed intermittent passive ROM exercises are usually performed. In 2 to 3 days, when the swelling has resolved and tissue perfusion has been restored, the wound is débrided and closed (possibly with skin grafts).

Figure 37-5 • The Stryker Intra-Compartmental Pressure Monitor. Reprinted with permission from Stryker Inc.

Nursing Management

The nurse should frequently assess pain and neurovascular status of the affected limb and report any negative changes that may suggest compartment syndrome immediately to the primary provider. The limb should be maintained in a functional position at the level of the heart to promote optimal blood flow.

Quality and Safety Nursing Alert

Acute compartment syndrome is managed by maintaining the extremity at heart level (not above heart level) and removing constrictive dressings by opening and bivalving the cast or opening the splint, if one or the other is present.

Pain management is essential and is accomplished with opioid analgesia, as prescribed. Careful assessment of intake and output and urinalysis could alert the nurse to the development of rhabdomyolysis (see Chapter 48).

Education is necessary for those patients discharged to home-based or community settings with fractures and casts and should include recognition of the unique characteristics of acute compartment syndrome (increasing, refractory pain and neurovascular manifestations) and instructions when to contact the primary provider for emergent follow-up.

Other Early Complications

VTE, including DVT and PE, are associated with reduced skeletal muscle contractions and bed rest. Patients with fractures of the lower extremities and pelvis are at high risk for VTE (Buckley & Page, 2018). PE may cause death several days to weeks after injury. See Chapter 26 for a discussion of VTE, PE, and DVT.

Disseminated intravascular coagulation (DIC) is a systemic disorder that results in widespread hemorrhage and microthrombosis with ischemia. Its causes are diverse and can include massive tissue trauma. Early manifestations of DIC include ecchymoses, unexpected bleeding after surgery and bleeding from the mucous membranes, venipuncture sites, and gastrointestinal and urinary tracts (Iyer, 2019). See Chapter 29 for discussion of treatment for DIC.

All open fractures are considered contaminated and are treated as soon as possible with copious irrigation, débridement, tetanus immunization/prophylaxis, and IV antibiotics (Schaller, 2018). Surgical internal fixation of fractures carries a risk of infection. The nurse must monitor and educate the patient regarding signs and symptoms of infection, including tenderness, pain, redness, swelling, local warmth, elevated temperature, and purulent drainage.

Delayed Complications

Delayed Union, Nonunion, and Malunion

Delayed union occurs when healing does not occur within the expected timeframe for the location and type of fracture. Delayed union may be associated with distraction (pulling apart) of bone fragments, systemic or local infection, poor nutrition, or comorbidity (e.g., diabetes, autoimmune disease). The healing time is prolonged, but the fracture eventually heals (Nyary & Scammell, 2018). **Nonunion** is an incomplete healing of a fracture and results from failure of the ends of a fractured bone to unite, whereas **malunion** is the healing of a fractured bone in a malaligned (deformed) position (see Fig. 37-6). In both of these instances, the patient complains of persistent discomfort and abnormal movement at the fracture site. Nonunion occurs most commonly in tibial fractures, whereas malunion occurs most commonly in fractures of the hand (or fingers) (Howe, 2018). Factors contributing to delayed union, nonunion, and malunion are those associated with impaired bone healing (see Chart 37-3).

Medical Management

Impaired bone healing can be treated with nonsurgical and surgical interventions. Nonsurgical treatment modalities include low-intensity pulsed ultrasound and externally applied electrical bone growth stimulators (Osman,

Gabr, & Haddad, 2019). Electrical stimulation techniques enhance the process of bone healing by exposure of osteoblasts to electromagnetic fields, which stimulate the secretion of growth factors (Bhavsar, Leppik, Oliveira, et al., 2019). In some cases, electrical bone stimulators can also be invasive: completely implanted or partially implanted in the form of pins to the site of impaired healing (see Fig. 37-7). Surgical interventions include bone grafts and internal and external fixation (Weinlein, 2017; Whittle, 2017b).

Grafted bone undergoes a reconstructive process that results in a gradual replacement of the graft with new bone. During surgery, the bone fragments are débrided and aligned, infection (if present) is removed, and a bone graft is placed in the bony defect. The bone graft may be an **autograft** (tissue, frequently from the iliac crest, harvested from the patient for their own use; also called autogenous), an **allograft** (tissue harvested from a donor), or a bone graft substitute (Baldwin, Li, Auston, et al., 2019). The bone graft fills the bone gap and provides a lattice structure for invasion by bone cells and actively promotes bone growth. The type of bone selected for grafting depends on function—cortical bone is used for structural strength, cancellous bone for osteogenesis, and corticocancellous bone for strength and rapid incorporation (Baldwin et al., 2019). Free vascularized bone autografts are grafted with their own blood supply, allowing for primary fracture healing.

Figure 37-7 • Bone healing stimulator applied to the arm. Reprinted with permission from EBI Medical Systems, Parsippany, NJ.

After grafting, immobilization and non–weight-bearing restrictions are required while the bone graft becomes incorporated and the fracture or defect heals, which may be confirmed on an x-ray (Whittle, 2017b). Depending on the type of bone grafted and the age of the patient, healing may take from 6 to 12 months or longer. Bone grafting complications include wound or graft infection, fracture of the graft, and nonunion. Specific problems associated with autografts include a limited quantity of bone available for harvest and harvest site pain that may persist for up to 2 years after harvest. Infrequent specific allograft complications include partial acceptance (lack of host and donor histocompatibility, which retards graft incorporation), graft rejection (rapid and complete resorption of the graft), and transmission of disease (rare) (Whittle, 2017b).

Nursing Management

The patient with a nonunion has experienced an extended time in fracture treatment and may become frustrated with prolonged therapy. The nurse provides emotional support and encouragement to the patient and encourages

adherence to the treatment regimen. The orthopedic surgeon evaluates the progression of bone healing with periodic x-rays.

Nursing care for the patient with a bone graft includes providing pain management and monitoring the patient for possible complications. The nurse needs to reinforce educational information concerning the objectives of the bone graft, immobilization, non–weight-bearing regimen and exercises, wound care, monitoring for signs of infection, and the importance of follow-up care with the orthopedic surgeon (Whittle, 2017b).

Nursing care for the patient using a bone growth stimulator focuses on patient education that addresses immobilization, weight-bearing restrictions, and correct use of the stimulator as prescribed (Mains, 2017).

Avascular Necrosis of Bone (AVN; Osteonecrosis)

AVN occurs when the bone loses its blood supply and dies; the process eventually leads to bony collapse and destruction of the associated joint. It may occur after a fracture with disruption of the blood supply to the distal area. It is also seen with prolonged high-dose corticosteroid therapy, exposure to radiation, sickle cell disease, rheumatoid arthritis, and other diseases; chronic alcohol use and cigarette smoking are other atraumatic etiologies (Graham, 2020). The process is often progressive, and the patient develops pain with movement that progresses to pain at rest. Diagnostics include history and physical examination with x-rays, CT scans, and bone scans. AVN of the hip is the most commonly affected site; the knee is the second most common site. The goal of treatment is to preserve the native joint for as long as possible and includes both conservative and surgical interventions (Graham, 2020). Nonoperative management includes activity modification, administration of analgesics, and partial weight bearing of the affected region. Joint preserving procedures are aimed at revascularizing the affected area by drilling the avascular segment or using a bone marrow graft. In extreme cases, it is advisable to remove the fragment and reconstruct the joint (Jones & Mont, 2018).

Complex Regional Pain Syndrome (CRPS)

CRPS is a complex and rare disorder characterized by regional pain in a limb that is disproportionate; it typically begins following a fracture, soft tissue injury, or surgery. Dysfunctional peripheral and central nervous system responses that mount an excessive response to the precipitating event (e.g., fracture, surgery) are thought to be the cause of the pain. Women are affected more often than men, and the average age of diagnosis is 40 years (National Institute of Neurological Disorders and Stroke [NINDS], 2017). Two subtypes of CRPS have been recognized: Type I (formerly called *reflex sympathetic dystrophy*) applies to patients with CRPS without evidence of peripheral nerve

injury, and Type II (formerly called *causalgia)* refers to patients with nerve injury (Abdi, 2020).

Clinical manifestations of CRPS include severe burning pain, local edema, hyperesthesia, stiffness, discoloration, vasomotor skin changes (e.g., fluctuating warm, red, dry and cold, sweaty, cyanotic), and trophic changes that may include glossy, shiny skin, and changes in hair and nail growth. This syndrome is frequently chronic, with extension of symptoms to adjacent areas of the body. Dysfunction of the affected limb may also be manifested in CRPS. The diagnosis is made through the history and physical examination and ruling out other organic causes (NINDS, 2017).

Nursing Management

The primary objective of treatment is physical functional maintenance or recovery of physical function (Stanton-Hicks, 2018). Early effective pain relief is the focus of management. Pain may be controlled with analgesic agents. NSAIDs, topical anesthetics (e.g., lidocaine patches), corticosteroids, and opioids. Anticonvulsant agents (e.g., gabapentin) and antidepressant agents (e.g., amitriptyline) can be effective in treating neuropathic pain. Additional treatments may include sympathetic nerve blocks, neural stimulation, and intrathecal delivery of prescribed medications. Novel treatments under investigation include infusions of immunoglobulin (IVIG) and ketamine and the use of hyperbaric oxygen (Abdi, 2020). The nurse evaluates the effectiveness of these interventions and therapies (see Chapter 9) and helps the patient cope with CRPS manifestations through therapeutic listening, initiation of relaxation techniques and behavior modification, and referral for rehabilitation therapy. Rehabilitation initiated early can improve circulation to the affected area and maximize function. Depression and anxiety are often associated with severe pain disorders; therefore, the nurse should recommend a mental health referral as necessary (NINDS, 2017).

Quality and Safety Nursing Alert

The nurse avoids using the affected extremity for blood pressure measurements and venipuncture in the patient with CRPS.

Heterotopic Ossification

Heterotopic ossification refers to benign bone growth in an atypical location, such as in the soft tissue (Speed, 2019). Heterotopic ossification that is categorized as traumatic myositis ossificans usually develops in response to soft tissue trauma (e.g., contusion, sprain). It is characterized by pain and joint stiffness that causes decreased ROM. It typically occurs in young males after musculoskeletal sports injuries (Meyers, Lisiecki, Miller, et al., 2019). If

significant ROM dysfunction persists, surgery may be indicated to remove the bone growth and restore function (Speed, 2019).

The Patient with a Cast, Splint, or Brace

The patient with musculoskeletal trauma typically requires immobilization at some point as part of the management plan. Casts, splints, and braces are external immobilizers that are frequently indicated to treat these injuries.

Casts

A **cast** is a rigid external immobilizing device that is molded to the contours of the body. The cast must fit the shape of the injured limb correctly to provide the best support possible (AAOS, 2019c). A cast is used to immobilize a reduced fracture, to correct or prevent a deformity (e.g., clubfoot, hip displacement), apply uniform pressure to underlying soft tissue, or support and stabilize weakened joints. Generally, casts permit mobilization of the patient while restricting movement of the affected body part.

Because of their ability to provide more complete immobilization, casting is the mainstay of treatment for many fractures as it provides a protected environment for bone healing to occur (Beutler & Titus, 2019). The most common casting materials consist of fiberglass or plaster of Paris, as these are materials that can be molded. The choice of material depends on several factors, which include the condition being treated, availability, and costs. Maximal immobilization is achieved with casts that include the joints proximal and distal to the fracture site (Alexandre & Hodax, 2017). However, with some fractures, cast construction and molding may allow movement of a joint while immobilizing a fracture (e.g., three-point fixation in a patellar tendon weight-bearing cast).

Generally, casts can be divided into three main groups: arm casts, leg casts, and body or spica casts:

Short arm cast: Extends from below the elbow to the palmar crease, secured around the base of the thumb. If the thumb is included, it is known as a thumb spica or gauntlet cast.

Long arm cast: Extends from the axillary fold to the proximal palmar crease. The elbow usually is immobilized at a right angle.

Short leg cast: Extends from below the knee to the base of the toes. The foot is flexed at a right angle in a neutral position.

Long leg cast: Extends from the junction of the upper and middle third of the thigh to the base of the toes. The knee may be slightly flexed.

Walking boot: Also called an air or walking cast; protects and supports the foot, ankle or lower leg by controlling alignment and reducing

movement; also supports the user's weight while walking.

Body cast: Encircles the trunk.

Shoulder spica cast: A body jacket that encloses the trunk, shoulder, and elbow.

Hip spica cast: Encloses the trunk and a lower extremity. A double hip spica cast includes both legs.

Figure 37-8 illustrates long arm and long leg casts and areas in which pressure problems commonly occur with these casts.

The application of a cast is a specialized skill, typically performed by orthopedic technologists. The skillset needed to apply and remove casts requires education, training, practice, and constant review of provider competence to ensure patients receive safe, high-quality care. Casts that are not properly applied or cared for may hinder healing and predispose patients to a number of complications (Adib-Hajbaghery & Mokhtari, 2018).

Fiberglass Casts

Fiberglass casts are composed of polyurethane resins that have the versatility of plaster but are lighter in weight, stronger, water resistant, and more durable than plaster. In addition, fiberglass casts facilitate radiographic imaging better than plaster (AAOS, 2019c) and have the benefit of reaching full rigidity within 30 minutes of application. Because they tend to be more difficult to contour and mold, fiberglass casts are more commonly used for simple fractures of the upper and lower extremities. They consist of an open-weave, nonabsorbent fabric that requires tepid water for activation. Heat is given off (an exothermic reaction) while the cast is applied. The heat given off during this reaction can be uncomfortable, and the nurse should prepare the patient for the sensation of increasing warmth so that the patient does not become alarmed. Fiberglass casts can cause thermal injury like plaster casts, but the risk is less (Beutler & Titus, 2019).

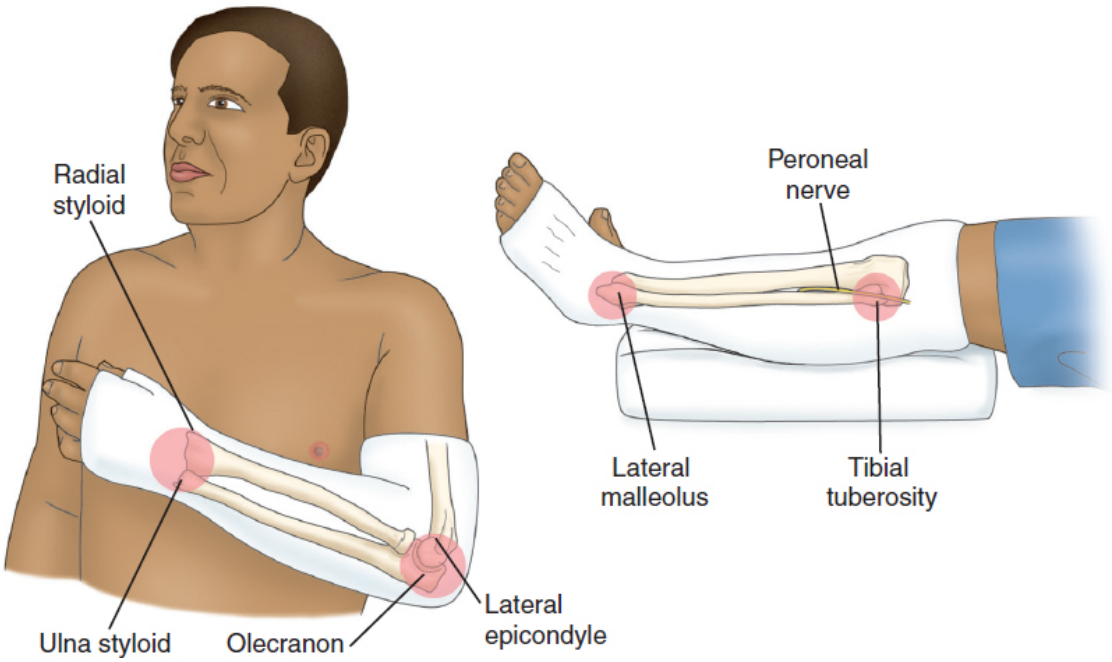

Figure 37-8 • Pressure areas in common types of casts. **Left.** Long arm cast. **Right.** Long leg cast.

Some fiberglass casts use a waterproof lining (Gore-Tex), which permits the patient to shower, swim, or engage in hydrotherapy (the use of water for treatment). When the cast is wet, the patient is instructed to remove excess water by blotting or patting the cast with a towel and making sure to drain the water out of it. The patient must understand that thorough drying is important to prevent skin breakdown, infection, or irritation; sweeping motions with a blow dryer on a cool or warm setting for approximately 1 hour can help to dry the cast inside and out (Mains, 2017). The best results are achieved with casts that can easily drain, such as short arm casts. Heels and elbows encased in wet casts may become macerated from the trapped water and therefore are associated with more skin breakdown.

Plaster Casts

Casts made of plaster of Paris are less costly and achieve a better mold than fiberglass casts; however, they are heavy, not water resistant, and can take up to 24 to 72 hours to dry postapplication. The exothermic reaction during cast application has the potential to cause serious burns (Szostakowski, Smitham, & Khan, 2017). Extra care should be taken when these types of casts are applied to older adults because their skin is more temperature sensitive than average adult skin. During the cast application process, clean, room temperature water should be used. Minimal layers of padding should be used. In addition, the cast should not be covered while it is drying because the heat generated by the chemical reaction cannot escape.

The time that it takes for a plaster cast to dry completely depends on its size, thickness, and location, as well as environmental drying conditions (Nemeth, Halanski, & Noonan, 2020). A freshly applied cast should be handled as little as possible to prevent denting and cracking (Mains, 2017). The wet plaster cast should be handled by only the palms so that indentations in the cast may be prevented; indentations can result in areas of pressure on the skin (Mains, 2017). The cast should be exposed to circulating air to dry and supported on a firm and smooth surface; it should not be placed on a metallic surface or one with sharp edges. If elevation is requested to reduce swelling, a cloth-covered pillow is preferred to one covered in plastic, which could retain heat and prevent drying. A wet plaster cast feels damp, appears dull and gray, sounds dull on percussion, and smells musty. The cast is dry when it feels hard and firm, has a white and shiny appearance, is resonant to percussion, and odorless.

On occasion, the plaster cast may have rough edges, which can crumble and cause skin irritation. Petaling, or smoothing the rough edges of the cast, resolves this problem if the underlying stockinette does not cover the edges of the cast. To prevent skin breakdown, moleskin can be used over any rough area of the cast that may rub against the patient's skin.

Splints and Braces

Many injuries that were treated previously with casts may now be treated with other immobilization devices such as splints and braces. Application of a **splint** (i.e., a process called splinting) is usually more practical and common and is the preferred method of fracture immobilization in the acute care setting and for the initial treatment of fractures that eventually require casting (Beutler & Titus, 2019). Splints are often used for simple and stable fractures, sprains, tendon injuries, and other soft tissue injuries. They offer many advantages over casts in that they are faster and easier to apply; however, increased joint mobility and decreased patient adherence may be a concern (Eubanks & Chien, 2019). Splints are also noncircumferential and allow for natural swelling during the inflammatory phase of injury. Pressure-related complications (e.g., skin breakdown, necrosis, acute compartment syndrome) are more prevalent when soft tissue swelling occurs within a contained space (e.g., a circumferential cast). Splints are easily removed, facilitating inspection of the injury site. In addition, splints can be indicated to provide initial stability for fractures that are unstable while awaiting definitive care (Schub & Balderrama, 2017).

Contoured splints of plaster or pliable thermoplastic materials may be used for conditions that do not require rigid immobilization, for those in which swelling may be anticipated, and for those that require special skin care. Splints made of thermoplastics are warmed and molded to custom-fit the

affected body part (e.g., hand and thoracolumbosacral orthotics [TLSOs], clamshell-type back braces). The splint needs to immobilize and support the body part in a functional position, and it must be well padded to prevent pressure, skin abrasion, and skin breakdown (Eubanks & Chien, 2019). The splint is overwrapped with an elastic bandage applied in a spiral fashion and with pressure uniformly distributed so that circulation is not restricted.

Braces (e.g., orthoses) are used to provide support, control movement, and prevent additional injury. They are custom-fitted to various parts of the body; thus, they tend to be indicated for longer-term use than splints. The orthotist adjusts the brace for fit, positioning, and motion so that movement is enhanced, any deformities are corrected, and discomfort is minimized.

Many splints and braces are prefabricated and fastened with Velcro straps. They may be made of plastic and other materials such as cloth, leather, metal, and elastic. Knee immobilizers, ankle stirrups, and cock-up wrist splints are types of prefabricated splints and braces. Both splints and braces may be either custom-made or standard "off the shelf." Splints and braces are generally less compliant and permit more motion at the injury site than casts, which can be a serious disadvantage in that underlying injuries are not as well stabilized (Schub & Balderrama, 2017).

Nursing Management

Before the cast, splint, or brace is applied, the nurse completes an assessment of the patient's general health, presenting signs and symptoms, emotional status, understanding of the need for the device, and condition of the body part to be immobilized (Schub & Balderrama, 2017). Physical assessment of the part to be immobilized must include a thorough assessment of the skin and neurovascular status, including the degree and location of swelling, bruising, and skin abrasions (Mains, 2017).

To promote healing, any skin lacerations and abrasions that may have occurred as a result of the trauma that caused the fracture must be treated before the cast, brace, or splint is applied. The nurse thoroughly cleanses the skin and treats it as prescribed. The patient may require a tetanus booster if the wound is dirty and if the last known booster was given more than 5 years ago. Sterile dressings are used to cover the injured skin. If the skin wounds are extensive, an alternative method (e.g., external fixator) may be chosen to immobilize the body part (AAOS, 2019c).

The nurse gives the patient or family information about the underlying pathologic condition and the purpose and expectations of the prescribed treatment regimen. This knowledge promotes the patient's active participation in and adherence to the treatment program.

The nurse prepares the patient for the application of the cast, splint, or brace by describing the anticipated sights, sounds, and sensations (e.g., heat from the

hardening reaction of the fiberglass or plaster) that they may experience (Chinai, Walker, Rebesco, et al., 2019). Asking the patient and family what they know about the application and care of the cast can help determine opportunities for education. The patient needs to know what to expect during application and the reason the body part must be immobilized.

The main concern following the application of an immobilization device is assessment and prevention of neurovascular dysfunction or compromise of the affected extremity. Assessments are performed at least every hour for the first 24 hours and every 1 to 4 hours thereafter to prevent neurovascular compromise related to edema and/or the device. Neurovascular assessment includes the assessment of peripheral circulation, motion, and sensation of the affected extremity, assessing the fingers or toes of the affected extremity, and comparing them with those of the opposite extremity. When assessing peripheral circulation, the nurse must check peripheral pulses as well as capillary refill response (within 3 seconds), edema, and the color and temperature of the skin. While assessing motion, the nurse should note any weakness or paralysis of the injured body part. While assessing sensation, the nurse monitors for **paresthesia** (i.e., numbness or tingling) or absence of feeling in the affected extremity, which could indicate nerve damage (Schub & Balderrama, 2017).

Nurses must be vigilant in assessing for subtle neurovascular changes in these patients (Schub & Balderrama, 2017). The "5 Ps" indicative of symptoms of neurovascular compromise, described previously, including ***p***ain, ***p***allor, ***p***ulselessness, ***p***aresthesia, and ***p***aralysis, are assessed (Papachristos & Giannoudis, 2018). Early recognition of diminished circulation and nerve function is essential to prevent loss of function. Swelling is a concern and can create excessive pressure under the cast (AAOS, 2019c). To augment the flow of fluid, the nurse elevates the extremity so that it is above the level of the heart during the first 24 to 48 hours postapplication to enhance arterial perfusion and control edema and notifies the primary provider at once if signs of compromised neurovascular status are present.

The nurse must carefully evaluate pain associated with the musculoskeletal condition, asking the patient to indicate the exact site and to describe the character and intensity of the pain using a pain rating scale (see Chapter 9). Pain associated with the underlying condition (e.g., fracture) is frequently controlled by immobilization. Pain due to edema that is associated with trauma, surgery, or bleeding into the tissues can frequently be controlled by elevation and, if prescribed, intermittent application of ice or cold packs (AAOS, 2019c). Ice bags (one third to one half full) or cold application devices are placed on each side of the cast, if prescribed, making sure not to indent or wet the cast. Unrelieved or pain out of proportion following cast application may indicate complications. Pain associated with acute compartment syndrome (see previous discussion) is relentless and is not

controlled by modalities such as elevation, application of ice or cold, and usual dosages of analgesic agents. Severe burning pain over bony prominences, especially the heels, anterior ankles, and elbows, warns of an impending pressure injury (Chinai et al., 2019). This may also occur from too-tight elastic wraps used to hold splints in place.

Quality and Safety Nursing Alert

The nurse must never ignore complaints of pain from the patient in a cast because of the possibility of problems, such as impaired tissue perfusion, acute compartment syndrome or pressure injury formation. A patient's unrelieved pain and increasing analgesic requirements must be reported immediately to the primary provider to avoid necrosis, neuromuscular damage, and possible paralysis.

The nurse observes the patient for systemic signs of infection, which include an unpleasant odor from the cast, splint, or brace, and purulent drainage staining the cast. Infection is more common from an open wound, but the moist, warm environment of a splint or cast can be an ideal conduit for infection. Foul-smelling casts should be removed to prevent skin and wound infections (Nemeth et al., 2020). If the infection progresses, a fever may develop. The nurse must notify the primary provider if any of these signs occur.

Finally, some degree of joint stiffness is an inevitable complication of immobilization. Every joint that is not immobilized should be exercised and moved through its ROM to maintain function. The nurse encourages the patient to move all fingers or toes hourly when awake to stimulate circulation.

Monitoring and Managing Potential Complications

It is important to assess for potential complications resulting from casts, splints, and braces that can be serious and life-threatening, such as acute compartment syndrome, pressure injury formation, and disuse syndrome.

Acute Compartment Syndrome

Acute compartment syndrome—the most serious complication of casting and splinting—occurs when increased pressure within a confined space (e.g., cast, muscle compartment) compromises blood flow and tissue perfusion (Schub & Balderrama, 2017). Ischemia and potentially irreversible damage to the soft tissues within that space can occur within a few hours if action is not taken (see Fig. 37-4). A tight or rigid cast/splint that constricts a swollen limb is associated with this complication.

If the complication is due to a cast or tight splint, the splint may be loosened or removed and the cast univalved or bivalved (cut in half longitudinally, on one side or two parallel sides of the cast, respectively) to release constriction and allow for inspection of the skin (Nemeth et al., 2020). The nurse assists in maintaining limb alignment, and the extremity must then be elevated no higher than heart level to maintain arterial perfusion. If pressure is not relieved and circulation is not restored, an emergent surgical fasciotomy may be necessary to relieve the pressure within the muscle compartment. The nurse closely monitors the patient's response to conservative and surgical management of compartment syndrome. The nurse records frequent neurovascular responses and promptly reports changes to the primary provider.

Pressure Injuries

Casts or splints can put pressure on soft tissues, particularly if they are inappropriately applied, causing tissue anoxia and pressure injuries. Although the term pressure ulcer has been previously used, the European Pressure Ulcer Advisory Panel, National Pressure Ulcer Advisory Panel and Pan Pacific Pressure Injury Alliance (2019) currently considers pressure injury the best term to use, given that open ulceration does not always occur. Lower extremity sites most susceptible are the heel, malleoli, dorsum of the foot, head of the fibula, and anterior surface of the patella. The main pressure sites on the upper extremity are located at the medial epicondyle of the humerus and the ulnar styloid (see Fig. 37-8).

If pressure necrosis occurs, the patient typically reports a very painful "hot spot" and tightness under the cast. The cast may feel warmer in the affected area, suggesting underlying tissue erythema (Beutler & Titus, 2019). Drainage may stain the cast or splint and emit an unpleasant odor. Even if discomfort does not occur, there may still be extensive loss of tissue with skin breakdown and tissue necrosis. To assess for pressure injury development, the primary provider may univalve, bivalve, or cut an opening (window) in the cast to allow for inspection, access, and possible treatment (Szostakowski et al., 2017). A dressing may be applied over the exposed skin, and the cutout portion of the cast is replaced and held in place by an elastic compression dressing or tape. This prevents "window edema" from occurring, which is the swelling or bulging of the underlying soft tissue through the window opening.

Disuse Syndrome

Immobilization in a cast, splint, or brace can cause muscle atrophy and loss of strength, and can place patients at risk for disuse syndrome, which is the deterioration of body systems as a result of prescribed or unavoidable musculoskeletal inactivity. To prevent this, the nurse instructs the patient to tense or contract muscles (e.g., isometric muscle contraction) without moving the underlying bone (Arora, Erosa, & Danesh, 2019). Isometric exercises, such

as instructing the patient with a leg or arm cast to splint or brace to "push down" the knee or to "make a fist," respectively, helps reduce muscle atrophy and maintain strength. Muscle setting exercises (e.g., quadriceps and gluteal setting exercises) are important in maintaining muscles essential for walking (see Chart 37-4). Isometric exercises should be performed hourly while the patient is awake.

Promoting Home, Community-Based, and Transitional Care

Educating the Patient About Self-Care

Self-care deficits occur when a portion of the body is immobilized. The nurse encourages the patient to participate actively in personal care and to use assistive devices safely. The nurse must assist the patient in identifying areas of self-care deficit and in developing strategies to achieve independence in ADLs (see Chart 37-5). Participating in self-care activities can have a positive effect on patient's knowledge and physical and psychological health (Khorais, Ebraheim, & Barakat, 2018). Patient and family education are also described in Chart 37-5.

Chart 37-4 PATIENT EDUCATION

Muscle Setting Exercises

The nurse instructs the patient to perform isometric contractions of the muscle to maintain muscle mass and strength and to prevent atrophy:

Quadriceps Setting Exercise

- Position patient supine with leg extended.
- Instruct patient to push knee back onto the mattress by contracting the anterior thigh muscles.
- Encourage patient to hold the position for 5 to 10 seconds.
- Let patient relax.
- Have patient repeat the exercise 10 times each hour when awake.

Gluteal Setting Exercise

- Position patient supine with legs extended, if possible.
- Instruct patient to contract the muscles of the buttocks.
- Encourage patient to hold the contraction for 5 to 10 seconds.
- Let the patient relax.
- Have patient repeat the exercise 10 times each hour when awake.

Chart 37-5  HOME CARE CHECKLIST

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the musculoskeletal injury/disorder on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State rationale for use of cast, splint or brace and resulting changes in lifestyle (e.g., activity, exercise, rest) necessary to maintain health and safety.
  - Avoid excessive use of injured extremity.
  - Observe prescribed weight-bearing limits.
  - Demonstrate ability to transfer (e.g., from a bed to a chair) and/or safe use of mobility aid.
  - Demonstrate exercises to promote circulation and minimize disuse syndrome.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe techniques to promote cast drying (e.g., do not cover cast; expose cast to circulating air; handle damp plaster cast with palms of hands; do not rest the cast on hard surfaces or sharp edges that can dent soft cast).
- Describe approaches to controlling swelling and pain (e.g., elevate immobilized extremity to heart level, apply ice bag intermittently if prescribed, take analgesic agents as prescribed).
- Report pain uncontrolled by elevating the immobilized limb and by analgesic agents (may be an indicator of impaired tissue perfusion—acute compartment syndrome or pressure injury).
- Verbalize care for minor skin irritations (e.g., for skin irritation from edge of cast, splint, or brace, pad rough edges with tape or moleskin; to relieve itching, blow cool air from hair dryer; do not insert foreign objects inside the cast, splint, or brace).
- Demonstrate ability to perform ADLs independently or with assistive devices/adaptive equipment.
- State indicators of complications to report promptly to primary provider (e.g., uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage staining cast; signs of systemic infection; cast, splint, or brace breaks).
- State how to reach primary provider with questions or complications
  - State time and date of follow-up appointments and testing
- Identify the need for health promotion, disease prevention, and screening activities
- Describe care of extremity following cast, splint, or brace removal (e.g., skin care, gradual resumption of normal activities to protect limb

from undue stresses, management of swelling).

Resources

See Chapter 2, Chart 2-6, for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care

For the patient with a cast that is ready for removal, the nurse should provide an explanation about what to expect, as the patient may be apprehensive about the procedure due to noise and vibration from the electric saw and fear of being cut (Mains, 2017). The cast saw uses an oscillating blade that vibrates but does not spin; thus, it cuts through the outer cast layer but does not penetrate deeply enough to injure the patient's skin. The cast will be cut in several places, usually along both sides of the cast. The cast is then spread and opened, and a special tool is used to lift it off. Scissors are used to cut through the protective padding and stockinette layers to ensure that the patient's skin will not be cut.

The formerly immobilized body part will be weak from disuse, stiff, and may appear atrophied. As the cast or splint is removed, the affected body part should be supported to prevent injury. The skin, which is usually dry and scaly from accumulated dead skin, is vulnerable to injury from scratching. The extremity is soaked in warm water to soften the skin; a warm washcloth may be used to loosen dead skin and an emollient lotion may be used as lubrication (Mains, 2017). The patient should be instructed to avoid rubbing and scratching the skin, because doing so can cause damage to newly exposed skin.

The nurse and physical therapist educate the patient to resume activities gradually within the prescribed therapeutic regimen. Exercises prescribed to help the patient restore muscle strength, joint motion, and flexibility are explained and demonstrated. Because the muscles are weak from disuse, the body part that has been immobilized cannot withstand normal stresses immediately. In addition, the patient should be instructed to control swelling by elevating the formerly immobilized body part, no higher than the heart, until normal muscle tone and use are reestablished (AAOS, 2019c).

Nursing Management of the Patient with an Immobilized Upper Extremity

The patient whose arm is immobilized must readjust to many routine tasks. The unaffected arm will assume all upper extremity activities. The nurse, in consultation with an occupational therapist, suggests devices designed to aid one-handed activities. The patient may experience fatigue due to modified

activities and the weight of the cast, splint, or brace. Frequent rest periods are necessary.

To control swelling, the immobilized arm is elevated above heart level with a pillow. When the patient is lying down, the arm is elevated so that each joint is positioned higher than the preceding proximal joint (e.g., elbow higher than the shoulder, hand higher than the elbow).

A sling may be used when the patient ambulates. To prevent pressure on the cervical spinal nerves, the sling should distribute the supported weight over a large area of the shoulders and trunk, not just the back of the neck. The nurse encourages the patient to remove the arm from the sling and elevate it frequently.

Circulatory disturbances in the hand may become apparent with signs of cyanosis, swelling, and an inability to move the fingers. A missed acute compartment syndrome in the arm can result in a Volkmann ischemic contracture, which may lead to devastating impairment of motor function and sensibility (Rubinstein, Ahmed, & Vosbikian, 2018). Contracture of the fingers and wrist occurs as the result of obstructed arterial blood flow to the forearm and hand. The patient is unable to extend the fingers, describes abnormal sensation (e.g., unrelenting pain, pain on passive stretch), and exhibits signs of diminished circulation to the hand. Irreversible damage develops within a few hours if action is not taken. This serious complication can be prevented with nursing surveillance and proper care (Ferla, Ciravegna, Mariani, et al., 2019).

Nursing Management of the Patient with an Immobilized Lower Extremity

The application of a leg cast, splint, or brace imposes a degree of immobility on the patient. Casts may include short leg casts, extending to the knees, or long leg casts, extending to the groin. Hinged knee braces and immobilizers typically extend from ankle to groin.

The patient's leg must be supported on pillows to the level of the heart to control swelling. Cold therapy or ice packs should be applied as prescribed over the fracture site for 1 to 2 days. The patient is taught to elevate the immobilized leg when seated. The patient should also assume a recumbent position several times a day with the immobilized leg elevated to promote venous return and control swelling (Rasmussen, 2019). Gentle toe and ankle exercises that allow for isometric contraction of muscles beneath the cast have also been shown to increase venous return and diminish edema (AAOS, 2019c).

The nurse assesses circulation by observing the color, temperature, and capillary refill of the exposed toes. Nerve function is assessed by observing the patient's ability to move the toes and by asking about the sensations in the

foot. Numbness, tingling, and burning may indicate peroneal nerve injury resulting from pressure at the head of the fibula.

Quality and Safety Nursing Alert

Injury to the peroneal nerve as a result of pressure is a cause of footdrop (the inability to maintain the foot in a normally flexed position). Consequently, the patient drags the foot when ambulating.

The nurse and physical therapist instruct the patient how to transfer and ambulate safely with assistive devices (e.g., crutches, walker) (see Chapter 2). The gait to be used depends on whether the patient is permitted to bear weight. If weight bearing is allowed, the cast, splint, or brace is reinforced to withstand the body weight. A cast boot or shoe, which is worn over the casted foot, provides a broad, nonskid walking surface.

Nursing Management of the Patient with a Body or Spica Cast

Casts that encase the trunk of the body (body cast) and portions of one or two extremities (spica cast) require special nursing strategies. Body casts are used to immobilize the spine. Hip spica casts are utilized to treat various fractures of the hip or femur or to correct or maintain the correction of hip deformities after reduction or surgery. These casts typically remain in place for 4 to 6 weeks (Nemeth et al., 2020). Shoulder spica casts are used for some humeral neck fractures.

Nursing responsibilities include preparing and positioning the patient, assisting with skin care and hygiene, and monitoring for complications. Explaining the casting procedure helps reduce the patient's apprehension about being encased in a large cast. The nurse reassures the patient that several people will provide care during the application, support for the injured area will be adequate, and care providers will be as gentle as possible. Patients immobilized in large casts may develop superior mesenteric artery syndrome, also known as cast syndrome, a rare condition characterized by compression of the third portion of the duodenum between the aorta and superior mesenteric artery (Karrer & Jones, 2018). A partial or complete obstruction of the duodenum can occur within days or weeks after the cast has been applied and includes psychological or physiologic manifestations. The psychological component is similar to a claustrophobic reaction. The patient exhibits an acute anxiety reaction characterized by behavioral changes and autonomic responses (e.g., increased respiratory rate, diaphoresis, dilated pupils, increased heart rate, elevated blood pressure). The nurse needs to recognize the anxiety

reaction and provide an environment in which the patient feels secure. The administration of pain and antianxiety medications prior to the casting procedure may help to reduce this reaction.

With decreased physical activity, gastrointestinal motility decreases, and intestinal gases accumulate. Physiologic manifestations include abdominal distention and discomfort, nausea, and bilious vomiting, which can lead to food aversion, poor intake, malnourishment, and weight loss (Rai, Shah, Palliyil, et al., 2019). Eventually, increased abdominal pressure and ileus may occur. As with other instances of adynamic ileus, the patient is treated conservatively with decompression (nasogastric intubation connected to suction) and IV fluid therapy until gastrointestinal motility is restored. If conservative measures are ineffective, surgical intervention is warranted. Rarely, the abdominal distention can place added pressure on the superior mesenteric artery, reducing the blood supply to the bowel, which can result in gangrenous bowel. The descending aorta may also sustain pressure, as it may be compressed between the spine and pressure of abdominal distention, which results in ischemia. These complications can be severe, and the pressure needs to be relieved as soon as possible by cutting a window in the abdominal portion of the cast or bivalving the cast; these measures may be sufficient to prevent or relieve pressure on the duodenum.

Quality and Safety Nursing Alert

The nurse monitors the patient in a large body cast for potential superior mesenteric artery syndrome, noting bowel sounds every 4 to 8 hours, and reports abdominal discomfort and distention, nausea, and vomiting to the primary provider.

Caring for a patient with a body or spica cast at home can be very stressful for the caregiver(s); therefore, it is essential that nurses provide appropriate support and discharge education. To minimize complications after the cast is applied, the nurse should give the patient a comprehensive discharge package that supplements home care instructions with visual training instructions, as well as provide telephone counseling after discharge (Schweich, 2019). Specifically, the nurse educates the family about how to care for the patient, including providing hygienic, cast and skin care, proper positioning, preventing complications, and recognizing symptoms that should be reported to the primary provider.

The Patient with an External Fixator

External fixator devices are used to manage fractures with large amounts of soft tissue damage. Complicated fractures of the humerus, forearm, femur, tibia, and pelvis are also managed with external skeletal fixators. They are also used to correct defects, treat nonunion, and lengthen limbs. Their use has increased in recent years with advances in orthopedic trauma care. The fixator provides skeletal stability for severe comminuted (crushed or splintered) fractures while permitting active treatment of extensive soft tissue damage (see Fig. 37-9).

Figure 37-9 • External fixation device. Pins are inserted into bone. The fracture is reduced and aligned and then stabilized by attaching the pins to a rigid portable frame. The device facilitates treatment of soft tissue damaged in complex fractures.

External fixation is a technique that involves the surgical insertion of pins through the skin and soft tissues into and through the bone. A metal external

frame is attached to these pins and is designed to hold the fracture in proper alignment to enable healing to occur (Kani, Porrino, & Chew, 2020). Advantages of external fixation, compared to other modes of treatment, include immediate fracture stabilization, minimization of blood loss (in comparison to internal fixation), increased patient comfort, improved wound care, promotion of early mobilization and weight bearing on the affected limb, and active exercise of adjacent uninvolved joints (AAOS, 2019d). The disadvantages are an increased risk for pin site loosening and infection, which can lead to osteomyelitis, septic arthritis, and progressive pain (Sayed, Mohammed, Mostafa, et al., 2019).

Management

Patients should be prepared psychologically for application of the external fixator, as they may be at risk for an altered body image related to the size and bulk of the apparatus. To promote acceptance of the device, patients should be given comprehensive information about the frame and reassurance that the discomfort associated with the device is minimal and that early mobility is anticipated (Walker, 2018); however, among patients who have had significant trauma, there may not be time to engage them in this type of preparation. Nurses should initiate open discussions to help patients describe their concerns about the apparatus and expectations about care.

After the external fixator is applied, the extremity is elevated to the level of the heart to reduce swelling, if appropriate. Any sharp points on the fixator or pins are covered with caps to prevent device-induced injuries. The nurse must be alert for potential problems caused by pressure from the device on the skin, nerves, or blood vessels and for the development of acute compartment syndrome. The nurse monitors the neurovascular status of the extremity every 2 to 4 hours and promptly reports changes to the primary provider (Hadeed, Werntz, & Varacallo, 2019). Because the pins are inserted externally, particular attention is focused on the pin sites for signs of inflammation and infection. The goal is to avoid osteomyelitis. The nurse assesses each pin site at least every 8 to 12 hours for redness, swelling, pain around the pin sites, warmth, and purulent drainage, because these are the most common indicators of pin site infections. In the first 48 to 72 hours postinsertion, some serous drainage, skin warmth, and mild redness at the pin sites are expected (Walker, 2018); these are expected to subside after 72 hours.

Currently, there is no consensus or research-based evidence to direct the best method for cleansing and dressing percutaneous pin sites to minimize infection rates and complications (Lobst, 2017). Additionally, there continues to be a lack of evidence regarding best management of crusting on pin sites (Georgiades, 2018). In the absence of such research, aseptic technique during pin insertion is advised (Gasiorowski, 2017), along with general strategies

such as cleansing each pin site separately to avoid cross contamination with nonshedding material (e.g., gauze, cotton-tip swab) and using chlorhexidine 2 mg/mL solution once weekly. Chlorhexidine can be an allergen, however. Therefore, the patient should be monitored for manifestations of an allergic reaction, which may include pruritus and/or contact dermatitis at the pin site, or, rarely in severe cases, angioedema and even anaphylactic shock (Campbell & Watt, 2020). Pin sites should be cleaned and dressed as prescribed unless there is copious drainage, the dressing becomes wet, or infection is suspected, in which case cleaning and dressing may be more frequent. If signs of an allergic reaction or infection are present or if the pins or clamps seem loose, the nurse notifies the primary provider.

Chart 37-6  HOME CARE CHECKLIST

The Patient with an External Fixator

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the musculoskeletal injury/disorder on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State rationale for use of external fixation and resulting changes in lifestyle (e.g., activity, exercise, rest) necessary to maintain health and safety.
  - Avoid excessive use of injured extremity.
  - Observe prescribed weight-bearing limits.
  - Demonstrate ability to transfer (e.g., from a bed to a chair) and/or safe use of mobility aid.
  - Demonstrate exercises to promote circulation and minimize disuse syndrome.
- State signs of pin site infection (e.g., redness, tenderness, increased or purulent pin site drainage) to be reported promptly.
- Describe approaches to controlling swelling and pain (e.g., elevate extremity to heart level, take analgesic agents as prescribed).
- Verbalize plan to report pain uncontrolled by elevation and analgesic agents (may be an indicator of impaired tissue perfusion, acute compartment syndrome, or pin tract infection).
- State indicators of complications to report promptly to primary provider (e.g., uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of systemic infection; loose fixator pins or clamps).
- State how to reach primary provider with questions or complications
  - State time and date of follow-up appointments and testing
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify the need for health promotion, disease prevention, and screening activities
- Describe care of extremity after fixator removal (e.g., gradual resumption of normal activities to protect limb from undue stresses).

Resources

See Chapter 2, Chart 2-6, for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Quality and Safety Nursing Alert

The nurse never adjusts the clamps on the external fixator frame. It is the primary provider's responsibility to do so.

If activity is restricted, the nurse encourages isometric exercises as tolerated to prevent complications of mobility (e.g., thrombus formation). When the swelling subsides, the nurse helps the patient become mobile within the prescribed weight-bearing limits (non–weight bearing to full weight bearing). Adherence to weight-bearing instructions minimizes the chance of loosening of the pins when stress is applied to the bone–pin interface. The external fixator may be removed once the soft tissue heals and there are no signs of infection. The fracture may require additional stabilization by a cast, molded orthosis, or internal fixation while healing.

Ilizarov fixation is a specialized type of external fixator consisting of numerous wires that penetrate the limb and are attached to a circular metal frame (Kani et al., 2020). This device is used to correct angulation and rotational defects, to treat nonunion (failure of bone fragments to heal), and to lengthen limbs. The device gently pulls apart the cortex of the bone and stimulates new growth through daily adjustment of the telescoping rods. The nurse must educate the patient about adjusting the telescoping rods and caring for the pin sites and apparatus, because this fixator can be in place for many months. When discharge is anticipated, the nurse educates the patient or caregiver about how to perform pin site care according to the prescribed protocol (clean technique can be used at home) and to promptly report any signs of pin site inflammation, irritation, infection, or pin loosening (Sayed et al., 2019; Walker, 2018). The nurse also instructs the patient or family to monitor neurovascular status and report any changes promptly. The patient or family members are instructed to check the integrity of the fixator frame daily and to report loose pins or clamps. A physical therapy referral is helpful in educating the patient how to transfer, use ambulatory aids safely, and adjust to weight-bearing limits and altered gait patterns (see Chart 37-6).

The Patient in Traction

Traction uses a pulling force to promote and maintain alignment to an injured part of the body (Flynn, 2018). The goals of traction include decreasing muscle spasms and pain, realignment of bone fractures, and correcting or preventing deformities. The type of traction, amount of weight, and whether traction can be removed for nursing care must be determined to obtain its therapeutic effects.

At times, traction needs to be applied in more than one direction to achieve the desired line of pull. When this is done, one of the lines of pull counteracts

the other. These lines of pull are known as the vectors of force. The actual resultant pulling force is somewhere between the two lines of pull (see Fig. 37-10). The effects of traction are evaluated with x-ray studies, and adjustments are made if necessary.

Traction is used primarily as a short-term intervention until other modalities, such as external or internal fixation, are possible (AAOS, 2019d). These operative techniques reduce the risk of disuse syndrome and minimize hospital lengths of stay, often allowing the patient to be cared for in the home setting.

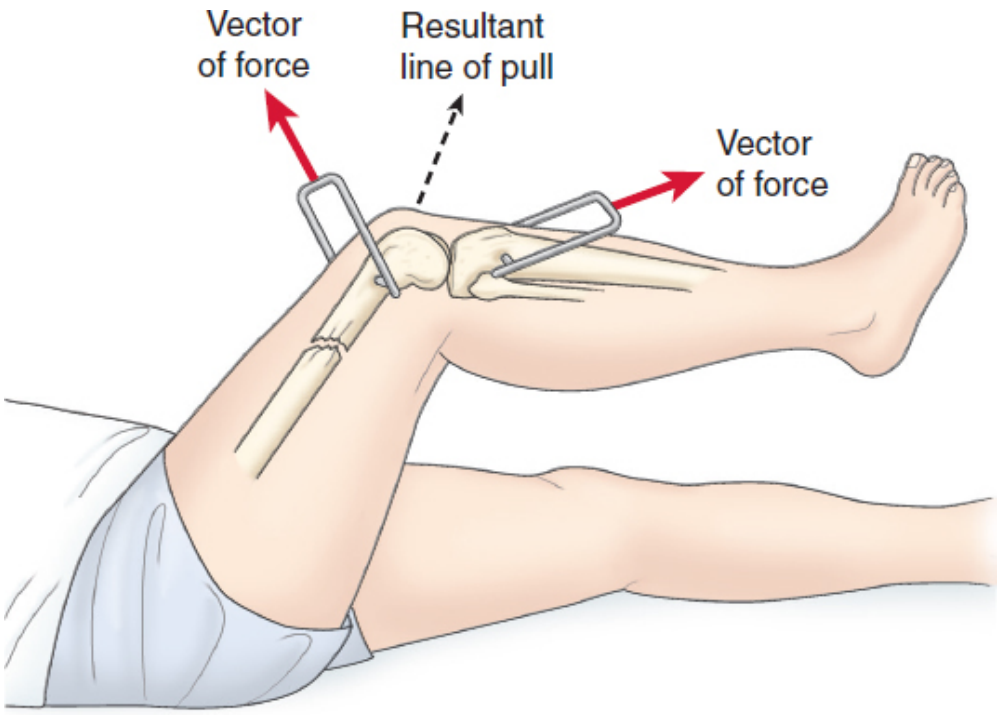

Figure 37-10 • Traction may be applied in different directions to achieve the desired therapeutic line of pull. Adjustments in applied forces may be prescribed over the course of treatment.

Principles of Effective Traction

Whenever traction is applied, countertraction must be used to achieve effective results. Countertraction is the force acting in the opposite direction. Usually, the patient's body weight and bed position adjustments supply the needed countertraction.

When caring for the patient in traction, the nurse should follow these additional principles:

- Traction must be continuous to be effective in reducing and immobilizing fractures.
- Skeletal traction is *never* interrupted.
- Weights are not removed unless intermittent traction is prescribed.

- Any factor that might reduce the effective pull or alter its resultant line of pull must be eliminated.
- The patient must be in good body alignment in the center of the bed when traction is applied.
- Ropes must be unobstructed.
- Weights must hang freely and not rest on the bed or floor.
- Knots in the rope or the footplate must not touch the pulley or the foot of the bed.

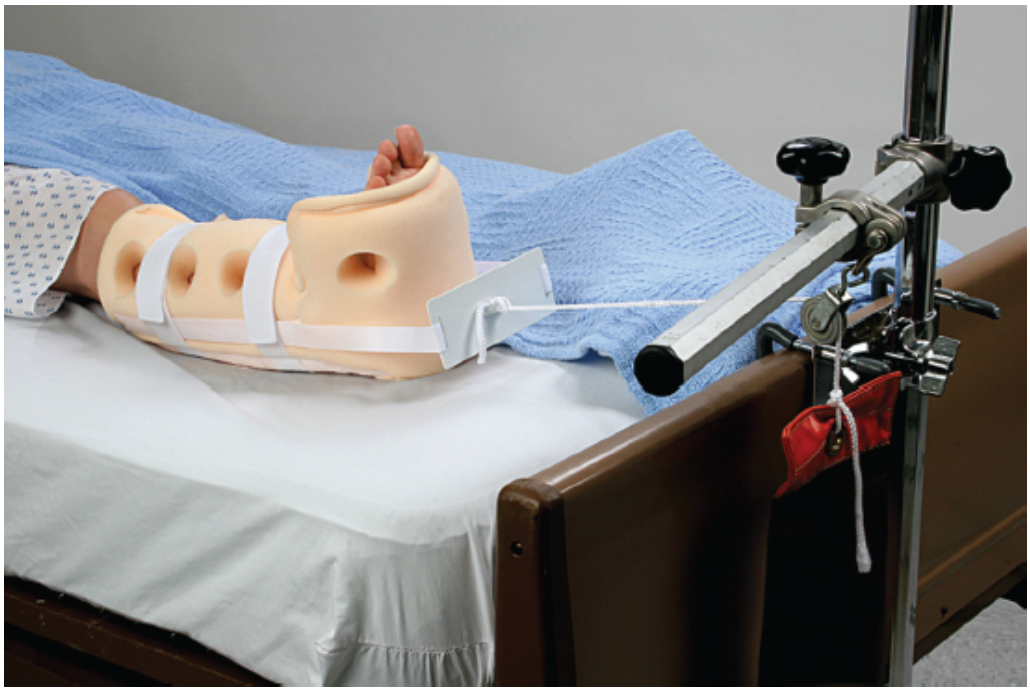

Figure 37-11 • Buck's extension traction. Lower extremity in unilateral Buck's extension traction is aligned in a foam boot and traction applied by the free-hanging weight. The Heelift® Traction Boot is shown here. Photo courtesy of DM Systems, Inc.

Types of Traction

The use of traction has decreased significantly due to advances in the surgical reduction of fractures, shortened lengths of hospital stay, and research that queries the effectiveness of its use (Biz, Fantoni, Crepaldi, et al., 2019). However, a basic working knowledge of the use of traction is necessary, because some orthopedic surgeons still prescribe traction for their patients (Santy-Tomlinson, 2017).

There are several types of traction. *Straight* or *running traction* applies the pulling force in a straight line with the body part resting on the bed. The countertraction is provided by the patient's body and movement can alter the traction provided. Buck's extension traction (discussed later; see Fig. 37-11) is

an example of straight traction. *Balanced suspension traction* (see Fig. 37-12) supports the affected extremity off the bed and allows for some patient movement without disruption of the line of pull. With this traction, the countertraction is produced by devices such as slings or splints.

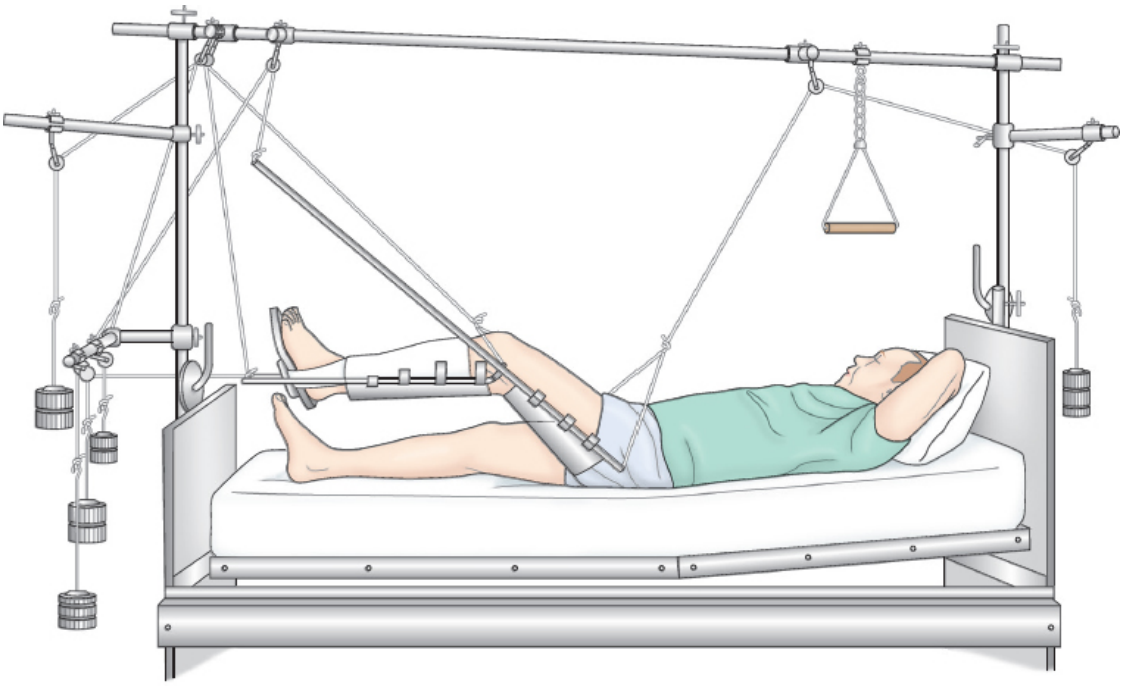

Figure 37-12 • Balanced suspension skeletal traction with Thomas leg splint. The patient can move vertically as long as the resultant line of pull is maintained. Note the use of overhead trapeze.

Traction may be applied to the skin (*skin traction*) or directly to the bony skeleton (*skeletal traction*). The mode of application is determined by the purpose of the traction. Traction can be applied with the hands (*manual traction*). This is temporary traction that may be used when applying a cast, giving skin care under a Buck's extension foam boot, or adjusting the traction apparatus.

Skin Traction

Skin traction is not frequently used but it may be prescribed as a temporary measure to stabilize a fractured leg, control muscle spasms, and immobilize an area before surgery. The pulling force is applied by weights that are attached to the patient with Velcro, tape, straps, boots, or cuffs (Duperouzel, Gray, & Santy-Tomlinson, 2018). The amount of weight applied must not exceed the tolerance of the skin. No more than 2 to 3.5 kg (4.5 to 8 lb) of traction can be used on an extremity. Pelvic traction is usually limited to 4.5 to 9 kg (10 to 20 lb), depending on the weight of the patient. Buck's extension traction (applied

to the lower leg) is the most common type of skin traction indicated for select adults with musculoskeletal injury.

Buck's Extension Traction

Buck's extension traction (unilateral or bilateral) is skin traction to the lower leg. The pull is exerted in one plane when partial or temporary immobilization is desired (see Fig. 37-11). It is used as a temporary measure to overcome muscle spasms and promote immobilization of hip fractures in adult patients waiting for more definitive treatment such as surgery. However, current data show no direct benefit; that is, there is no improvement in pain and better fracture reduction when Buck's traction is applied preoperatively in patients with hip fractures (Etxebarria-Foronda & Caeiro-Rey, 2018).

Before the traction is applied, the nurse inspects the skin for abrasions and circulatory disturbances. The skin and circulation must be in healthy condition to tolerate the traction. The extremity should be clean and dry before the foam boot or traction tape is applied.

To apply Buck's traction, the extremity is elevated and supported under the patient's heel and knee while the foam boot is placed under the leg, with the patient's heel in the heel of the boot. Next, the Velcro straps are secured around the leg. Traction tape that is overwrapped with an elastic bandage in a spiral fashion may be used instead of the boot. Excessive pressure is avoided over the malleolus and proximal fibula during application to prevent pressure injuries and nerve damage. The rope is then affixed to the spreader or footplate over a pulley fastened to the end of the bed and attaches the prescribed weight —usually approximately 2.25 to 3.5 kg (or more precisely 5 to 8 lb)—to the rope. The weight should hang freely, not touching parts of the bed or floor as this compromises the efficiency of the traction system (Duperouzel et al., 2018).

Nursing Interventions

To ensure effective skin traction, it is important to avoid wrinkling and slipping of the traction bandage and to maintain countertraction. Proper positioning must be maintained to keep the leg in a neutral position. To prevent bony fragments from moving against one another, the patient should not turn from side to side; however, the patient may shift position slightly with assistance.

Monitoring and Managing Potential Complications

The nurse monitors for complications of skin traction, which can include skin breakdown, nerve damage, and circulatory impairment.

Skin Breakdown

During the initial assessment, the nurse identifies sensitive, fragile skin (common in older adults). The nurse also inspects the skin area that is in contact with tape, foam, or shearing forces, at least every 8 hours, for signs of irritation or inflammation (Duperouzel et al., 2018). The nurse performs the following procedures to monitor and prevent skin breakdown:

- Removes the foam boots to inspect the skin, the ankle, and the Achilles tendon at least twice daily. A second person is needed to support the extremity during the inspection and skin care.
- Palpates the area of the traction tapes daily to detect underlying tenderness.
- Provides frequent repositioning to alleviate pressure and discomfort, because the patient who must remain in a supine position is at increased risk for development of a pressure injury.
- Uses advanced static mattresses or overlays rather than standard hospital foam or alternating-air/low-air-loss mattresses to reduce the risk of pressure injury formation (Kirman, 2018).

Nerve Damage

Skin traction can place pressure on peripheral nerves. Care must be taken to avoid pressure on the peroneal nerve at the point at which it passes around the neck of the fibula just below the knee when traction is applied to the lower extremity. Pressure at this point can cause footdrop. The nurse regularly questions the patient about sensation and asks the patient to move the toes and foot. The nurse should immediately investigate any complaint of a burning sensation under the traction bandage or boot. Dorsiflexion of the foot demonstrates function of the peroneal nerve. Weakness of dorsiflexion or foot movement and inversion of the foot might indicate pressure on the common peroneal nerve. Plantar flexion demonstrates function of the tibial nerve. In addition, the nurse should promptly report altered sensation or impaired motor function.

Circulatory Impairment

After skin traction is applied, the nurse assesses circulation of the foot within 15 to 30 minutes and then every 1 to 2 hours. Circulatory assessment consists of:

- Peripheral pulses, color, capillary refill, and temperature of the fingers or toes.
- Manifestations of DVT, which include unilateral calf tenderness, warmth, redness, and swelling.

The nurse also encourages the patient to perform active foot exercises every hour when awake.

Skeletal Traction

Skeletal traction is often used when continuous traction is desired to immobilize, position, and align a fracture of the femur, tibia, and cervical spine. It is used when traction is to be maintained for a significant amount of time, when skin traction is not possible, and when greater weight (11 to 18 kg [25 to 40 lb]) is needed to achieve the therapeutic effect. Skeletal traction involves passing a metal pin or wire (e.g., Steinmann pin, Kirschner wire) through the bone (e.g., proximal tibia or distal femur) under local anesthesia, avoiding nerves, blood vessels, muscles, tendons, and joints (Buckley & Page, 2018). Traction is then applied using ropes and weights attached to the end of the pin. Alternatively, skeletal traction may involve the application of tongs to the head that are fixed to the skull to immobilize cervical fractures (see Chapter 63).

The surgeon applies skeletal traction using surgical asepsis. The insertion site is prepared with a surgical scrub agent such as chlorhexidine solution. A local anesthetic agent is given at the insertion site and periosteum. The surgeon makes a small skin incision and drills the sterile pin or wire through the bone. The patient feels pressure during this procedure and possibly some pain when the periosteum is penetrated.

After insertion, the pin or wire is attached to the traction bow or caliper. The ends of the pin or wire are covered with caps to prevent injury to the patient or caregivers. The weights are attached to the pin or wire bow by a rope and pulley system that exerts the appropriate amount and direction of pull for effective traction (Biz et al., 2019). The weights applied initially must overcome the shortening spasms of the affected muscles. As the muscles relax, the traction weight is reduced to prevent fracture dislocation and to promote healing.

Often, skeletal traction is balanced traction, which supports the affected extremity, allows for some patient movement, and facilitates patient independence and nursing care while maintaining effective traction. The Thomas splint with a Pearson attachment is frequently used with skeletal traction for fractures of the femur (see Fig. 37-12). Because upward traction is required, an overbed frame is used (Gray & Santy-Tomlinson, 2018).

When skeletal traction is discontinued, the extremity is gently supported while the weights are removed. The pin is cut close to the skin and removed by the surgeon. Internal fixation, casts, or splints are then used to immobilize and support the healing bone.

Nursing Interventions

When skeletal traction is used, the nurse checks the traction apparatus to see that the ropes are in the wheel grooves of the pulleys, the ropes are not frayed, the weights hang freely, and the knots in the rope are tied securely. The nurse also evaluates the patient's position, making sure that the traction force is

always in correct alignment with the leg, with the patient in the mid-line position (Gray & Santy-Tomlinson, 2018).

Quality and Safety Nursing Alert

The nurse must never remove weights from skeletal traction unless a life-threatening situation occurs. Removal of the weights defeats their purpose and may result in injury to the patient.

The nurse must maintain alignment of the patient's body in traction as prescribed to promote an effective line of pull (Gray & Santy-Tomlinson, 2018). The nurse positions the patient's foot to avoid footdrop (plantar flexion), inward rotation (inversion), and outward rotation (eversion). The patient's foot may be supported in a neutral position by orthopedic devices (e.g., foot supports).

If the patient reports severe pain from muscle spasm, the weights may be too heavy, or the patient may need realignment. Pain must be reported to the primary provider if body alignment fails to reduce discomfort. Opioid and nonopioid analgesics may be used to control pain. Muscle relaxants may be prescribed to relieve muscles spasms as needed.

Preventing Skin Breakdown

The patient's elbows frequently become sore, and nerve injury may occur if the patient repositions by pushing on the elbows. In addition, patients frequently push on the heel of the unaffected leg when they raise themselves. This digging of the heel into the mattress may injure the tissues. It is important to instruct patients not to use their heels or elbows to push themselves up in bed (El-saidy & Aboshehata, 2019). To encourage movement without using the elbows or heel, an assistive device called a **trapeze** can be suspended overhead within easy reach of the patient (see Fig. 37-12). The trapeze helps the patient move about in bed and move on and off the bedpan. Transparent film, hydrocolloid dressings, or skin sealants may also be applied to bony prominences (such as elbows) or critical areas to decrease the force of shearing and friction (Gaspar, Peralta, Marques, et al., 2019).

Specific pressure points are assessed for irritation and inflammation at least every 8 hours. Patients at high risk for skin breakdown (e.g., older adults, patients who are malnourished or who have impaired mobility or sensation) may need to be assessed more frequently (Mervis & Phillips, 2019). Areas that are particularly vulnerable to pressure caused by a traction apparatus applied to the lower extremity include the ischial tuberosity, popliteal space, Achilles tendon, and heel. If the patient is not permitted to turn on one side or the other, the nurse must make a special effort to provide back care and to keep the bed

dry and free of crumbs and wrinkles. The patient can assist by holding the overhead trapeze and raising the hips off the bed. If the patient cannot do this, the nurse can push down on the mattress with one hand to relieve pressure on the back and bony prominences and to provide for some shifting of weight. Given the supine position that most patients with skeletal traction assume, the use of advanced static mattresses or overlays should be considered rather than foam or alternating-air/low-air-loss mattresses to reduce the risk of pressure injury (Serraes, Van Leen, Schols, et al., 2018). The patient's heel should be "off-loaded" and carefully placed on a pillow or heel suspension device to keep the heel from the bed's surface (Gray & Santy-Tomlinson, 2018).

For change of bed linens, the patient raises the torso while caregivers on both sides of the bed roll down and replace the upper mattress sheet. Then, as the patient raises the buttocks off the mattress, the sheets are slid under the buttocks. Finally, the lower section of the bed linens is replaced while the patient rests on the back. Sheets and blankets are placed over the patient in such a way that the traction is not disrupted.

Monitoring Neurovascular Status

The nurse evaluates the body part to be placed in traction and compares its neurovascular status (e.g., color, temperature, capillary refill, edema, pulses, ability to move, and sensations) to the unaffected extremity every hour for the first 24 hours after traction is applied and every 4 hours thereafter. The nurse instructs the patient to report any changes in sensation or movement immediately so that they can be promptly evaluated. VTE formation is a significant risk for the patient who is immobilized. The nurse encourages the patient to do active flexion–extension ankle exercises and isometric contraction of the calf muscles (calf-pumping exercises) 10 times an hour while awake to decrease venous stasis. In addition, anti-embolism stockings, compression devices, and anticoagulant therapy may be prescribed to help prevent thrombus formation.

Quality and Safety Nursing Alert

The nurse must immediately investigate every report of discomfort expressed by the patient in traction. Prompt recognition of a developing neurovascular problem is essential so that corrective measures can be instituted quickly.

Providing Pin Site Care

The wound at the pin insertion site requires attention, and it is important to follow the facility's specific policy pertaining to skeletal pin care. The goal is to avoid infection and development of osteomyelitis (see Chapter 36). For the

first 48 hours after insertion, the site is covered with a sterile absorbent nonstick dressing and a rolled gauze or Ace-type bandage. After this time, a loose cover dressing or no dressing is recommended (a bandage is necessary if the patient is exposed to airborne dust). Expert consensus-based recommendations for pin site care include the following (Walker, 2018):

- Pins located in areas with soft tissue are at greatest risk for infection.
- After the first 48 to 72 hours following skeletal pin placement, pin site care should be performed daily or weekly.
- Chlorhexidine 2 mg/mL solution is the most effective cleansing solution. If chlorhexidine is contraindicated (due to known hypersensitivity or skin reaction), saline solution should be used for cleansing.
- Strict hand hygiene before and after skeletal pin site care should always take place.

The nurse must inspect the pin sites at least every 12 hours for signs of hypersensitivity/allergic reaction (e.g., contact dermatitis, pruritus, urticaria, angioedema), irritation (e.g., normal changes that occur at the pin site after insertion) and infection. Signs of irritation may include redness, warmth, and serosanguineous drainage at the site, which tend to subside after 72 hours. Signs of infection may mirror those of reaction but also include the presence of purulent drainage, pain, pin loosening, tenting of skin at pin site, odor, and fever. Patient descriptions of their pin sites might be helpful as they are often the first to notice subtle changes in their symptoms and may be able to differentiate between different pin site states (Santy-Tomlinson, Jomeen, & Ersser, 2019). Prophylactic broad-spectrum IV antibiotics may be given for 24 to 48 hours postinsertion to prevent infection; however, the evidence is confounding and there is no general consensus on the advisability of this practice (Walker, 2018). Minor infections may be readily treated with antibiotics, and infections that result in systemic manifestations may additionally warrant pin removal until the infection resolves.

Due to a lack of evidence-based research findings, controversy exists about skeletal pin care, showering, and the overall management of pin site crusts, which are the hardened plugs of exudate that adhere to and block the pin sites. Current evidence suggests that crusting at the pin site should be retained as long as the pin site remains uninfected as the retained crusts provides a natural barrier from the external environment, which can prevent bacterial contamination (Georgiades, 2018). The patient and family should be educated on the performance of any prescribed pin site care prior to discharge from the hospital and should be provided with written follow-up instructions that include the signs and symptoms of infection.

Promoting Exercise

Patient exercises, within the therapeutic limits of the traction, assist in maintaining muscle strength and tone, and in promoting circulation. Active exercises include pulling up on the trapeze, flexing and extending the feet, and range-of-motion and weight-resistance exercises for noninvolved joints. Isometric exercises of the immobilized extremity (quadriceps and gluteal setting exercises) are important for maintaining strength in major ambulatory muscles (see Chart 37-4). Without exercise, the patient will lose muscle mass and strength, and rehabilitation will be greatly prolonged.

Nursing Management of the Patient in Traction

Nursing management of the patient in traction includes assessing for and addressing anxiety, assisting with self-care, and monitoring for complications.

Assessing Anxiety

The nurse must consider the psychological and physiologic impact of the musculoskeletal problem, traction device, and immobility. Traction restricts mobility and independence. The equipment can look threatening, and its application can be frightening. Confusion, disorientation, and behavioral problems may develop in patients who are confined in a limited space for an extended time. Therefore, the nurse must assess and monitor the patient's anxiety level and psychological responses to traction.

Assisting with Self-Care

Initially, the patient may require assistance with self-care activities. The nurse helps the patient eat, bathe, dress, and toilet. Convenient arrangement of items such as the telephone, tissues, water, and assistive devices (e.g., reachers, overbed trapeze) may facilitate self-care. With resumption of self-care activities, the patient feels less dependent and less frustrated and experiences improved self-esteem. Because some assistance is required throughout the period of immobility, the nurse and the patient can creatively develop routines that maximize the patient's independence.

Monitoring and Managing Potential Complications

Immobility-related complications may include pressure injuries (see Chapter 56), atelectasis, pneumonia, constipation, loss of appetite, urinary stasis, urinary tract infections, and VTE formation. Early identification of preexisting or developing conditions facilitates prompt interventions to resolve them.

Atelectasis and Pneumonia

The nurse auscultates the patient's lungs every 4 to 8 hours to assess respiratory status and educates the patient about performing deep breathing

and coughing exercises to aid in fully expanding the lungs and clearing pulmonary secretions. If the patient history and baseline assessment indicate that the patient is at risk for development of respiratory complications, specific therapies (e.g., the use of an incentive spirometer) may be indicated (see Chapter 19, Chart 19-1). If a respiratory complication develops, prompt institution of prescribed therapy is needed.

Constipation and Anorexia

Reduced gastrointestinal motility results in constipation and anorexia. A diet high in fiber and fluids may help stimulate gastric motility. If constipation develops, therapeutic measures may include stool softeners, laxatives, suppositories, and enemas. To improve the patient's appetite, the patient's food preferences are included, as appropriate, within the prescribed therapeutic diet.

Urinary Stasis and Infection

Incomplete emptying of the bladder related to positioning in bed can result in urinary stasis and infection. In addition, the patient may find the use of a bedpan uncomfortable and may limit fluids to minimize the frequency of urination. The nurse monitors the fluid intake and the character of the urine. Adequate hydration is important; therefore, the nurse instructs the patient to consume adequate amounts of fluid and to void every 3 to 4 hours. If the patient exhibits signs or symptoms of urinary tract infection (e.g., burning or pain on urination, hematuria), the nurse notifies the primary provider.

Venous Thromboembolism

Venous stasis that predisposes the patient to VTE occurs with immobility. The nurse educates the patient about how to perform ankle and foot exercises within the limits of the traction therapy every 1 to 2 hours when awake to prevent DVT. To increase adherence and promote the family's involvement with the patient's care, it is important to include the family members in any education and care decisions about VTE prevention (Health Services Advisory Group, 2019). The patient is encouraged to drink fluids to prevent dehydration and associated hemoconcentration, which contribute to stasis. The nurse monitors the patient for signs of DVT, including unilateral calf tenderness, warmth, redness, and swelling (increased calf circumference). The nurse promptly reports findings to the primary provider for evaluation and therapy.

During traction therapy, the nurse encourages the patient to exercise muscles and joints that are not in traction to prevent deterioration, deconditioning, and venous stasis. The physical therapist can design bed exercises that minimize loss of muscle strength. During the patient's exercise, the nurse ensures that traction forces are maintained and that the patient is properly positioned to prevent complications resulting from poor alignment.

Fractures of Specific Sites

Common sites of fractures include the clavicle, humeral neck, humeral shaft, elbow, proximal radius, radial and ulnar shafts, wrist, hand, pelvis, acetabulum, hips, femoral shaft, tibia and fibula, ribs, and thoracolumbar spine.

Clavicle

Fracture of the clavicle (collar bone) is a common injury that can result from a fall or a direct blow to the shoulder. The clavicle helps maintain the shoulder in the upward, outward, and backward position from the thorax. Therefore, when the clavicle is fractured, the patient assumes a protective position, slumping the shoulders and immobilizing the arm to prevent shoulder movements. The treatment goal is to align the shoulder in its normal position by means of closed reduction and immobilization. Surgical intervention is not typical but may be indicated if the fracture is located in the distal third of the clavicle or is severely displaced, which may result in neurovascular compromise or pneumothorax (Kleinhenz, 2019).

The majority of clavicle fractures occur in the middle third of the clavicle; clinical union (healing) takes 6 to 12 weeks in adults (Eiff, Hatch, & Higgins, 2020b). A clavicular strap, also called a *figure-eight bandage* (see Fig. 37-13), may be used to pull the shoulders back, reducing and immobilizing the fracture. The nurse monitors the circulation and nerve function of the affected arm and compares it with the unaffected arm to determine variations, which may indicate disturbances in neurovascular status. A sling may be used to support the arm and relieve pain. The patient may be permitted to use the arm for light activities as pain allows (Hatch, Clugston, & Taffee, 2019).

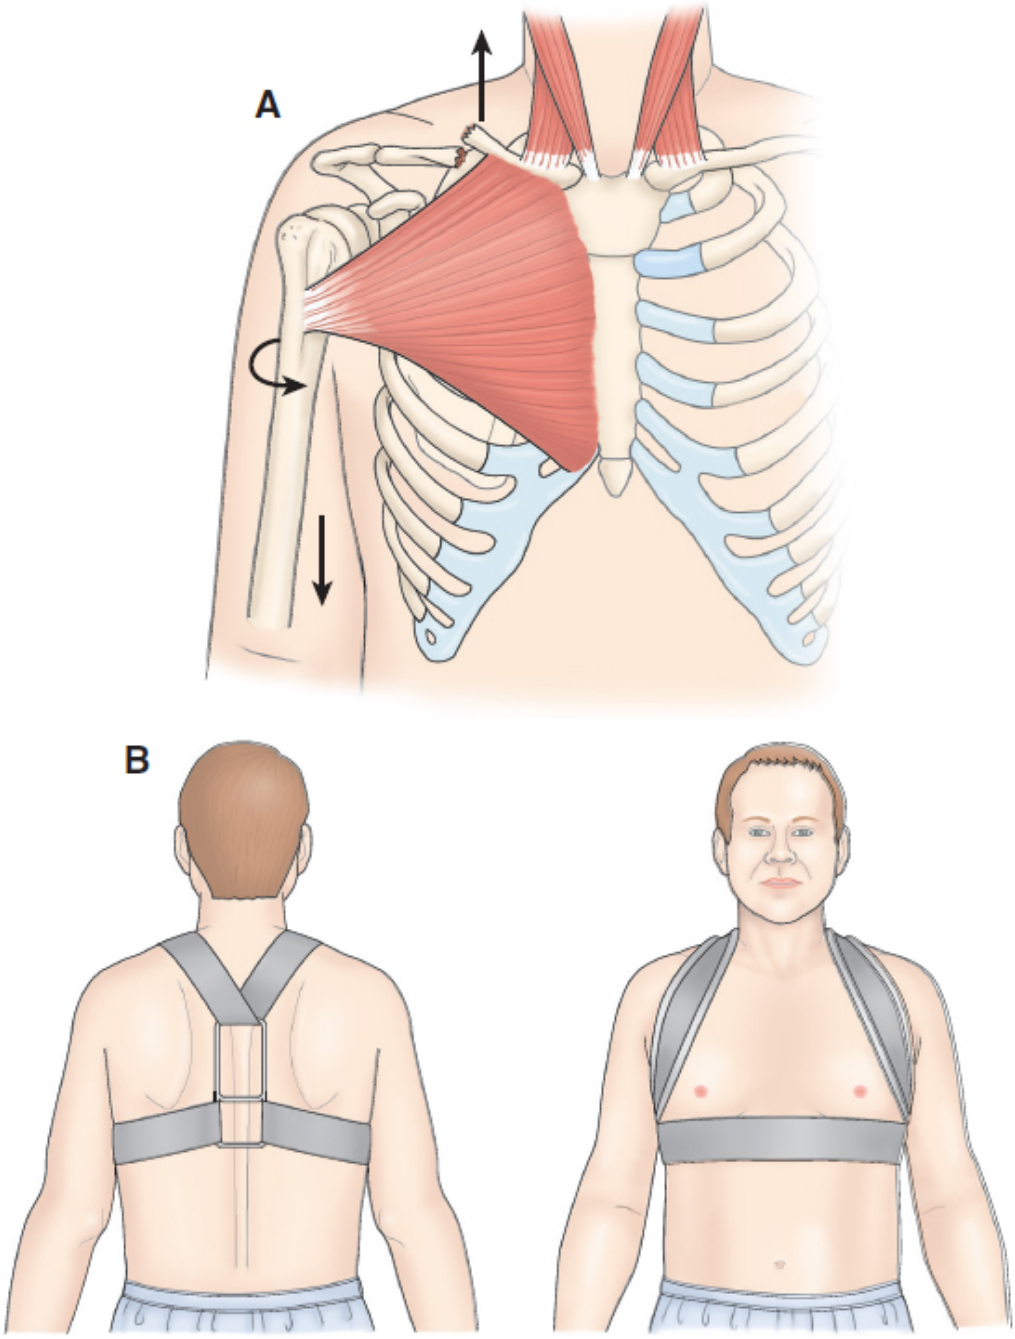

Figure 37-13 • Fracture of the clavicle. **A.** Anteroposterior view shows typical displacement in midclavicular fracture. **B.** Immobilization is accomplished with a clavicular strap.

Fracture of the distal third of the clavicle, without displacement and ligament disruption, is treated with a sling and restricted motion of the arm. When a fracture in the distal third is accompanied by a disruption of the coracoclavicular ligament that connects the coracoid process of the scapula and the inferior surface of the clavicle, the bony fragments are frequently displaced. This type of injury may be treated surgically by ORIF.

Immobilization of the shoulder in the figure-eight bandage or arm sling should be continued until clinical union occurs (e.g., the fracture site is nontender and the patient can move the arm with little or no discomfort) (Hatch et al., 2019). The nurse cautions the patient not to elevate the arm above shoulder level until the fracture has healed but encourages the patient to exercise the elbow, wrist, and fingers as soon as possible. When prescribed, shoulder exercises are performed to obtain full shoulder motion (see Fig. 37-14). Contact sports or activities with potential for falling should be avoided for 1 to 2 months after healing is complete, and has been confirmed by clinical assessment and x-ray findings (Eiff et al., 2020b).

Complications of clavicular fractures are uncommon but can include neurovascular injuries (brachial plexus injury, subclavian vein or artery injury from a bony fragment, and thoracic outlet syndrome), pneumothorax, malunion, and nonunion (Hatch et al., 2019).

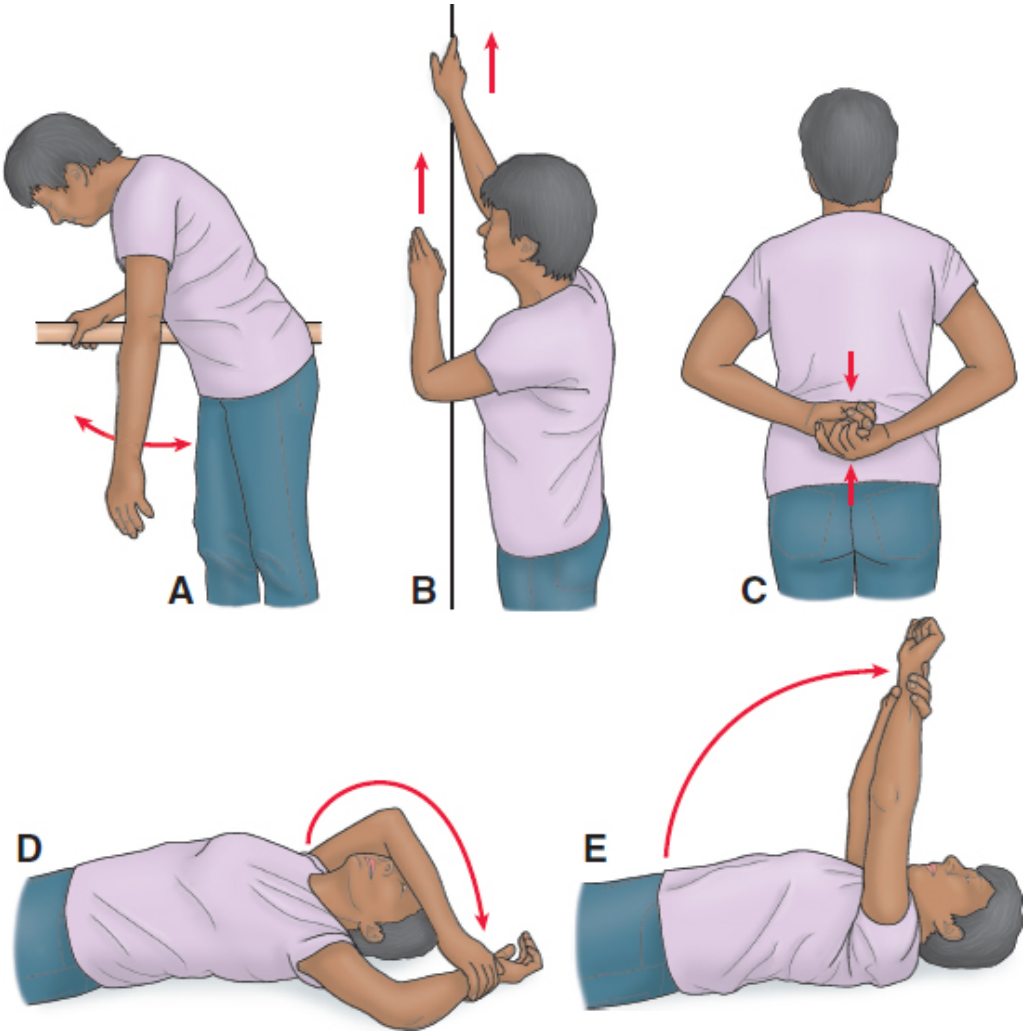

Figure 37-14 • Exercises that promote shoulder range of motion include pendulum exercise (**A**) and wall climbing (**B**). The unaffected arm is used to assist with internal rotation (**C**), external rotation(**D**), and elevation (**E**). In **C, D,** and **E,** the unaffected arm is used for power.

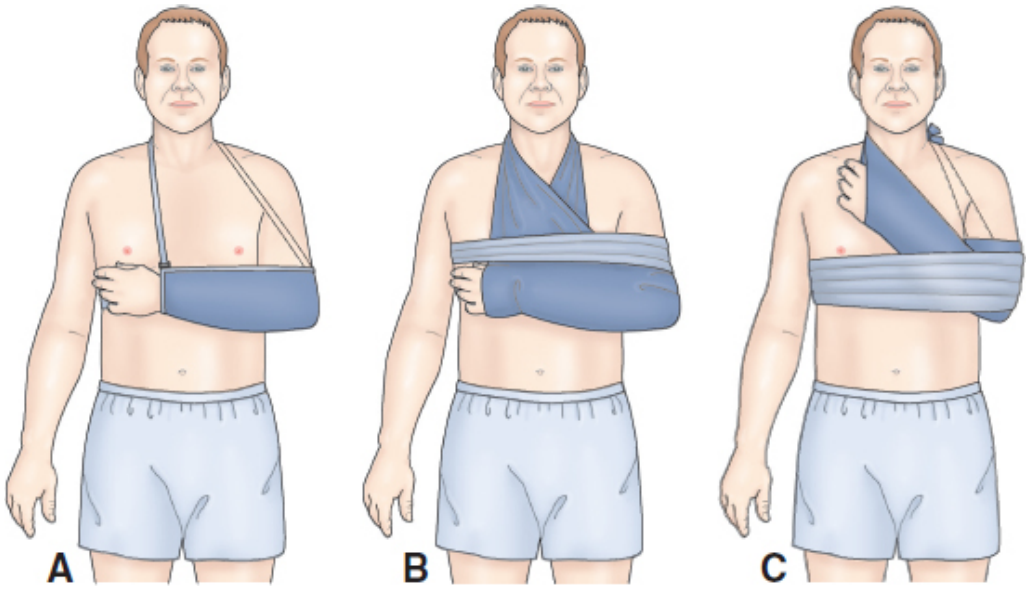

Figure 37-15 • Immobilizers for proximal humeral fractures. **A.** Commercial sling with immobilizing strap permits easy removal for hygiene and is comfortable on the neck. **B.** Conventional sling and swathe. **C.** Stockinette Velpeau and swathe are used when there is an unstable surgical neck component. This position relaxes the pectoralis major.

Humeral Neck

Fractures of the proximal humerus may occur through the neck of the humerus and are most often the result from a fall onto an outstretched hand. Most proximal humerus fractures occur in those older than 60 years of age and are more common in older women because of their greater risk of low bone density (Dorsey, 2020).

The patient presents with moderate to severe shoulder pain with the affected arm hanging limp at the side or supported by the uninjured hand. Neurovascular assessment of the extremity is essential to evaluate the full extent of injury and the possible involvement of the nerves and blood vessels of the arm.

The majority of proximal humerus fractures are impacted with little to no displacement and do not require surgical reduction. The arm is supported and immobilized by a sling and swathe splint that secures the supported arm to the trunk (see Fig. 37-15). Limitation of motion and stiffness of the shoulder occur with disuse. Therefore, pendulum exercises begin as soon as tolerated by the patient. In pendulum or circumduction exercises, the physical therapist instructs the patient to lean forward and allow the affected arm to hang in abduction and rotate. These fractures heal rapidly in about 6 to 10 weeks due to the large areas of cancellous bone (Dorsey, 2020). The goal of treatment is to restore as much function as possible; therefore, shoulder rehabilitation

should begin as pain allows. Residual stiffness, aching, and some loss of shoulder motion ("frozen shoulder") and function may persist and is more likely to develop in patients who do not perform ROM exercises regularly during recovery (Bassett, 2019).

When a humeral neck fracture is significantly displaced, treatment consists of closed reduction with splinting, ORIF, hemiarthroplasty, and reverse shoulder arthroplasty. Exercises begin after an adequate period of immobilization (Bassett, 2019).

Humeral Shaft

Fractures of the midshaft of the humerus are most frequently caused by either a direct blow or trauma that results in a transverse, oblique, or comminuted fracture, or an indirect twisting force that results in a spiral fracture. Patients usually present with considerable swelling and severe arm pain in the area of the mid-arm but may have referred pain to the shoulder or the elbow; shortening of the upper arm may indicate significant displacement (Dorsey, 2020). A thorough neurovascular assessment is important as injury to the radial nerve is often present and may require immediate attention.

There are absolute indications for emergent surgical exploration such as open fractures and fractures associated with neurovascular injuries (Dorsey, 2020). External fixators are used to treat open fractures of the humeral shaft. ORIF is necessary with nerve injury, blood vessel damage, or comminuted or displaced fractures (Bassett, 2018).

However, most humeral midshaft fractures can be treated nonsurgically. Initial splinting is commonly done with a coaptation (*sugar tong*) splint. (A sugar tong splint is a U-shaped splint that looks like tongs used for sugar cubes.) The splint is placed around the medial and lateral arm to the elbow and up to the top of the shoulder. The splint supports the arm in 90 degrees of flexion at the elbow; a sling or collar and cuff support the forearm. The weight of the hanging arm and splints put traction on the fracture site.

The preferred definitive treatment for a humerus shaft fracture is functional bracing. A contoured thermoplastic sleeve is secured in place with interlocking fabric (Velcro) closures around the upper arm, immobilizing the reduced fracture. As swelling decreases, the sleeve is tightened, and uniform pressure and stability are applied to the fracture. The forearm is supported with a collar and cuff sling (see Fig. 37-16). Functional bracing allows active use of muscles, shoulder and elbow motion, and good approximation of fracture fragments. Pendulum shoulder exercises are performed as prescribed to provide active movement of the shoulder, thereby preventing a "frozen shoulder." Isometric exercises may be prescribed to prevent muscle atrophy. The callus that develops is substantial, and the sleeve can be discontinued in about 8 weeks. Complications that are seen with humeral shaft fractures

include neurovascular compromise and nonunion because of decreased blood supply in that area.

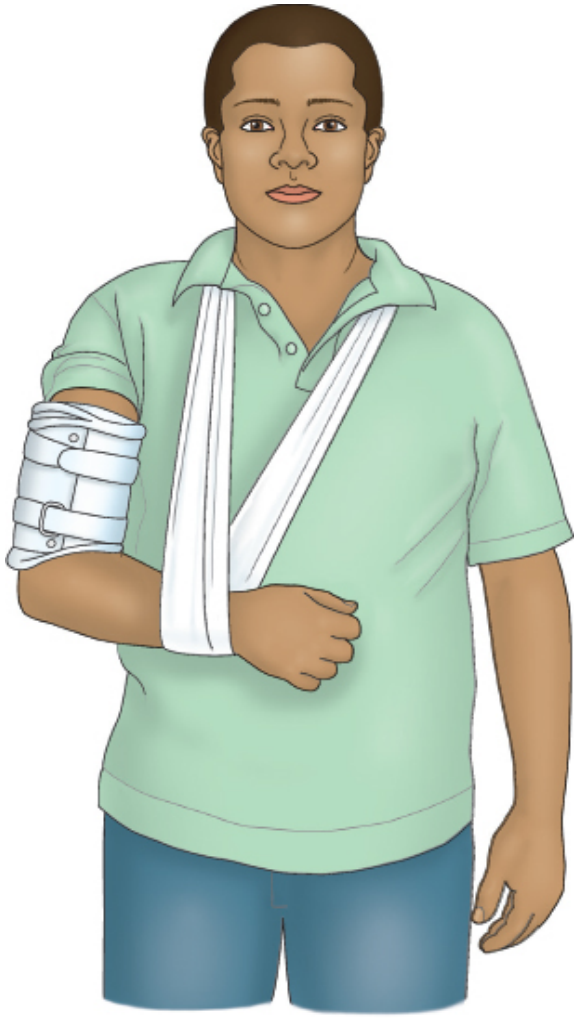

Figure 37-16 • Functional humeral brace with collar and cuff sling.

Elbow

About 30% of adult elbow fractures involve the distal part of the humerus (Eiff, Hatch, & Higgins, 2020c) and are classified as supracondylar, single column (condyle), bicolumn and coronal shear fractures. Most fractures result from high-energy mechanisms such as motor vehicle crashes, falls directly on the elbow (in the extended or flexed position), or a direct blow. These fractures can be very painful and may result in injury to the brachial artery and median nerves (Yian, 2019).

A comprehensive examination of the neurovascular status of the affected extremity should be conducted. The patient is evaluated for paresthesia and signs of compromised circulation in the forearm and hand. The most serious complication of a supracondylar fracture of the humerus is Volkmann ischemia

contracture (an acute compartment syndrome), which results from antecubital swelling or damage to the brachial artery and leads to contracture (shortening) of the forearm muscles. This more commonly occurs in children than in adults and will result in a "clawlike" appearance to the hand and wrist. The nurse needs to monitor the patient regularly for compromised neurovascular status with the "5 Ps"; marked swelling and induration of the forearm are other signs (Kare, 2019). Emergency fasciotomy with débridement of the muscle may be necessary to prevent progression to Volkmann contracture (Eiff et al., 2020c). Other potential complications are damage to the joint articular surfaces and hemarthrosis (e.g., blood in the joint), which may be treated by needle aspiration by the primary provider to relieve the pressure and pain.

The goal of therapy is prompt reduction and stabilization of the distal humeral fracture, followed by controlled active motion after swelling has subsided and healing has begun. If the fracture is not displaced, the arm is immobilized in a posterior splint for 2 to 3 weeks. At that point, ROM exercises can begin with the use of a hinged functional brace (Yian, 2019).

Usually, a displaced fracture is treated with ORIF. Excision of bone fragments may be necessary. Additional external support with a splint is then applied. Active finger exercises are encouraged. Gentle ROM exercise of the injured joint is begun early. Motion promotes healing of injured joints by producing movement of synovial fluid into the articular cartilage. Active exercise to prevent residual limitation of motion is performed as prescribed. Total elbow arthroplasty may be indicated in the presence of significant comminution (e.g., fragmentation of bone). Pain management is achieved through the use of NSAIDs or opioid medications (Yian, 2019).

Proximal Radius

Radial head and neck fractures are fractures of the proximal radius. They are common and are usually the result of a fall on an outstretched hand with the elbow extended. The patient presents with localized swelling over the lateral elbow, tenderness, and decreased motion; pain increases with passive rotation. If blood has collected in the elbow joint, it is aspirated to relieve pain and to allow early active elbow and forearm ROM exercises (Eiff et al., 2020c). Nondisplaced fractures are typically managed nonsurgically with a sling for comfort; elbow flexion and extension as tolerated out of the sling should begin as soon as tolerated, usually within the first few days after injury (Eiff et al., 2020c). If the fracture is displaced, surgery is typically indicated, with excision of or replacement of the radial head when necessary (Rabin, 2018).

Radial and Ulnar Shafts

Fractures of the distal radius are among the most common fractures and occur more frequently in children and adolescents but can occur in adults. The radius or the ulna may be fractured at any level. Frequently, displacement occurs when both bones are broken. The forearm serves an integral role in upper extremity function; therefore, the unique functions of pronation and supination must be preserved with proper anatomic alignment (Kakarala & Simons, 2019).

In adults, if the fragments are not displaced, the fracture is treated by closed reduction with immobilization in a bivalved long arm cast with the wrist in slight extension, the forearm in neutral rotation, and the elbow at 90 degrees (Michaudet, 2020). Circulation, motion, and sensation of the hand are assessed before and after the cast is applied. The arm is elevated to control edema. Frequent finger flexion and extension are encouraged to reduce edema. Active motion of the involved shoulder is essential. The reduction and alignment are monitored closely by x-rays at weekly intervals for the first 4 weeks to ensure proper alignment and then every 2 weeks until healing has occurred (usually 12 to 16 weeks). During the last 6 weeks, the arm may be in a functional forearm brace that allows exercise of the wrist and elbow. Lifting and twisting are avoided.

Displaced fractures of the radius and ulna require an ORIF, using a compression plate with screws, intramedullary nails, or rods. The arm is usually immobilized in a plaster splint or cast. Open and displaced fractures may be managed with external fixation devices. The arm is elevated to control swelling. Neurovascular status is assessed and documented. Elbow, wrist, and hand exercises are begun when prescribed by the primary provider.

Wrist

Fractures of the distal radius (Colles fracture) are common and are usually the result of a fall on an open, outstretched hand, with the wrist in extension. This fracture is frequently seen in older adults with osteoporotic bones that do not dissipate the energy of the fall; it can also occur in youth who are involved in sports who sustain a high-energy fall. The patient presents with a deformed wrist, pain, swelling, weakness, and limited finger ROM, and possibly reports of “tingling” in the affected hand. Tingling sensation may indicate injury to the median nerve (Nelson, 2018).

Treatment usually consists of closed reduction and immobilization with a sugar-tong splint until swelling resides. The splint is placed so that it extends from the palm around the elbow to the back of the hand just below the fingers. This splint should remain in place until the edema lessens and usually the splint is changed to a short arm cast in 2 to 3 weeks. For fractures with extensive comminution, ORIF, plating, percutaneous pinning, or external

fixation is used to achieve and maintain reduction. Pain medication is given as prescribed to aid in pain control (Petron, 2018).

Chart 37-7 PATIENT EDUCATION

Encouraging Exercise After Treatment for Wrist Fracture

The nurse encourages active motion of the fingers and shoulder. The patient is instructed to perform the following exercises to reduce swelling and prevent stiffness:

- Hold the hand at the level of the heart.
- Move the fingers from full extension to flexion. Hold and release. Repeat at least 10 times every hour when awake.
- Use the hand in functional activities.
- Actively exercise the shoulder and elbow, including complete range-of-motion exercises of both joints.

Active motion of the fingers and shoulder should begin promptly to reduce swelling and prevent stiffness (see Chart 37-7).

The fingers may swell due to diminished venous and lymphatic return. The nurse assesses the sensory function of the median nerve by pricking the distal aspect of the index finger. The motor function is assessed by the patient's ability to touch the thumb to the little finger. Diminished circulation and nerve function must be treated promptly (see previous discussion of acute compartment syndrome).

Hand

Fractures of the bones of the hand, phalanges and metacarpals, are a common injury of the skeletal system and a frequent reason that patients seek care in EDs (Muttath, Chung, & Ono, 2019). The most common type of metacarpal fracture in adults is referred to as boxer's fracture, which occurs when a closed fist bangs against a hard surface, fracturing the neck of the fifth finger. Falls and occupational injuries (e.g., machinery injuries, crushes) are the most common cause of phalangeal injury in adults (Lakshmanan, Damodaran, & Sher, 2018). When any of the bones of the hand are fractured, the objectives of treatment are to regain maximum function of the hand and minimize cosmetic deformities. X-rays are the diagnostic studies of choice (Muttath et al., 2019).

For a nondisplaced fracture of the phalanx (finger bone), the finger is splinted for 3 to 4 weeks to relieve pain and to protect the finger from further trauma. Splinting sometimes consists of "buddy taping" a fractured finger to an adjoining nonfractured finger. Serial x-rays may be done to monitor

healing. Displaced fractures and open fractures may require ORIF, using wires or pins. If the fracture is open, or if a fingernail is avulsed, antibiotics may be prescribed (Basset, 2019).

The neurovascular status of the injured hand is evaluated and documented. Swelling is controlled by elevation of the hand. Functional use of the uninvolved portion of the hand is encouraged. Assistive devices might be recommended to aid the patient in performing ADLs until the hand has healed and functional status returns.

Pelvis

The sacrum, ilium, pubis, and ischium bones form the bony pelvis, which unites to form an anatomic ring in adults (see Fig. 37-17). Falls from a great height, motor vehicle and motorcycle crashes, vehicle versus pedestrian, and crush injuries can cause pelvic fractures. There is a high mortality rate associated with unstable pelvic fractures, second only to head injuries among trauma-related deaths; this is primarily related to hemorrhage, although pulmonary complications, fat emboli, thromboembolic complications, and infection are also implicated (Fiechtl, 2018). Management of severe, life-threatening pelvic fractures is coordinated with the trauma team.

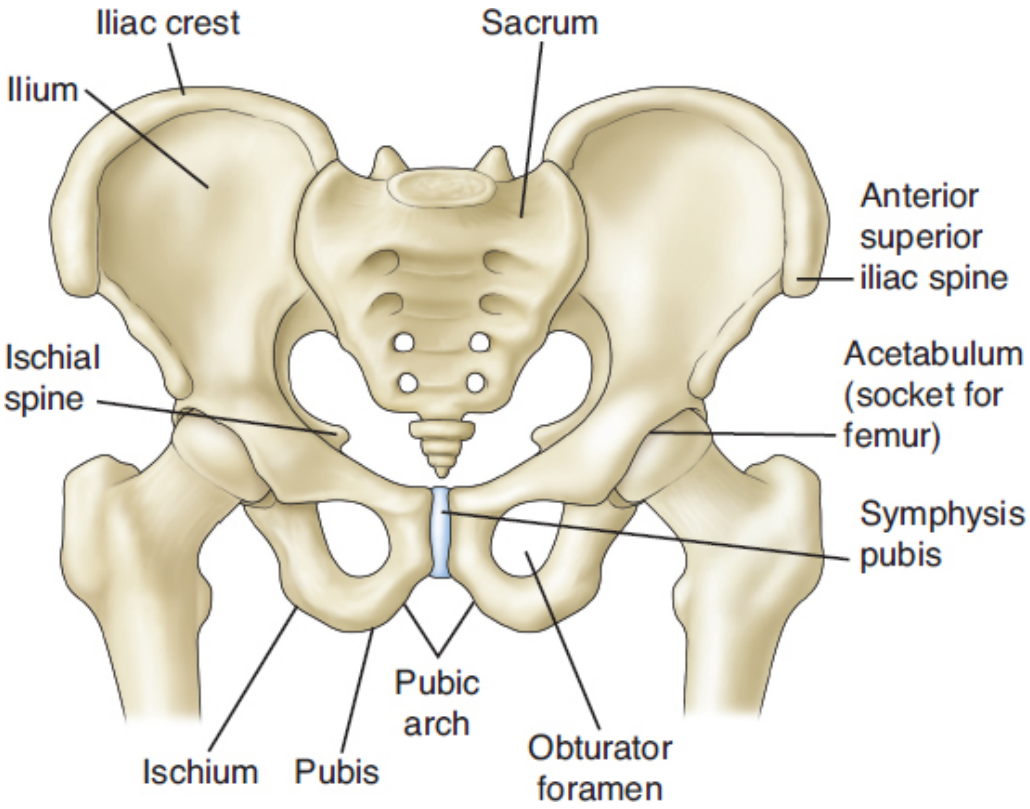

Figure 37-17 • Pelvic bones.

Signs and symptoms of pelvic fracture may include ecchymosis; tenderness over the symphysis pubis, anterior iliac spines, iliac crest, sacrum, or coccyx; local edema; numbness or tingling of the pubis, genitals, and proximal thighs; inability to bear weight without discomfort; severe back pain (retroperitoneal bleed); alterations in neurovascular status of lower extremities (see later discussion of pedal pulse assessment); and clinical manifestations of shock (see Chapter 11). CT scanning of the pelvis helps determine the extent of injury by demonstrating sacroiliac joint disruption, soft tissue trauma, pelvic hematoma, and fractures. Neurovascular assessment of the lower extremities is completed to detect any injury to pelvic blood vessels and nerves. Assessment of underlying organs for injury is indicated especially in high-impact trauma (Eiff, Hatch, & Higgins, 2020d). Trauma to the ureters, urethra, rectum, vagina; abdominal vascular trauma to veins (more common) and arteries; and neurologic trauma, particularly spinal column and cord injury, should be assessed as potential concomitant injuries (Eiff et al., 2020d). See Chapter 67 for discussion of multi trauma and abdominal trauma.

Hemorrhage and shock are two of the most serious consequences that can occur. Bleeding arises mainly from the laceration of veins and arteries by bone fragments and possibly from a torn iliac artery. The peripheral pulses, especially the dorsalis pedis pulses of both lower extremities, are palpated; absence of a pulse may indicate a tear in the iliac artery or one of its branches. Abdominal CT may be performed to detect intra-abdominal hemorrhage. Excessive movement of the pelvis should be avoided, and the patient is handled gently so that bony fragments are not displaced, which may exacerbate bleeding and shock. Fluid replacement and analgesics are administered as needed. Exploratory laparotomy may be performed to further visualize the peritoneum (Moore & Doty, 2017).

Assessment of adjacent structures must be completed when pelvic injury is suspected.

Numerous classification systems have been used to describe pelvic fractures in relation to anatomy, stability, and mechanism of injury. Some fractures of the pelvis do not disrupt the pelvic ring; others disrupt the ring, which may be rotationally or vertically unstable. The severity of pelvic fractures varies. Long-term complications of pelvic fractures include malunion, nonunion, DVTs, residual gait disturbances, back pain from ligament injury, and dyspareunia and erectile dysfunction (Eiff et al., 2020d).

Stable Pelvic Fractures

Stable fractures of the pelvis (see Fig. 37-18) include fracture of a single pubic or ischial ramus, fracture of ipsilateral pubic and ischial rami, fracture of the pelvic wing of the ilium (Duverney fracture), and fracture of the sacrum or coccyx. If injury results in only a slight widening of the pubic symphysis or the anterior sacroiliac joint and the pelvic ligaments are intact, the disrupted

pubic symphysis is likely to heal spontaneously with conservative management. Most fractures of the pelvis heal rapidly because the pelvic bones are mostly cancellous bone, which has a rich blood supply.

Stable pelvic fractures can be treated with a few days of bed rest, analgesics, and progressive mobilization, depending on the level of patient discomfort, which can seriously hamper patient mobility. Fluids, dietary fiber, ankle and leg exercises, anti-embolism stockings to aid venous return, logrolling, deep breathing, early immobilization, and skin care reduce the risk of complications and increase the patient's comfort. The patient with a fractured sacrum is at risk for paralytic ileus; therefore, bowel sounds should be monitored.

The patient with a fracture of the coccyx experiences pain when sitting and when defecating. A donut ring cushion, sitz baths, and stool softeners to ease defecation are beneficial adjuncts to ease pain. As pain resolves, activity is gradually resumed with the use of assistive mobility devices. Early mobilization reduces problems related to immobility (Eiff et al., 2020d). Most patients should be managed with these conservative measures for at least 2 months until symptoms improve (Foye, 2020).

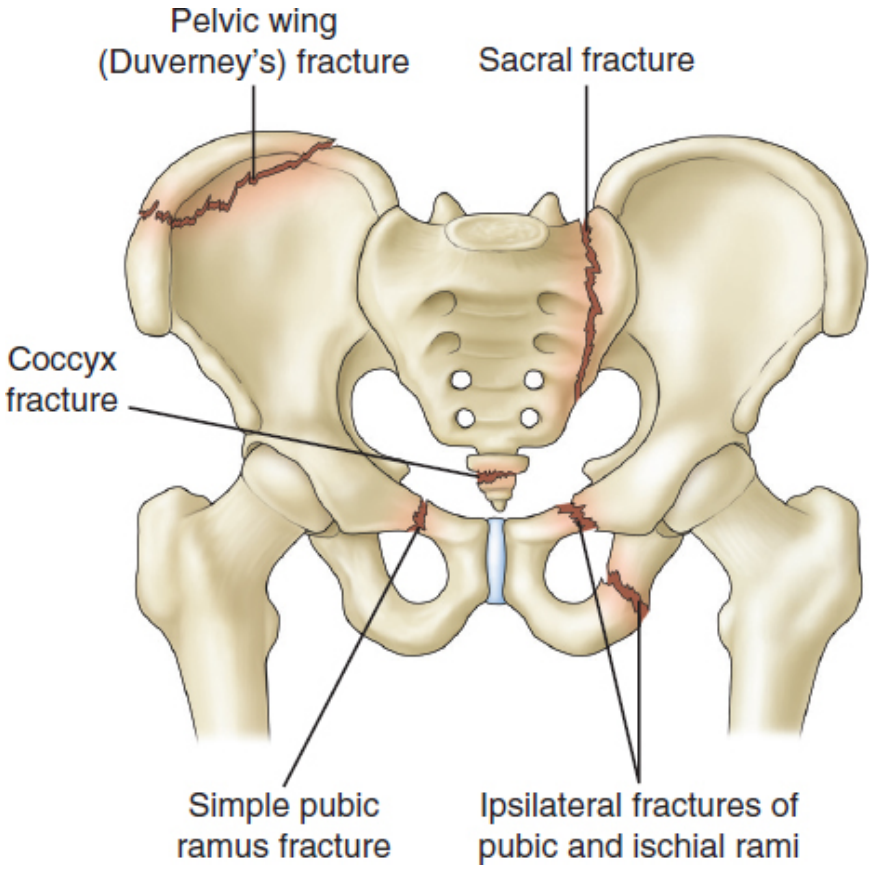

Figure 37-18 • Stable pelvic fractures.

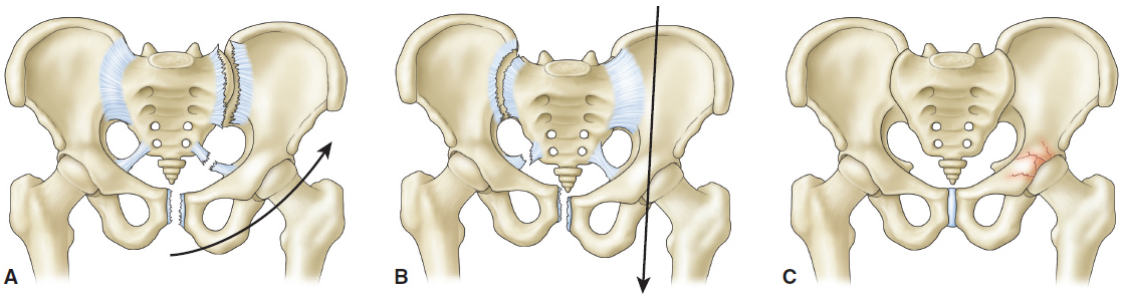

Figure 37-19 • Unstable pelvic fracture. **A.** Rotationally unstable fracture. The symphysis pubis is separated and the anterior sacroiliac, sacrotuberous, and sacrospinous ligaments are disrupted. **B.** Vertically unstable fracture. The hemipelvis is displaced anteriorly and posteriorly through the symphysis pubis, and the sacroiliac joint ligaments are disrupted. **C.** Undisplaced fracture of the acetabulum.

Unstable Pelvic Fractures

Unstable fractures of the pelvis (see Fig. 37-19) may result in rotational instability (e.g., the "open book" type, in which a separation occurs at the symphysis pubis with sacroiliac ligament disruption), vertical instability, or a combination of both. Lateral or anteroposterior compression of the pelvis produces rotationally unstable pelvic fractures. Vertically unstable pelvic fractures occur when force is exerted on the pelvis vertically, as may occur when the patient falls onto extended legs or is struck from above by a falling object. Vertical shear pelvic fractures involve the anterior and posterior pelvic ring with vertical displacement, usually through the sacroiliac joint. There is generally complete disruption of the posterior sacroiliac, sacrospinous, and sacrotuberous ligaments.

Trauma to soft-tissue, urethral, skeletal, neurovascular, and/or neurologic structures that are contiguous with the pelvis may also occur in unstable pelvic fractures as a result of high-energy mechanisms of injury (e.g., motor vehicle or motorcycle crashes, motor vehicles striking pedestrians, falls from great heights) (Russell & Jarrett, 2020). Immediate treatment in the ED for a patient with an unstable pelvic fracture includes stabilizing the pelvic bones and compressing bleeding vessels with a pelvic girdle, which is an external binding and stabilizing device. If major vessels are lacerated, the bleeding may be stopped through embolization using interventional radiology techniques prior to surgery. Because of the tremendous force necessary to cause an unstable pelvic fracture, hemorrhage and associated head injury are the most common causes of death within 24 hours post arrival to the hospital, and multiple organ dysfunction syndrome and sepsis resulting from infection are the main causes of death after that timeframe (Moore & Doty, 2017). See Chapter 11 for nursing management of the patient in shock. When the patient is hemodynamically stable, treatment generally involves external fixation or

ORIF. These measures promote hemostasis, hemodynamic stability, comfort, and early mobilization.

Acetabulum

Acetabular fractures are a type of intra-articular fracture that require a very precise and delicate surgical reduction. The typical mechanism of injury is that an external force drives the femoral shaft into the hip joint, fracturing the acetabulum. This may be caused by high-speed motor vehicle crashes (e.g., knees driven into dashboard, pedals forcibly driven upward into legs) or from falls from heights (Thacker, Tejwani, & Thakkar, 2018). Treatment depends on the pattern of fracture. Stable, nondisplaced fractures may be managed with traction and protective weight bearing so that the affected foot is placed on the floor only for balance. Displaced and unstable acetabular fractures are treated either with closed reduction and skeletal traction or ORIF (Eiff et al., 2020d). Internal fixation permits early non–weight-bearing ambulation and ROM exercise. Complications seen with acetabular fractures include nerve damage, AVN, malunion, heterotopic ossification, and posttraumatic arthritis (Thacker et al., 2018).

Hip

Annually, more than 300,000 adults older than 65 years of age sustain a hip fracture requiring hospitalization; 95% of these result from falls (United Health Foundation, 2019). Hip fracture is a debilitating condition in older adults, particularly women (Veronese & Maggi, 2018). As the U.S. population ages, the annual number of hip fractures is expected to increase. The costs of treatment are high, due to long periods of hospitalization and subsequent rehabilitation. Contributing factors for falls and resultant hip fracture include weak quadriceps muscles, slowed reflexes, osteoporosis, poor vision, diminished balance, general frailty due to age, and conditions that produce decreased cerebral arterial perfusion and cognitive impairment (e.g., transient ischemic attacks, anemia, thromboemboli, cardiovascular disease). In addition to these factors, many medications may cause orthostasis and instability in the older adult. In recognition of this, the American Geriatrics Society periodically publicizes an updated list of *Potentially Inappropriate Medications* (PIM) for Older Adults, and a tool to evaluate medication use for problems in older adults, called the *Beers Criteria.* Medications that can cause orthostasis and instability in older adults, particularly if they take multiple medications (i.e., polypharmacy) include antihypertensive agents, diuretics, beta-blockers, sedatives and hypnotics, neuroleptics and antipsychotics, antidepressants, benzodiazepines, opioid analgesics, and NSAIDs (Fick, Semla, Steinman, et al., 2019; Ming & Zecevic, 2018).

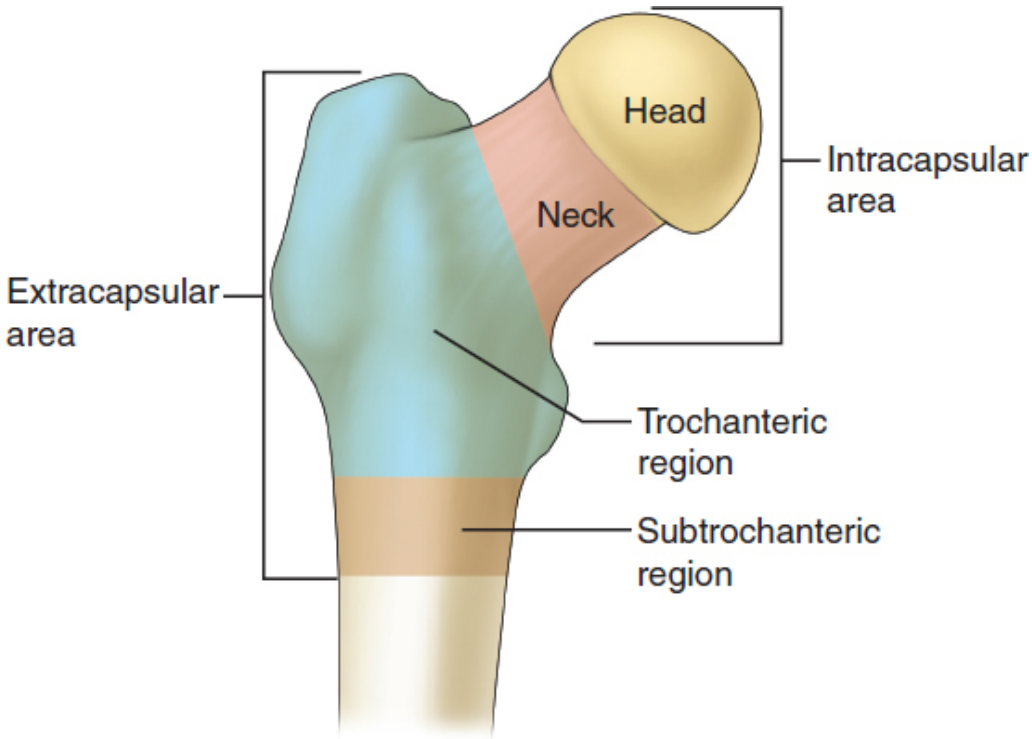

Figure 37-20 • Regions of the proximal femur.

Hip fractures are classified by anatomic location and fracture type. *Extracapsular fractures* (extending from the base of the femoral neck to the area just distal to the lesser trochanter) are fractures of the trochanteric, intertrochanteric, and subtrochanteric region. *Intracapsular fractures* are fractures of the femoral head and neck. Intrascapular fractures have a higher rate of nonunion or malunion and femoral neck fractures may damage the vascular system that supplies blood to the head and the neck of the femur, and the bone may become ischemic (Foster, 2020). For this reason, AVN is common in patients with femoral neck fractures (see Fig. 37-20). *Periprosthetic fractures* are fractures to the regions surrounding prosthetics joints which are increasing due to the growing number patients having previously had total joint replacements (Capone, Congia, Civinini, et al., 2017).

Clinical Manifestations

The patient with a hip fracture will have pain over the outer thigh or in the groin and limited ROM. There will be significant discomfort with any attempt to flex or rotate the hip (Bhatti & Ertl, 2019). With fractures of the femoral neck, the leg may be shortened, adducted, and externally rotated. With most fractures of the femoral neck, the patient cannot move the leg without a significant increase in pain. The patient is most comfortable with the leg slightly flexed in external rotation. Impacted intracapsular femoral neck

fractures cause moderate discomfort (even with movement), may allow the patient to bear weight, and may not demonstrate obvious shortening or rotational changes. With extracapsular femoral fractures of the trochanteric or subtrochanteric region, the extremity is significantly shortened, externally rotated to a greater degree than intracapsular fractures, exhibits muscle spasm that resists positioning of the extremity in a neutral position, and has an associated area of ecchymosis. The diagnosis is confirmed by x-ray (Morrison & Siu, 2019).

Gerontologic Considerations

Populations at higher risk of hip fracture include older adults (particularly women) who have decreased bone density and muscle mass and those with chronic conditions (e.g., endocrine and intestinal disorders) that lead to weakened bones or who have cognitive impairment which increases the risk of falling (United Health Foundation, 2019). Stress and immobility related to the trauma predispose the older adult to atelectasis, pneumonia, sepsis, VTE, pressure injuries, and reduced ability to cope with other health problems. Many older adults hospitalized with hip fractures are vulnerable for delirium as a result of stress of the trauma, pain, unfamiliar surroundings, sleep deprivation, and medications. In addition, delirium that develops in some older adult patients may be caused by mild cerebral ischemia or mild hypoxemia. Other factors associated with delirium include frailty, malnutrition, dehydration, infectious processes, mood disturbances, and blood loss. In older patients with hip fractures who have dementia, the same factors that may cause delirium may exacerbate their dementia, further complicating recovery and increasing the risk for adverse outcomes (Mosk, Mus, Vroemen, et al., 2017).

To prevent complications, the nurse must assess the older patient for chronic conditions that require close monitoring. Examination of the legs may reveal edema due to heart failure or absence of peripheral pulses from peripheral vascular disease. Similarly, chronic respiratory problems may be present and may contribute to the possible development of atelectasis or pneumonia. Coughing and deep-breathing exercises are encouraged. Frequently, older adults take cardiac, antihypertensive, or respiratory medications that need to be continued. The patient's responses to these medications should be monitored.

Dehydration and poor nutrition may be present. At times, older adults who live alone cannot call for help at the time of injury. A day or two may pass before assistance is provided, and as a result, dehydration and debilitation occur. Nutritional status may have been poor prior to admission, so the nurse should monitor for complications of dehydration and malnutrition (e.g., pressure injuries, etc.). Screening for malnutrition and high-protein nutritional supplementation may be effective in improving outcomes in older adults with

hip fractures and should be incorporated into the plan of care (Kramer, Blokhuis, Verdijk, et al., 2019).

Muscle weakness may have initially contributed to the fall and fracture. Bed rest and immobility cause an additional loss of muscle strength unless the nurse encourages the patient to move all joints except the involved hip and knee. Patients are encouraged to use their arms and the overhead trapeze to reposition themselves. This strengthens the arms and shoulders, which facilitates walking with assistive devices.

Medical Management

Surgery is indicated for most patients with hip fracture. Nonoperative management may be considered in some older patients with advanced comorbidities or cognitive impairment; certain types of fractures may be sufficiently stable to benefit from nonoperative treatment (Morrison & Sui, 2019). Buck's extension traction, a type of temporary skin traction, was traditionally applied because it was believed to reduce muscle spasm, to immobilize the extremity, and to relieve pain. However, skin traction is rarely used as a definitive therapy. It may be prescribed as a temporary measure until definitive therapy is achieved (Buckley & Page, 2018; Morrison & Siu, 2019). The goal of surgical treatment for hip fractures is to obtain a satisfactory fixation so that the patient can be mobilized quickly and avoid secondary medical complications. Surgical treatment consists of open or closed reduction of the fracture and internal fixation, hemiarthroplasty (replacement of the femoral head with a prosthesis), or closed reduction with percutaneous stabilization for an intracapsular fracture. Surgical intervention is carried out as soon as possible after injury. The preoperative objective is to ensure that the patient is in as favorable a condition as possible for the surgery. Displaced femoral neck fractures are treated as emergencies, with reduction and internal fixation performed within 24 hours after fracture. The femoral head is often replaced with an orthopedic implant if there is complete disruption of blood flow to the femoral head, which may cause AVN (Lu & Uppal, 2019).

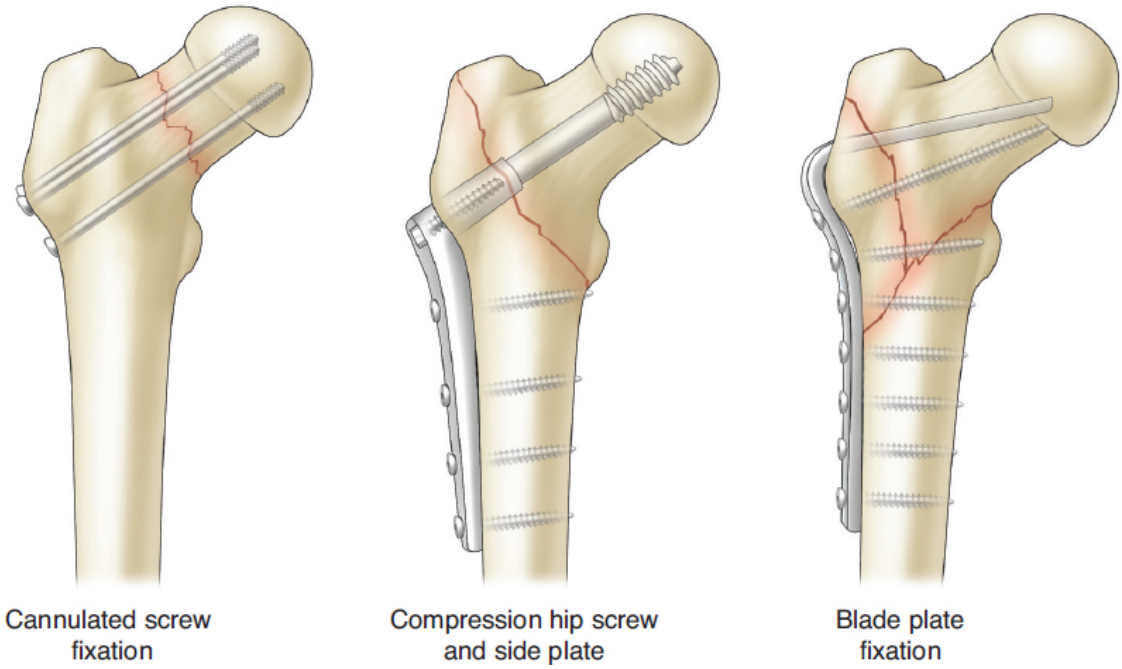

Figure 37-21 • Examples of internal fixation for hip fractures. Internal fixation is achieved through the use of screws and plates specifically designed for stability and fixation.

After general or spinal anesthesia, the hip fracture is reduced under fluoroscopic visualization. A stable fracture is usually fixed with nails, a nail and plate combination, multiple pins, or compression screw devices (see Fig. 37-21). The orthopedic surgeon determines the specific fixation device based on the fracture site or sites. Adequate reduction is important for fracture healing—the better the reduction, the better the healing.

Total hip arthroplasty (i.e., replacement of both the femoral head and acetabulum) or hemiarthroplasty (i.e., replacement of only the femoral head) (see Chapter 36) may be used in select patients with intracapsular fractures (Lu & Uppal, 2019).

Nursing Management

The immediate postoperative care for a patient with a hip fracture is similar to that for other patients undergoing major surgery (see Chapter 16). Attention is given to pain management, prevention of secondary medical problems, and early mobilization of the patient so that independent functioning can be restored.

During the first 24 to 48 hours, relief of pain and prevention of complications are important, and continuous neurovascular assessment is essential. The nurse encourages deep breathing and dorsiflexion and plantar flexion exercises every 1 to 2 hours. Thigh-high anti-embolism stockings or pneumatic compression devices are used, and anticoagulants are given as

prescribed to prevent the formation of VTE. The nurse administers prescribed analgesic medications and monitors the patient's hydration, nutritional status, and urine output.

Repositioning the Patient

The most comfortable and safest way to turn the patient is to turn to the uninjured side. The standard method involves placing a pillow between the patient's legs to keep the affected leg in an abducted position. Proper alignment and supported abduction are maintained while turning (Hohler, 2018).

Promoting Exercise

The patient is encouraged to exercise as much as possible by means of the overbed trapeze. This device helps strengthen the arms and shoulders in preparation for protected ambulation (e.g., toe touch, partial weight bearing). On the first postoperative day, the patient transfers to a chair with assistance and begins assisted ambulation. The amount of weight bearing that can be permitted depends on the stability of the fracture reduction. The primary provider prescribes the degree of weight bearing. In general, hip flexion and internal rotation restrictions apply only if the patient has had a hemiarthroplasty or total arthroplasty (Kellam, 2020) (see Chapter 36). Physical therapists work with the patient on transfers, ambulation, and the safe use of assistive devices.

The patient can anticipate discharge to home or to an extended-care facility with the use of assistive devices (see Chapter 2). Some modifications in the home may be needed, such as installation of elevated toilet seats and grab bars.

Monitoring and Managing Potential Complications

Neurovascular complications may occur from direct injury or edema in the area that causes compression of nerves and blood vessels. With hip fracture, bleeding into the tissues and edema are expected. Monitoring and documenting the neurovascular status of the affected leg are vital.

To prevent VTE, the nurse encourages intake of fluids and ankle and foot exercises. Anti-embolism stockings, pneumatic compression devices, and prophylactic anticoagulant therapy are indicated and should be prescribed (Forsh, 2019). During hospitalization, the patient or the patient's caregiver should be educated regarding the signs, symptoms, and risks of VTE, and how to administer anticoagulant prophylaxis as prescribed. Intermittent assessment of the patient's legs for signs of DVT, which may include unilateral calf tenderness, warmth, redness, and swelling, is indicated.

Pulmonary complications (e.g., atelectasis, pneumonia) are a threat to older patients undergoing hip surgery. Coughing and deep-breathing exercises,

intermittent changes of position, and the use of an incentive spirometer may help prevent respiratory complications. Pain must be treated with analgesic agents, typically opioids; otherwise, the patient may not be able to cough, deep breathe, or engage in prescribed activities. The nurse assesses breath sounds to detect adventitious or diminished sounds.

Skin breakdown is often seen in older patients with hip fracture. Blisters caused by tape are related to the tension of soft tissue edema under a nonelastic tape. An elastic hip wrap dressing or elastic tape applied in a vertical fashion may reduce the incidence of tape blisters. In addition, patients with hip fractures tend to remain in one position and may develop pressure injuries. Proper skin care, especially on the bony prominences, helps to relieve pressure. High-density foam mattress overlays may provide protection by distributing pressure evenly.

Loss of bladder control (incontinence or retention) may occur. If an indwelling catheter is inserted at the time of surgery, it usually is removed within 24 hours of surgery to avoid a hospital-acquired urinary tract infection (Morrison & Siu, 2020). If the patient does not void within 6 hours of catheter removal and/or is expressing symptoms of urinary retention (e.g., abdominal fullness, discomfort), a bladder scan should be performed to determine the volume of urine; intermittent catheterization may be indicated.

Delayed complications of hip fractures include infection, nonunion, and AVN of the femoral head (particularly with femoral neck fractures) (Bhatti & Ertl, 2019). Infection is suspected if the patient complains of constant pain in the hip and has an elevated erythrocyte sedimentation rate.

The nursing management of the older adult patient with a hip fracture is summarized in the Plan of Nursing Care (see Chart 37-8).

Promoting Home, Community-Based, and Transitional Care

Educating the Patient About Self-Care

Most patients are discharged from the hospital to an inpatient rehabilitation facility. The patient and family members or caregivers are assessed for their readiness to commence activities that promote healing and mobility. The nurse collaborates with other members of the multidisciplinary physiotherapy team (e.g., physical therapist, occupational therapist) to gather baseline data on the patient's anticipated long-term care environment post discharge, whether that is home or a long-term care facility, such as a skilled nursing facility. The patient begins a rehabilitation routine geared to meet the needs of this environment. For instance, if the patient is to be discharged home, and there are stairs in the home, then a goal of rehabilitation is that the patient will be able to get up and down stairs before discharge.

The patient engages in regular exercises to improve muscle tone and balance. The safe use of ambulatory aids, any specific activity restrictions (e.g., hip precautions if total hip arthroplasty was performed), and fall prevention measures (e.g., appropriate footwear, proper lighting, removal of throw rugs, getting rid of clutter) are also vitally important education topics that must be adequately addressed prior to discharge (Walker & Revell, 2019). The patient and caregiver are educated on the indications for any newly prescribed medications, wound care, and the importance of proper nutrition. Identification of any potential complications (e.g., reddened wound, fever) and when and how to contact the patient's primary provider are also important to understand.

Continuing and Transitional Care

Referral for home, community-based, or transitional care is important to enable assessment of the patient's home environment and the adequacy of resources and support of caregivers. Home-based intensive physical therapy improves strength and gait for older adults with hip fractures; accommodations to the home may need to be made to ensure the patient's continuing care, safety, and mobility (Hohler, 2018). During follow-up home health or outpatient clinic visits, the nurse reevaluates the patient's healing process and the continued adequacy of resources and support of caregivers. Based upon these findings, modifications may need to be made. For instance, an older adult spouse may require assistance or respite care. Home health agencies, local area agencies on aging (for older adult patients), and faith community nursing organizations, may be tapped into to provide assistance within the home or with transporting the patient to follow-up outpatient appointments.

Osteoporosis screening of patients who have experienced hip fracture is important for prevention of future fractures. With dual-energy x-ray absorptiometry (DEXA) scan testing, the risk of additional fracture can be predicted. Specific patient education regarding dietary requirements, lifestyle changes, and weight-bearing exercise to promote bone health is needed. Adequate dietary or supplemental vitamin D and calcium supplements are also recommended (Conley, Adib, Adler, et al., 2020). Specific therapeutic interventions need to be initiated to slow bone loss and to build bone mineral density (see Chapter 36).

Femoral Shaft

The femur is the longest and strongest tubular bone in the body; it requires considerable force to break the shaft of a femur in adults. Most femoral fractures occur in young adults who have been involved in motor vehicle crashes or who have fallen from heights. Due to high-energy force, these

patients frequently have associated multiple traumatic injuries (Asplund & Mezzanotte, 2019).

The patient presents with an edematous, deformed, painful thigh and cannot move the hip or the knee. The fracture may be transverse, oblique, spiral, or comminuted. Frequently, the patient develops shock, because the loss of 1 to 2.5 L of blood into the tissues is common with these fractures (Makhni, Makhni, Swartz, et al., 2017). Types of femoral fractures are illustrated in Figure 37-22.

Chart 37-8 PLAN OF NURSING CARE

Care of the Older Adult Patient with a Fractured Hip

NURSING DIAGNOSIS: Acute pain associated with fracture, soft tissue damage, muscle spasm, and surgery
GOAL: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Assess type and location of patient's pain whenever vital signs are obtained and as needed.	1. Pain is expected after fracture; soft tissue damage and muscle spasm contribute to discomfort; pain is subjective and is best evaluated on a pain scale of 0–10 and through description of characteristics and location, which are important for identifying cause of discomfort and for proposing interventions. Continuing pain may indicate development of neurovascular problems. Pain must be assessed periodically to gauge effectiveness of continuing analgesic therapy.	• Patient describes and rates pain on scale of 0–10. • Expresses confidence in efforts to control pain. • Expresses comfort with position changes. • Expresses comfort when leg is positioned and immobilized. • Minimizes movement of extremity before reduction and fixation. • Uses physical, psychological, and pharmacologic measures to reduce discomfort. • Describes acceptable pain level that does not interfere with ability to participate in rehabilitation
2. Acknowledge existence of pain; inform patient of available analgesic agents and advocate for preemptive analgesia (e.g., prior to physical therapy); record patient's baseline discomfort.	2. Reduces stress experienced by the patient by communicating concern and availability of help in dealing with pain. Documentation provides baseline data.	
3. Handle the affected extremity gently, supporting it with hands or pillow.	3. Movement of bone fragments is painful; muscle spasms occur with movement; adequate support diminishes soft tissue tension.	
4. Apply Buck's traction if prescribed; advocate for its removal if pain worsens or is not improved; use trochanter roll.		

5. Use pain-modifying strategies. a. Modify the environment. b. Administer prescribed analgesic agents preemptively and as needed. c. Encourage patient to use pain-relief measures to relieve pain. d. Evaluate patient's response to medications and other pain reduction techniques. e. Consult with primary provider if relief of pain is not obtained. 6. Position for comfort and function. 7. Assist with frequent changes in position.	4. Routine use of Buck's traction has not been proven to be effective. 5. Pain perception can be diminished by distraction and refocusing of attention. a. Interaction with others, distraction, and environmental stimuli may modify pain experiences. b. Analgesics reduce the pain; muscle relaxants may be prescribed to decrease discomfort associated with muscle spasm. c. Mild pain is easier to control than severe pain. d. Assessment of effectiveness of measures provides basis for future management interventions; early identification of adverse reactions is necessary for corrective measures and care plan modifications. e. Change in treatment plan may be necessary. 6. Alignment of body facilitates comfort; positioning for function diminishes stress on musculoskeletal system. 7. Change of position relieves pressure and	activities within 24–48 hours after surgery. • Requests pain medications and uses pain-relief measures early in pain cycle. • Appears comfortable and relaxed. • Moves with increasing comfort as healing progresses.

associated discomfort.

NURSING DIAGNOSIS: Impaired mobility associated with fractured hip
GOAL: Achieves pain-free, functional, stable hip

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain neutral positioning of hip. 2. Use trochanter roll; roll to uninjured side. 3. Place pillow between legs when turning. 4. Instruct and assist in position changes and transfers. 5. Instruct in and supervise isometric and quadriceps and gluteal setting exercises. 6. Encourage the use of trapeze.	1. Prevents stress at the site of fixation. 2. Minimizes external rotation. 3. Supports leg; prevents adduction. 4. Encourages patient's active participation while preventing stress on hip fixation. 5. Strengthens muscles needed for walking. 6. Strengthens shoulder and arm muscles necessary for use of ambulatory aids.	• Patient engages in therapeutic positioning. • Uses pillow between legs when turning. • Assists in position changes; shows increased independence in transfers. • Exercises every 2 hours while awake.
7. In consultation with physical therapist, instruct in and supervise progressive safe ambulation within limitations of weight-bearing prescription. 8. Offer encouragement and support	7. Amount of weight bearing depends on the patient's condition, fracture stability, and fixation device; ambulatory aids are used to assist the patient with non–weight-bearing and partial–weight-bearing ambulation. 8. Reconditioning exercises can be uncomfortable and	• Uses trapeze. • Participates in progressive ambulation program. • Actively participates in exercise regimen. • Uses ambulatory aids correctly and safely.

	exercise regimen.	fatiguing; encouragement helps patient adhere to the program.
9.	Instruct in and supervise safe use of ambulatory aids.	9. Prevents injury from unsafe use.

NURSING DIAGNOSIS: Risk for infection associated with surgical incision
GOAL: Maintains asepsis

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor vital signs. 2. Perform aseptic dressing changes. 3. Assess wound appearance and character of drainage. 4. Assess report of pain. 5. Administer preoperative antibiotic as prescribed and postoperative antibiotics if prescribed, and observe for side effects.	1. Temperature, pulse, and respiration increase in response to infection. (Magnitude of response may be minimal in older adult patients.) 2. Avoids introducing infectious organisms. 3. Red, swollen, draining incision is indicative of infection. 4. Pain may be due to wound hematoma, a possible locus of infection, which needs to be surgically evacuated. 5. Administration of 1–3 doses of perioperative antibiotics improves outcomes and reduces the risk of wound infection.	• Patient maintains vital signs within normal range. • Exhibits well-approximated incision without drainage or excessive inflammatory response. • Relates minimal discomfort; demonstrates no hematoma. • Tolerates antibiotics if prescribed; exhibits no evidence of osteomyelitis.

NURSING DIAGNOSIS: Impaired urination associated with immobility
GOAL: Maintains normal urinary elimination patterns

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor intake and output. 2. Avoid or minimize use of indwelling catheter.	1. Adequate fluid intake ensures hydration; adequate urinary output minimizes urinary stasis.	• Intake and output are adequate; patient exhibits normal voiding patterns.

3. Use bladder scanner if available to confirm urinary stasis or postvoid residual (see Chapter 47, Fig. 47-8); perform intermittent catheterization for urinary retention as prescribed.	2. Source of bladder infection. 3. Empties bladder; reduces urinary tract infections	• Demonstrates no evidence of urinary tract infection.

NURSING DIAGNOSIS: Stress overload associated with injury, anticipated surgery, and dependence

GOAL: Uses effective coping mechanisms to modify stress

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage patient to express concerns and to discuss the possible impact of fractured hip. 2. Support the use of coping mechanisms. Involve significant others and support services as needed. 3. Contact social services, if needed. 4. Explain anticipated treatment regimen and routines to facilitate positive attitude in relation to rehabilitation. 5. Encourage patient to	1. Verbalization helps patient deal with problems and feelings. Clarification of thoughts and feelings promotes problem solving. 2. Coping mechanisms modify disabling effects of stress; sharing concerns lessens the burden and facilitates necessary modification. 3. Anxiety may be related to financial or social problems; facilitates management of problems associated with continuing care. 4. Understanding of plan of care helps to diminish fears of the unknown.	• Patient describes feelings concerning fractured hip and implications for lifestyle. • Uses available resources and coping mechanisms; develops health promotion strategies. • Uses community resources as needed. • Participates in development of health care plan.

participate in planning.	5. Participating in care provides for some control of self and environment.	

NURSING DIAGNOSIS: Risk for acute confusion associated with age, stress of trauma, unfamiliar surroundings, and medication therapy
GOAL: Remains oriented and participates in decision making

Nursing Interventions	Rationale	Expected Outcomes
1. Assess orientation status. 2. Interview family regarding patient's orientation and cognitive abilities before injury. 3. Assess patient for auditory and visual deficits. a. Assist patient with the use of sensory aids (e.g., glasses, hearing aid) b. Control environmental distractors. 4. Orient to and stabilize environment. a. Use orientation activities and aids (e.g., clock, calendar, pictures, introduction of self).	1. Evaluate presenting orientation of patient; confusion may result from stress of fracture, unfamiliar surroundings, coexisting systemic disease, cerebral ischemia, hypoxemia, or other factors. Baseline data are important for determining change. 2. Provides data for evaluation of current findings. 3. Diminished vision and auditory acuity frequently occur with aging; glasses and hearing aid may increase patient's ability to interact with environment. a. Aids must be in good working order and available for use. b. Facilitates communication 4. a. Short-term memory may be faulty in the older	• Patient establishes effective communication. • Demonstrates orientation to time, place, and person. • Participates in self-care activities. • Remains mentally alert. • Does not exhibit episodes of confusion.

b. Minimize number of staff working with patient. 5. Give simple explanations of procedures and plan of care. 6. Encourage participation in hygiene and nutritional activities. 7. Provide for safety. a. Keep light on at night. b. Have call bell available. c. Provide prompt response to requests for assistance. 8. Assess mental responses to medications, especially sedative and analgesic agents.	adult; frequent reorientation helps. b. Consistency of caregivers promotes trust. 5. Promotes understanding and active participation. 6. Participation in routine activities promotes orientation and increases awareness of self. 7. Mechanism for securing assistance is available to patient; independent activities based on faulty judgment may result in injury. 8. Older adults tend to be more sensitive to medications; abnormal responses (e.g., hallucinations, depression) may occur.	

Collaborative Problems: Hemorrhage; pulmonary complications; peripheral neurovascular dysfunction; venous thromboemboli; pressure injuries associated with surgery and immobility

GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Hemorrhage		
1. Monitor vital signs, observing for shock.	1. Changes in pulse, blood pressure, and respirations may indicate development of shock; blood loss and stress may contribute to development of shock.	• Vital signs are stabilized within normal limits.
2. Consider preinjury blood pressure values and management of coexisting hypertension, if present.	2. Necessary for interpretation of current blood pressure determinations.	• Experiences no excessive or bright red drainage.
3. Note character and amount of drainage.	3. Excessive drainage and bright red drainage may indicate active bleeding.	• Exhibits stable postoperative hemoglobin and hematocrit values.
4. Notify primary provider if patient develops shock or excessive bleeding.	4. Corrective measures need to be instituted.	
5. Note hemoglobin and hematocrit values, and report decreases in values.	5. Anemia due to blood loss may develop; bleeding into tissues after hip fracture may be extensive; blood replacement may be needed.	
Pulmonary Complications		

1. Assess respiratory status: respiratory rate, depth, and duration; breath sounds; sputum. Monitor temperature. 2. Report adventitious and diminished breath sounds and elevated temperature. 3. Supervise deep-breathing and coughing exercises. Encourage the use of incentive spirometer if prescribed. 4. Administer oxygen as prescribed. 5. Turn and reposition patient at least every 2 hours. Mobilize patient (assist patient out of bed) as soon as possible. 6. Ensure adequate hydration.	1. Anesthesia and bed rest diminish respiratory effort and cause pooling of respiratory secretions. Adventitious breath sounds, pain on respiration, shortness of breath, blood-tinged sputum, cough may indicate pulmonary dysfunction. 2. Elevated temperature in the early postoperative period may be due to atelectasis or pneumonia. 3. Deep-breathing and coughing exercises promote optimal ventilation. Coexisting respiratory conditions diminish lung expansion. 4. Reduced ventilatory efforts may diminish SaO_2 when patient is breathing room air. 5. Promotes optimal ventilation; diminishes pooling of respiratory secretions. 6. Liquefies respiratory secretions; facilitates expectoration.	• Vital signs are stabilized within normal limits. • Patient has clear breath sounds. • Breath sounds are present in all fields. • Exhibits no shortness of breath, chest pain, or elevated temperature. • Arterial oxygen saturation (SaO_2) on room air is within normal limits. • Performs respiratory exercises; uses incentive spirometer as instructed. • Changes position frequently. • Consumes adequate fluids.

Peripheral Neurovascular Dysfunction

1. Assess affected extremity for color and temperature.	1. The skin becomes pale and feels cool with decreased tissue perfusion. Venous congestion may cause cyanosis.	• Patient has normal color and the extremity is warm.
2. Assess toes for capillary refill response.	2. After compression of the nail, rapid return of pink color indicates good capillary perfusion.	• Demonstrates normal capillary refill response.
3. Assess affected extremity for edema and swelling.	3. The trauma of surgery will cause swelling; excessive swelling and hematoma formation can compromise circulation and function; edema may be due to coexisting cardiovascular disease.	• Exhibits moderate swelling; tissue not palpably tense.
4. Elevate affected extremity.	4. Minimizes dependent edema.	
5. Assess for deep, throbbing, unrelenting pain.	5. Surgical pain can be controlled; pain due to neurovascular compromise is refractory to treatment with analgesic medications.	• States pain is tolerable.
6. Assess for pain on passive flexion of foot.	6. With nerve ischemia, there will be pain on passive stretch.	• Reports no pain with passive dorsiflexion.
7. Assess for sensations and numbness.	7. Diminished pain and paresthesia may indicate nerve damage. Sensation in web between great and second toe—peroneal nerve; sensation on sole of foot—tibial nerve.	• Reports normal sensations and no paresthesia.
8. Assess ability to move foot and toes.	8. Dorsiflexion of ankle and extension of toes indicate function of peroneal nerve. Plantar flexion of ankle and flexion of toes indicate functioning of tibial nerve.	• Demonstrates normal motor abilities and no paresis or paralysis.
9. Assess pedal pulses in both feet.		• Has strong and equal pulses bilaterally.
10. Notify primary provider of changes in		

neurovascular status.	9. Indicates circulatory status of extremities. 10. Function of extremity needs to be preserved.	
Venous Thromboemboli		
1. Apply thigh-high anti-embolism stockings and/or sequential compression device as prescribed. 2. Remove stockings and/or sequential compression device for 20 minutes twice a day, and provide skin care. 3. Assess popliteal, dorsalis pedis, and posterior tibial pulses. 4. Assess skin temperature of legs. 5. Assess calf intermittently for tenderness, warmth, redness, and swelling.	1. Compression aids venous blood return and prevents stasis. 2. Skin care is necessary to avoid skin breakdown. Extended removal of stocking or device defeats purpose. 3. Pulses indicate arterial perfusion of extremity. With coexisting arteriosclerotic vascular disease, pulses may be diminished or absent. 4. Local inflammation increases local skin temperature. 5. Unilateral calf tenderness, warmth, redness, and swelling may indicate deep vein thrombosis.	• Wears thigh-high anti-embolism stockings. • Uses sequential compression device. • Experiences no more warmth than usual in skin areas. • Exhibits no increase in calf circumference. • Demonstrates no evidence of calf tenderness, warmth, redness, or swelling. • Changes position with assistance and supervision.
6. Measure calf circumference daily.	6. Increased calf circumference indicates	• Participates in exercise regimen.

7. Avoid pressure on popliteal blood vessels from appliances or pillows. 8. Change patient's position and increase activity as prescribed. 9. Supervise ankle exercises hourly while patient is awake. 10. Ensure adequate hydration. 11. Monitor body temperature.	edema or altered perfusion. 7. Compression of blood vessels diminishes blood flow. 8. Activity promotes circulation and diminishes venous stasis. 9. Muscle exercise promotes circulation. 10. Older adults may become dehydrated because of low fluid intake, resulting in hemoconcentration. 11. Body temperature increases with inflammation (magnitude of response minimal in older adults).	• Experiences no chest pain; has lungs clear to auscultation; presents no evidence of pulmonary emboli. • Exhibits no signs of dehydration; has normal hematocrit. • Maintains normal body temperature.
Pressure Injuries		
1. Monitor condition of skin at pressure points (e.g., heels, sacrum, shoulders); inspect heels at least twice a day. 2. Reposition patient at least every 2 hours. Avoid skin shearing. 3. Administer skin care,	1. Older adults are more prone to skin breakdown at points of pressure because of diminished subcutaneous tissue. 2. Avoids prolonged pressure and trauma to the skin. 3. Immobility causes pressure at bony prominences; position changes relieve pressure. 4. Devices minimize pressure on skin at bony prominences. 5. Early interventions prevent tissue destruction	• Patient exhibits no signs of skin breakdown. • Skin remains intact. • Repositions self frequently. • Uses protective devices.

especially to pressure points. 4. Use pressure redistribution mattress and other protective devices (e.g., heel protectors); support heel off the mattress. 5. Institute care according to protocol at first indication of potential skin breakdown.	and prolonged rehabilitation.	

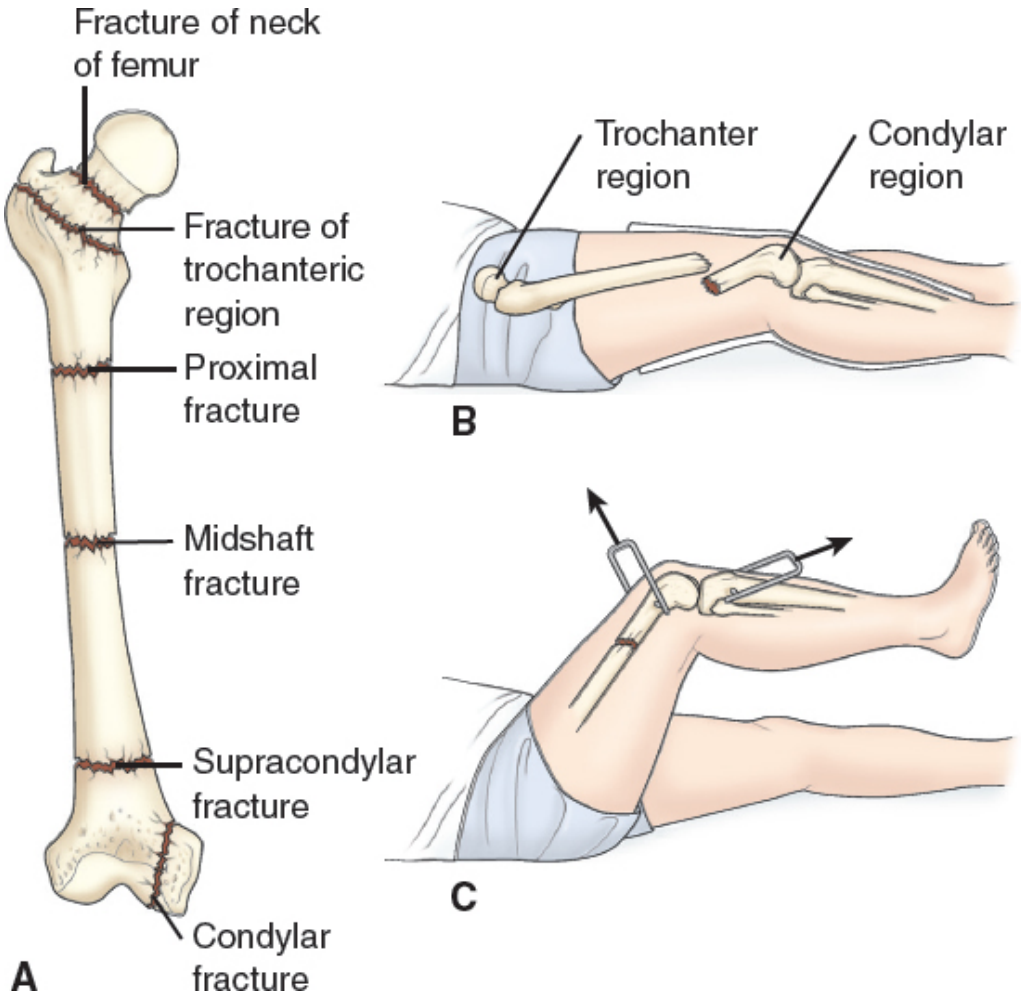

Figure 37-22 • **A.** Types of femoral fractures. **B.** Example of deformity on admission to hospital. **C.** Adequate reduction is achieved when additional wire is inserted in the lower femoral fragment and vertical lift is secured.

Assessment and Diagnostic Findings

Assessment includes checking the neurovascular status of the extremity, especially circulatory perfusion of the lower leg and foot (popliteal, posterior tibial, and pedal pulses and toe capillary refill time), and comparing with the unaffected leg. A Doppler ultrasound may be indicated to assess blood flow. X-rays are used to confirm the diagnosis and determine the extent of injury (Asplund & Mezzanotte, 2019). Dislocation of the hip and knee may accompany these fractures. Knee effusion suggests ligament damage and possible instability of the knee joint.

Management

Continued neurovascular monitoring and documentation are important. The fracture is immobilized so that additional soft tissue damage does not occur. Generally, skeletal traction (see Fig. 37-22B,C) or splinting is used to reduce the fracture to anatomic alignment which helps reduce pain and prevent hematoma formation (Keany & McKeever, 2019). IV opioid analgesic agents (e.g., morphine) are typically given to treat pain (Asplund & Mezzanotte, 2019).

Early fracture stabilization decreases morbidity and mortality; therefore, internal fixation usually is carried out as soon as the patient is physiologically stable. Intramedullary locking nail devices are typically used. Internal fixation permits early mobilization, which is associated with improved outcomes and recovery (Keany & McKeever, 2019).

Open femoral fractures require immediate and extensive irrigation and débridement in the operating suite (see previous discussion of treatment for open fractures). Tetanus toxoid (unless given within 5 years) and antibiotics with staphylococcal coverage and good tissue penetration are often administered. Depending on needs for continued débridement, intramedullary nailing may be delayed (Keany & McKeever, 2019).

Postoperatively, to preserve muscle strength, the patient is instructed to exercise the hip and the lower leg, foot, and toes on a regular basis. Active muscle movement enhances healing by increasing blood supply and electrical potentials at the fracture site. Prescribed weight-bearing limits are based on the type and location of the fracture and treatment approach. Physical therapy includes ROM and strengthening exercises, safe use of assistive devices, and gait training (Makhni et al., 2017).

A common complication after fracture of the femoral shaft is restriction of knee motion. Active and passive knee exercises begin as soon as possible, depending on the stability of the fracture and knee ligaments. Other complications in the immediate postoperative period can include hemorrhage, acute compartment syndrome, and neurovascular compromise. Long-term complications may include malrotation, malunion, delayed union, and nonunion (Keany & McKeever, 2019).

Tibia and Fibula

Fractures of the tibia and fibula often occur in association with each other and tend to result from a direct blow, falls with the foot in a flexed position, or a violent twisting motion. Most of these fractures tend to be more distal than proximal; distal fractures may extend into the ankle joint (e.g., distal fractures of the tibia that extend into the joint are collectively referred to as pilon fractures). The patient may present with severe pain, deformity or instability of the leg, obvious hematoma, swelling, and the inability to walk or bear weight on the leg (Norvell & Steele, 2017).

Assessment and Diagnostic Findings

The peroneal nerve is assessed; if damaged, the patient cannot dorsiflex the great toe and has diminished sensation in the first web space. The tibial artery is assessed for damage by evaluating pulses, skin temperature, and color and by testing the capillary refill response. The affected leg and ankle are compared with the unaffected leg and ankle. X-rays are indicated to determine the location, type, and extent of the fracture (Fields, 2020).

Management

Most closed, nondisplaced fractures that do not involve the ankle joint (e.g., extra-articular fractures) are treated with closed reduction and immobilization in a non–weight-bearing short leg cast or brace. The leg is elevated to control edema. Weight-bearing status varies and depends on the type of fracture. Activity decreases edema and increases circulation. Fracture healing, based upon clinical assessment and x-ray findings, takes about 10 to 14 weeks; it takes about 6 to 9 months until full function is restored (Eiff, Hatch, & Higgins, 2020e).

Displaced, open, or articular fractures may be treated with skeletal traction, internal fixation with intramedullary nails or plates and screws, or external fixation. External support may be used with internal fixation. Hip, foot, and knee exercises are encouraged within the limits of the immobilizing device. Partial weight bearing is begun when prescribed and is progressed as the fracture heals, which is dependent on the extent of injury (Eiff et al., 2020e).

As with any fracture, continued neurovascular evaluation is important. The development of acute compartment syndrome requires prompt recognition and communication to the primary provider. Other complications to monitor for include fat emboli, nonunion, delayed union, infection, impaired wound edge healing, long-term calf atrophy, sport limitation, and osteoarthritis (Fields, 2020).

Rib

Rib fractures are some of the most common thoracic injuries; they occur frequently in adults of all ages, typically from blunt trauma such as motor vehicle crashes or falls, and usually result in no impairment of function. They are typically diagnosed based on clinical presentation and confirmed with anteroposterior (AP) and lateral chest x-rays, CT scan (to rule out suspected thoracic or abdominal injury) or ultrasound (Eiff, Hatch, & Higgins, 2020f). Because these fractures cause pain with respiratory effort, the patient tends to decrease respiratory excursions and refrains from coughing. As a result, tracheobronchial secretions are not mobilized, aeration of the lung is diminished, and a predisposition to atelectasis and pneumonia results. The mainstay of treatment is pain control to decrease chest wall splinting and subsequent atelectasis. To help the patient cough and take deep breaths and use an incentive spirometer, the nurse may splint the chest with their hands, or may educate the patient on using a pillow to temporarily splint the affected site. Regularly scheduled analgesics such as acetaminophen in combination with an NSAID may be prescribed to provide analgesic relief. Topical anesthetic patches can provide local pain relief. Occasionally, an anesthesia care provider administers an intercostal nerve block, intrapleural infusion, or epidural infusion to relieve pain and to improve respiratory function (Eiff et al., 2020f).

Chest binders to immobilize the rib fracture are not used, because decreased chest expansion may result in atelectasis and pneumonia. Incentive spirometer use may aid in prevention of these complications.

The fracture heals within 6 weeks. The more ribs that are fractured, the greater the likelihood of complications. In addition to atelectasis and pneumonia, complications may include a flail chest, pneumothorax, and hemothorax (Melendez & Doty, 2017). The assessment and management of patients with these conditions are discussed in Chapter 19.

Gerontologic Considerations

Older adults sustaining rib fractures are at an increased risk for complications. Even in the presence of isolated rib trauma, hospital admission is recommended for the older adult with multiple rib fractures or for the older adult who cannot effectively cough and mobilize sputum (Melendez & Doty, 2017). Careful monitoring of respiratory status and encouraging the patient to mobilize early, and, for the patient on bed rest, encouraging turning, coughing, and deep breathing and use of an incentive spirometer, can prevent respiratory complications.

Thoracolumbar Spine

Fractures of the thoracolumbar spine may involve the vertebral body, the laminae and articulating processes, and the spinous processes or transverse processes. The T12 to L2 area of the spine, called the *thoracolumbar junction,* is the second most commonly injured region of the spinal column; 90% of all thoracolumbar spine injuries occur at this junction. Fractures generally result from indirect trauma caused by excessive loading, sudden muscle contraction, or excessive motion beyond physiologic limits. Osteoporosis contributes to vertebral body collapse (compression fracture) and accounts for 50% to 70% of all thoracolumbar fractures (Kaji & Hockberger, 2018).

Stable spinal fractures are caused by flexion, extension, lateral bending, or vertical loading. The anterior structural column (vertebral bodies and discs) or the posterior structural column (neural arch, articular processes, ligaments) is disrupted. Unstable fractures occur with fracture dislocations and involve disruption of both anterior and posterior structural columns.

The patient with a spinal fracture presents with acute tenderness, swelling, paravertebral muscle spasm, and change in the normal curves or in the gap between spinous processes. Pain is greater with moving, coughing, or weight bearing. Thoracolumbar fractures can also present with lower extremity paresis, lower extremity or saddle anesthesia (i.e.,

loss of sensation to the perineum), or loss of bladder or rectal continence (Kaji & Hockberger, 2018). Immobilization is essential until initial assessments have determined if there is any spinal cord injury and whether the fracture is stable or unstable. X-rays are initially indicated to confirm the fracture(s), and CT scans or MRI studies are then indicated to precisely determine the extent of injury and spinal cord involvement (Vinas, 2018). If spinal cord injury with neurologic deficit does occur, it usually requires immediate surgery (laminectomy with spinal fusion) to decompress the spinal cord.

Stable spinal fractures are treated conservatively with limited bed rest. Analgesic medications are prescribed for pain relief. A spinal brace or plastic thoraco-lumbar-sacral orthosis is applied for support during progressive ambulation and resumption of activities (Kaji & Hockberger, 2018).

The patient with an unstable fracture is treated with bed rest, possibly with the use of a special turning device or bed to maintain spinal alignment. Within 24 hours after fracture, open reduction, decompression, and fixation with spinal fusion and instrument stabilization are usually accomplished. Neurologic status is monitored closely during the preoperative and postoperative periods. Postoperatively, the patient may be cared for on the turning device or in a bed with a firm mattress. Progressive ambulation is begun a few days after surgery, with the patient using a molded lumbar or thoracolumbar orthosis for approximately 3 months. Patient education emphasizes good posture, good body mechanics, and, after healing is sufficient, back-strengthening exercises. X-rays with flexion and extension views are taken to monitor the healing process at 6 weeks, 3 months, 6 months postoperatively; a CT scan can provide a clearer evaluation (Vinas, 2018). See Chapter 63 for discussion of spinal cord injury.

Sports-Related Musculoskeletal Injuries

Sports-related injuries are common. Table 37-1 displays common musculoskeletal sports injuries, their mechanisms of injury, assessment findings, and acute care management.

Management

Patients who have experienced sports-related musculoskeletal injuries are often highly motivated to return to their previous level of activity.

Adherence to restriction of activities and gradual resumption of activities need to be reinforced. Injured athletes are at risk for reinjury and require follow-up and monitoring. With recurrence of symptoms, athletes need to diminish their level and intensity of activity to a comfortable level. The time required to recover from a sports-related injury can be as short as a few days or as long as 12 weeks, depending on the severity of the injury. The patient should be pain free with good ROM before returning to play (Norris, 2020).

Sports-related musculoskeletal injuries can often be prevented by using proper equipment and by effectively training and conditioning the body. Specific training needs to be tailored to the person and the sport. Stretching, maintaining hydration, and proper nutrition aid in injury prevention (Norris, 2020).

Occupation-Related Musculoskeletal Disorders

According to the U.S. Department of Labor, work-related musculoskeletal disorders (also called *ergonomic injuries*) are injuries or illnesses of the muscles, nerves, tendons, joints, cartilage, and spinal discs that occur because of exposure to work-related risks. In 2018, sprains, strains, or tears caused the highest incidence of days away from work among private industry workers in all occupations; soreness and pain accounted for the next highest incidence, with a smaller incidence related to fractures, cuts, lacerations, contusions, and bruises (U.S. Department of Labor, Bureau of Labor Statistics, 2019).

Occupation-Related Musculoskeletal Disorders in Nursing Personnel

Nurses working in all settings face workplace hazards performing their routines duties. The nursing profession is consistently ranked among the top 10 occupations that are most involved in occupation-related injuries and illnesses that result in lost days of work (Dressner & Kissinger, 2018). Nurses experience a higher-than-average incidence of musculoskeletal disorders that result from overexertion and strain due to heavy workloads and unsafe patient handling techniques. Organizations like the American Nurses Association (ANA) and the National Association of Orthopaedic Nurses (NAON) recognize the seriousness of work-related musculoskeletal disorders among nurses, and advocates for

the implementation of evidence-based methods for safe patient handling and movement tasks whenever feasible (see Resources).

Amputation

Amputation is the removal of a body part by a surgical procedure or trauma. The majority of amputations are often consequences of vascular disease, especially from diabetes (see Chapters 26 and 46); trauma is the second most common indication. African Americans are at heightened risk of having amputations. Approximately 2 million individuals in the United States are living with some type of limb loss; by 2050, there will be an estimated 3.6 million (AAOS, 2019e).

TABLE 37-1 Common Musculoskeletal Sports Injuries

Anatomic Area	Mechanism of Injury	Assessment Findings	Sports Activity	Acute Management
Clavicle fracture	Fall on shoulder or outstretched arm Direct blow to the clavicle	Crepitus Holds arm closely to body Unable to raise affected arm above head Can feel movement of both ends of clavicle	Football Rugby Hockey Wrestling Gymnastics	Sling or shoulder immobilizer Ice NSAIDs
Dislocated shoulder	*Anterior:* Some combination of hyperextension, external rotation, and abduction Anterior blow to shoulder *Posterior:* Fall on flexed and adducted arm Direct axial load to humerus	Pain Lack of motion May feel empty shoulder socket Uneven posture in comparison to other shoulder Affected arm appears longer Abduction limited	Rugby Hockey Wrestling Skiing	Closed reduction Immobilizer Pendulum exercises
Dislocated elbow	Falling on a hand with a flexed elbow Elbow overextended	Intense pain Edema Limited motion Deformity Ecchymosis	Football Gymnastics Squash Wrestling Cycling Skiing	Immobilization Ice ROM exercises
Wrist sprain or fracture	Falling on an outstretched arm	Pain Edema Ecchymosis Deformity Limited motion	Skating Hockey Wrestling Skiing Soccer Handball Horseback riding	Ice Elevation Immobilization Gentle ROM for 4–6 wks (for sprain only)
Knee sprain	Twisting injury that produces incomplete tear of ligaments and capsule around the joint	Pain Limited motion Edema Ecchymosis Tenderness over joint Joint appears stable	Basketball Football High jump	Ice Elevation Compression wrap Active ROM exercises Isometric exercises May immobilize
Knee strain	Sudden forced motion causing muscle to be stretched beyond normal capacity	Pain Limited motion Pain aggravated by activity	Soccer Swimming Skiing	Ice Elevation Rest Gradual return to activities
Meniscal tears of knee	Sharp, sudden pivot Direct blow to knee Forced internal rotation Wear from repetitive squatting or climbing Torsional weight-bearing force	Edema *Medial tear:* Pain occurs with hyperflexion, hyperextension, and turning in of knee with knee flexed. *Lateral tear:* Pain occurs with hyperflexion and hyperextension and internal rotation of foot with knee flexed. *Displaced fragment:* Inability to extend knee; "locked" Positive McMurray sign[a]	Hockey Basketball Football	*Conservative:* RICE Exercising of quadriceps and hamstrings Resistive exercising NSAIDs Physical therapy *Surgical:* Arthroscopy
Ankle sprain	Foot is twisted, causing stretching or tearing of ligaments.	Pain Edema Limited motion Ecchymosis	Tennis Basketball Football Skating	Immobilization in cast or brace Ice Elevation Rest
Ankle strain	Sudden forced motion, stretching muscles beyond normal capacity	*Acute:* Severe pain *Chronic:* Achy pain	Running All ball sports	Immobilization in cast or brace Ice Elevation Rest
Ankle fracture	Inward turning on sole of foot and front of foot Supination with internal rotation Pronation with external rotation	Pain Edema Deformity Inability to bear weight	Contact sports Tennis Basketball	Ice Elevation Cast (4–6 wks) Surgery if fracture is displaced or unstable
Metatarsal stress fracture	Occurs with repeated loading of bone; often in an unconditioned extremity	Forefoot pain that progressively worsens with activity Minimal or no forefoot swelling	Running Dance Skating	Rest Stop sports-related activity for 6 wks Ice Weight bearing as indicated

[a]McMurray sign—manipulation of tibia while knee flexed produces audible "click."
NSAIDs, nonsteroidal anti-inflammatory drugs; RICE, rest, ice, compression, elevation; ROM, range of motion.

An amputation is performed to control pain or disease process, to improve function, and to save or improve the patient's quality of life. If the health care team communicates a positive attitude, the patient adjusts

to the amputation more readily and actively participates in the rehabilitative plan, learning how to modify activities and how to use assistive devices for ADLs and mobility.

Level of Amputation

The level of amputation is performed at the most distal point that will heal successfully and should take into account the ability of the patient to achieve a successful rehabilitation. The site and extent of amputation is determined by circulation in the area (and whether or not necrosis is present), the degree of tissue loss and viability of the tissues, functional usefulness (i.e., meets the requirements for the use of a prosthesis) and the presence of infection (Guest, Marshall, & Stansby, 2019).

The circulatory status of the limb is evaluated through physical examination and diagnostic studies. Muscle and skin perfusion are important for healing. Doppler flow studies with duplex ultrasound, segmental pressure determinations, and transcutaneous oxygen measurements of the limb are valuable diagnostic aids. Angiography is performed if revascularization is considered an option.

The objective of surgery is to conserve as much limb length as needed to preserve function and possibly to achieve a good prosthetic fit. Preservation of knee and elbow joints is desirable. Figure 37-23 shows the levels at which a limb may be amputated. Most amputations involving limbs eventually can be fitted with a prosthesis.

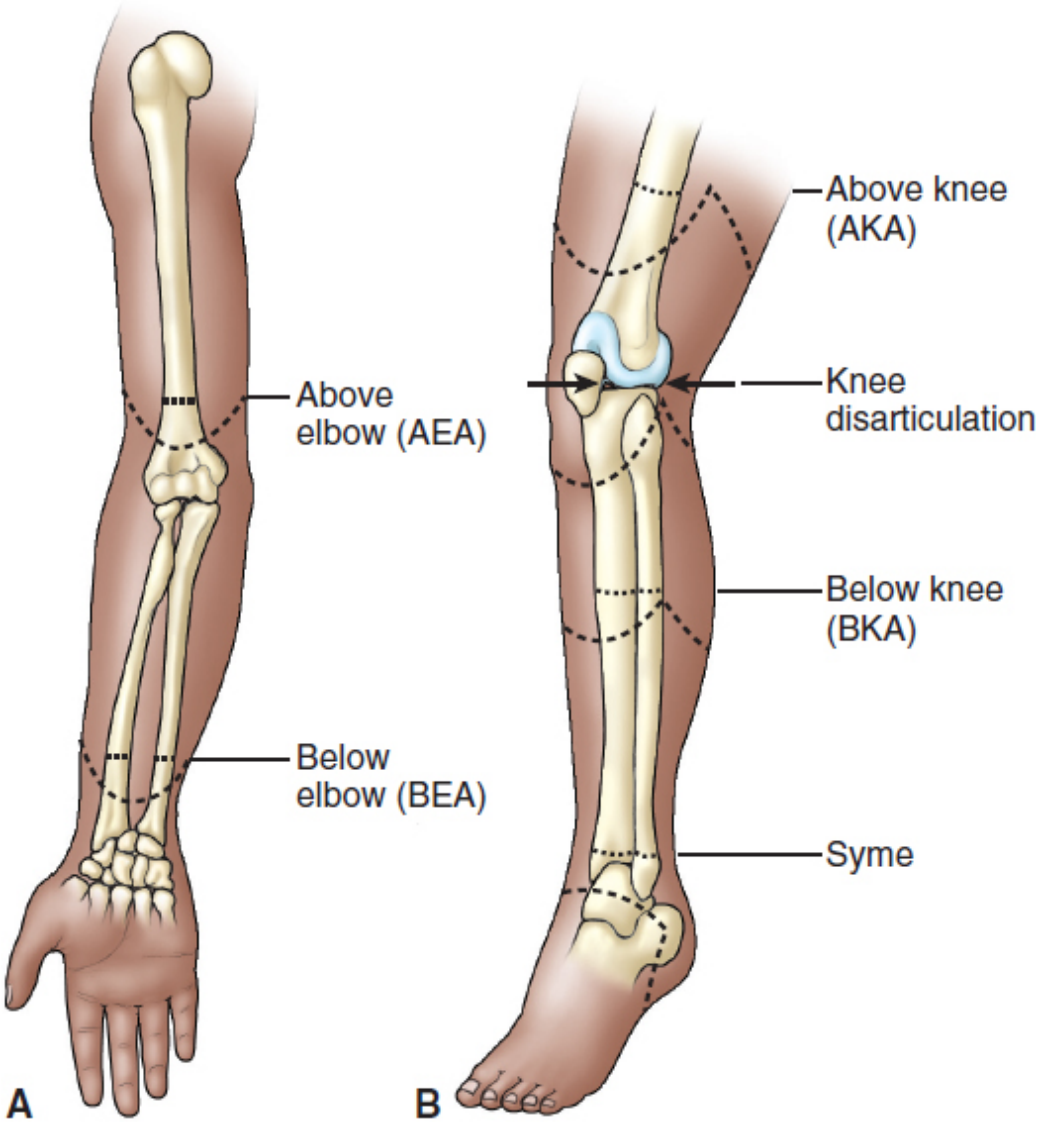

Figure 37-23 • Level of amputation is determined by circulatory adequacy, type of prosthesis, function of the part, and muscle balance. **A.** Level of amputation of upper limb. **B.** Level of amputation of lower limb.

The amputation of toes and portions of the foot can cause changes in gait and balance. A Syme amputation (modified ankle disarticulation amputation) is performed most frequently for extensive foot trauma and aims to produce a durable residual limb that can withstand full weight bearing. Below-knee amputation (BKA) is preferred to above-knee amputation (AKA) because of the importance of the knee joint and the energy requirements for walking. A knee **disarticulation** (e.g., amputation through the joint) is most successful with a young, active patient who can develop precise control of the prosthesis. When AKAs are performed, all possible length is preserved, muscles are stabilized and

shaped, and hip contractures are prevented to maximize ambulatory potential (Guest et al., 2019). Most people who have a hip disarticulation amputation must rely on a wheelchair for mobility.

Upper limb amputations are performed with the goal of preserving maximal functional length. The prosthesis is fitted early to ensure maximum function.

A "staged" amputation may be used when gangrene and infection exist. Initially, a débriding amputation in the form of a guillotine amputation (i.e., transfemoral, transtibial) is performed to remove the infected and necrotic tissue. Once the infected limb is removed, systemic antibiotics are administered, and the wound is left open and allowed to drain. In a few days, after the infection has been controlled and the patient's condition has stabilized, a definitive amputation with skin closure is performed; a drain may be left in place (Kalapatapu, 2019).

Complications

Complications that may occur with amputation include hemorrhage, infection, skin breakdown, phantom limb pain, and joint contracture. Because major blood vessels have been severed, hemorrhage may occur. Infection is a risk with all surgical procedures. The risk of infection increases with contaminated wounds after traumatic amputation. Antibiotic prophylaxis prior to surgery is recommended. Skin irritation caused by the prosthesis may result in skin breakdown. **Phantom limb pain** (pain perceived in the amputated section) is caused by the severing of peripheral nerves. Joint contracture is caused by positioning and a protective flexion withdrawal pattern associated with pain and muscle imbalance (Kalapatapu, 2019). Associated comorbidities such as ischemic disease and psychological disorders such as depression and anxiety must also be monitored closely as they can contribute to further complications and chronic limb pain (Chung & Yoneda, 2020).

Medical Management

The objective of treatment is to achieve healing of the amputation wound, the result being a nontender residual limb with healthy skin for prosthetic use. Healing is enhanced by gentle handling of the residual limb, control of residual limb edema and pain, and the use of aseptic technique in wound care to avoid infection (Kalapatapu, 2019).

The primary postoperative dressings to support soft tissues, control pain and edema, and prevent joint contractures include nonremovable rigid dressings, removable rigid dressings, soft dressings (elastic and crepe), and weight-bearing immediate postoperative prostheses (Reichmann, Stevens, Rheinstein, et al., 2018).

The type of dressing used in patients with lower limb amputations varies. A reduction in edema, pain, contractures, healing time, time to prosthetic fitting, and injury due to falls has been shown for certain types of amputations (e.g., transtibial) with the use of removable rigid dressings as compared to soft dressings (Reichmann et al., 2018). However, a soft dressing with or without compression may be used if there is significant wound drainage, frequent inspection of the residual limb is required, and the patient has poor skin integrity (Kwah, Webb, Go, et al., 2019). An immobilizing splint may be incorporated in the soft dressing. Good clinical judgment over which dressing to use should consider the risks and benefits for each individual patient. A wound drain can be placed to remove excess blood and drainage from the surgical site (Schreiber, 2017). Staples or sutures maintain closure at the operative site and are typically removed approximately 3 weeks postoperatively.

Rehabilitation

The multidisciplinary rehabilitation team (patient, nurse, primary provider, social worker, physical therapist, occupational therapist, psychologist, prosthetist, vocational rehabilitation worker) helps the patient achieve the highest possible level of function and participation in life activities (see Fig. 37-24). Prosthetic clinics, amputee support programs, and peer visits (face-to-face, telephone, digital) for patients with a limb amputation facilitate the rehabilitation process, both physically and psychosocially (Reichmann & Bartman, 2018).

Patients who undergo amputation need support as they grieve the loss and change in body image. Their reactions can include anger, bitterness, and hostility. Psychological issues (e.g., denial, anxiety, avoidance) may be influenced by the type of support the patient receives from the rehabilitation team, the effectiveness of pain management, and by how quickly ADLs and the use of the prosthesis are learned. Providing education about the full options and capabilities available with the various prosthetic devices, as well as the recovery of walking capacity, if appropriate, can give the patient a sense of control over the resulting

disability and promote independence (Luza, Ferreira, Minsky, et al., 2019).

Figure 37-24 • Many patients with amputations receive prostheses soon after surgery and begin learning how to use them with the help and support of the rehabilitation team, which includes nurses, primary providers, physical therapists, and others.

Patients undergoing amputation because of severe trauma are usually young and healthy. These patients heal rapidly and are physically able to participate in a vigorous rehabilitation program. Because the amputation is the result of an injury, the patient needs holistic multidisciplinary support from the beginning in order to accept the sudden change in body image and to deal with the stresses of hospitalization, long-term

rehabilitation, and modification of lifestyle (Noblet, Lineham, Wiper, et al., 2019).

Veterans Considerations

Within the past two decades, numerous U.S. military personnel have sustained conflict-related amputations from exposure to blasts from improvised explosive devices. The Department of Veterans Affairs/Department of Defense (VA/DoD) follows its own set of periodically updated evidence-based guidelines to ensure that veterans with amputations consistently receive quality care (VA/DoD, 2017). In addition, so that the complex needs of these young, previously healthy men and women may be met, the U.S. Army instituted both a specialized treatment center for patients with amputations and a database registry to facilitate long-term treatment and management. Treatment for these injured service members addresses not only physical rehabilitation needs, but also ways to optimize psychosocial functioning (VA/DoD, 2017). A multidisciplinary rehabilitation team with referral to behavioral health services are considered key components to therapy.

NURSING PROCESS

The Patient Undergoing an Amputation

Assessment

Before surgery, the nurse must evaluate the neurovascular and functional status of the limb through history and physical assessment. If the patient has experienced a traumatic amputation, the nurse assesses the function and condition of the residual limb. The nurse also assesses the circulatory status and function of the unaffected limb. If infection or gangrene develops, the patient may have associated enlarged lymph nodes, fever, and purulent drainage. A culture and sensitivity test is obtained to determine the appropriate antibiotic therapy.

The nurse evaluates the patient's nutritional status and develops a postoperative plan for nutritional care in consultation with a dietitian or metabolic nutrition support team, if indicated. A diet with adequate protein and vitamins is essential to promote wound healing. Additional calories may be necessary due to the energy required for transfers and ADLs when using a prosthesis (Schreiber, 2017).

Any concurrent health problems (e.g., dehydration, anemia, cardiac insufficiency, chronic respiratory problems, diabetes) need to be identified and treated so that the patient is in the best possible condition to withstand the surgical procedure. The use of corticosteroids, anticoagulants, vasoconstrictors, or vasodilators may influence management and prolong or delay wound healing.

The nurse assesses the patient's psychological status. Evaluation of the patient's emotional reaction to amputation is important. Grief responses to permanent alterations in body image, function, and mobility are likely. Professional counseling and available support services can help the patient cope in the aftermath of amputation surgery.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain associated with amputation
- Impaired skin integrity associated with surgical amputation
- Disturbed body image associated with amputation

- Grief and/or risk for dysfunctional grief associated with loss of body part and resulting disability
- Impaired ability to perform hygiene, impaired ability to dress, impaired self feeding, or impaired self toileting associated with amputation
- Impaired mobility associated with amputation

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- Infection
- Skin breakdown

Planning and Goals

The major goals of the patient may include relief of pain, including phantom limb pain, wound healing, acceptance of altered body image, resolution of the grieving process, independence in self-care, restoration of physical mobility, and absence of complications.

Nursing Interventions

Relieving Pain

Pain may be incisional or may be caused by inflammation, infection, pressure on a bony prominence, hematoma, or phantom limb pain. Muscle spasms may add to the patient's discomfort. Surgical pain can be effectively controlled with opioid analgesics that may be accompanied with evacuation of a hematoma or accumulated fluid. Changing the patient's position or placing a light sandbag on the residual limb to counteract the muscle spasm may improve the patient's level of comfort. Evaluation of the patient's pain and responses to interventions is an important component of pain management.

Many patients who have amputations begin to experience phantom limb pain soon after surgery. It is a complex pain condition that has been reported in 60% to 80% of patients with amputations (Hall, Abd-Elsayed, & Eldabe, 2019). The patient reports pain in the missing limb as if it were still present. The pain is described as if the amputated limb feels crushed, cramped, or twisted in an abnormal position; this pain is sometimes accompanied by numbness, tingling, or sensations of burning or electric shock. Phantom limb pain occurs intermittently and unpredictably; episodes of pain may last seconds or hours. When a patient describes phantom pains or sensations, the nurse acknowledges

these feelings as real and encourages the patient to verbalize when in pain so that effective treatment may be given. Phantom limb pain typically diminishes over time for most patients, with episodes gradually becoming less frequent and of lesser duration; however, some patients continue to experience phantom limb pain as long as 2 years after the amputation.

The pathogenesis of the phantom limb pain phenomenon is believed to involve changes in both peripheral and central neuronal mechanisms. Disruption in neuronal pathways are thought to cause neuroplastic changes that in turn result in changes in cortical representation, or the proprioceptive, tactile, and visual image of body parts as perceived by the cerebral cortex (Hall et al., 2019). Preoperative epidural analgesia (preemptive analgesia) may reduce the incidence and severity of phantom limb pain over the long term (Guest et al., 2019). Perioperatively, the patient may be managed with acetaminophen, NSAIDs, anticonvulsants (gabapentin), opioids, and NMDA receptor antagonists (ketamine infusion). Epidural and perineural catheter analgesia may be used during and immediately after the operation (Hall et al., 2019). Opioid analgesics may be effective in relieving postoperative pain. In addition, beta-blockers may relieve dull, burning discomfort; anticonvulsants control stabbing and cramping pain; and tricyclic antidepressants may not only alleviate phantom limb pain but may also be prescribed to improve mood and coping ability. Therapies that may be used as adjuncts to pharmacologic treatments include mirror therapy (i.e., the patient views and moves the unaffected limb in a mirror that is in a box or blocking the view of the affected limb), massage, biofeedback, acupuncture, repositioning, TENS, guided imagery, virtual reality, and neuromodulation (Hall et al., 2019; Herrador Colmenero, Perez Marmol, Marti-Garcia, et al., 2018). The nurse monitors the effectiveness of these treatments and collaborates with the multidisciplinary team to advocate for optimal pain control. Successful pain management following amputation promotes positive patient outcomes and lowers the cost of care (VA/DoD, 2017).

Promoting Wound Healing

Following amputation, the incision should be examined daily for signs of infection. The residual limb must be handled gently and should be measured once every 8 to 12 hours postoperatively to assess for edema formation. Neurovascular assessments (including the most distal pulse, movement, sensation, skin temperature) are also performed at these

intervals, and compared to the unaffected limb to ensure that there is adequate blood supply. The dressing is changed as prescribed and whenever soiled, using aseptic technique to prevent infection and possible osteomyelitis (Kalapatapu, 2019). Drains are maintained and can be discontinued when the volume in the drain reservoir is minimal.

If the rigid or soft dressing inadvertently comes off, the nurse must immediately wrap the residual limb with an elastic compression bandage. If this is not done, excessive edema will develop in a short time, resulting in a delay in rehabilitation. The nurse notifies the surgeon if the dressing comes off so that another one can be applied promptly.

Chart 37-9  NURSING RESEARCH PROFILE

Patients' Postamputation Viewing of Selves in the Mirror

Freysteinson, W., Thomas, L., Sebastian-Deutsch, A., et al. (2017). A study of the amputee experience of viewing self in the mirror. *Rehabilitation Nursing*, *37*(1), 22–32.

Purpose

Approximately two million individuals are living with the loss of a limb in the United States, and this incidence is expected to nearly double by 2050. The amputation of a limb is a traumatic event and affects an individual physically and psychologically. A visible disfigurement such as an amputation can lead to distortions in body image, depression, and low self-esteem as well as nonacceptance of a prosthesis in the rehabilitation phase. For a patient with an amputation, one of the most shocking and anxiety producing situations that can negatively impact the perception of body image is the mirror-viewing experience (viewing one's self in a mirror after the amputation of a limb). However, the research evidence addressing this topic is limited. The purpose of this study was to describe the experience of viewing of self in a mirror after an amputation and the perceptions of what nurses should know about clinical mirror interventions.

Design

A hermeneutic phenomenologic design was used. Snowball sampling was used to recruit 17 participants who consented to be in the study. In order to be included in the study, participants had to be at least 18 years of age, have an amputation of an upper or lower limb, and have an ability to speak, read, and understand English. Five focus groups of 3 to 6 participants, lasting approximately 60 to 90 minutes, were conducted in a research rehabilitative hospital setting. Key questions asked included: Describe an experience about one of the first times you saw yourself in a mirror after amputation; what were your feelings and emotions? What was your self-talk before/during/after looking in the mirror? How would you describe the journey of viewing self in the mirror the first time to what it is like to view self in the mirror now, and what might each of the stages of this journey be called? The question which provided the most information about participant perceptions of potential mirror interventions was: What would you say is really important for health care providers to know about mirrors?

Findings

The interpretation of data revealed that the act of viewing self in a mirror at any time after an amputation had three key elements: decision, seeing self, and consent. The trajectory of mirror shock, mirror anguish, recognizing self, and accepting a new normal are key themes and adds to the existing literature. Reasons to decide to view self in the mirror included curiosity, appearance, care of incision or residual limb, and gait/posture assessment. The experience of viewing self in the mirror after an amputation changes over time, and each person's mirror trajectory begins when initially making the decision of viewing self in a mirror after the amputation. Participants recommend that the nurse facilitate the initial mirror viewing experience and use the mirror as a tool to assess for skin breakdown and to help correct gait and balance.

Nursing Implications

The viewing of self in the mirror after an amputation can be a very difficult and emotional experience. Nurses are in a unique position to show support and understanding of the situation by facilitating the initial mirror viewing of the patient's amputation in a proper and controlled setting. When nurses are present during the initial mirror viewing process, the patient realizes that they are not alone in this experience and that the nurse understands what they are going through. There appears to be a lack of mirrors in health care settings; therefore, it is recommended that rooms in private hospitals and rehabilitation facilities have more small and full-length mirrors.

Application of consistent pressure to the residual limb reduces edema formation and helps to shape the residual limb so that it may fit a prosthetic. The wound should be assessed to ensure that it is healing and that there are no signs of infection (e.g., redness, purulent drainage), which can also hamper optimal prosthetic fit. After the incision is healed and the limb is shaped appropriately, the patient is instructed how to care for the residual limb (VA/DoD, 2017).

Enhancing Body Image

Amputation is a procedure that alters the patient's body image. The nurse who has established a trusting relationship with the patient is better able to communicate acceptance of the patient who has experienced an amputation. The nurse encourages the patient to look at, feel, and care for the residual limb. Nursing research findings suggest that the nurse be present with patients who view themselves in mirrors after an amputation (Freysteinson, Thomas, Sebastian-Deutsch, et al., 2017) (see Nursing Research Profile: Chart 37-9). It is

important to identify the patient's strengths and resources to facilitate rehabilitation. The nurse helps the patient regain the previous level of independent functioning. The patient who is accepted as a whole person is more readily able to resume responsibility for self-care; self-concept improves, and body image changes are accepted. Even with highly motivated patients, this process may take months.

Concept Mastery Alert

The nurse can provide the following interventions to foster a positive self-image: encouraging the patient to care for the residual limb, allowing the expression of grief, and promoting utilization of available resources.

Helping the Patient to Resolve Grieving

The loss of a limb (or part of one) may come as a shock even if the patient was prepared preoperatively. The patient's behavior (e.g., crying, withdrawal, apathy, anger) and expressed feelings (e.g., depression, fear, helplessness) reveal how the patient is coping with the loss and working through the grieving process.

The nurse creates an accepting and supportive atmosphere in which the patient and family are encouraged to express and share their feelings and work through the grief process. The support from family and friends promotes the patient's acceptance of the loss. The nurse helps the patient deal with immediate needs and become oriented to realistic rehabilitation goals and future independent functioning. Psychological needs can be further addressed by mental health professionals; referrals for support services and spiritual advisors (e.g., pastoral care) may be appropriate (Myers, VanDamme, & Pasquina, 2018).

Promoting Independent Self-Care

Amputation affects the patient's ability to provide adequate self-care. The patient is encouraged to be an active participant in self-care. The patient needs time to accomplish these tasks and must not be rushed. Practicing an activity with consistent, supportive supervision in a relaxed environment enables the patient to learn self-care skills. The patient and the nurse need to maintain positive attitudes and minimize fatigue and frustration during the learning process.

Independence in dressing, toileting, and bathing depends on balance, transfer abilities, and physiologic tolerance of the activities.

The nurse works with the physical therapist and occupational therapist to educate and supervise the patient in these self-care activities.

The patient with an upper limb amputation has self-care deficits in feeding, bathing, and dressing. Assistance is provided only as needed; the nurse encourages the patient to learn to do these tasks, using assistive feeding and dressing aids when needed. The nurse, therapists, and prosthetist work with the patient to achieve maximum independence.

Assisting the Patient to Achieve Physical Mobility

Assisting the Patient with a Lower Limb Amputation. Proper positioning of the residual limb prevents the development of hip or knee joint contracture in the patient with a lower limb amputation. The limb should be elevated for 24 hours after amputation to promote venous return and decrease edema (Schreiber, 2017). After this period, elevation, abduction, external rotation, and flexion of the lower limb are to be avoided. The patient is encouraged not to sit for long periods of time to prevent flexion contracture or with the affected extremity dangling or in a dependent position to prevent edema (Schreiber, 2017).

The residual limb should not be placed on a pillow because a flexion contracture of the hip may result. The nurse encourages the patient to turn from side to side and to assume a prone position, 20 to 30 minutes several times per day to stretch the flexor muscles and to prevent flexion contracture of the hip. The legs should remain close together to prevent an abduction deformity. The nurse encourages the patient to use assistive devices to more readily perform self-care activities and to identify what home modifications, if any, should be made to perform these activities in the home environment.

Postoperative ROM exercises are started early because contracture deformities develop rapidly. ROM exercises include hip and knee exercises for patients with BKAs and hip exercises for patients with AKAs. It is essential that the patient understands the importance of exercising the residual limb as well as the unaffected extremities for joint mobility and strengthening (Schreiber, 2017).

The upper limbs, trunk, and abdominal muscles are exercised and strengthened. The extensor muscles in the arm and the depressor muscles in the shoulder play an important part in crutch walking. The patient uses an overbed trapeze to change position and strengthen the biceps. The patient may flex and extend the arms while holding weights. Doing push-ups while seated strengthens the triceps muscles.

Exercises (such as hyperextension of the residual limb), conducted under the supervision of the physical therapist, also aid in strengthening muscles as well as increasing circulation, reducing edema, and preventing atrophy.

Strength and endurance are assessed, and activities are increased gradually to prevent fatigue. As the patient progresses to independent use of the wheelchair, the use of ambulatory aids, or ambulation with a prosthesis, the nurse emphasizes safety considerations. Environmental barriers (e.g., steps, inclines, doors, throw rugs, wet surfaces) are identified, and methods of managing them are implemented. It is important to anticipate, identify, and manage problems associated with the use of the mobility aids. Proper education in using assistive devices will help prevent these problems.

Amputation of the leg changes the center of gravity; therefore, the patient may need to practice position changes (e.g., standing from sitting, standing on one foot). The patient is taught transfer techniques early and is reminded to maintain good posture when getting out of bed. A well-fitting shoe with a nonskid sole should be worn. During position changes, the patient should be guarded and stabilized with a transfer belt at the waist to prevent falling.

As soon as possible, the patient with a lower limb amputation is assisted to stand between parallel bars to allow extension of the temporary prosthesis to the floor with minimal weight bearing. How soon after surgery the patient is allowed to bear full body weight on the prosthesis depends on the patient's physical status and wound healing. As endurance increases and balance is achieved, ambulation is started with the use of parallel bars or crutches. The patient learns to use a normal gait, with the residual limb moving back and forth while walking with the crutches. To prevent a permanent flexion deformity from occurring, the residual limb should not be held up in a flexed position (Kalapatapu, 2019).

Assisting the Patient with an Upper Limb Amputation. Because a patient who has had an upper limb amputated uses both shoulders to operate the prosthesis, the muscles of both shoulders are exercised. A patient with an above-elbow amputation or shoulder disarticulation is likely to develop a postural abnormality caused by loss of the weight of the amputated limb. Postural exercises are helpful.

The patient with an upper limb amputation is taught how to carry out ADLs with one arm. The patient is started on one-handed self-care activities as soon as possible. The use of a temporary prosthesis is

encouraged. The patient who learns to use the prosthesis soon after the amputation is less dependent on one-handed self-care activities.

The patient with an upper limb amputation may wear a cotton T-shirt to prevent contact between the skin and shoulder harness and to promote absorption of perspiration. The prosthetist advises about cleaning the washable portions of the harness. Periodically, the prosthesis is inspected for potential problems.

Preparing the Patient for a Prosthesis. The residual limb must be conditioned and shaped into a conical form to permit accurate fit, maximum comfort, and function of the prosthetic device. Elastic bandages, an elastic residual limb shrinker, or an air splint is used to condition and shape the residual limb. The nurse educates the patient or a member of the family about the correct method of bandaging.

Bandaging supports the soft tissue and minimizes the formation of edema while the residual limb is in a dependent position. The bandage is applied in such a manner that the remaining muscles required to operate the prosthesis are as firm as possible. An improperly applied elastic bandage contributes to circulatory problems and a poorly shaped residual limb.

Effective preprosthetic care is important to ensure proper fitting of the prosthesis. The major problems that can delay prosthetic fitting during this period are flexion deformities, nonshrinkage of the residual limb, and abduction deformities of the hip.

The primary provider usually prescribes activities to condition or "toughen" the residual limb in preparation for a prosthesis. The patient begins by pushing the residual limb into a soft pillow, then into a firmer pillow, and finally against a hard surface. The patient is taught to massage the residual limb to mobilize the surgical incision site, decrease tenderness, and improve vascularity. Massage is usually started once healing has occurred and is first performed by the physical therapist. Skin inspection and preventive care are taught; mirrors may be used to visualize the skin on the residual limb (Rossbach, 2017).

The prosthesis socket is custom-shaped to the residual limb by the prosthetist. Prostheses are designed for specific activity levels and patient abilities. Types of prostheses include those that are hydraulic, pneumatic, biofeedback controlled, myoelectrically controlled, and synchronized. Adjustments of the prosthetic socket are made by the prosthetist to accommodate the residual limb changes that occur during the first 6 months to 1 year after surgery.

Assisting the Patient Who Is Not a Candidate for a Prosthesis. Some patients with amputations are not candidates for a prosthesis due to preexisting factors (e.g., nonambulatory before amputation, dementia, AKA). If the use of a prosthesis is not possible, the patient is educated in safe use of a wheelchair to achieve independence. A special wheelchair designed for a patient who has had an amputation is recommended. Because of the decreased weight in the front, a regular wheelchair may tip backward when the patient sits in it. In wheelchairs designed for patients who have had amputations, the rear axle is set back about 5 cm (2 inches) to compensate for the change in weight distribution.

Monitoring and Managing Potential Complications

After any surgery, efforts are made to reestablish homeostasis and to prevent complications related to surgery, anesthesia, and immobility. The nurse assesses body systems (e.g., respiratory, hematologic, gastrointestinal, genitourinary, skin) for problems associated with immobility (e.g., atelectasis, pneumonia, DVT, PE, anorexia, constipation, urinary stasis, pressure injuries).

Massive hemorrhage due to a loosened suture is a potentially life-threatening problem. The nurse monitors the patient for any signs or symptoms of bleeding and monitors the patient's vital signs and suction drainage.

Quality and Safety Nursing Alert

Immediate postoperative bleeding may develop slowly or may take the form of massive hemorrhage resulting from a loosened suture. A large tourniquet should be in plain sight at the patient's bedside so that if severe bleeding occurs, it can be applied to the residual limb to control the hemorrhage. The nurse immediately notifies the surgeon in the event of excessive bleeding.

Infection is a common complication of amputation. Patients who have undergone traumatic amputation have contaminated wounds. The nurse administers prophylactic antibiotics as prescribed. The nurse must monitor the incision, dressing, and drainage for indications of infection (e.g., change in color, odor, or consistency of drainage; increasing discomfort). The nurse also assesses for systemic indicators

of infection (e.g., elevated temperature, leukocytosis with an increase of more than 10% bands on the differential) and promptly reports indications of infection to the surgeon.

Skin breakdown may result from immobilization or pressure from various sources. The prosthesis may cause pressure areas to develop. The nurse and the patient assess for breaks in the skin. Careful skin hygiene is essential to prevent skin irritation, infection, and breakdown. The healed residual limb is washed and dried (gently) at least twice daily. The skin is inspected for persistent erythema, pressure areas, dermatitis, and blisters. If they are present, the prosthesis should not be worn until the complication is evaluated and treated in order to prevent further skin breakdown. Usually, a residual limb sock is worn to absorb perspiration and to prevent direct contact between the skin and the prosthetic socket. The sock is changed daily and must fit smoothly to prevent irritation caused by wrinkles. The socket of the prosthesis is washed with a mild detergent, rinsed, and dried thoroughly with a clean cloth. It must be thoroughly dry before the prosthesis is applied (Rossbach, 2017).

Promoting Home, Community-Based, and Transitional Care

Educating the Patient About Self-Care. Before the patient is discharged to home or to a rehabilitation facility, the patient and family are encouraged to become active participants in care. They participate in care of the skin, residual limb, and prosthesis as appropriate. The patient receives ongoing education and practice sessions to learn to transfer and to use mobility aids and other assistive devices safely. The nurse explains the signs and symptoms of complications that must be reported to the primary provider (see Chart 37-10).

Continuing and Transitional Care.After the patient has achieved physiologic homeostasis and has demonstrated achievement of major health care goals, rehabilitation continues either in a rehabilitation facility or at home. An inpatient rehabilitation facility may be indicated; these facilities have been shown to improve quality of life, ambulation and patient confidence, mobility, and prosthesis use with less associated pain (VA/DoD, 2017). In any case, continued support and evaluation by the home health nurse is essential.

The patient's home environment should be assessed prior to discharge. Modifications are made to ensure the patient's continuing care, safety, and mobility. An overnight or weekend experience at home may be tried to identify problems that were not identified on the

assessment visit. Physical therapy and occupational therapy may continue in the home or on an outpatient basis. Transportation to continuing health care appointments must be arranged. The social service department of the hospital or the home health agency may be of great assistance in securing personal assistance and transportation services.

Chart 37-10  HOME CARE CHECKLIST

The Patient with an Amputation

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., durable medical equipment, adaptive equipment, ADL assistance), used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
  - Identify professionals and community agencies to help with transition to home.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Describe care of residual limb and conditioning for prosthesis.
  - Consume a healthy diet to promote wound healing.
  - Participate in rehabilitation program to regain functional independence, promote circulation, maintain the health of unaffected muscles and those muscles now needed for safe transfer, mobility, etc.
  - If indicated, demonstrate safe use of mobility aid, assistive device, and transfer technique.
  - Observe prescribed weight-bearing and activity limits.
- State the name, dose, side effects, frequency, and schedule for all prescribed therapeutic and prophylactic medications (e.g., antibiotics, anticoagulants, analgesic agents).
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- State indicators of complications to report promptly to primary provider (e.g., uncontrolled pain; signs of local or systemic infection; residual limb skin breakdown).
- Relate how to reach primary provider with questions or complications.

- State time and date of follow-up appointments, therapy, and testing.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify the contact details for support services for patients and their caregivers/families.
- Identify the need for health promotion, disease prevention, and screening activities.

Resources

See Chapter 2, Chart 2-6, for additional information related to durable medical equipment, adaptive equipment, and mobility skills.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

During follow-up health visits, the nurse evaluates the patient's physical and psychosocial adjustment. Periodic preventive health assessments are necessary. An older adult spouse may not be able to provide the assistance required if needed at home. Modifications in the plan of care are made on the basis of such findings. Often, the patient and family find involvement in a postamputation support group and peer support programs to be of value; here, they can share problems, solutions, and resources (Reichmann & Bartman, 2018). Talking with those who have successfully dealt with a similar problem may help the patient develop a satisfactory solution.

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices, such as regular physical examinations and diagnostic screening tests. Accessible facilities for screening, health care, and exercise are identified. Patients are instructed about their importance and are referred to appropriate health care providers.

Evaluation

Expected patient outcomes may include:

1. Experiences no pain, including phantom limb pain
   a. Appears relaxed
   b. Verbalizes comfort

c. Uses measures to increase comfort and mitigate pain
d. Participates in self-care and rehabilitative activities
e. Reports diminished phantom sensations

2. Achieves wound healing
   a. Controls residual limb edema
   b. Exhibits healed, nontender, nonadherent scar
   c. Demonstrates residual limb care
3. Demonstrates improved body image and effective coping
   a. Acknowledges change in body image
   b. Participates in self-care activities
   c. Demonstrates increasing independence
   d. Projects self as a whole person
   e. Resumes role-related responsibilities
   f. Reestablishes social contacts
   g. Demonstrates confidence in abilities
4. Exhibits resolution of grieving
5. Expresses grief
6. Works through feelings with family, friends, and health care professionals
7. Focuses on future functioning
8. Utilizes available support
9. Achieves independent self-care
   a. Asks for assistance when needed
   b. Uses aids and assistive devices to facilitate self-care
   c. Verbalizes satisfaction with abilities to perform ADLs
10. Achieves maximum independent mobility
    a. Avoids positions contributing to contracture development
    b. Demonstrates full active ROM
    c. Maintains balance when sitting and transferring
    d. Increases strength and endurance
    e. Demonstrates safe transferring technique
    f. Achieves functional use of prosthesis
    g. Overcomes environmental barriers to mobility
    h. Uses community services and resources as needed
11. Exhibits absence of complications of hemorrhage, infection, or skin breakdown

a. Does not experience excessive bleeding
b. Maintains normal blood values
c. Is free of local or systemic signs of infection
d. Repositions self frequently
e. Is free of pressure-related problems
f. Reports any skin discomfort and irritations promptly

CRITICAL THINKING EXERCISES

1 ebp A 74-year-old woman was admitted to the hospital after she fell down a flight of stairs and fractured her right hip. She is now 48 hours postoperative after a right ORIF to that hip. She is moderately overweight and has a history of smoking. She has been reluctant to get out of bed to ambulate and complains that her intermittent compression devices are uncomfortable, and she does not want to wear them. What is the strength of the evidence that supports the use of compression devices postoperatively for patients who have had ORIF post-hip fractures? What are her risks if she does not wear these devices postoperatively? How will you respond to the patient's request to not wear these devices?

---

2 ipc You are caring for a 30-year-old female who was involved in a motor vehicle crash and had a traumatic amputation of her left upper extremity at the scene. She is 7 days postoperative and is now complaining of phantom limb sensation and severe pain in the missing limb. She describes the quality of the pain as crushing, burning, and "electric shock like" and it spreads from her missing fingers to the length of her arm. She is becoming anxious with the severity of the pain and does not understand what is happening to her. Describe the assessments and interventions as you prioritize care for this patient. Identify the multidisciplinary collaboration necessary to provide a comprehensive treatment plan for this patient to promote the best outcomes.

---

2 pq You have been assigned to care for a 36-year-old male admitted to the inpatient orthopedic unit following a motorcycle crash. He had an external fixation device applied 8 hours ago for a fracture of the left tibia. During shift report, the nurse reports that the patient has been complaining of throbbing pain and paresthesia in his left lower leg that has not been alleviated despite administration of prescription opioid pain medication. Upon your initial assessment, you note that the patient's left calf is very swollen, shiny, and taut. Describe the additional physical assessments that should be conducted for this patient. What is your priority nursing diagnosis and plan of care?

UNIT 9 Digestive and Gastrointestinal Function

Case Study

IMPROVING NUTRITION UTILIZING QUALITY INDICATORS

You are working in an outpatient clinic that has a high volume of patients with inflammatory bowel disease (IBD). You know that nutrition is an important focus for patients with IBD and that a low-residue, high-protein, high-calorie, and high-vitamin diet can help

decrease symptoms such as diarrhea and weight loss. You recall several patients in the past few months who have presented with diarrhea and weight loss. For this reason, you report your observations to the nurse manager and suggest a quality improvement project for assessing the nutritional status of patients with IBD.

QSEN Competency Focus: **Quality Improvement**

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Quality Improvement Definition: Use data to monitor the outcomes of care processes and use improvement methods to design and test changes to continuously improve the quality and safety of health care systems.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Describe strategies for learning about the outcomes of care in the setting in which one is engaged in clinical practice	What strategies will you use to learn about the best indicators of nutritional status for patients with IBD?
Skills	
Seek information about outcomes of care for populations served in care setting Use quality measures to understand performance	After a review of the literature, you determine that frequent diarrhea and weight loss are important indicators of the nutritional status of patients with IBD. Identify the indicators that will need to be monitored, the frequency with which they will be monitored, and what type of interventions might be used to improve these indicators.
Attitudes	
Appreciate that continuous quality improvement is an essential part of the daily work of all health professionals	Reflect on how long it will take for this project to show an improvement in nutritional outcomes in these patients. Think about how the other members of the health care team can contribute to the project.

38 Assessment of Digestive and Gastrointestinal Function

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the structure and function of the organs of the gastrointestinal tract.
2. Explain the mechanical and chemical processes involved in digesting and absorbing nutrients and eliminating waste products.
3. Discriminate between normal and abnormal assessment findings of the gastrointestinal system.
4. Recognize and evaluate the major symptoms of gastrointestinal dysfunction by applying the patient's health history and physical assessment findings.
5. Identify the diagnostic tests used to evaluate gastrointestinal tract function and related nursing implications.

NURSING CONCEPTS

Assessment
Elimination

GLOSSARY

absorption: phase of the digestive process that occurs when small molecules, vitamins, and minerals pass through the walls of the small and large intestine and into the bloodstream

amylase: an enzyme that aids in the digestion of starch

anus: last section of the gastrointestinal (GI) tract; outlet for waste products from the GI system

chyme: mixture of food with saliva, salivary enzymes, and gastric secretions that is produced as food passes through the mouth, esophagus, and stomach

digestion: phase of the digestive process that occurs when digestive enzymes and secretions mix with ingested food and when proteins, fats, and sugars are broken down into their component smaller molecules

dyspepsia: indigestion; upper abdominal discomfort associated with eating

elimination: phase of the digestive process that occurs after digestion and absorption, when waste products are evacuated from the body

esophagus: collapsible tube connecting the mouth to the stomach, through which food passes as it is ingested

hydrochloric acid: acid secreted by the glands in the stomach; mixes with chyme to break it down into absorbable molecules and to aid in the destruction of bacteria

ingestion: phase of the digestive process that occurs when food is taken into the GI tract via the mouth and esophagus

intrinsic factor: a gastric secretion that combines with vitamin B_{12} so that the vitamin can be absorbed

large intestine: the portion of the GI tract into which waste material from the small intestine passes as absorption continues and elimination begins; consists of several parts—ascending segment, transverse segment, descending segment, sigmoid colon, and rectum (*synonym:* colon)

lipase: an enzyme that aids in the digestion of fats

microbiome: the collective genome of all microbes in a microbiota

microbiota: the complement of microbes in a given environment

pepsin: a gastric enzyme that is important in protein digestion

small intestine: longest portion of the GI tract, consisting of three parts —duodenum, jejunum, and ileum—through which food mixed with all secretions and enzymes passes as it continues to be digested and begins to be absorbed into the bloodstream

stomach: distensible pouch into which the food bolus passes to be digested by gastric enzymes

trypsin: enzyme that aids in the digestion of protein

Abnormalities of the gastrointestinal (GI) tract are numerous and represent every type of major pathology that can affect other organ systems, including bleeding, perforation, obstruction, inflammation, and cancer. Congenital, inflammatory, infectious, traumatic, and neoplastic lesions have been encountered in every portion and at every site along the length of the GI tract. As with all other organ systems, the GI tract is subject to circulatory disturbances, faulty nervous system control, and aging.

Apart from the many organic diseases to which the GI tract is susceptible, many extrinsic factors can interfere with its normal function and produce symptoms. Stress and anxiety, for example, often find their chief expression in indigestion, anorexia, or motor disturbances of the intestines, sometimes producing constipation or diarrhea. In addition, factors such as fatigue and an inadequate or abruptly changed dietary intake can markedly affect the GI tract. When assessing and educating the patient, the nurse should consider the variety of mental and physical factors that affect the function of the GI tract.

Anatomic and Physiologic Overview

The GI tract is a pathway 7 to 7.9 m (23 to 26 feet) in length that extends from the mouth to the esophagus, stomach, small and large intestines, and rectum, to the terminal structure, the **anus** (Fig. 38-1). The **esophagus** is located in the mediastinum, anterior to the spine and posterior to the trachea and heart. This hollow muscular tube, which is approximately 25 cm (10 inches) in length, passes through the diaphragm at an opening called the *diaphragmatic hiatus*.

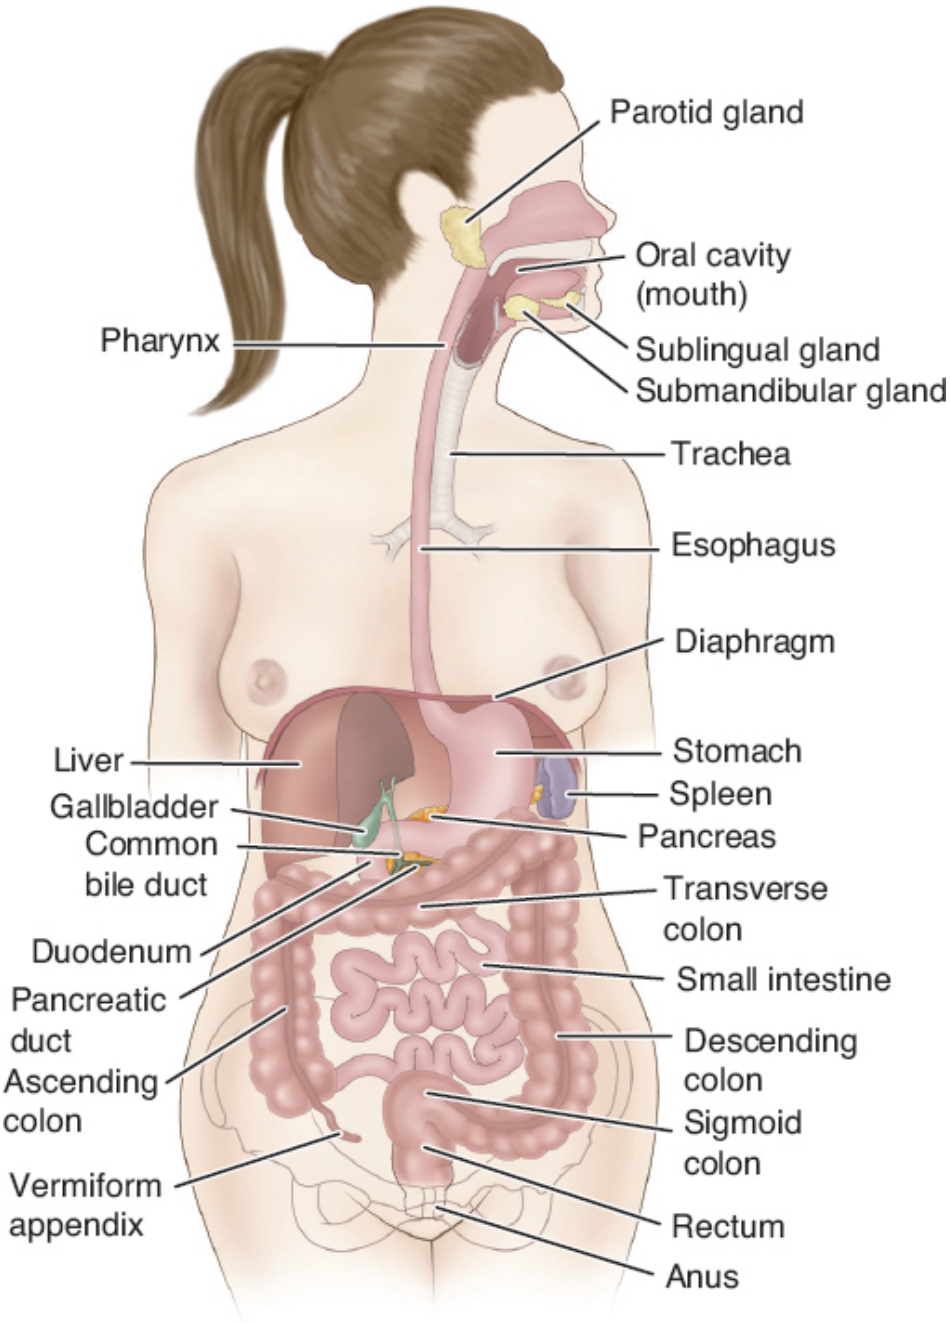

Figure 38-1 • Organs of the digestive system and associated structures.

The remaining portion of the GI tract is located within the peritoneal cavity. The **stomach** is situated in the left upper portion of the abdomen under the left lobe of the liver and the diaphragm, overlaying most of the pancreas (see Fig. 38-1). A hollow muscular organ with a capacity of approximately 1500 mL, the stomach stores food during eating, secretes digestive fluids, and propels the partially digested food, or chyme, into the small intestine. The gastroesophageal junction is the inlet to the stomach. The stomach has four anatomic regions: the cardia (entrance), fundus, body, and pylorus (outlet).

Circular smooth muscle in the wall of the pylorus forms the pyloric sphincter and controls the opening between the stomach and the small intestine.

The **small intestine** is the longest segment of the GI tract, accounting for about two thirds of the total length. It folds back and forth on itself, providing approximately 70 m (230 feet) of surface area for secretion and **absorption,** the process by which nutrients enter the bloodstream through the intestinal walls. It has three sections: The most proximal section is the duodenum, the middle section is the jejunum, and the distal section is the ileum. The ileum terminates at the ileocecal valve. This valve, or sphincter, controls the flow of digested material from the ileum into the cecal portion of the large intestine and prevents reflux of bacteria into the small intestine. Attached to the cecum is the vermiform appendix, an appendage that has little or no physiologic function. Emptying into the duodenum at the ampulla of Vater is the common bile duct, which allows for the passage of both bile and pancreatic secretions.

The **large intestine** consists of an ascending segment on the right side of the abdomen, a transverse segment that extends from right to left in the upper abdomen, and a descending segment on the left side of the abdomen. The sigmoid colon, the rectum, and the anus complete the terminal portion of the large intestine. A network of striated muscle that forms both the internal and the external anal sphincters regulates the anal outlet.

The GI tract receives blood from arteries that originate along the entire length of the thoracic and abdominal aorta and veins that return blood from the digestive organs and the spleen. This portal venous system is composed of five large veins: the superior mesenteric, inferior mesenteric, gastric, splenic, and cystic veins, which eventually form the vena portae that enters the liver. Once in the liver, the blood is distributed throughout and collected into the hepatic veins that then terminate in the inferior vena cava. Of particular importance are the gastric artery and the superior and inferior mesenteric arteries. Oxygen and nutrients are supplied to the stomach by the gastric artery and to the intestine by the mesenteric arteries (Fig. 38-2). Venous blood is returned from the small intestine, cecum, and the ascending and transverse portions of the colon by the superior mesenteric vein, which corresponds with the distribution of the branches of the superior mesenteric artery. Blood flow to the GI tract is about 20% of the total cardiac output and increases significantly after eating.

Both the sympathetic and parasympathetic portions of the autonomic nervous system innervate the GI tract. In general, sympathetic nerves exert an inhibitory effect on the GI tract, decreasing gastric secretion and motility and causing the sphincters and blood vessels to constrict. Parasympathetic nerve stimulation causes peristalsis and increases secretory activities. The sphincters relax under the influence of parasympathetic stimulation, except for the sphincter of the upper esophagus and the external anal sphincter, which are under voluntary control (Norris, 2019).

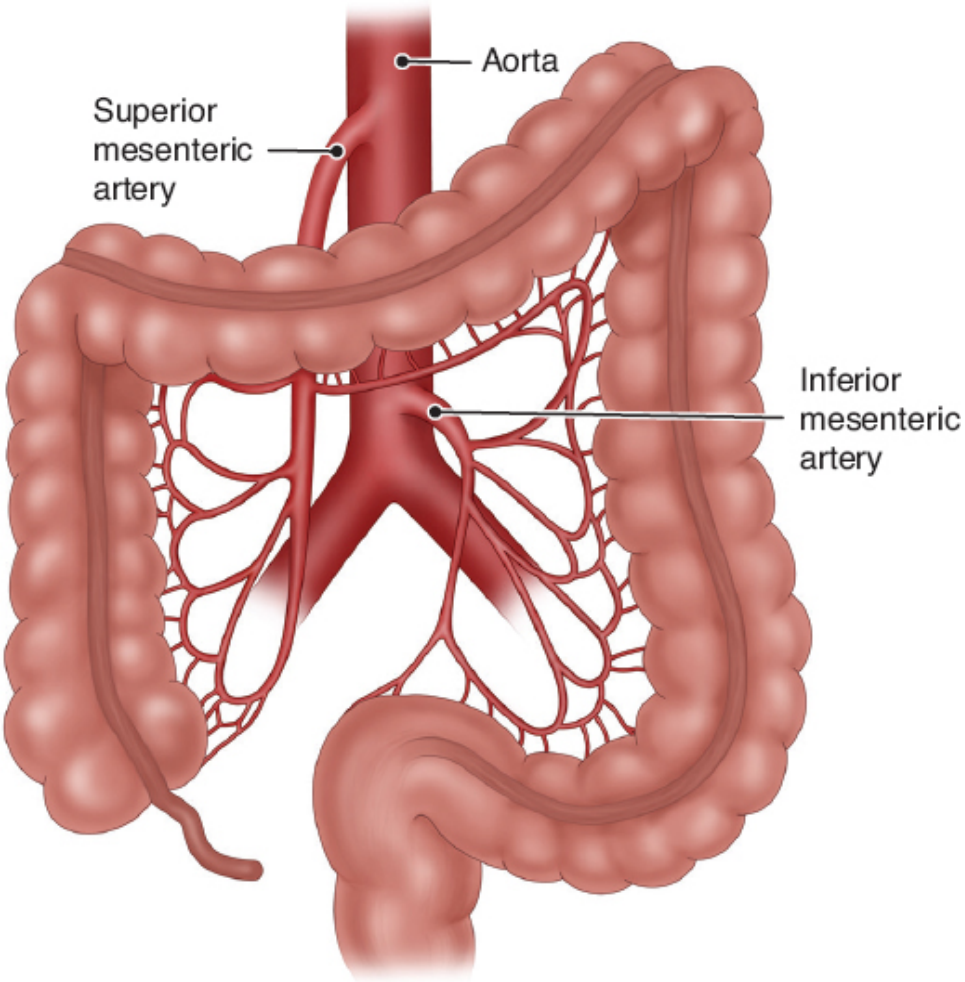

Figure 38-2 • Anatomy and blood supply of the large intestine.

Function of the Digestive System

All cells of the body require nutrients. These nutrients are derived from the intake of food that contains proteins, fats, carbohydrates, vitamins, minerals, and cellulose fibers and other vegetable matter, some of which has no nutritional value. Major functions of the GI tract include:

- Breakdown of food particles into the molecular form for **digestion**
- Absorption into the bloodstream of small nutrient molecules produced by digestion
- **Elimination** of undigested unabsorbed foodstuffs and other waste products

After food is ingested, it is propelled through the GI tract, coming into contact with a wide variety of secretions that aid in its digestion, absorption, or elimination from the GI tract.

Chewing and Swallowing

The process of digestion begins with the act of chewing, in which food is broken down into small particles that can be swallowed and mixed with digestive enzymes. Eating—or even the sight, smell, or taste of food—can cause reflex salivation. Approximately 1.5 L of saliva is secreted daily from the parotid, the submaxillary, and the sublingual glands. Ptyalin, or salivary **amylase,** is an enzyme that begins the digestion of starches. Water and mucus, also contained in saliva, help lubricate the food as it is chewed, thereby facilitating swallowing.

Swallowing begins as a voluntary act that is regulated by the swallowing center in the medulla oblongata of the central nervous system (CNS). As a bolus of food is swallowed, the epiglottis moves to cover the tracheal opening and prevent aspiration of food into the lungs. Swallowing, which propels the bolus of food into the upper esophagus, thus ends as a reflex action. The smooth muscle in the wall of the esophagus contracts in a rhythmic sequence from the upper esophagus toward the stomach to propel the bolus of food along the tract. During this process of esophageal peristalsis, the lower esophageal sphincter relaxes and permits the bolus of food to enter the stomach. Subsequently, the lower esophageal sphincter closes tightly to prevent reflux of stomach contents into the esophagus.

Gastric Function

The stomach, which stores and mixes food with secretions, secretes a highly acidic fluid in response to the presence or anticipated **ingestion** of food. This fluid, which can total 2.4 L/day, can have a pH as low as 1 and derives its acidity from **hydrochloric acid** (HCl) secreted by the glands of the stomach. The function of this gastric secretion is twofold: to break down food into more absorbable components and to aid in the destruction of most ingested bacteria. **Pepsin,** an important enzyme for protein digestion, is the end product of the conversion of pepsinogen from the chief cells (Table 38-1). **Intrinsic factor,** also secreted by the gastric mucosa, combines with dietary vitamin B_{12} so that the vitamin can be absorbed in the ileum. In the absence of intrinsic factor, vitamin B_{12} cannot be absorbed, and pernicious anemia results (see Chapter 29).

Peristaltic contractions in the stomach propel the stomach's contents toward the pylorus. Because large food particles cannot pass through the pyloric sphincter, they are churned back into the body of the stomach. In this way, food in the stomach is mechanically broken down into smaller particles. Food remains in the stomach for a variable length of time, from 30 minutes to several hours, depending on the volume, osmotic pressure, and chemical composition of the gastric contents. Peristalsis in the stomach and contractions of the pyloric sphincter allow the partially digested food to enter the small intestine at a rate that permits efficient absorption of nutrients. This partially digested food mixed with gastric secretions is called **chyme.** Hormones,

neuroregulators, and local regulators found in the gastric secretions control the rate of gastric secretions and influence gastric motility (Table 38-2).

Small Intestine Function

The digestive process continues in the duodenum. Duodenal secretions come from the accessory digestive organs—the pancreas, liver, and gallbladder—and the glands in the wall of the intestine itself. These secretions contain digestive enzymes: amylase, lipase, and bile. Pancreatic secretions have an alkaline pH due to their high concentration of bicarbonate. This alkalinity neutralizes the acid entering the duodenum from the stomach. Digestive enzymes secreted by the pancreas include **trypsin,** which aids in digesting protein; amylase, which aids in digesting starch; and **lipase,** which aids in digesting fats. These secretions drain into the pancreatic duct, which empties into the common bile duct at the ampulla of Vater. Bile, secreted by the liver and stored in the gallbladder, aids in emulsifying ingested fats, making them easier to digest and absorb. The sphincter of Oddi, found at the confluence of the common bile duct and duodenum, controls the flow of bile. Hormones, neuroregulators, and local regulators found in these intestinal secretions control the rate of intestinal secretions and also influence GI motility. Intestinal secretions total approximately 1 L/day of pancreatic juice, 0.5 L/day of bile, and 3 L/day of secretions from the glands of the small intestine. Tables 38-1 and 38-2 give further information about the actions of digestive enzymes and GI regulatory substances.

TABLE 38-1 The Major Digestive Enzymes and Secretions

Enzyme/Secretion	Enzyme Source	Digestive Action
Enzymes That Digest Carbohydrates		
Ptyalin (salivary amylase)	Salivary glands	Starch→dextrin, maltose, glucose
Amylase	Pancreas and intestinal mucosa	Starch→dextrin, maltose, glucose
		Dextrin→maltose, glucose
Maltase	Intestinal mucosa	Maltose→glucose
Sucrase	Intestinal mucosa	Sucrose→glucose, fructose
Lactase	Intestinal mucosa	Lactose→glucose, galactose
Enzymes/Secretions That Digest Protein		
Pepsin	Gastric mucosa	Protein→polypeptides
Trypsin	Pancreas	Proteins and polypeptides→polypeptides, dipeptides, amino acids
Aminopeptidase	Intestinal mucosa	Polypeptides→dipeptides, amino acids
Dipeptidase	Intestinal mucosa	Dipeptides→amino acids
Hydrochloric acid	Gastric mucosa	Protein→polypeptides, amino acids
Enzymes/Secretions That Digest Fat (Triglyceride)		
Pharyngeal lipase	Pharynx mucosa	Triglycerides→fatty acids, diglycerides, monoglycerides
Steapsin	Gastric mucosa	Triglycerides→fatty acids, diglycerides, monoglycerides
Pancreatic lipase	Pancreas	Triglycerides→fatty acids, diglycerides, monoglycerides
Bile	Liver and gallbladder	Fat emulsification

→, converts to.

Two types of contractions occur regularly in the small intestine: segmentation contractions and intestinal peristalsis. *Segmentation contractions* produce mixing waves that move the intestinal contents back and forth in a churning motion. *Intestinal peristalsis* propels the contents of the small intestine toward the colon. Both movements are stimulated by the presence of chyme.

Food, ingested as fats, proteins, and carbohydrates, is broken down into absorbable particles (constituent nutrients) by the process of digestion. Carbohydrates are broken down into disaccharides (e.g., sucrose, maltose, galactose) and monosaccharides (e.g., glucose, fructose). Glucose is the major carbohydrate that tissue cells use as fuel. Proteins are a source of energy after they are broken down into amino acids and peptides. Ingested fats become monoglycerides and fatty acid through emulsification, which makes them

smaller and easier to absorb. Chyme stays in the small intestine for 3 to 6 hours, allowing for continued breakdown and absorption of nutrients.

TABLE 38-2 The Major Gastrointestinal Regulatory Substances

Substance	Stimulus for Production	Target Tissue	Effect on Secretions	Effect on Motility
Neuroregulators				
Acetylcholine	Stomach distention, vagal and local nerves in the stomach	Gastric glands, other secretory glands, gastric and intestinal muscle	↑ Gastric acid	Generally increased
Norepinephrine	Stress, other various stimuli	Secretory glands, gastric and intestinal muscle	Generally inhibitory	Generally decreased; increased sphincter tone
Hormonal Regulators				
Gastrin	Vagal stimulation, calcium containing foods	Gastric glands, stomach antrum, duodenum	↑ Secretion of gastric acid and pepsinogen	Increased motility of stomach; stimulates smooth muscle contraction
Cholecystokinin	Protein digestion products, long-chain fatty acids, presence of chyme in duodenum	Gallbladder Pancreas Stomach	Release of bile into duodenum ↑ Production of enzyme-rich pancreatic secretions	Slows gastric emptying
Secretin	pH of chyme in duodenum (pH <3)	Pancreas Stomach	Inhibits gastrin and gastric acid secretion	Decreases GI motility
Local Regulator				
Histamine	Unclear; substances in food	Gastric glands	↑ Gastric acid production	

HCl, hydrochloric acid; ↑, increased.
Adapted from McCance, K. L., & Huether, S. E. (2019). *Pathophysiology: The biologic basis for disease in adults and children* (8th ed.). St. Louis, MO: Elsevier; Norris, T. L. (2019). *Porth's pathophysiology. Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Small, fingerlike projections called *villi* line the entire intestine and function to produce digestive enzymes as well as to absorb nutrients. Absorption is the major function of the small intestine. Vitamins and minerals are absorbed essentially unchanged. Absorption begins in the jejunum and is accomplished by active transport and diffusion across the intestinal wall into the circulation. Nutrients are absorbed at specific locations in the small intestine and duodenum, whereas fats, proteins, carbohydrates, sodium, and chloride are absorbed in the jejunum. Vitamin B_{12} and bile salts are absorbed in the ileum. Magnesium, phosphate, and potassium are absorbed throughout the small intestine.

Colonic Function

Within 4 hours after eating, residual waste material passes into the terminal ileum and slowly into the proximal portion of the right colon through the ileocecal valve. With each peristaltic wave of the small intestine, the valve opens briefly and permits some of the contents to pass into the colon.

Gut microbes (bacteria), a major component of the contents of the large intestine, assist in completing the breakdown of waste material, especially of undigested or unabsorbed proteins and bile salts. Two types of colonic secretions are added to the residual material: an electrolyte solution and mucus. The electrolyte solution is chiefly a bicarbonate solution that acts to neutralize the end products formed by the colonic bacterial action, whereas the mucus protects the colonic mucosa from the intraluminal contents and provides adherence for the fecal mass.

Slow, weak peristalsis moves the colonic contents along the tract. This slow transport allows for efficient reabsorption of water and electrolytes, which is the major function of the colon. Intermittent strong peristaltic waves propel the contents for considerable distances. This generally occurs after another meal is eaten, when intestine-stimulating hormones are released. The waste materials from a meal eventually reach and distend the rectum, usually in about 12 hours. As much as one fourth of the waste materials from a meal may still be in the rectum 3 days after the meal was ingested.

Waste Products of Digestion

Feces consist of undigested foodstuffs, inorganic materials, water, and bacteria. Fecal matter is about 75% fluid and 25% solid material (Norris, 2019). The composition is relatively unaffected by alterations in diet because a large portion of the fecal mass is of nondietary origin, derived from the secretions of the GI tract. The brown color of the feces results from the breakdown of bile by the intestinal bacteria. Chemicals formed by intestinal bacteria are responsible in large part for the fecal odor. Gases formed contain methane, hydrogen sulfide, and ammonia, among others. The GI tract normally contains approximately 150 mL of these gases, which are either absorbed into the portal circulation and detoxified by the liver or expelled from the rectum as flatus.

Elimination of stool begins with distention of the rectum, which initiates reflex contractions of the rectal musculature and relaxes the normally closed internal anal sphincter. The internal sphincter is controlled by the autonomic nervous system; the external sphincter is under the conscious control of the cerebral cortex. During defecation, the external anal sphincter voluntarily relaxes to allow colonic contents to be expelled. Normally, the external anal sphincter is maintained in a state of tonic contraction. Thus, defecation is seen to be a spinal reflex (involving the parasympathetic nerve fibers) that can be inhibited voluntarily by keeping the external anal sphincter closed. Contracting the abdominal muscles (straining) facilitates emptying of the colon. The average frequency of defecation in humans is once daily, but this varies among people.

Gut Microbiome

In addition to assisting in the breakdown of waste material, the gut **microbiota** (the complement of microbes in the GI tract) also has a role in vitamin synthesis and immune function, including protection against invading pathogens, regulatory influences on innate and adaptive immune responses, and inflammation. Colonization of the GI tract begins shortly after birth; the normal gut microbiota is established by 2 years of age. Several factors over time affect the composition of normal gut microbiota including genetics, diet, personal hygiene, infection, and vaccinations. The number and diversity of

microbes within the gut change with aging and are influenced by diet, chronic disease, and medications. Additionally, administration of broad-spectrum antibiotics can disrupt the gut microbiota and lead to overgrowth of potentially pathogenic species (McCance & Huether, 2019; Norris, 2019).

The gut **microbiome,** the collective genome of the microbiota, protects the host against invasion by pathogenic organisms; it produces anti-inflammatory metabolites, destroys toxins, prevents colonization of pathogens, and provokes an immune response (McCance & Huether, 2019; Norris, 2019). The intestinal epithelium is the first line of defense against pathogenic microbes and microbial agents, as it contains innate immune cells such as macrophages, dendritic cells, granulocytes, and mast cells, and has a role in T-cell responses (Günther, 2018; Haller, 2018; Pezoldt, Yang, Zou, et al., 2018; Strowig, Thiemann, & Diefenbach, 2018). In addition, Peyer's patches (gut-associated lymph tissue) also have a role in antigen processing and immune defense (McCance & Huether, 2019). Collectively, the gut microbiome serves the roles of protection and defense.

Gerontologic Considerations

Although an increased prevalence of several common GI disorders occurs in the older adult population, aging per se appears to have minimal direct effect on most GI functions, in large part because of the functional reserve of the GI tract. Normal physiologic changes of the GI system that occur with aging are identified in Table 38-3. Careful assessment and monitoring of signs and symptoms related to these changes are imperative. Although irritable bowel symptoms decrease with aging, there seems to be an increase in many GI disorders of function and motility. Older adult patients frequently report dysphagia, anorexia, dyspepsia, and disorders of colonic function (Eliopoulos, 2018).

Assessment of the Gastrointestinal System

The nursing assessment of the GI system involves obtaining a focused health history and physical examination.

TABLE 38-3 Age-Related Changes in the Gastrointestinal System

Structural Changes	Implications
Oral Cavity and Pharynx	
• Injury/loss or decay of teeth • Atrophy of taste buds • ↓ Saliva production • Reduced ptyalin and amylase in saliva	Difficulty chewing and swallowing
Esophagus	
• ↓ Motility and emptying • Weakened gag reflex • ↓ Resting pressure of lower esophageal sphincter	Reflux and heartburn
Stomach	
• Degeneration and atrophy of gastric mucosal surfaces with ↓ production of HCl • ↓ Secretion of gastric acids and most digestive enzymes • ↓ Gastric motility and emptying	Food intolerances, malabsorption, or ↓ vitamin B_{12} absorption
Small Intestine	
• Atrophy of muscle and mucosal surfaces • Thinning of villi and epithelial cells	↓ Motility and transit time, which lead to complaints of indigestion and constipation
Large Intestine	
• ↓ Mucus secretion • ↓ Elasticity of rectal wall • ↓ Tone of internal anal sphincter • Slower and duller nerve impulses in rectal area	↓ Motility and transit time, which lead to complaints of indigestion and constipation ↓ Absorption of nutrients (dextrose, fats, calcium, and iron) Fecal incontinence

↓, decreased; HCl, hydrochloric acid.

Health History

A focused GI assessment begins with a complete history. Information about abdominal pain, dyspepsia, gas, nausea and vomiting, diarrhea, constipation, fecal incontinence, jaundice, and previous GI disease is obtained (Weber & Kelley, 2018).

Common Symptoms

Common GI symptoms that may lead patients to seek health care referrals include pain, dyspepsia, gas, nausea and vomiting, diarrhea, and constipation.

Pain

Pain can be a major symptom of GI disease; in particular, abdominal pain is a frequent presenting problem in general practice (Babakhanlou, 2018). The character, duration, pattern, frequency, location, distribution of referred abdominal pain (Fig. 38-3), and time of the pain can vary greatly depending on the underlying cause. Other factors such as meals, rest, activity, and defecation patterns may directly affect this pain (Weber & Kelley, 2018).

Dyspepsia

Dyspepsia—upper abdominal discomfort associated with eating (commonly called *indigestion*)—is the most common symptom of patients with GI dysfunction. Indigestion is an imprecise term that refers to a host of upper abdominal or epigastric symptoms such as pain, discomfort, fullness, bloating, early satiety, belching, heartburn, or regurgitation. Annually, dyspepsia affects approximately 25% of Americans (Longstreth & Lacy, 2019) while gastroesophageal reflux disease (GERD), which increases with age and manifests with dyspepsia (most frequently with heartburn), affects approximately 20% of adults in western cultures (Antunes & Curtis, 2019). Typically, fatty foods cause the most discomfort because they remain in the stomach for digestion longer than proteins or carbohydrates. Salads, coarse vegetables, and highly seasoned foods may also cause considerable GI distress. In some cases, health care providers make a distinction between gastroesophageal reflux (GER) and GERD; GERD is the more serious and longer-lasting condition (Mayo Clinic, 2019).

Intestinal Gas

The accumulation of gas in the GI tract may result in belching (expulsion of gas from the stomach through the mouth) or flatulence (expulsion of gas from the rectum). Usually, gases in the small intestine pass into the colon and are released as flatus. Patients often complain of bloating, distention, or feeling "full of gas" with excessive flatulence as a symptom of food intolerance or gallbladder disease.

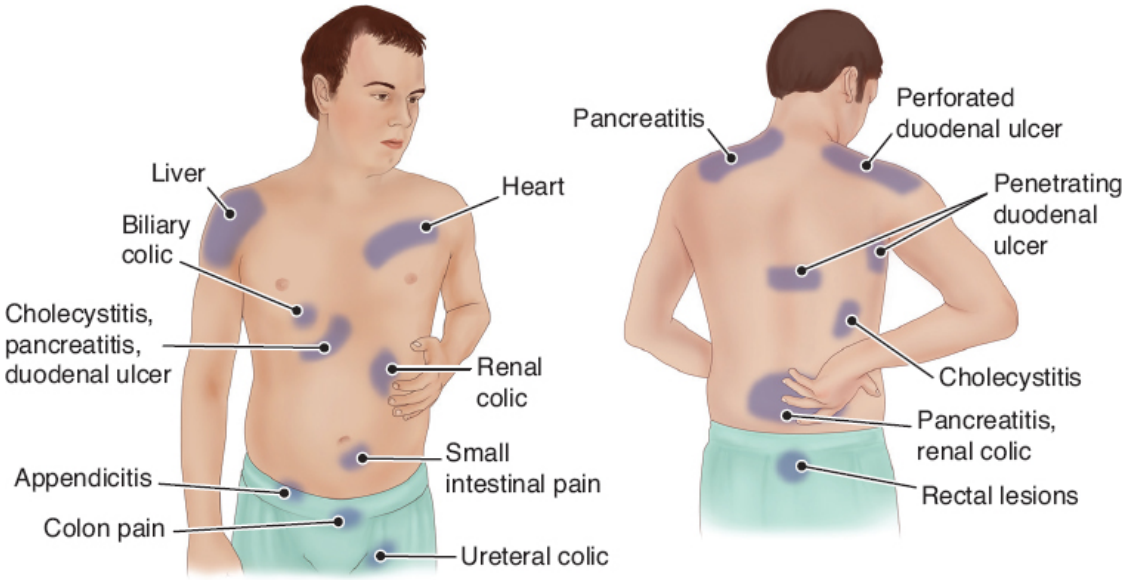

Figure 38-3 • Common sites of referred abdominal pain.

Nausea and Vomiting

Nausea is a vague, uncomfortable sensation of sickness or "queasiness" that may or may not be followed by vomiting. Distention of the duodenum or upper intestinal tract is a common cause of nausea; it may also be an early warning sign of a pathologic process. Nausea can be triggered by odors, activity, medications, or food intake. Vomiting is the forceful emptying of the stomach and intestinal contents through the mouth (McCance & Huether, 2019). The emesis, or vomitus, may vary in color and content and may contain undigested food particles, blood (hematemesis), or bilious material mixed with gastric juices. An acute onset of emesis that appears bright red or as coffee grounds is characteristic of a Mallory-Weiss tear (i.e., a laceration in the mucosal lining of the gastroesophageal junction) and indicates upper GI bleeding (Rich, 2018).

The causes of nausea and vomiting are many and may include visceral pain; motion or motion sickness; anxiety; several types of intestinal, vagal or sympathetic input including side effects of medications; and torsion or trauma of the ovaries, testes, uterus, bladder or kidney (McCance & Huether, 2019). Pathways for initiation of the vomiting reflex include medication therapy, metabolic abnormalities (chemoreceptor trigger zone), ingested toxins, chemotherapy, radiation therapy (vagal and splanchnic receptors), inner ear disorders, motion sickness (vestibular center), and anticipatory emesis (cerebral cortex) (Hainsworth, 2020).

Change in Bowel Habits and Stool Characteristics

Changes in bowel habits may signal colonic dysfunction or disease. Diarrhea, an abnormal increase in the frequency and liquidity of the stool or in daily stool weight or volume, commonly occurs when the contents move so rapidly

through the intestine and colon that there is inadequate time for the GI secretions and oral contents to be absorbed. This physiologic function is typically associated with abdominal pain or cramping and nausea or vomiting. Constipation—a decrease in the frequency of stool, or stools that are hard, dry, and of smaller volume than typical—may be associated with anal discomfort and rectal bleeding, and is a frequent reason patients seek health care referrals (see the Nursing Research Profile in Chart 38-1) (Shen, Zhu, Jiang, et al., 2018). See Chapter 41 for further discussion of diarrhea and constipation.

The characteristics of the stool can vary greatly. Stool is normally light to dark brown; however, specific disease processes and ingestion of certain foods and medications may change the appearance of stool (Table 38-4). Blood in the stool can present in various ways and must be investigated. If blood is shed in sufficient quantities into the upper GI tract, it produces a tarry-black color (melena), whereas blood entering the lower portion of the GI tract or passing rapidly through it will appear bright or dark red. Lower rectal or anal bleeding is suspected if there is streaking of blood on the surface of the stool or if blood is noted on toilet tissue. Other common abnormalities in stool characteristics described by the patient may include:

- Bulky, greasy, foamy stools that are foul in odor and may or may not float
- Light gray or clay-colored stool, caused by a decrease or absence of conjugated bilirubin
- Stool with mucus threads or pus that may be visible on gross inspection of the stool
- Small, dry, rock-hard masses occasionally streaked with blood
- Loose, watery stool that may or may not be streaked with blood

Past Health, Family, and Social History

The nurse asks about the patient's normal toothbrushing and flossing routine; frequency of dental visits; awareness of any lesions or irritated areas in the mouth, tongue, or throat; recent history of sore throat or bloody sputum; discomfort caused by certain foods; daily food intake; the use of alcohol and tobacco, including smokeless chewing tobacco; and the need to wear dentures or a partial plate. For information about denture care, see Chart 38-2.

Chart 38-1 NURSING RESEARCH PROFILE

Nurse-Led Educational Intervention for Patients with Functional Constipation

Shen, Q., Zhu, H., Jiang, G., et al. (2018). Nurse-led self-management educational intervention improves symptoms of patients with functional constipation. *Western Journal of Nursing Research*, *40*(60), 874–888.

Purpose

Functional constipation (FC) is described as a persistent problem with defecation that may be characterized by a decrease in bowel movements, a feeling of incomplete bowel emptying post defection, or difficulty having bowel movements. The purpose of the study was to investigate the effects of a self-management educational intervention on patients with FC and to compare outcomes to a control group that received routine nursing care.

Design

The pretest/posttest scores of *The Constipation Assessment Scale* and *The Constipation Cognition Scale* were collected on admission, discharge, and 1-month post discharge for 66 eligible participants who were randomly assigned to either an intervention group or a control group. Both groups received routine nursing care for constipation. In addition, the intervention group received the following support: visits from the multidisciplinary intervention team, dietary and lifestyle evaluation, education, assistance in developing a self-management plan, timely consultations and weekly group meetings both inpatient and outpatient, and the option to include family members in sessions. Patients in the intervention group were also encouraged to maintain a diary to document food and lifestyle choices. Members of the educational intervention team checked the diaries daily during hospitalization and provided follow-up via a phone call 1 week and then 1 month after discharge.

Findings

The constipation scores of all clinical symptoms were lower (improved) in the intervention group at 1 month after discharge ($p < 0.05$). Additionally, the intervention group had a higher number of patients with good health habits, including diet, exercise, and defecation habits, and proper use of laxatives ($p < 0.05$).

Nursing Implications

The findings of this study suggest that a multifaceted educational intervention can improve clinical symptoms and adherence behaviors, and promote healthy lifestyle choices in patients with FC. Nurses can apply findings to better manage FC, educate patients to improve outcomes, and tailor interventions to best meet the needs of this patient population.

TABLE 38-4 Foods and Medications That Alter Stool Color

Altering Substance	Color
Leafy green vegetables, spinach, kale	Green
Beets, red gelatin, tomato soup, food coloring	Red
Bismuth, iron, black licorice	Black
Barium	Milky white

Adapted from McEvoy, G. E. (Ed.). (2020). *AHFS Drug Information®*. Bethesda, MD: American Society of Health-System Pharmacists. *STAT!Ref Online Electronic Medical Library.* Retrieved on 2/14/2020 at: www.ahfsdruginformation.com/ahfs-drug-information; Wedro, B. (2019). Stool color, changes in color, texture, and form. *MedicineNet.* Retrieved on 1/14/2020 at: www.medicinenet.com/stool_color_changes/article.htm

Past and current medication use and any previous diagnostic studies, treatments, or surgery are noted. Current nutritional status is assessed via history; laboratory tests (complete metabolic panel including liver function studies, triglyceride, iron studies, and complete blood count [CBC]) are obtained. History of the use of tobacco and alcohol includes details about type, amount, length of use, and the date of discontinuation, if any. The nurse and patient discuss changes in appetite or eating patterns and any unexplained weight gain or loss over the past year. The nurse also asks questions about psychosocial, spiritual, or cultural factors that may be affecting the patient.

Physical Assessment

The physical examination includes assessment of the mouth, abdomen, and rectum and requires a good source of light, full exposure of the abdomen, warm hands with short fingernails, and a comfortable and relaxed patient with an empty bladder.

Oral Cavity Inspection and Palpation

Dentures should be removed to allow good visualization of the entire oral cavity.

Lips

The examination begins with inspection of the lips for moisture, hydration, color, texture, symmetry, and the presence of ulcerations or fissures. The lips should be moist, pink, smooth, and symmetric. The patient is instructed to open the mouth wide; a tongue blade is then inserted to expose the buccal mucosa for an assessment of color and lesions. Stensen duct of each parotid gland is visible as a small red dot in the buccal mucosa next to the upper molars.

Chart 38-2 HEALTH PROMOTION

Denture Care

- Brush dentures twice a day.
- Clean well under partial dentures, where food particles tend to get caught.
- Consume nonsticky foods that have been cut into small pieces; chew slowly.
- Remove dentures at night and soak them in water or a denture product. Never put dentures in hot water, because they may warp.
- Rinse mouth with warm salt water in the morning, after meals, and at bedtime.
- See dentist regularly to assess and adjust fit.

Gums

The gums are inspected for inflammation, bleeding, retraction, and discoloration. The odor of the breath is also noted. The hard palate is examined for color and shape.

Tongue

The dorsum (back) of the tongue is inspected for texture, color, and lesions. A thin white coat and large, vallate papillae in a "V" formation on the distal portion of the dorsum of the tongue are normal findings. The patient is instructed to protrude the tongue and move it laterally. This provides the examiner with an opportunity to estimate the tongue's size as well as its symmetry and strength (to assess the integrity of the 12th cranial nerve [hypoglossal nerve]).

Further inspection of the ventral surface of the tongue and the floor of the mouth is accomplished by asking the patient to touch the roof of the mouth with the tip of the tongue. Any lesions of the mucosa or any abnormalities involving the frenulum or superficial veins on the undersurface of the tongue are assessed for location, size, color, and pain. This is a common area for oral cancer, which presents as a white or red plaque, lesions, ulcers, or nodules (Weber & Kelley, 2018).

A tongue blade is used to depress the tongue for adequate visualization of the pharynx. It is pressed firmly beyond the midpoint of the tongue; proper placement avoids a gagging response. The patient is told to tip the head back, open the mouth wide, take a deep breath, and say "ah." Often, this flattens the posterior tongue and briefly allows a full view of the tonsils, uvula, and posterior pharynx. These structures are inspected for color, symmetry, and

evidence of exudate, ulceration, or enlargement. Normally, the uvula and soft palate rise symmetrically with a deep inspiration upon saying "ah"; this indicates an intact vagus nerve (10th cranial nerve).

A complete assessment of the oral cavity is essential because many disorders, such as cancer, diabetes, and immunosuppressive conditions resulting from medication therapy or acquired immunodeficiency syndrome, may be manifested by changes in the oral cavity, including stomatitis.

Abdominal Inspection, Auscultation, Percussion, and Palpation

The patient lies supine with knees flexed slightly for inspection, auscultation, percussion, and palpation of the abdomen. For the purposes of examination and documentation, the abdomen can be divided into either four quadrants or nine regions (Fig. 38-4).

Consistent use of one of these mapping methods results in a thorough evaluation of the abdomen and appropriate documentation. The four-quadrant method involves the use of an imaginary line drawn vertically from the sternum to the pubis through the umbilicus and a horizontal line drawn across the abdomen through the umbilicus. Inspection is performed first, noting skin changes, nodules, lesions, scarring, discolorations, inflammation, bruising, or striae. Lesions are of particular importance, because GI diseases often produce skin changes. The contour and symmetry of the abdomen are noted, and any localized bulging, distention, or peristaltic waves are identified. Expected contours of the anterior abdominal wall can be described as flat, rounded, or scaphoid.

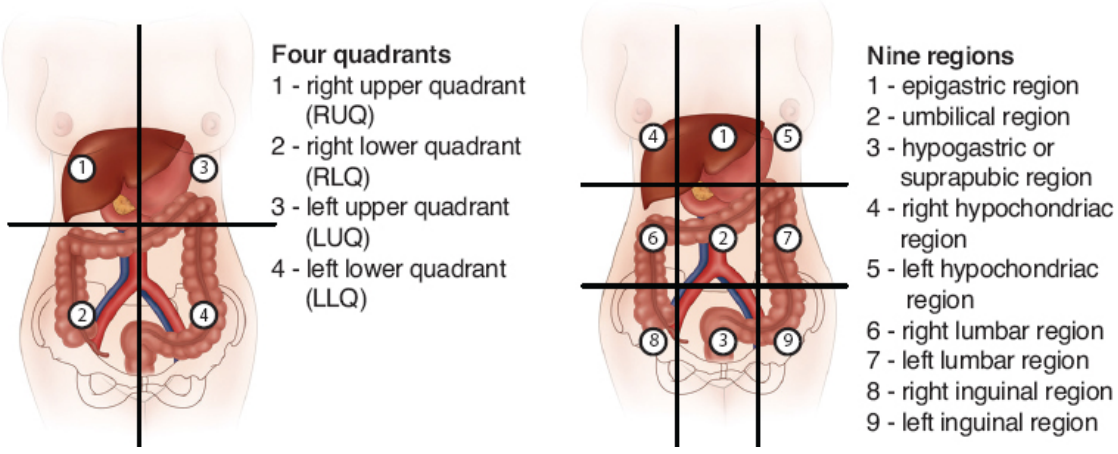

Figure 38-4 • Division of the abdomen into four quadrants or nine regions.

Auscultation always precedes percussion and palpation, because they may alter sounds. Auscultation is used to determine the character, location, and

frequency of bowel sounds and to identify vascular sounds. Bowel sounds are assessed using the diaphragm of the stethoscope for soft clicks and gurgling sounds (Weber & Kelley, 2018). The frequency and character of the sounds are usually heard as clicks and gurgles that occur irregularly and range from 5 to 30 per minute. Bowel sounds are designated as normal, hyperactive, hypoactive, or absent. The nurse should auscultate for a minimum of 5 minutes; listening for at least 1 minute in each quadrant to confirm the absence of bowel sounds (Weber & Kelley, 2018). Using the bell of the stethoscope, any bruits in the aortic, renal, iliac, and femoral arteries are noted. Friction rubs are high pitched and can be heard over the liver and spleen during respiration. Borborygmus ("stomach growling") is heard as a loud prolonged gurgle.

Percussion is used to assess the size and density of the abdominal organs and to detect the presence of air-filled, fluid-filled, or solid masses. Percussion is used either independently or concurrently with palpation because it can validate palpation findings. All quadrants are percussed for overall tympani and dullness. Tympani is the sound that results from the presence of air in the stomach and small intestines; dullness is heard over organs and solid masses. The use of light palpation is appropriate for identifying areas of tenderness or muscular resistance, and deep palpation is used to identify masses. Testing for rebound tenderness is not performed by many examiners because it can cause severe pain; light percussion is used instead to produce a mild localized response when peritoneal irritation is present.

Rectal Inspection and Palpation

The final part of the examination is evaluation of the terminal portions of the GI tract, the rectum, perianal region, and anus. The anal canal is approximately 2.5 to 4 cm (1 to 1.6 inches) in length and opens into the perineum. Concentric rings of muscle, the internal and external sphincters, normally keep the anal canal securely closed. Gloves, water-soluble lubrication, a penlight, and drapes are necessary tools for the evaluation. Although the rectal examination is generally uncomfortable and often embarrassing for the patient, it is a mandatory part of every thorough examination. For women, the rectal examination may be part of the gynecologic examination. Positions for the rectal examination include knee-chest, left lateral with hips and knees flexed, or standing with hips flexed and upper body supported by the examination table. Most patients are comfortable on the right side with knees brought up to the chest. External examination includes inspection for lumps, rashes, inflammation, excoriation, tears, scars, pilonidal dimpling, and tufts of hair at the pilonidal area. The discovery of tenderness, inflammation, or both should alert the examiner to the possibility of a pilonidal cyst, perianal abscess, or anorectal fistula or fissure. The patient's buttocks are carefully spread and visually inspected until the patient has relaxed the external sphincter control.

The patient is asked to bear down, thus allowing the ready appearance of fistulas, fissures, rectal prolapse, polyps, and internal hemorrhoids. Internal examination is performed with a gloved lubricated index finger inserted into the anal canal while the patient bears down. The tone of the sphincter is noted, as are any nodules or irregularities of the anal ring. Because this is an uncomfortable part of the examination for most patients, the patient is encouraged to focus on deep breathing and visualization of a pleasant setting during the brief examination.

Diagnostic Evaluation

GI diagnostic studies can confirm, rule out, stage, or diagnose various disease states, including cancer. After the diagnosis, time should be allotted for discussion with the patient, in addition to offering resource materials for information.

Many modalities are available for diagnostic assessment of the GI tract. The majority of these tests and procedures are performed on an outpatient basis in special settings designed for this purpose (e.g., endoscopy suite or GI laboratory). Preparation for many of these studies includes either a clear liquid or low residue diet, fasting, ingestion of a liquid bowel preparation, the use of laxatives or enemas, and ingestion or injection of a contrast agent or a radiopaque dye. These measures are poorly tolerated by some patients and are especially problematic in older adults or patients with comorbidities because bowel preparations can significantly alter the internal fluid and electrolyte balance. If further assessment or treatment is needed after any outpatient procedure, the patient may be admitted to the hospital.

Specific nursing interventions for each test are provided later in this chapter. General nursing interventions for the patient who is undergoing a GI diagnostic evaluation include:

- Establishing the need for more information
- Providing education to patients and families on the diagnostic test, and pre- and postprocedure restrictions and care
- Helping the patient cope with discomfort and alleviating anxiety
- Informing the primary provider of known medical conditions or abnormal laboratory values that may affect the procedure
- Assessing for adequate hydration before, during, and immediately after the procedure, and providing education about maintenance of hydration

Serum Laboratory Studies

Initial diagnostic tests begin with serum laboratory studies, including but not limited to CBC, complete metabolic panel, prothrombin time/partial thromboplastin time, triglycerides, liver function tests, amylase, and lipase; possibly, more specific studies may be indicated, such as carcinoembryonic antigen (CEA), cancer antigen (CA) 19-9, and alpha-fetoprotein, which are sensitive and specific for colorectal and hepatocellular carcinomas, respectively. CEA is a protein that is normally not detected in the blood of a healthy person; therefore, when detected it indicates that cancer is present, although not what type of cancer is present. CA 19-9 is also a protein that exists on the surface of certain cells and is shed by tumor cells, making it useful as a tumor marker to follow the course of the cancer. Tumor markers (e.g., mCEA and CA 19-9), along with other tests, are used in patients diagnosed with colorectal cancer to demonstrate the effectiveness of treatment or to provide an early warning that the cancer has returned (American Cancer Society [ACS], 2018).

Stool Tests

Basic examination of the stool includes inspecting the specimen for consistency, color, and occult (not visible) blood. Additional studies, including fecal urobilinogen, fecal fat, nitrogen, *Clostridium difficile,* fecal leukocytes, calculation of stool osmolar gap, parasites, pathogens, food residues, and other substances, require laboratory evaluation.

Stool samples are usually collected on a random basis unless a quantitative study (e.g., fecal fat, urobilinogen) is to be performed. Random specimens should be sent promptly to the laboratory for analysis; however, the quantitative 24- to 72-hour collections must be kept refrigerated until transported to the laboratory. Some stool collections require the patient to follow a specific diet or refrain from taking certain medications before the collection; patient education is important.

Guaiac-based fecal occult blood testing (gFOBT) is one of the most commonly performed stool tests. It can be useful in initial screening for several disorders, although it is used most frequently in early cancer detection programs. gFOBT can be performed at the bedside, in the laboratory, or at home. It is inexpensive, noninvasive, and carries minimal risk to the patient. However, it should not be performed when there is hemorrhoidal bleeding. Patients are advised to avoid ingesting red meats, aspirin, and nonsteroidal anti-inflammatory drugs for 72 hours prior to the study because it is thought that these factors are associated with false-positive results; likewise, patients are advised to avoid ingesting vitamin C from supplements or foods as it is believed that this is associated with false-negative results (ACS, 2019). A small amount of the specimen is applied to the guaiac-impregnated paper slide. If the test is performed at home, the patient mails the slide to the primary

provider or the lab in an envelope provided for that purpose. The ACS (2019) recommends using the highly sensitive versions of this type of test (e.g., fecal immunochemical test [FIT], FIT-fecal DNA test) for screening.

The FIT reacts to the human hemoglobin protein. The stool sample can be obtained at home, and dietary or medication restrictions are not required prior to collecting the stool specimen. This test is less likely to react to bleeding from other areas of the digestive tract and is done annually (ACS, 2019).

FIT-fecal DNA testing can detect abnormal sections of DNA from cancer or polyp cells (ACS, 2019). The Centers for Medicare & Medicaid Services approved this test for reimbursement and recommends performing the test every 3 years (Rex, Boland, Dominitz, et al., 2017). The FIT-fecal DNA test does not require any dietary or medication restrictions and can detect neoplasia anywhere in the colon.

Breath Tests

The hydrogen breath test was developed to evaluate carbohydrate absorption, in addition to aiding in the diagnosis of bacterial overgrowth in the intestine and short-bowel syndrome. This test determines the amount of hydrogen expelled in the breath after it has been produced in the colon (on contact of galactose with fermenting bacteria) and absorbed into the blood.

Urea breath tests detect the presence of *Helicobacter pylori,* the bacteria that can live in the mucosal lining of the stomach and cause peptic ulcer disease. After the patient ingests a capsule of carbon-labeled urea, a breath sample is obtained 10 to 20 minutes later. Because *H. pylori* metabolizes urea rapidly, the labeled carbon is absorbed quickly; it can then be measured as carbon dioxide in the expired breath to determine whether *H. pylori* is present. Prior to urea breath testing, the patient is instructed to avoid antibiotics or bismuth subsalicylate for 1 month before the test; proton pump inhibitors for 2 weeks before the test; and cimetidine and famotidine for 24 hours before the test (HealthLinkBC, 2018). *H. pylori* also can be detected by assessing serum antibody levels without requiring medication therapy adjustments.

Abdominal Ultrasonography

Ultrasonography is a noninvasive diagnostic technique in which high-frequency sound waves are passed into internal body structures, and the ultrasonic echoes are recorded on an oscilloscope as they strike tissues of different densities. It is particularly useful in the detection of an enlarged gallbladder or pancreas, the presence of gallstones, an enlarged ovary, an ectopic pregnancy, or appendicitis. Ultrasonography can be limited by patient body type, bowel gas patterns, and operator experience (Babakhanlou, 2018).

Advantages of abdominal ultrasonography include an absence of ionizing radiation, no noticeable side effects, relatively low cost, and almost immediate results. It cannot be used to examine structures that lie behind bony tissue, because bone prevents sound waves from traveling into deeper structures. Gas and fluid in the abdomen or air in the lungs also prevent transmission of ultrasound. An ultrasound produces no ill effects. However, some patients, such as pregnant women, have concerns regarding the energy emitted by the probe.

Endoscopic ultrasonography (EUS) is a specialized enteroscopic procedure that aids in the diagnosis of GI disorders by providing direct imaging of a target area. A small high-frequency ultrasonic transducer is mounted at the tip of the fiberoptic scope, which displays images that are of higher-quality resolution and definition than regular ultrasound imaging. EUS may be used to evaluate submucosal lesions, specifically their location and depth of penetration. In addition, EUS may aid in the evaluation of Barrett esophagus, portal hypertension, chronic pancreatitis, suspected pancreatic neoplasm, biliary tract disease, and changes in the bowel wall due to ulcerative colitis. Intestinal gas, bone, and thick layers of adipose tissue that hamper conventional ultrasonography are not problems when EUS is used.

Nursing Interventions

The patient is instructed to fast for 8 to 12 hours before ultrasound testing to decrease the amount of gas in the bowel. If gallbladder studies are being performed, the patient should eat a fat-free meal the evening before the test. If barium studies are to be performed, they should be scheduled after ultrasonography; otherwise, the barium could interfere with the transmission of the sound waves. Patients who receive moderate sedation are observed for about 1 hour to assess for level of consciousness, orientation, and ability to ambulate. Patients treated on an outpatient basis are given instructions regarding diet, activity, and how to monitor for complications (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2017).

Genetic Testing

Researchers have refined methods for genetics risk assessment, preclinical diagnosis, and prenatal diagnosis to identify people who are at risk for certain GI disorders (e.g., gastric cancer, lactose deficiency, inflammatory bowel disease, colon cancer) (Chart 38-3). People who are identified as being at risk for certain GI disorders may choose to have genetic counseling to learn about the disease and options for preventing and treating the disease, and to receive support in coping with the situation. Lynch syndrome is inherited in an autosomal dominant manner and is associated with colonic and extracolonic cancers; 3% of new cases of colon cancer are attributed to Lynch syndrome

(Kohlmann & Gruber, 2018; Sinicrope, 2018). See Chapter 6 for further discussion of genetic counseling.

Chart 38-3  GENETICS IN NURSING PRACTICE

Digestive and Gastrointestinal Disorders

Several digestive and gastrointestinal disorders are associated with genetic abnormalities. Some examples include:
Autosomal dominant:

- Hereditary diffuse gastric cancer
- Hereditary non-polyposis colorectal cancer (Lynch syndrome)
- Hirschsprung disease (aganglionic megacolon)

Autosomal recessive:

- Glucose galactose malabsorption
- Glycogen storage disease (von Gierke disease)
- Pompe disease
- Zellweger syndrome

Inheritance pattern includes autosomal dominant and autosomal recessive:

- Familial adenomatous polyposis

X-linked:

- Fabry disease

Inheritance pattern is not distinct; however, there is a genetic predisposition for the disease:

- Crohn's disease
- Type 1 diabetes
- Celiac disease
- Pancreatic cancer

Other genetic disorders that will impact the digestive and gastrointestinal system:

- Cleft lip and/or palate
- Cystic fibrosis

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Related to Digestive and Gastrointestinal Disorders

- Careful family history assessment for other family members with a similar condition (e.g., cleft lip/palate, pyloric stenosis).
- Assess for other family members in several generations with early-onset colorectal cancer.
- Inquire about other family members with inflammatory bowel disease.

- Assess family history for other cancers (e.g., endometrial, ovarian, kidney).

Patient Assessment Specific to Digestive and Gastrointestinal Disorders

- Ask about bowel pattern and color of stool.
- Assess if patient experiences episodes of abdominal cramping, diarrhea, or dehydration.
- Assess for unexplained weight loss.
- Identify intolerance to specific foods (e.g., gluten, high-fat foods, lactose).
- Assess for prior history of liver disorders.

Assess for presence of other clinical conditions:

- With clefting—congenital heart defect, other birth defects suggestive of a genetic syndrome.
- With familial adenomatous polyposis—congenital hypertrophy of retinal pigment epithelium.

Imaging Studies

Numerous minimally invasive and noninvasive imaging studies, including x-ray and contrast studies, computed tomography (CT) scan, magnetic resonance imaging (MRI) scan, positron emission tomography (PET) scan, scintigraphy (radionuclide imaging), and virtual colonoscopy are available today.

Upper Gastrointestinal Tract Study

An upper GI fluoroscopy delineates the entire GI tract after the introduction of a contrast agent. A radiopaque liquid (e.g., barium sulfate) is commonly used; however, thin barium, diatrizoate sodium (Hypaque), and at times water are used due to their low associated risks. The GI series enables the examiner to detect or exclude anatomic or functional disorders of the upper GI organs or sphincters. It also aids in the diagnosis of ulcers, varices, tumors, regional enteritis, and malabsorption syndromes. The procedure may be extended to examine the duodenum and small bowel (small-bowel follow-through). As the barium descends into the stomach, the position, patency, and caliber of the esophagus are visualized, enabling the examiner to detect or exclude any anatomic or functional derangement of that organ. Fluoroscopic examination

next extends to the stomach as its lumen fills with barium, allowing observation of stomach motility, thickness of the gastric wall, the mucosal pattern, patency of the pyloric valve, and the anatomy of the duodenum. Multiple x-ray images are obtained during the procedure, and additional images may be taken at intervals for up to 24 hours to evaluate the rate of gastric emptying. Small-bowel x-rays taken while the barium is passing through that area allow for observation of the motility of the small bowel. Obstructions, ileitis, and diverticula can also be detected.

Variations of the upper GI study include double-contrast studies and enteroclysis. The double-contrast method of examining the upper GI tract involves administration of a thick barium suspension to outline the stomach and esophageal wall, after which tablets that release carbon dioxide in the presence of water are given. This technique has the advantage of showing the esophagus and stomach in finer detail, permitting signs of early superficial neoplasms to be noted.

Enteroclysis is a very detailed, double-contrast study of the entire small intestine that involves the continuous infusion (through a duodenal tube) of 500 to 1000 mL of a thin barium sulfate suspension; after this, methylcellulose is infused through the tube. The barium and methylcellulose fill the intestinal loops and are observed continuously by fluoroscopy and viewed at frequent intervals as they progress through the jejunum and the ileum. Air may also be used, but methylcellulose is preferred as it is associated with enhanced visibility (Lampignano & Kendrick, 2018). This process (even with normal motility) can take up to 6 hours and can be quite uncomfortable for the patient. The procedure aids in the diagnosis of partial small-bowel obstructions or diverticula. After completion of the fluoroscopic component of the study, the patient may have a CT scan to assess for lesions or adhesions, and in this case an iodinated contrast media may be used (Lampignano & Kendrick, 2018).

Nursing Interventions

Instruction regarding dietary changes prior to the study may include a low residue or clear liquid diet, and nothing by mouth (*nil per os;* NPO) after midnight the night before the study. In addition, the patient is advised to not smoke or chew gum during the NPO period because these can increase gastric secretions and salivation (Lampignano & Kendrick, 2018). Polyethylene glycol (PEG)-based solutions are considered the most effective bowel cleansing preparatory agent; other agents include sodium phosphate, magnesium citrate, and preparations containing sodium picosulfate, citric acid, and magnesium oxide (Harrison & Hielkrem, 2016; Tan, Lin, Ma, et al., 2018). Typically, oral medications are withheld on the morning of the study and resumed that evening, but each patient's medication regimen should be evaluated on an individual basis. When a patient with insulin-dependent

diabetes is NPO, their insulin requirements will need to be adjusted accordingly (see Chapter 46).

Follow-up care is provided after the upper GI procedure to ensure that the patient has eliminated most of the ingested barium. Fluids may be increased to facilitate evacuation of stool and barium.

Lower Gastrointestinal Tract Study

Visualization of the lower GI tract is obtained after rectal installation of barium. The barium enema can be used to detect the presence of polyps, tumors, or other lesions of the large intestine and demonstrate any anatomic abnormalities or malfunctioning of the bowel. After proper preparation and evacuation of the entire colon, each portion of the colon may be readily observed. The procedure usually takes about 15 to 30 minutes, during which time x-ray images are obtained.

Other means for visualizing the colon include double-contrast studies and a water-soluble contrast study. These tests are still occasionally used because they are relatively inexpensive and simple. A double-contrast or air-contrast barium enema involves the instillation of a thicker barium solution, followed by the instillation of air. The patient may feel some cramping or discomfort during this process. This test provides a contrast between the air-filled lumen and the barium-coated mucosa, allowing easier detection of smaller lesions. CT colonography has replaced double-contrast barium enema for nearly all indicated GI disorders (Rex et al., 2017) (see later discussion).

If active inflammatory disease, fistulas, or perforation of the colon is suspected, a water-soluble iodinated contrast agent (e.g., diatrizoic acid [Gastrografin]) can be used. The procedure is the same as for a barium enema, but the patient must first be assessed for allergy to iodine or contrast agent. The contrast agent is eliminated readily after the procedure, so there is no need for postprocedure laxatives. Diarrhea may occur in some patients until the contrast agent has been totally eliminated.

Nursing Interventions

Preparation of the patient includes emptying and cleansing the lower bowel. This often necessitates a low residue diet 1 to 2 days before the test, a clear liquid diet and a laxative the evening before, NPO after midnight, and cleansing enemas until returns are clear the following morning. The nurse makes sure that barium enemas are scheduled before any upper GI studies. If the patient has active inflammatory disease of the colon, enemas are contraindicated. Barium enemas also are contraindicated in patients with signs of perforation or obstruction; instead, a water-soluble contrast study may be performed. Active GI bleeding may prohibit the use of laxatives and enemas.

Postprocedural patient education includes information about increasing fluid intake, evaluating bowel movements for evacuation of barium, and noting

increased number of bowel movements, because barium, due to its high osmolarity, may draw fluid into the bowel, thus increasing the intraluminal contents and resulting in greater output.

Computed Tomography

A CT scan provides cross-sectional images of abdominal organs and structures. Multiple x-ray images are taken from numerous angles, digitized in a computer, reconstructed, and then viewed on a computer monitor. As the sensitivity and specificity of CT scans have increased in recent years, so has their use. Volume CT scanners (i.e., helical or spiral scanning) provide more accurate reconstruction of patient data into alternate planes, require shorter scan times, and have less artifact when compared to single slice scanning (Lampignano & Kendrick, 2018). CT is a valuable tool for detecting and localizing many inflammatory conditions in the colon, such as appendicitis, diverticulitis, regional enteritis, and ulcerative colitis, as well as evaluating the abdomen for diseases of the liver, spleen, kidney, pancreas, and pelvic organs, and structural abnormalities of the abdominal wall. The CT procedure is completely painless, but radiation doses are considerable. A CT scan may be performed with or without oral or intravenous (IV) contrast, but the enhancement of the study is greater with the use of a contrast agent. In patients at risk for complications from use of contrast, the radiologist and provider must be in agreement that the scan is medically necessary and that the benefits outweigh the risks (Yale School of Medicine, 2019).

Nursing Interventions

Common risks from IV contrast agents include allergic reactions and contrast-induced nephropathy (CIN); therefore, patients must be screened for these risks (Hossain, Costanzo, Cosentino, et al., 2018). Any allergies to contrast agents, iodine, or shellfish, the patient's current serum creatinine level, and pregnancy status in females must be determined before administration of a contrast agent. Patients allergic to the contrast agent may be premedicated with a corticosteroid and antihistamine.

The most effective ways to prevent CIN include careful selection of patients, maintaining hydration status, using newer contrast agents, and avoiding nephrotoxic agents pre- and postprocedure (Hossain et al., 2018).

Magnetic Resonance Imaging

MRI is used in gastroenterology to supplement ultrasonography and CT. This noninvasive technique uses magnetic fields and radio waves to produce images of the area being studied. The use of oral contrast agents to enhance the image has increased the application of this technique for the diagnosis of GI diseases.

It is useful in evaluating abdominal soft tissues as well as blood vessels, abscesses, fistulas, neoplasms, and other sources of bleeding.

The physiologic artifacts of heartbeat, respiration, and peristalsis may create a less-than-clear image; however, newer, fast-imaging MRI techniques help eliminate these physiologic motion artifacts. MRI is not totally safe for all people; having the patient complete a preprocedure MRI tool that screens for contraindications to MRI is required (Lampignano & Kendrick, 2018). Any ferromagnetic objects (metals that contain iron) can be attracted to the magnet and cause injury. Items that can be problematic or dangerous include jewelry, dental implants, paper clips, pens, keys, IV poles, clips on patient gowns, and oxygen tanks.

Quality and Safety Nursing Alert

MRI is contraindicated in patients with any device containing metal because the magnetic field could cause malfunction. MRI is also contraindicated for patients with internal metal devices (e.g., aneurysm clips), intraocular metallic fragments, or cochlear implants. Foil-backed skin patches (e.g., nicotine, nitroglycerin, scopolamine, clonidine) should be removed before an MRI because of the risk of burns; however, the patient's primary provider should be consulted before the patch is removed to determine whether an alternate form of the medication should be provided.

Nursing Interventions

Preprocedure patient education includes NPO status 6 to 8 hours before the study and removal of all jewelry and other metals. The patient and family are informed that the study may take 60 to 90 minutes; during this time, the technician will instruct the patient to take deep breaths at specific intervals. The close-fitting scanners used in many MRI facilities may induce feelings of claustrophobia, and the machine will make a knocking sound during the procedure. Patients may choose to wear a headset and listen to music or wear a blindfold during the procedure. Open MRIs that are less close fitting eliminate the claustrophobia that many patients experience; however, they produce lower-resolution images.

Positron Emission Tomography

PET scans produce images of the body by detecting the radiation emitted from radioactive substances. The radioactive substances are injected into the body IV and are usually tagged with radioactive isotopes of oxygen, nitrogen, carbon, or fluorine (Lampignano & Kendrick, 2018). These isotopes decay quickly, do not harm the body, have lower radiation levels than a typical x-ray

or CT scan, and are eliminated in the urine or feces. The scanner essentially "captures" where the radioactive substances are in the body, transmits information to a scanner, and produces a scan with "hot spots" for evaluation by the radiologist or oncologist.

Scintigraphy

Scintigraphy (radionuclide testing) relies on the use of radioactive isotopes (i.e., technetium, iodine, indium) to reveal displaced anatomic structures, changes in organ size, and the presence of neoplasms or other focal lesions such as cysts or abscesses. Scintigraphic scanning is also used to measure the uptake of tagged red blood cells and leukocytes. Tagging of red blood cells and leukocytes by injection of a radionuclide is performed to define areas of inflammation, abscess, blood loss, or neoplasm. A sample of blood is removed, mixed with a radioactive substance, and reinjected into the patient. Abnormal concentrations of blood cells are then detected at 24- and 48-hour intervals. Tagged red cell studies are useful in determining the source of internal bleeding when all other studies have returned a negative result.

Gastrointestinal Motility Studies

Radionuclide testing also is used to assess gastric emptying and colonic transit time. During gastric emptying studies, the liquid and solid components of a meal (typically scrambled eggs) are tagged with radionuclide markers. After ingestion of the meal, the patient is positioned under a scintiscanner, which measures the rate of passage of the radioactive substance from the stomach (Parkman, 2018). This is useful in diagnosing disorders of gastric motility, diabetic gastroparesis, and dumping syndrome.

Colonic transit studies are used to evaluate colonic motility and obstructive defecation syndromes. The patient is given a capsule containing 20 radionuclide markers and instructed to follow a regular diet and usual daily activities. Abdominal x-rays are taken every 24 hours until all markers are passed. This process usually takes 4 to 5 days; in the presence of severe constipation it may take as long as 10 days. Patients with chronic diarrhea may be evaluated at 8-hour intervals. The amount of time that it takes for the radioactive material to move through the colon indicates colonic motility.

Endoscopic Procedures

Endoscopic procedures used in GI tract assessment include fibroscopy/esophagogastroduodenoscopy (EGD), colonoscopy, anoscopy, proctoscopy, sigmoidoscopy, small-bowel enteroscopy, and endoscopy through an ostomy.

Upper Gastrointestinal Fibroscopy/Esophagogastroduodenoscopy

Fibroscopy of the upper GI tract allows direct visualization of the esophageal, gastric, and duodenal mucosa through a lighted endoscope (gastroscope) (Fig. 38-5). EGD is valuable when esophageal, gastric, or duodenal disorders or inflammatory, neoplastic, or infectious processes are suspected. This procedure also can be used to evaluate esophageal and gastric motility and to collect secretions and tissue specimens for further analysis.

Figure 38-5 • Patient undergoing gastroscopy.

In EGD, the gastroenterologist views the GI tract through a viewing lens and can obtain images through the scope to document findings. Electronic video endoscopes also are available that attach directly to a video processor, converting the electronic signals into pictures that are projected on a screen. This allows larger and continuous viewing capabilities, as well as the simultaneous recording of the procedure.

PillCam ESO, or capsule endoscopy, requires that the patient swallows a capsule that travels by peristalsis through the small intestines. The capsule contains an oxide metal silicon chip video camera, which transmits digital images of the GI mucosa to a data recorder that is worn on the patient's waist. This technology is a diagnostic option for patients with esophageal diseases who cannot tolerate an EGD (Park, Cho, & Kim, 2018). Capsule colonoscopy is FDA approved for patients with previous incomplete colonoscopies, and for those who are not candidates for colonoscopies or sedation (Rex et al., 2017).

Endoscopic retrograde cholangiopancreatography (ERCP) uses the endoscope in combination with x-rays to view the bile ducts, pancreatic ducts,

and gallbladder (MedlinePlus, 2019). The side-viewing flexible scopes are used to visualize the common bile duct and the pancreatic and hepatic ducts through the ampulla of Vater in the duodenum. ERCP is helpful in evaluating jaundice, pancreatitis, pancreatic tumors, common bile duct stones, and biliary tract disease. Current trends show an increase in ERCP use for therapeutic indications (sphincterotomy, stone removal, and biliary stenting), with a decline in its use for conventional diagnostic testing (Ahmed, Kanotra, Savani, et al., 2017). ERCP is described further in Chapter 44.

Upper GI fibroscopy also can be a therapeutic procedure when combined with other procedures. Therapeutic endoscopy can be used to remove common bile duct stones, dilate strictures, and treat gastric bleeding and esophageal varices. Laser-compatible scopes can be used to provide laser therapy for upper GI neoplasms. Sclerosing solutions can be injected through the scope in an attempt to control upper GI bleeding.

After the patient is sedated, the endoscope is lubricated with a water-soluble lubricant and passed smoothly and slowly along the back of the mouth and down into the esophagus. The gastroenterologist views the gastric wall and the sphincters and then advances the endoscope into the duodenum for further examination. Biopsy forceps to obtain tissue specimens or cytology brushes to obtain cells for microscopic study can be passed through the scope. The procedure usually takes about 30 minutes.

The patient may experience nausea, gagging, or choking. The use of topical anesthetic agents and moderate sedation makes it important to monitor and maintain the patient's oral airway during and after the procedure. Finger or ear oximeters are used to monitor oxygen saturation, and supplemental oxygen may be given if needed. Precautions must be taken to protect the scope, because the fiberoptic bundles can be broken if the scope is bent at an acute angle. The patient wears a mouth guard to keep from biting the scope.

Nursing Interventions

The patient should be NPO for 8 hours prior to the examination. Before the introduction of the endoscope, the patient is given a local anesthetic gargle or spray. Midazolam, a sedative that provides moderate sedation with loss of the gag reflex and relieves anxiety during the procedure, is given. Atropine may be given to reduce secretions, and glucagon may be given to relax smooth muscle. The patient is positioned in the left lateral position to facilitate clearance of pulmonary secretions and provide smooth entry of the scope.

After gastroscopy, assessment includes level of consciousness, vital signs, oxygen saturation, pain level, and monitoring for signs of perforation (i.e., pain, bleeding, unusual difficulty swallowing, rapidly elevated temperature). Temporary loss of the gag reflex is expected; after the patient's gag reflex has returned, lozenges, saline gargle, and oral analgesic agents may be offered to relieve minor throat discomfort. Patients who were sedated for the procedure

must remain in bed until fully alert. After moderate sedation, the patient must be transported home with a family member or friend if the procedure was performed on an outpatient basis. Someone should stay with the patient until the morning after the procedure. Because of sedation, many patients will not remember postprocedure instructions. For this reason, discharge and follow-up verbal and written instructions are provided to the person accompanying the patient home, as well as to the patient. In addition, many endoscopy suites have a program in which a nurse telephones the patient the morning after the procedure to find out if the patient has any concerns or questions related to the procedure.

Fiberoptic Colonoscopy

Historically, direct visualization of the bowel was the only means to evaluate the colon, but virtual colonoscopy (also known as CT colonography) is now available. Advantages include less risk for perforation when compared to colonoscopy; however, the need for bowel preparation is considered a disadvantage (Rex et al., 2017).

Direct visual inspection of the large intestine (anus, rectum, sigmoid, transcending and ascending colon) is possible by means of a flexible fiberoptic colonoscope (Fig. 38-6). These scopes have the same capabilities as those used for EGD but are larger in diameter and longer. Still and video recordings can be used to document the procedure and findings.

This procedure is used commonly as a diagnostic aid and screening device. It is most frequently used for cancer screening and for surveillance in patients with previous colon cancer or polyps. (See Chapter 12, Table 12-3 for details on the ACS's screening guidelines.) In addition, tissue biopsies can be obtained as needed, and polyps can be removed and evaluated. Other uses of colonoscopy include the evaluation of patients with diarrhea of unknown cause, occult bleeding, or anemia; further study of abnormalities detected on barium enema; and diagnosis, clarification, and determination of the extent of inflammatory or other bowel disease.

The procedure can be used to remove all visible polyps with a special snare and cautery through the colonoscope. Many colon cancers begin with adenomatous polyps of the colon; therefore, one goal of colonoscopic polypectomy is early detection and prevention of colorectal cancer. This procedure also can be used to treat areas of bleeding or stricture. The use of bipolar and unipolar coagulators and heater probes, as well as injections of sclerosing agents or vasoconstrictors, is possible during this procedure. Laser-compatible scopes provide laser therapy for bleeding lesions or colonic neoplasms. Bowel decompression (removal of intestinal contents to prevent gas and fluid from distending the coils of the intestine) can also be completed during the procedure.

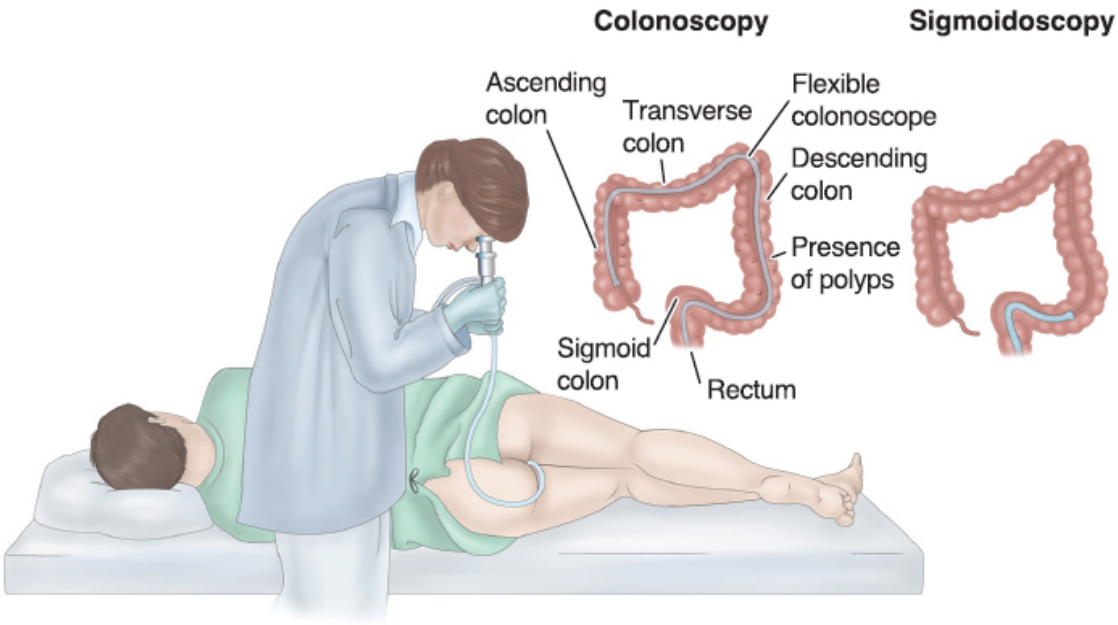

Figure 38-6 • Colonoscopy and flexible fiberoptic sigmoidoscopy. For the colonoscopy, the flexible scope is passed through the rectum and sigmoid colon into the descending, transverse, and ascending colon. For the flexible fiberoptic sigmoidoscopy, the flexible scope is advanced past the proximal sigmoid and then into the descending colon.

Colonoscopy is performed while the patient is lying on the left side with the legs drawn up toward the chest. The patient's position may be changed during the test to facilitate advancement of the scope. Biopsy forceps or a cytology brush may be passed through the scope to obtain specimens for histology and cytology examinations. Complications during and after the procedure can include cardiac arrhythmias and respiratory depression resulting from the medications given, vasovagal reactions, and circulatory overload or hypotension resulting from overhydration or underhydration during bowel preparation. The patient's cardiac and respiratory function and oxygen saturation are monitored continuously, with supplemental oxygen used as necessary. Typically, the procedure takes about 1 hour, and postprocedure discomfort results from instillation of air to expand the colon and insertion and movement of the scope during the procedure.

Capsule colonoscopy is another option for patients who cannot tolerate colonoscopy or for patients with incomplete colonoscopies. This minimally invasive test consists of an ingestible capsule with a two-sided camera (similar to the PillCam ESO). This test requires that the patient completes a more extensive bowel preparation than required for a colonoscopy; patients with a positive test then require a follow-up colonoscopy on a separate day (Rex et al., 2017).

Nursing Interventions

The success of colonoscopy depends on how well the colon is prepared (Tariq, Kamal, Sapkota, et al., 2019). Adequate colon cleansing provides optimal visualization and decreases the time needed for the procedure. Cleansing of the colon can be accomplished in various ways. The primary provider may prescribe a laxative for two nights before the examination and a Fleet or saline enema until the return is clear the morning of the test. However, more commonly, PEG electrolyte lavage solutions (GoLYTELY, CoLyte, and NuLYTELY) are used for effective cleansing of the bowel. Current preparations include either the nonsplit dose regimen, in which the entire solution is ingested the night before the procedure, or the split-dose regimen, in which half of the dose is ingested the night before and half is ingested the morning of the procedure, 3 hours prior to the scheduled test. Tariq et al. (2019) report improved bowel preparation and cleansing with the split prep.

Patient health history and comorbidities such as diabetes, chronic constipation, or history of opioid use, or problematic colonoscopies influence patient preparation. Preprocedure diet instructions include a clear liquid or a low residue diet starting the day before the procedure; diet type has not been shown to affect bowel preparation in patients ingesting the split preparations (Tariq et al., 2019). If necessary, the nurse can give the solution through a feeding tube if the patient cannot swallow. Patients with a colostomy can receive this same bowel preparation. The use of lavage solutions is contraindicated in patients with intestinal obstruction or inflammatory bowel disease.

A sodium phosphate tablet (OsmoPrep, Visicol) can be used for colon cleansing prior to colonoscopy. Dosing consists of 32 tablets: 20 tablets (4 tablets every 15 minutes) with 8 oz of any clear liquid (water, any clear carbonated beverage, or juice) on the evening prior to the examination, and 12 tablets (taken in the same manner) on the morning of the examination.

With the use of lavage solutions, bowel cleansing is fast (rectal effluent is clear in about 4 hours) and is tolerated fairly well by most patients. Side effects of the electrolyte solutions include nausea, bloating, cramps or abdominal fullness, fluid and electrolyte imbalance, and hypothermia (patients are often told to drink the preparation as cold as possible to make it more palatable). The side effects are especially problematic for older adults, and sometimes they have difficulty ingesting the required volume of solution. Monitoring older patients after a bowel preparation is especially important because their physiologic ability to compensate for fluid loss is diminished. Many older adults take multiple medications each day; therefore, the nurse's knowledge of their daily medication regimen can prompt assessment for and prevention of potential problems and early detection of physiologic changes.

Additionally, the nurse advises the patient with diabetes to consult with their primary provider about medication adjustment to prevent hyperglycemia

or hypoglycemia resulting from the dietary modifications required in preparing for the test. The nurse also instructs all patients, especially older adults, to maintain adequate fluid, electrolyte, and caloric intake while undergoing bowel cleansing.

Special precautions must be taken for some patients. Implantable defibrillators and pacemakers are at high risk for malfunction if electrosurgical procedures (i.e., polypectomy) are performed in conjunction with colonoscopy. A cardiologist should be consulted before the test is performed for device management. These patients require careful cardiac monitoring during the procedure (American Society of Anesthesiology Taskforce, 2020; Neubauer, Wellman, Herzog-Niescery, et al., 2018).

Colonoscopy cannot be performed if there is a suspected or documented colon perforation, acute severe diverticulitis, or acute colitis. Patients with prosthetic heart valves or a history of endocarditis require prophylactic antibiotics before the procedure.

Informed consent is obtained by the practitioner before the patient is sedated. Before the examination, an opioid analgesic agent or sedative (e.g., midazolam) is given to provide moderate sedation and relieve anxiety during the procedure. Glucagon may be given, if needed, to relax the colonic musculature and to reduce spasm during the test. Patients who are older or debilitated may require a reduced dosage of the analgesic agent or sedative to decrease the risks of oversedation and cardiopulmonary complications.

During the procedure, the patient is monitored for changes in oxygen saturation, vital signs, color and temperature of the skin, level of consciousness, abdominal distention, vagal response, and pain intensity. After the procedure, patients are maintained on bed rest until fully alert. Some patients have abdominal cramps caused by increased peristalsis stimulated by the air insufflated into the bowel during the procedure.

Immediately after the test, the patient is monitored for signs and symptoms of bowel perforation (e.g., rectal bleeding, abdominal pain or distention, fever, focal peritoneal signs). Because of the amnesic effects of midazolam, the patient may be unable to recall verbal information and should receive written instructions. If the procedure is performed on an outpatient basis, someone must transport the patient home. After a therapeutic procedure, the nurse instructs the patient to report any bleeding to the primary provider.

Anoscopy, Proctoscopy, and Sigmoidoscopy

Endoscopic examination of the anus, rectum, and sigmoid and descending colon is used to evaluate chronic diarrhea, fecal incontinence, ischemic colitis, and lower GI hemorrhage and to observe for ulceration, fissures, abscesses, tumors, polyps, or other pathologic processes.

The flexible fiberoptic sigmoidoscope (see Fig. 38-6) permits the colon to be examined up to 40 to 50 cm (16 to 20 inches) from the anus, much more

than the 25 cm (10 inches) that can be visualized with the rigid sigmoidoscope. It has many of the same capabilities as the scopes used for the upper GI study, including the use of still or video images to document findings.

For flexible scope procedures, the patient assumes a comfortable position on the left side with the right leg bent and placed anteriorly. It is important to keep the patient informed throughout the examination and to explain the sensations associated with it. Biopsies and polypectomies can be performed during this procedure. Biopsy is performed with small biting forceps introduced through the endoscope; one or more small pieces of tissue may be removed. If polyps are present, they may be removed with a wire snare, which is used to grasp the pedicle, or stalk. An electrocoagulating current is then used to sever the polyp and prevent bleeding. It is extremely important that all excised tissue be placed immediately in moist gauze or in an appropriate receptacle, labeled correctly, and delivered without delay to the pathology laboratory for examination.

Nursing Interventions

These examinations require only limited bowel preparation, including a warm tap water or Fleet enema until returns are clear. Dietary restrictions usually are not necessary, and sedation usually is not required. During the procedure, the nurse monitors vital signs, skin color and temperature, pain tolerance, and vagal response. After the procedure, the nurse monitors the patient for rectal bleeding and signs of intestinal perforation (i.e., fever, rectal drainage, abdominal distention, pain). On completion of the examination, the patient can resume regular activities and diet.

Small Bowel Studies

Several methods are available for visualization of the small intestine, including capsule endoscopy and double-balloon enteroscopy. Capsule endoscopy allows the noninvasive visualization of the mucosa throughout the entire small intestine. It is particularly useful in the evaluation of obscure GI bleeding. The technique consists of the patient swallowing a capsule embedded with a wireless miniature camera, a light source, and an image transmission system. The capsule is the size of a large vitamin pill. It is propelled through the intestine by peristalsis. Images are transmitted from the end of the capsule to a recording device worn by the patient. The capsule allows for inspection of the small intestine without patient discomfort (Yamamoto & Aabakken, 2019).

Double-balloon enteroscopy has made it possible to visualize the mucosa of the entire small bowel as well as carry out diagnostic and therapeutic interventions (Yamamoto & Aabakken, 2019). This endoscope is comprised of two balloons, one attached to the distal end of the scope and the other attached to the transparent overtube that slides over the endoscope. The endoscope is advanced alternately inflating and deflating the balloons; this causes

telescoping of the small intestine onto the overtube. As a result of this telescoping, the endoscope can visualize much more of the small intestine than the length of the scope itself. The procedure takes between 1 and 3 hours and requires moderate sedation. Nursing interventions are similar to those for other endoscopic procedures.

Endoscopy through an Ostomy

Endoscopy through an ostomy stoma is useful for visualizing a segment of the small or large intestine and may be indicated to evaluate the anastomosis for recurrent disease, or to visualize and treat bleeding in a segment of the bowel. Nursing interventions are similar to those for other endoscopic procedures.

Manometry and Electrophysiologic Studies

Manometry and electrophysiologic studies are methods for evaluating patients with GI motility disorders. The manometry test measures changes in intraluminal pressures and the coordination of muscle activity in the GI tract with the pressures transmitted to a computer analyzer.

Esophageal manometry is used to detect motility disorders of the esophagus and the upper and lower esophageal sphincter. Also known as esophageal motility studies, these studies are very helpful in the diagnosis of achalasia (i.e., absence of peristalsis), diffuse esophageal spasm, scleroderma, and other esophageal motor disorders. The patient must refrain from eating or drinking for 8 to 12 hours before the test. Medications that could have a direct effect on motility (e.g., calcium channel blockers, anticholinergic agents, sedatives) are withheld for 24 to 48 hours. A pressure-sensitive catheter is inserted through the nose and is connected to a transducer and a video recorder. The patient then swallows small amounts of water while the resultant pressure changes are recorded. Evaluation of a patient for GERD typically includes esophageal manometry.

Gastroduodenal, small intestine, and colonic manometry procedures are used to evaluate delayed gastric emptying and gastric and intestinal motility disorders such as irritable bowel syndrome or atonic colon. This is often an ambulatory outpatient procedure lasting 24 to 72 hours. Anorectal manometry measures the resting tone of the internal anal sphincter and the contractibility of the external anal sphincter. It is helpful in evaluating patients with chronic constipation or fecal incontinence and is useful in biofeedback for the treatment of fecal incontinence. It can be performed in conjunction with rectal sensory functioning tests. Dibasic sodium (Phospho-soda) or a saline cleansing enema is given 1 hour before the test, and positioning for the test is either the prone or the lateral position.

Rectal sensory function studies are used to evaluate rectal sensory function and neuropathy. A catheter and balloon are passed into the rectum, with

increasing balloon inflation until the patient feels distention. Then the tone and pressure of the rectum and anal sphincter are measured. The results are especially helpful in the evaluation of patients with chronic constipation, diarrhea, or incontinence.

Electrogastrography, an electrophysiologic study, also may be performed to assess gastric motility disturbances and can be useful in detecting motor or nerve dysfunction in the stomach. Electrodes are placed over the abdomen, and gastric electrical activity is recorded for up to 24 hours. Patients may exhibit rapid, slow, or irregular waveform activity.

Defecography measures anorectal function and is performed with very thick barium paste instilled into the rectum. Fluoroscopy is used to assess the function of the rectum and anal sphincter while the patient attempts to expel the barium. The test requires no preparation. The nurse educates the patient about what to expect during these procedures.

Gastric Analysis, Gastric Acid Stimulation Test, and pH Monitoring

Analysis of the gastric juice yields information about the secretory activity of the gastric mucosa and the presence or degree of gastric retention in patients thought to have pyloric or duodenal obstruction. It is also useful for diagnosing Zollinger-Ellison syndrome or atrophic gastritis.

The patient is NPO for 8 to 12 hours before the procedure. Any medications that affect gastric secretions are withheld for 24 to 48 hours before the test. Smoking is not allowed on the morning of the test because it increases gastric secretions. A small nasogastric tube with a catheter tip marked at various points is inserted through the nose. When the tube is at a point slightly less than 50 cm (21 inches), it should be within the stomach, lying along the greater curvature. Once in place, the tube is secured to the patient's cheek and the patient is placed in a semireclining position. The entire stomach contents are aspirated by gentle suction into a syringe, and gastric samples are collected every 15 minutes for the next hour.

Important diagnostic information to be gained from gastric analysis includes the ability of the mucosa to secrete HCl. This ability is altered in various disease states, including:

- *Pernicious anemia:* Patients with this disease secrete no acid under basal conditions or after stimulation.
- *Severe chronic atrophic gastritis or gastric cancer:* Patients with these diseases secrete little or no acid.
- *Gastric ulcer:* Patients with this disease secrete some acid.
- *Duodenal ulcers:* Patients with this disease usually secrete an excess amount of acid.

The gastric acid stimulation test usually is performed in conjunction with gastric analysis. Histamine or pentagastrin is given subcutaneously to stimulate gastric secretions. It is important to inform the patient that this injection may produce a flushed feeling. The nurse monitors the patient's blood pressure and pulse frequently to detect hypotension. Gastric specimens are collected after the injection every 15 minutes for 1 hour and are labeled to indicate the time of specimen collection after histamine injection. The volume and pH of the specimen are measured; in certain instances, cytologic study by the Papanicolaou technique may be used to determine the presence or absence of malignant cells.

Esophageal reflux of gastric acid may be diagnosed and evaluated by ambulatory pH monitoring (Triadafilopoulos, Zikos, Regalia, et al., 2018). The patient is NPO for 6 hours before the test. A sensor that measures pH is inserted and positioned via endoscopy. The sensor is then connected to an external recording device and is worn for 24 hours while the patient continues usual daily activities. The result is a computer analysis and graphic display of the results.

The Bravo pH monitoring system offers the advantage of pH monitoring of the esophagus without the transnasal catheter. The clinician, by means of endoscopy, attaches a capsule (approximately the size of a gel cap) to the patient's esophageal wall. Data related to pH are transmitted from the capsule to a pager-sized receiver that the patient wears. Data are collected for up to 96 hours and then downloaded and analyzed. The capsule spontaneously detaches from the esophagus in 7 to 10 days and then is passed through the patient's digestive system. The accuracy of this method of pH testing is greater than methods in which a catheter is used because the patient can eat normally and continue typical activities during the testing. The patient is evaluated for both acid reflux and nonacid reflux events (Medtronic, 2019).

Laparoscopy (Peritoneoscopy)

With the tremendous advances in minimally invasive surgery, diagnostic laparoscopy is efficient, cost-effective, and useful in the diagnosis of GI disease. After a pneumoperitoneum (injecting carbon dioxide into the peritoneal cavity to separate the intestines from the pelvic organs) is created, a small incision is made lateral to the umbilicus, allowing for the insertion of the fiberoptic laparoscope. This permits direct visualization of the organs and structures within the abdomen, permitting visualization and identification of any growths, anomalies, and inflammatory processes. In addition, biopsy samples can be taken from the structures and organs as necessary. This procedure can be used to evaluate peritoneal disease, chronic abdominal pain, abdominal masses, and gallbladder and liver disease. However, laparoscopy has not become an important diagnostic modality in patients with acute

abdominal pain, because less invasive tools (e.g., CT and MRI scans) are readily available. Laparoscopy usually requires general anesthesia and sometimes requires that the stomach and bowel be decompressed. Gas (usually carbon dioxide) is insufflated into the peritoneal cavity to create a working space for visualization. One of the benefits of this procedure is that after visualization of a problem, excision (e.g., removal of the gallbladder) can then be performed at the same time, if appropriate.

CRITICAL THINKING EXERCISES

1 pq You are caring for a 45-year-old woman recently admitted to the emergency department (ED) with new onset of right upper quadrant pain with radiation to the mid-upper back, accompanied by nausea and bloating. The symptoms began several hours after the patient ate lunch, which included several fatty foods. The patient's past medical history is unremarkable. Identify questions that you should ask when taking the patient's history. What are your priority assessments? What diagnostic tests would you expect? While in the ED, the patient reports that the pain has increased in intensity, and abdominal guarding and temperature elevation are noted. Given these new developments, what questions will you now ask and what are your priority assessments?

2 ipc A 50-year-old man presents to the ED with midsternal chest discomfort, nausea, and diaphoresis. He has a history of elevated cholesterol, which is managed with an oral medication. You recognize the symptoms of a potential cardiac or gastrointestinal condition. Given the urgency of the evolving situation, which members of the health care team do you anticipate will participate in the care of this patient? How can you best coordinate care to assure positive patient outcomes?

39 Management of Patients with Oral and Esophageal Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Define the relationship of dental hygiene and dental problems to nutrition and disease.
2. Describe the nursing management of patients with abnormalities of the oral cavity, jaw, and salivary glands, including cancer of the oral cavity and disorders of the esophagus.
3. Describe the nursing management of the patient receiving enteral nutrition support.
4. Use the nursing process as a framework for care of the patient undergoing neck dissection, having a gastrostomy or jejunostomy feeding tube placed, or with noncancerous disorders of the esophagus.

NURSING CONCEPTS

Elimination
Nutrition

GLOSSARY

achalasia: absent or ineffective peristalsis (wavelike contraction) of the distal esophagus accompanied by failure of the esophageal sphincter to relax in response to swallowing

aspiration: inhalation of fluids or foods into the trachea and bronchial tree

dumping syndrome: physiologic response to rapid emptying of gastric contents into the small intestine; manifested by nausea, weakness, sweating, palpitations, syncope, and possibly diarrhea (*synonym:* vagotomy syndrome)

dysphagia: difficulty swallowing

dysplasia: bizarre cell growth resulting in cells that differ in size, shape, or arrangement from other cells of the same tissue type

enteral nutrition: nutritional formula feedings infused through a tube directly into the gastrointestinal tract

enteric: of or relating to the intestines

gastroesophageal reflux disease (GERD): disorder marked by backflow of gastric or duodenal contents into the esophagus that causes troublesome symptoms and mucosal injury to the esophagus

gastrostomy: surgical creation of an opening into the stomach for the purpose of administering fluids, nutrition formulas, and medications or for decompression and drainage of stomach contents

gingivitis: inflammation of the gums; change in color from pink to red, with associated swelling, bleeding, and sensitivity/tenderness

halitosis: foul odor from the oral cavity; in laypersons' terms, "bad breath"

hernia: protrusion of an organ or part of an organ through the wall of the cavity that normally contains it

jejunostomy: surgical creation of an opening into the jejunum for the purpose of administering fluids, nutrition formulas, and medications

lithotripsy: the use of shock waves to break up or disintegrate stones

odynophagia: pain on swallowing

osmolality: ionic concentration of fluid

parotitis: inflammation of the parotid gland

percutaneous endoscopic gastrostomy (PEG): a feeding tube inserted endoscopically into the stomach

periapical abscess: abscessed tooth

pyrosis: a burning sensation in the stomach and esophagus that moves up to the mouth; commonly called heartburn

sialadenitis: inflammation of the salivary glands

stoma: artificially created opening between a body cavity (e.g., stomach or intestine) and the body surface

stomatitis: inflammation of the oral mucosa

vagotomy syndrome: gastrointestinal symptoms that includes diarrhea and abdominal cramping, resulting from rapid gastric emptying (*synonym*: dumping syndrome)

xerostomia: dry mouth

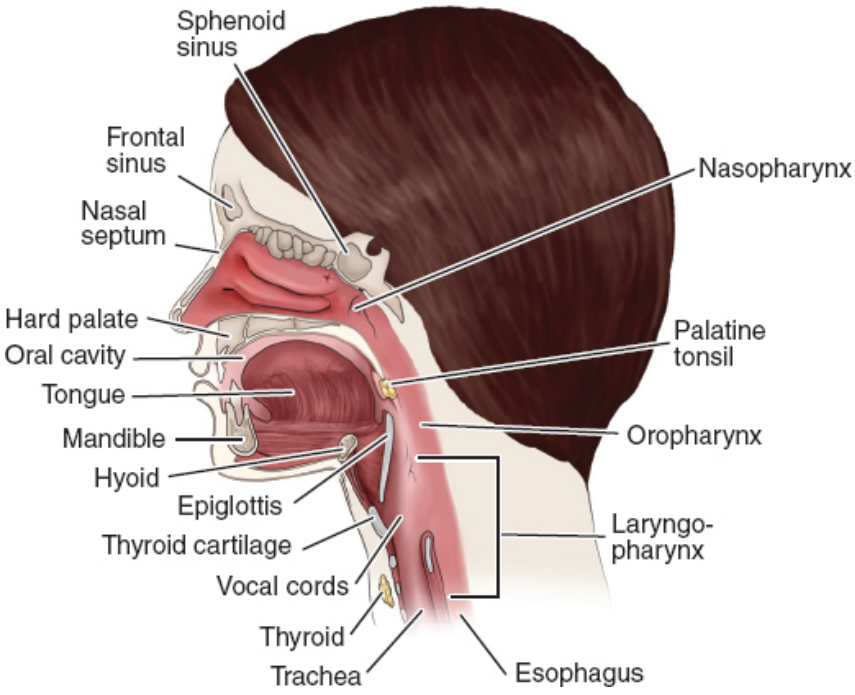

Figure 39-1 • Anatomy of the head and neck.

Because digestion normally begins in the mouth, adequate nutrition is related to good dental health and the general condition of the mouth. Any discomfort, abnormalities, or disease processes in the oral cavity can affect a person's nutritional status. Changes in the oral cavity can influence the type and amount of food ingested as well as the degree to which food particles are properly mixed with salivary enzymes. Disorders of the mouth or tongue can interfere with speech and thus affect communication and self-image. Esophageal problems related to swallowing can also adversely affect food and fluid intake, thereby jeopardizing general health and well-being. Given the close relationship between adequate nutritional intake and the structures of the upper gastrointestinal (GI) tract (lips, mouth, teeth, pharynx, esophagus), health education can help prevent disorders associated with these structures (see Fig. 39-1).

DISORDERS OF THE ORAL CAVITY

Oral health is a very important component of a person's physical and psychological sense of well-being. Periodontal disease, which encompasses both **gingivitis** (inflammation of the gums) and periodontitis (which involves the soft tissue and bone supporting the teeth), is the most common cause of tooth loss among adults (Office of the Surgeon General, 2003; U.S. Department of Health and Human Services [HHS], 2000). From 2011 to 2012, 44.7% of adults age 30 and older in the United States had periodontitis. When this prevalence is combined with the 2009 to 2010 data, there is a 45.9% prevalence of periodontitis, which means approximately 141 million adults ages 30 and older have diagnosed periodontitis. Severe periodontitis was diagnosed in 8.9% of adults ages 30 and older, but is most prevalent among adults ages 50 and older, males, Hispanic/Latino Americans (63.5%) and non-Hispanic/Latino African Americans (59.1%), those who didn't graduate high school, people living below 200% of the poverty level, and current smokers (Eke, Dye, Wei, et al., 2015). Current cigarette smoking, which increases the likelihood of periodontitis by at least 50%, remains a key modifiable risk factor for

periodontitis at all severity levels (Eke, Wei, Thornton-Evans, et al., 2016). Periodontal disease can be connected to a variety of other systemic diseases, such as cardiovascular disease, diabetes, and rheumatoid disease (American Academy of Periodontology [AAP], 2021). Table 39-1 reviews common abnormalities of the oral cavity, their possible causes, and nursing considerations. Figure 39-2 illustrates structures of the oral cavity.

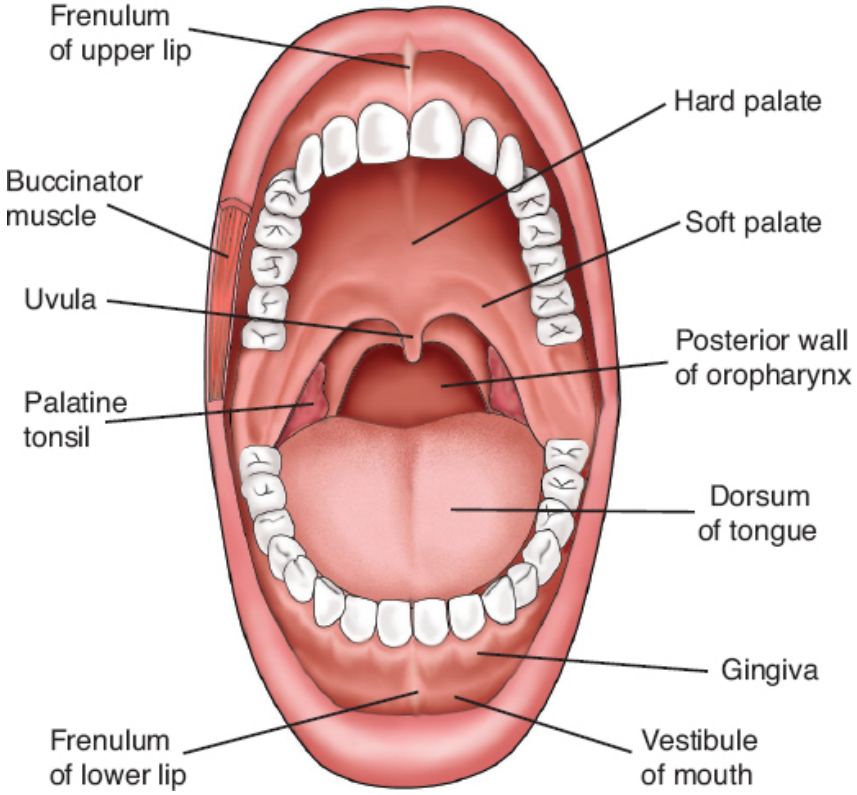

Figure 39-2 • Structures of the mouth, including the tongue and palate.

Dental Plaque and Caries

Tooth decay is an erosive process that begins with the action of bacteria on fermentable carbohydrates in the mouth, which produces acids that dissolve tooth enamel. Despite the fact tooth enamel is the hardest substance in the human body, caries and periodontal disease can still occur for several reasons. Contributing factors include nutrition, soft drink consumption, and genetic predisposition. In addition, the extent of damage to the teeth may be related to the following:

- Presence of dental plaque, which is a gluey, gelatinlike substance that adheres to the teeth
- Length of time acids are in contact with the teeth
- Strength of acids and the ability of the saliva to neutralize them
- Susceptibility of the teeth to decay

Dental decay begins with a small hole, usually in a fissure (a break in the tooth's enamel) or in an area that is hard to clean. Left unchecked, the decay extends into the dentin. Because dentin is not as hard as enamel, decay progresses more rapidly and in time, reaches the pulp of the tooth. The prevalence of dental caries in permanent teeth for adolescents ages 12 to 19 remains high at 56.8%, even though there is an increased use

(48.1%) of sealants on permanent teeth in this age group. Adults ages 20 to 64 years have an 89.9% prevalence of dental caries in permanent teeth; however, only 26.1% of adults have untreated tooth decay in permanent teeth. Older adults (65 years and older) present with a 96.2% prevalence of dental caries, with 15.9% of their tooth decay untreated (Centers for Disease Control and Prevention [CDC], 2019). Older adults are subject to decay from drug-induced or age-related oral dryness (see Chart 39-1).

TABLE 39-1 Disorders of the Lips, Mouth, and Gums

Condition	Signs and Symptoms	Possible Causes and Sequelae	Nursing Considerations
Abnormalities of the Lips			
Actinic cheilitis	Irritation of lips associated with scaling, crusting, fissure; white hyperkeratosis (overgrowth of horny layer of epidermis) Considered a premalignant squamous cell skin cancer	Exposure to sun; more common in fair-skinned people and in those whose occupations involve sun exposure, such as farmers Chronic inflammatory lesion that may lead to squamous cell cancer of the lip	Educate patient on importance of protecting lips from the sun by using protective ointment such as sun block. Instruct patient to have a periodic checkup by primary provider.
Chancre	Reddened circumscribed lesion that ulcerates and becomes crusted	Primary lesion of syphilis	Use comfort measures such as cold soaks to lip, mouth care. Administer antibiotics as prescribed. Instruct patient regarding contagion. Use topical over-the-counter agents (e.g., Blistex, Carmex) or antiviral agents (e.g., acyclovir, penciclovir) as prescribed.
Contact dermatitis (i.e., allergic contact cheilitis)	Red area or rash; itching	Allergic reaction to lipstick, cosmetic ointments, or toothpaste	Instruct patient to avoid possible causes. Administer corticosteroids as prescribed.
Herpes simplex virus-1 (cold sore or fever blister)	Symptoms may be delayed up to 20 days after exposure; singular or clustered, irregular, painful vesicles throughout the oral cavity and lips that may rupture	An opportunistic infection; frequently seen in patients who are immunosuppressed May recur with menstruation, fever, or sun exposure	Use acyclovir ointment or systemic medications as prescribed. Administer analgesic agents as prescribed. Instruct patient to avoid irritating foods.
Abnormalities of the Mouth			
Aphthous stomatitis (canker sore) (Classified as *major* or *minor* depending upon size)	Shallow ulcer with a white or yellow center and typically a well-defined red border; seen on the inner side of the lip and cheek or on the tongue; it begins with a burning or tingling sensation and slight swelling; painful; usually lasts 7–10 days (*minor*) and heals without a scar	Immune-mediated inflammatory disorder associated with HIV infection Associated with emotional or mental stress, fatigue, hormonal factors, minor trauma (e.g., biting), allergies, acidic foods and juices, and dietary deficiencies May recur	Instruct the patient in comfort measures (e.g., saline rinses) and a soft or bland diet. Antibiotics or corticosteroids may be prescribed. Use over-the-counter benzocaine as indicated.

Candidiasis (moniliasis/thrush)	Cheesy white plaque that looks like milk curds; when rubbed off, it leaves an erythematous and often bleeding base	*Candida albicans* fungus; predisposing factors include diabetes, antibiotic therapy, and immunosuppression	Antifungal medications such as nystatin or clotrimazole may be prescribed as suspensions or troche; when used as a suspension, instruct the patient to swish vigorously for at least 1 min and then swallow. If these treatments fail, oral agents such as fluconazole may be prescribed.
Ewing sarcoma	Located most commonly on the mandible; initial symptoms include swelling, pain, paresthesia, and dental displacement	Cancer (most often the primary site) that is often initially mistaken for dental infection. Median age at onset is 14 yrs old	Most commonly treated with chemotherapy and surgery, followed by chemotherapy and radiation therapy.
Erythroplakia	Red, velvety, asymptomatic patch on the oral mucous membrane; most commonly located on the mouth floor, the ventral aspect of the tongue, and the soft palate	Nonspecific inflammation with a high risk of malignant transformation More frequently seen in older adults	
Kaposi sarcoma	Appears first on the oral mucosa as a red, purple, or blue lesion; may be singular or multiple; may be flat or raised Lesions can occur in other parts of the body: skin, lymph nodes, lungs, digestive tract	Cancer that develops from the cells that line the blood vessels and lymph system Associated with HIV infection (AIDS), men who are HIV negative and who have sex with men, organ transplantation, and geographic region (Africa, Mediterranean)	Instruct patient regarding side effects of planned treatment for HIV.
Leukoplakia	White patches; may be hyperkeratotic; usually in buccal mucosa; typically painless	Fewer than 2% are malignant, but may progress to cancer (premalignant) Common among tobacco users	Instruct patient to see the primary provider if leukoplakia persists >2 wks. Eliminate risk factors, such as cigarettes, smokeless tobacco.
Oral hairy leukoplakia	White patches with rough hairlike projections; typically found on	Epstein–Barr virus-induced lesion	Instruct patient to see the primary provider if

	lateral border of the tongue	Related to smoking and the use of tobacco Associated with HIV infection	condition persists >2 wks.
Lichen planus	Radiating white, lacelike striations on the tongue and buccal mucosa; often association with painful ulcerations and erythema	Chronic inflammatory condition of unknown cause Recurrences are common May lead to a malignant process	Apply topical corticosteroids such as fluocinolone acetonide gel. Avoid foods that irritate. Administer corticosteroids systemically or intralesionally as prescribed. Instruct the patient of need for follow-up if condition is chronic.
Nicotine stomatitis (smoker's patch)	Two stages—begins as a red stomatitis; over time, the tongue and mouth become covered with a creamy, thick, white mucous membrane, which may slough, leaving a beefy red base	Chronic irritation by tobacco	Cessation of tobacco use; if condition exists >2 wks, a primary provider should be consulted and a biopsy may be needed.
Stomatitis	Mild erythema and edema; severe forms include painful ulcerations, bleeding, and secondary infection	Inflammation of the mucous lining of the mouth Associated with chemotherapy; radiation therapy; severe drug allergy; myelosuppression (bone marrow depression)	Prophylactic mouth care, including brushing, flossing, and rinsing, for any patient receiving chemotherapy or radiation therapy. Educate patient about proper oral hygiene, including the use of a soft-bristled toothbrush and nonabrasive toothpaste; for painful ulcers, oral swabs with spongelike applicators can be used in place of a toothbrush; avoid alcohol-based mouth rinses and hot or spicy foods. Apply topical anti-inflammatory, antibiotic, and anesthetic agents as prescribed.
Abnormalities of the Gums			
Gingivitis	Painful, inflamed, swollen gums; usually, the gums bleed in response to light contact	Reversible form of inflammation of the gingiva (i.e., mild	Educate patient about proper oral hygiene; tooth-brushing, flossing, rinsing (i.e.,

		form of periodontal disease) Associated with poor oral hygiene: food debris, bacterial plaque, and calculus (tartar) accumulate Gums may also swell in response to normal processes such as puberty and pregnancy, with certain medications (phenytoin, calcium channel blockers, cyclosporine), or with a deficiency in the immune system (i.e., AIDS) or nutritional status	chlorhexidine), dental appointments every 3–6 mo. Remove causal agents as appropriate—medications, smoking, dental appliances.
Herpetic gingivostomatitis	Burning sensation with the appearance of small vesicles 24–48 h later; vesicles may rupture, forming sore, shallow ulcers covered with a gray membrane	Herpes simplex viral infection Occurs most frequently in people who are immunosuppressed; may occur in other infectious processes such as streptococcal pneumonia, meningococcal meningitis, and malaria	Apply topical anesthetics as prescribed; may need opioids if pain is severe. Saline or 2–3% hydrogen peroxide irrigations Antiviral agents such as acyclovir may be prescribed.
Necrotizing gingivitis (trench mouth)	Gray-white pseudomembranous ulcerations affecting the edges of the gums, mucosa of the mouth, tonsils, and pharynx; halitosis; painful, bleeding gums; swallowing and talking are painful	Progressive, painful bacterial infection Related to poor oral hygiene, lack of access to dental care, inadequate rest, overwork, emotional stress, smoking, and poor nutrition	Educate patient about proper oral hygiene; see Chart 39-2. Irrigate with 2–3% hydrogen peroxide or normal saline solution. Avoid irritants such as smoking and spicy foods.
Periodontitis	Little discomfort at onset; may have bleeding, infection, gum recession, and loosening of teeth; later in the disease, tooth loss may occur	Deep, chronic inflammation of the gingiva May result from untreated gingivitis Poor or inadequate dental hygiene and inadequate diet contribute to development	Instruct patient in proper oral hygiene, chlorhexidine rinses. Instruct patient to consult a dentist or periodontist for antibiotic prescription, deep root scaling.

AIDS, acquired immune deficiency syndrome; HIV, human immune deficiency virus.

Chart 39-1

Oral Conditions in the Older Adult

Many medications taken by older adults cause dry mouth, which is uncomfortable, impairs communication, and increases the risk of oral infection. These medications include the following:

- Antidepressant medications
- Antihypertensive medications
- Anti-inflammatory agents
- Diuretic agents

Poor dentition can exacerbate problems of aging, such as:

- Decreased food intake
- Increased susceptibility to systemic infection (from periodontal disease)
- Loss of appetite
- Social isolation
- Trauma to the oral cavity secondary to thinner, less vascular oral mucous membranes

Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Philadelphia, PA: Wolters Kluwer.

Dentists can determine the extent of damage and the type of treatment needed using x-ray studies. Treatment for dental caries includes fillings, dental implants, or extraction, if necessary. In general, dental decay can occur in anyone.

Prevention

Measures used to prevent and control primary dental caries include applying fluoride varnish/gel (Marinho, Worthington, Walsh, et al., 2015), using fluoride toothpaste, use of silver diamine fluoride compounds (Donovan, Marzola, Murphy, et al., 2018), applying dental sealants (Twetman, 2015), and ensuring community water fluoridation (HHS, 2000; HHS Federal Panel on Community Water Fluoridation, 2015). Other recommendations include implementing daily oral hygiene practices, seeking routine professional dental treatment, refraining from smoking and excessive alcohol use, making good dietary choices, and managing related systemic diseases (HHS, 2019). The inability to afford dental care is associated with a decrease in the quality of life of adults ages 45 years and older (Naavaal, Griffin, & Jones, 2019), which must be considered when assisting patients in navigating health care systems.

Mouth Care

Healthy teeth must be cleaned several times a day. Brushing and flossing are particularly effective in mechanically breaking up the bacterial plaque that collects around teeth.

Mastication (chewing) and the normal flow of saliva also aid greatly in keeping the teeth clean. Because many ill patients do not consume adequate nutrients, they produce less saliva, which in turn reduces this natural tooth-cleaning process. The nurse may need to assume the responsibility for brushing the patient's teeth. Merely wiping the patient's mouth and teeth with a swab is ineffective. The most effective method is mechanical cleansing (brushing). If brushing is not possible, it is better to wipe the teeth with a gauze pad and then have the patient swish an antiseptic mouthwash several times before expectorating into an emesis basin. A soft-bristled toothbrush is more effective than a sponge or foam stick. Flossing should be performed daily. To prevent drying, the lips may be coated with a water-soluble gel.

Diet

Dental caries may be prevented by decreasing the amount of sugar and starch in the diet. Patients who snack should be encouraged to choose less cariogenic alternatives, such as fruits, vegetables, nuts, cheeses, or plain yogurt. Brushing after meals is recommended.

Fluoridation

Fluoridation of public water supplies has been found to decrease dental caries. Some areas of the country have natural fluoridation; other communities have added fluoride to public water supplies. As of 2014, 66.3% of Americans receive fluoridated water (CDC, 2020b). Studies suggest that by instituting a community water fluoridation program, tooth decay is reduced by 25% in both children and adults (CDC, 2018).

Fluoridation may also be achieved by having a dentist apply a concentrated gel or solution to the teeth; adding fluoride to home water supplies; using fluoridated toothpaste or mouth rinse; or using sodium fluoride tablets, drops, or lozenges.

Pit and Fissure Sealants

The occlusal surfaces of the teeth have pits and fissures—areas that are prone to caries. Some dentists apply a coating to fill and seal these areas on the primary and permanent molars to protect them from potential exposure to cariogenic processes. These sealants can last 36 to 48 months and significantly prevent tooth decay. The economic benefits of applying sealants, especially in high-risk groups, exceed the costs and provide solid evidence for their use (Donovan et al., 2018).

Dental Health and Disease

Studies are ongoing that show the link between oral health and chronic disease such as diabetes, heart disease, low birth weight, premature births, and stroke. It had long been posited that bacteria, specifically gram-negative bacteria, were the culprits that link periodontal disease to other systemic diseases, specifically coronary artery disease, including myocardial infarction and stroke. More recently, it was confirmed that these bacteria cause an inflammatory response that initiates an increase in inflammatory markers such as C-reactive protein, white blood cells, and fibrinogen. These markers are associated with an increased risk of cardiovascular disease. Data from short-term studies suggest that if periodontal disease is treated, systemic inflammation and endothelial dysfunction are reduced (Hegde & Awan, 2019). One study reported that thrombus

aspirate and arterial blood taken from patients who had an ischemic stroke contained streptococcal bacteria. The most commonly identified *Streptococcus* species (found in 79% of the sample), *Streptococcus mitis*, is typically found in the mouth. Although a preliminary study, there is evidence that these oral bacteria may contribute to the progression of cardiovascular thrombotic events (Patrakka, Pienimäki, Tuomisto, et al., 2019).

The World Health Organization (WHO) Global Oral Health Programme (2019) espouses a global focus on oral health promotion and disease prevention, with an emphasis on policy and guideline development to support equitable implementation of evidence-based practices in global communities. The Programme supports an emphasis on addressing modifiable risk factors (e.g., diet, nutrition, tobacco, alcohol, and oral hygiene), water sanitation, and fluoride initiatives. Initiatives recognize the impact of social, economic, political, and cultural determinants of health, and seek to integrate the existing and emerging systems that address the burden and disability that stem from oral disease (WHO, 2019).

Periapical Abscess

A **periapical abscess**, more commonly referred to as an abscessed tooth, involves a collection of pus in the apical dental periosteum (fibrous membrane supporting the tooth structure) and the tissue surrounding the apex of the tooth (where it is suspended in the jaw bone). The abscess may be acute or chronic. An acute periapical abscess arises from an infection, usually secondary to dental caries. The infection of the dental pulp extends through the apical foramen of the tooth to form an abscess around the apex.

A chronic periodontal abscess occurs from a slowly progressive infectious process. In contrast to the acute form, a fully formed abscess may occur without the patient's knowledge. The infection eventually leads to a "blind dental abscess," which is actually a periapical granuloma. It may enlarge to as much as 1 cm in diameter. It is often discovered on x-ray images and is treated by extraction or root canal therapy, often with apicoectomy (excision of the apex of the tooth root).

Clinical Manifestations

The abscess produces a dull, gnawing, continuous pain, often with a surrounding cellulitis and swelling of the adjacent facial structures, temperature sensitivity, and mobility of the involved tooth. The gum opposite the apex of the tooth is usually swollen on the cheek side. Swelling and cellulitis of the facial structures may make it difficult for the patient to open the mouth. There may also be a systemic response, fever, and malaise.

Medical Management

In the early stages of an infection, a dentist or oral surgeon may perform a needle aspiration or drill an opening into the pulp chamber to relieve pressure and pain and to provide drainage. Drainage is provided by an incision through the gingiva down to the jawbone. Purulent material escapes under pressure. This procedure may be performed in a dentist's office, an outpatient surgery center, or a same-day surgery department. After the inflammatory reaction has subsided, the tooth may be extracted or root canal therapy

performed. Antibiotics, in the presence of overt spreading infection, and analgesics may be prescribed (Robertson, Keys, Rautemaa-Richardon, et al., 2015).

Nursing Management

The patient is assessed for bleeding after treatment and is instructed to use a warm saline or warm water mouth rinse to keep the area clean. The patient is also instructed to take antibiotic and analgesic agents as prescribed, to advance from a liquid diet to a soft diet as tolerated, and to keep follow-up appointments.

DISORDERS OF THE JAW

Abnormal conditions affecting the mandible (jaw) and the temporomandibular joint (which connects the mandible to the temporal bone at the side of the head in front of the ear) include congenital malformation, fracture, chronic dislocation, cancer, and syndromes characterized by pain and limited motion. Temporomandibular disorders and jaw surgery, a treatment common in many structural abnormalities or cancer of the jaw, are presented in this section.

Temporomandibular Disorders

Temporomandibular disorders are categorized as follows (National Institute of Dental and Craniofacial Research [NIDCR], 2018):

- Myofascial pain—a discomfort in the muscles controlling jaw function and in neck and shoulder muscles
- Internal derangement of the joint—a dislocated jaw, a displaced disc, or an injured condyle
- Degenerative joint disease—rheumatoid arthritis or osteoarthritis in the jaw joint

Diagnosis and treatment of temporomandibular disorders remain somewhat ambiguous, but the condition is thought to affect about 10 million people in the United States (NIDCR, 2018). Misalignment of the joints in the jaw and other problems associated with the ligaments and muscles of mastication are thought to result in tissue damage and muscle tenderness. Suggested causes include arthritis of the jaw, head injury, trauma or injury to the jaw or joint, stress, and malocclusion, although research does not support malocclusion (misalignment of bite) or associated orthodonture as a cause (NIDCR, 2018).

Clinical Manifestations

Patients have jaw pain ranging from a dull ache to throbbing, debilitating pain that can radiate to the ears, teeth, neck muscles, and facial sinuses. They often have restricted jaw motion and locking of the jaw. There also may be a sudden change in the way the upper and lower teeth fit together. The patient may hear clicking, popping, and grating sounds when the mouth is opened, and chewing and swallowing may be difficult. Symptoms such as headaches, earaches, dizziness, and hearing problems may sometimes be related to temporomandibular disorders (Gauer & Semidey, 2015; NIDCR, 2018).

Assessment and Diagnostic Findings

Diagnosis is based on the patient's report of pain, limitations in range of motion, **dysphagia** (difficulty swallowing), difficulty chewing, difficulty with speech, or hearing difficulties. Magnetic resonance imaging (MRI) and other imaging studies are generally only used for severe or chronic symptoms.

Medical Management

Signs and symptoms improve over time for the majority of patients with temporomandibular joint disorders, with or without treatment. Conservative treatment is recommended (NIDCR, 2018). Most patients improve with a combination of simple noninvasive therapies that may include: (1) patient education on self-care—eating soft foods, icing the jaw; (2) cognitive behavior modifications—stress reduction, sleep hygiene, avoidance of extreme mandibular movement, and elimination of habits such as chewing ice; (3) physical therapy—stretching and relaxing; (4) acupuncture—highly effective with six to eight 15- to 30-minute sessions; (5) psychosocial interventions; (6) analgesics—trial of nonsteroidal anti-inflammatory drugs (NSAIDs) and muscle relaxants initially; and (7) oral appliance therapy—splints (Gauer & Semidey, 2015; NIDCR, 2018).

Jaw Disorders Requiring Surgical Management

Correction of mandibular structural abnormalities may require surgery involving repositioning or reconstruction of the jaw. Simple fractures of the mandible without displacement, resulting from a blow to the chin, and planned surgical interventions, as in the correction of long or short jaw syndrome, may require wiring or surgery. Jaw reconstruction may be necessary in the aftermath of trauma from a severe injury or cancer, both of which can cause tissue and bone loss. Research supports screening for concussion (see Chapter 63) with mandibular fractures associated with high-force impacts (Sobin, Kopp, Walsh, et al., 2016). Cervical spine injury must be ruled out since 2% to 10% of patients with facial fractures (up to 20% with panfacial injuries) also have a spinal injury (Pickrell, Serebrakian, & Maricevich, 2017).

Mandibular fractures are usually closed fractures. In the acute trauma setting, surgery providers should assess the patient's perception of the bite ("bite feels normal") for malocclusion, the fracture site for fragment mobility, dentition for loose or infected teeth, and sensation in the lower lip for nerve damage. When the dentition is sufficient and the fracture is isolated, maxillomandibular fixation (MMF; wiring the jaw shut) is a viable option. However, open reduction, internal fixation (ORIF) with plate fixation (insertion of one or more metal plates and screws or arch bars into the bone to approximate and stabilize the bone) is the surgery of choice (Pickrell et al., 2017). Current research revolves around the use of various types and number of reconstruction plates and fixation devices, quality of life after specific instrumentation, approach used (ORIF or endoscopic-assisted), and device choice (van den Bergh, de Mol van Otterloo, van der Ploeg, et al., 2015). Bone grafting may be performed to replace structural defects using bones from the patient's own ilium, ribs, or cranial sites.

Nursing Management

If used, MMF generally requires a short period (7 to 10 days) of a liquid diet and oral rinses followed by rehabilitation and a soft diet. After ORIF, patients are typically on a liquid or soft diet for 4 to 6 weeks to allow for healing. The most common complications are infection that may progress to osteomyelitis (infection of the bone), alignment issues or hardware failure (requiring surgical repair or MMF), and wound dehiscence (Pickrell et al., 2017). Dietary counseling is provided to ensure adequate protein intake with supplementation as needed. Oral care, including the use of medicated rinses, needs to be reinforced. To decrease the risk of complications, patients are advised to take prescribed medications and to abstain from smoking, use of electronic nicotine delivery systems (ENDS), including e-cigarettes, e-pens, e-pipes, e-hookah and e-cigars and use of alcohol and other substances. Regular follow-up with the surgeon is required to ensure healing is progressing.

DISORDERS OF THE SALIVARY GLANDS

The salivary glands consist of the parotid glands, one on each side of the face below the ear; the submandibular glands, located below the jawbone; the sublingual glands, in the floor of the mouth under the tongue; and the minor salivary glands in the lips, buccal mucosa, and the lining of the mouth and throat. About 1500 mL of saliva is produced daily and swallowed. The major functions of the salivary glands include lubrication, protection against harmful bacteria, and digestion.

Parotitis

Parotitis (inflammation of the parotid gland) is the most common inflammatory condition of the salivary glands. Inflammation of the parotid may be due to mumps (epidemic parotitis), a communicable disease caused by viral infection and most commonly affecting unvaccinated children (Grennan, 2019).

People who are older, acutely ill, or debilitated with decreased salivary flow from general dehydration or medications are at high risk for bacterial parotitis. The infecting organism, typically *Staphylococcus aureus,* travels from the mouth through the salivary duct. The onset of parotitis is sudden and associated with fever, chills, and other systemic signs of infection. The gland swells and becomes tense and tender. The patient feels pain in the ear, and swollen glands interfere with swallowing. The swelling increases rapidly, and the overlying skin soon becomes red and shiny.

Medical management includes maintaining adequate nutritional and fluid intake, good oral hygiene, applying cold packs, and discontinuing medications (e.g., tranquilizers, diuretic agents) that can diminish salivation. Antibiotic therapy is necessary for bacterial parotitis, and analgesics may be prescribed to control pain. If antibiotic therapy is not effective, the gland may need to be drained by a surgical procedure known as parotidectomy. This procedure may be necessary to treat chronic parotitis. The patient is advised to have any necessary dental work performed prior to surgery.

Sialadenitis

Sialadenitis (inflammation of the salivary glands) may be caused by dehydration, radiation therapy, stress, malnutrition, salivary gland calculi (stones; sialolithiasis), or

improper oral hygiene. The inflammation is commonly associated with infection by *S. aureus*, which requires antibiotic therapy. In hospitalized or institutionalized patients, the infecting organism may be methicillin-resistant *S. aureus* (MRSA). Symptoms include pain, swelling, and purulent discharge. Massage, hydration, warm compresses, and sialagogues (substances that trigger saliva flow like hard candy or lemon juice) frequently cure the problem. Chronic sialadenitis is typically due to decreased salivary flow and may be treated with sialendscopy, an endoscopic procedure that allows for direct visualization of Stensen duct (diagnostic) and instillation of antibiotics, corticosteroids, or irrigation (treatment), particularly in adolescents with recurrent parotitis (Papadopoulou-Alataki, Dogantzis, Chatziavramidis, et al., 2019). Surgical drainage or excision of the gland and its duct are considered in cases of sialadenitis that are recurrent or refractory to antibiotics.

Salivary Calculus (Sialolithiasis)

Sialolithiasis, or salivary calculi (stones), occur in 80% of cases in the submandibular gland (Fabie, Kompelli, Naylor, et al., 2019). Calculi within the salivary gland itself may cause no symptoms unless infection arises; however, a calculus that obstructs the gland's duct causes swelling and sudden, local, and often colicky pain, which is abruptly relieved by a gush of saliva. On physical assessment, the gland is swollen and quite tender, the stone itself may be palpable, and may be visualized by ultrasound, noncontrast computed tomography (CT), or sialendoscopy.

Salivary calculi are formed mainly from calcium phosphate. If located within the gland, the calculi are irregular and vary in diameter from 1 to 35 mm. Sialendoscopy is considered the standard in the treatment of sialothiasis, but gland-preserving incisional approaches alone may also be used for palpable stones 6 mm or larger (Fabie et al., 2019). **Lithotripsy**, a procedure that uses shock waves to disintegrate the stone, may be used instead of surgical extraction for parotid stones and smaller submandibular stones. Lithotripsy requires no anesthesia, sedation, or analgesia. Side effects can include local hemorrhage and swelling. Gland removal may be necessary if symptoms and calculi recur repeatedly.

Neoplasms

Salivary gland neoplasms (tumors or growths) of almost any type may develop in the salivary gland. Malignant (cancerous) salivary gland neoplasms account for more than 0.5% of all malignancies and approximately 3% to 5% of head and neck cancers (National Cancer Institute [NCI], 2021d). Risk factors include prior exposure to ionizing radiation to the head and neck, older age, and specific carcinogens introduced in specific work environments (asbestos, plumbing, and woodworking). Most patients with a benign tumor present with painless swelling of the glands; patients with a malignancy tend to have neurologic symptoms (weakness or numbness of the facial nerve) and persistent facial pain (NCI, 2021d). Diagnosis is based on the health history, physical examination, and the results of fine-needle aspiration biopsy.

Early-stage salivary gland tumors are usually curable with surgery alone. Dissection is carefully performed to preserve the seventh cranial nerve (facial nerve). It may not be possible to safely dissect if the tumor is extensive. Complications from surgery may

involve facial nerve dysfunction and Frey syndrome. Frey syndrome, also known as auriculotemporal syndrome, involves facial sweating and flushing in the general location of the (removed) parotid gland that occurs while eating. Frey syndrome may be successfully treated with botulinum toxin type A injections (NCI, 2021d). If the salivary gland tumor is malignant, radiation therapy may follow surgery. Radiation therapy alone may be a treatment choice for tumors thought to be localized or if there is risk of facial nerve damage from surgical intervention. Chemotherapy may be considered in late stages, but due to the many different subtypes of salivary gland cancer, tumor mapping, including immunohistochemistry and genomic profiling, should be used to optimize treatment (Lassche, van Boxtel, Ligtenberg, et al., 2019). Recurrent tumors usually are more aggressive than initial tumors.

CANCER OF THE ORAL CAVITY AND PHARYNX

Cancers of the oral cavity and pharynx, which can occur in any part of the mouth or throat, are curable if discovered early. Risk factors for cancer of the oral cavity and pharynx include any use of any form of tobacco or nicotine (cigarette, cigar, pipe, smokeless tobacco, ENDS), excessive use of alcohol, infection with human papillomavirus (HPV), and a history of previous head and neck cancer (NCI, 2021b). Oral cancers are often associated with the combined use of alcohol and tobacco—these substances have a synergistic carcinogenic effect. Patient education directed toward avoiding high-risk behaviors is critical to prevent oral cancers.

In the United States, approximately 53,000 new cases of oral cavity and oropharyngeal cancer occur annually, with an estimated 10,860 deaths. Men are diagnosed with oral and oropharyngeal cancer in almost 72% of diagnosed cases (Siegel, Miller, & Jemal, 2019). Despite a rise in rates associated with HPV over the past 10 years (0.8% rise each year), patients with cancer of the oral cavity and oropharynx have a relatively stable 5-year survival rate of 65.3% (NCI, 2021b; Siegel et al., 2019).

Pathophysiology

Malignancies of the oral cavity are usually squamous cell carcinomas (NCI, 2021c). Any area of the oropharynx can be a site of malignant growths, but the lips, the lateral aspects of the tongue, and the floor of the mouth are most commonly affected. High-risk HPV infection is associated with about 70% of oropharyngeal cancers. Vaccination against HPV shows promise in impacting rates of head and neck cancer. A study of young adults in the United Stated found oral HPV infections (including the two high-risk, cancer-causing types 16 and 18) were 88% lower among young adults who received at least one dose of the vaccine (NCI, 2017).

Clinical Manifestations

Many oral cancers produce few or no symptoms in the early stages. Later, the most frequent symptom is a painless sore or lesion that bleeds easily and does not heal. Oral cancer may also present as a red or white patch (leukoplakia) in the mouth or throat. A typical lesion in oral cancer is a painless indurated (hardened) ulcer with raised edges. Depending on the location (tonsil, base of the tongue, soft palate, or pharyngeal wall), the patient may report tenderness, difficulty in chewing, swallowing, or speaking, coughing

of blood-tinged sputum, trismus (limited jaw range of motion), weight loss, a neck mass, or enlarged cervical lymph nodes (NCI, 2021c).

Assessment and Diagnostic Findings

Diagnostic evaluation consists of an oral examination as well as an assessment of the cervical lymph nodes to detect possible metastases. Positron emission tomography-computed tomography scan (PET-CT scan), MRI, endoscopy, laryngoscopy, and biopsy, including testing of HPV status may be used to detect and guide therapy (NCI, 2021c).

Human Papillomavirus Prevention

HPV vaccine is generally recommended for all children ages 11 or 12 (can be started at age 9), up to the age of 26 years for women and 21 years for men. Men who have sex with men, transgender men and women, and immunocompromised people, including those with human immune deficiency virus (HIV), may receive the vaccine up to 26 years of age (CDC, 2020a).

Medical Management

In patients diagnosed with oropharyngeal cancer, management varies with the nature of the lesion, the preference of the provider, and patient choice. Surgical resection and chemoradiation (CRT) are associated with improved survival for all adults over age 70, including those who are positive for HPV infection (Lu, Luu, Nguyen, et al., 2019).

In cancer of the lip, small lesions are usually excised liberally. Radiation therapy may be more appropriate for larger lesions involving more than one third of the lip because of superior cosmetic results. The choice depends on the extent of the lesion and what is necessary to cure the patient while preserving the best appearance. Tumors larger than 4 cm often recur.

In cancer of the tongue, treatment with radiation therapy and chemotherapy may preserve function and maintain quality of life. A combination of radioactive interstitial implants (surgical implantation of a radioactive source into the tissue adjacent to or at the tumor site) and external-beam radiation may be used. Total glossectomy (removal of the tongue) remains the principal treatment of advanced stage or cancers at the base of the tongue; long-term data on functional outcomes following these procedures are being studied (Han, Kuan, Mallen-St. Clair, et al., 2019).

Often, cancer of the oral cavity has metastasized through the extensive lymphatic channel in the neck region, requiring a neck dissection and reconstructive surgery of the oral cavity. Reconstructive techniques involve the use of the traditional pedicled (attached and tunneled) regional tissue flaps (graft of tissue with its own blood supply) or the current mainstay of free (cut and removed) tissue transfer most commonly obtained from the pectoralis major, vertical rectus abdominis myocutaneous, anterolateral thigh, fibula, or radial forearm. Laryngeal preservation is associated with better speech and verbal communication, but swallowing and aspiration issues remain common functional deficits with total glossectomy and free flap reconstruction (Han et al., 2019).

Nursing Management

The nurse assesses the patient's nutritional status preoperatively, and a dietary consultation may be necessary. The patient may require enteral (through the GI tract) or parenteral (intravenous [IV]) feedings before and after surgery to maintain adequate nutrition (see Chapter 41). The interprofessional team, including a registered dietician (RD), provides continual nutritional assessment and reevaluation.

Verbal communication may be impaired by radical surgery for oral cancer, especially if the larynx is removed. It is therefore vital to assess the patient's ability to communicate in writing before surgery. Pen and paper are provided postoperatively to patients who can use them to communicate. A communication board with commonly used words or pictures is obtained preoperatively and given after surgery to patients who cannot write so that they may point to needed items. Electronic devices, such as tablets or smartphones, may also be options for facilitating communication. The interprofessional team benefits from the input of a speech therapist, with physical and occupational therapists consulted as needed.

Postoperatively, the priority for the nurse is assessing for and maintaining a patent airway. The patient may be unable to manage oral secretions, making suctioning necessary. If grafting was part of the surgery, suctioning is performed with care to prevent damage to the graft. Nurses assess the graft postoperatively for viability. Although color should be assessed (white may indicate arterial occlusion, and blue mottling may indicate venous congestion), it can be difficult to assess the graft by looking into the mouth. A Doppler ultrasound device may be used to locate the pulse at the graft site and to assess tissue perfusion. Depending on the extent of the surgery, the patient may require a temporary or permanent tracheostomy after surgery (see Chapter 19).

NURSING MANAGEMENT OF THE PATIENT WITH DISORDERS OF THE ORAL CAVITY

The nurse caring for the patient with disorders of the oral cavity promotes mouth care, ensures adequate food and fluid intake, minimizes pain and discomfort, and prevents infection.

Promoting Mouth Care

Incidences of oral complications, such as infection, during cancer therapy may be decreased and less severe with the incorporation of professional oral care before and during cancer treatment. Guidelines, based on systematic review of the literature, support the implementation of multi-agent combination oral care protocols in patients undergoing head and neck chemotherapy and radiotherapy (radiation therapy) to prevent oral mucositis (OM), a painful inflammatory, typically ulcerative condition that is also referred to as **stomatitis**. Although there are limited data, experts recognize that using saline or sodium bicarbonate rinses increases oral clearance, promotes oral hygiene, and promotes patient comfort (Hong, Gueiros, Fulton, et al., 2019). The nurse facilitates the patient rinsing or irrigating with a solution of ½ to 1 teaspoon of baking soda (or ¼-teaspoon salt) in 8 oz of warm water. The nurse reinforces the need to perform oral care and provides such care to patients who cannot provide it for themselves. Chlorhexidine has been studied more rigorously than other rinses and is generally not recommended for the prevention of OM, specifically not for patients undergoing head and neck radiotherapy (Hong et al., 2019). There is continued debate about the efficacy of *magic mouthwash*, particularly for chemotherapy-induced OM. The recipe for the mouthwash

varies and frequently involves out-of-pocket expense for the patient, but most commonly contains diphenhydramine, aluminum-magnesium hydroxide, and viscous lidocaine, with intended mechanism of action to both numb and protect the mouth. More research needs to be done on OM treatment and prevention (Uberoi, Brown, & Gupta, 2019a, 2019b).

Exciting developments regarding intra-oral photobiomodulation (PBM), specifically low-level laser therapy, show positive impact on the prevention of OM in patients with head and neck cancer undergoing radiotherapy with and without chemotherapy (Hong et al., 2019). If specific antimicrobial, antifungal, antibacterial, or antiviral agents are indicated (Maria, Eliopoulos, & Muanza, 2017), the nurse administers the prescribed medications and instructs the patient on how to administer the medications at home. The nurse monitors the patient's physical and psychological response to treatment.

Xerostomia (dryness of the mouth) is a frequent sequela of oral cancer, particularly when the salivary glands have been exposed to radiation or major surgery. It is also seen in patients who are receiving psychopharmacologic agents, taking multiple medications, or using drugs recreationally; in patients who have rheumatic diseases, eating disorders (Villa, Nordio, & Gohel, 2015) or HIV infection; and in patients who cannot close the mouth and, as a result, breathe through the mouth instead of the nose. Current recommendations to treat xerostomia include sipping water, using oral mucosal lubricants (saliva substitutes topically applied), incorporating the use of newer edible saliva substitutes such as oral moisturizing jelly (OMJ), and taking medications that stimulate saliva production (Nuchit, Lam-ubol, & Paemuang, 2020). The hope is that providing oral moisture increases swallowing ability, and ultimately improves nutritional status for these patients.

Ensuring Adequate Food and Fluid Intake

Determination of nutritional intake goals requires consideration of the patient's weight, age, and level of activity. A daily calorie count may be necessary to determine the exact quantity of food and fluid ingested. This intake should include enteral feedings, oral intake, and supplements. The frequency of intake; presence of symptoms such as oral discomfort/pain, dysphagia, nausea; increased or decreased saliva or mucous production; and changes in taste or smell all impact the typically diminishing food intake seen in these patients. The social aspects of eating, reasonable expectations for the timing and amount of intake, and the importance of supportive people are all important considerations. Recommendations to navigate this challenging time include involving a registered dietician or other health care professional with specific nutritional expertise (Sandmæl, Sand, Bye, et al., 2019). The goal is to help the patient attain and maintain desirable body weight and level of energy, as well as to promote the healing of tissue.

Supporting a Positive Self-Image

A patient who has a disfiguring oral condition or has undergone disfiguring surgery may experience an alteration in self-image. The patient is encouraged to verbalize the perceived and actual change in body appearance and to realistically discuss changes or losses. The nurse offers support while the patient verbalizes fears and negative feelings (withdrawal, depressed mood, anger). The nurse listens attentively and determines the patient's needs and individualizes the plan of care.

The nurse should determine the patient's concerns about relationships with others. Referral to support groups, a psychiatric liaison nurse, a social worker, or a spiritual

advisor may be useful in helping the patient cope with anxieties and fears. The patient's progress toward development of positive self-esteem is documented. The nurse should be alert to signs of effective and ineffective grieving and should document emotional changes. By providing acceptance and support, the nurse encourages the patient to verbalize feelings.

Minimizing Pain and Discomfort

Oral lesions can be painful. Strategies to reduce pain and discomfort include avoiding foods that are spicy, hot, or hard (e.g., pretzels, nuts). A soft or liquid diet may be preferred. The patient is instructed about mouth care, including the use of a soft toothbrush and any prescribed rinses or topical medications. The patient may require an analgesic agent such as viscous lidocaine or opioids, as prescribed. The nurse can reduce the patient's fear of pain by providing information about pain control methods.

Preventing Infection

Leukopenia (a decrease in white blood cells) may result from radiation, chemotherapy, acquired immune deficiency syndrome (AIDS), and some medications used to treat HIV infection. Leukopenia reduces defense mechanisms, increasing the risk of infections. Malnutrition, which is also common among these patients, may further decrease resistance to infection. If the patient has diabetes, the risk of infection is further increased.

Laboratory results should be evaluated frequently and the patient's temperature checked every 4 to 8 hours for an elevation that may indicate infection. Visitors who might transmit microorganisms are prohibited if the patient's immunologic system is depressed. Sensitive skin tissues are protected from trauma to maintain skin integrity and prevent infection. Aseptic technique is necessary when changing dressings. Desquamation (shedding of the epidermis) is a reaction to radiation therapy that can lead to a break in skin integrity and subsequent infection. Dry desquamation can be treated with topical lotions, but wet desquamation requires individualized treatment (see Chapter 12). Signs of wound infection (redness, swelling, drainage, tenderness) are reported to the primary provider. Antibiotics may be prescribed prophylactically.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient who is recovering from treatment of an oral disorder is instructed about mouth care, nutrition, prevention of infection, and signs and symptoms of complications (see Chart 39-2). Methods of preparing nutritious foods that are seasoned according to the patient's preference and at the preferred temperature are explained to the patient and family. For some patients, it may be more convenient (but also more expensive) to use commercial baby foods than to prepare liquid and soft diets. The patient who cannot take foods orally may receive enteral or parenteral nutrition; the nurse should demonstrate administration techniques and facilitate a return demonstration by the patient and/or caregiver(s).

Chart 39-2 HOME CARE CHECKLIST

The Patient with an Oral Disorder

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the oral disorder and treatment on communication and other physiologic functioning, ADLs, IADLs, body image, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., utilizing durable medical equipment, employing a home health aide) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Describe ongoing therapeutic regimen, including diet and activities to perform (e.g., oral care, suctioning) and to limit or avoid (e.g., oral foods if NPO).
  - Identify foods or therapies necessary to meet caloric needs and dietary needs (e.g., change in consistency, seasoning limitations, supplements, enteral or parenteral therapy).
  - Participate in prescribed therapy (e.g., speech therapy) to promote recovery and rehabilitation.
  - Demonstrate the use of suction equipment if indicated.
  - Demonstrate use of humidification if indicated.
  - Demonstrate effective oral hygiene.
  - Demonstrate care of incision as appropriate.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- Identify possible complications and interventions.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical/dental appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, cancer support, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living; NPO, nothing by mouth.

For patients with oral cancer, instructions are provided in the use and care of any dentures. The importance of keeping dressings clean and the need for conscientious oral hygiene are emphasized.

Continuing and Transitional Care

The need for ongoing care in the home depends on the patient's condition. The patient, family members, and other health care team members responsible for home care (e.g., nurse, speech therapist, registered dietician/nutritionist, and psychologist) work together to prepare an individual plan of care.

If suctioning of the mouth or tracheostomy tube is required, the necessary equipment is obtained and the patient and caregivers are taught how to use it. Considerations include the control of odors and humidification of the home to keep secretions moist. The patient and caregivers are educated to assess for obstruction, hemorrhage, and infection, as well as what actions to take if they occur. The nurse may provide physical care, monitor for changes in the patient's physical status (e.g., skin integrity, nutritional status, respiratory function), and assess the adequacy of pain control measures. The nurse also assesses the patient's and family's ability to manage incisions, drains, and feeding tubes and the use of recommended strategies for communication. The ability of the patient and family to accept physical, psychological, and role changes is assessed and addressed.

Follow-up visits to the primary provider are important to monitor the patient's condition and to determine the need for modifications in treatment and general care. Because patients and their family members, as well as health care providers, tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices and refers them to appropriate practitioners. The nurse also reinforces instructions in an effort to promote the patient's self-care and comfort.

NECK DISSECTION

Deaths from malignancies of the head and neck are primarily attributable to regional metastasis to the cervical lymph nodes in the neck and extra capsular spread, which is a specific characteristic of regional metastasis where the malignant tumor in the lymph node extends into the surrounding connective tissue (Stack & Moreno, 2019). Metastasis, both regional and distant, occurs by way of the lymphatics before the primary lesion has been treated. This regional metastasis is not amenable to surgical resection and responds poorly to chemotherapy and radiation therapy. The cervical lymph nodes are classified as anterior or posterior and divided into anatomic regions/nodal levels for classification (Grègoire, Ang, Budach, et al., 2014; Stack & Moreno, 2019) (see Fig. 39-3).

A radical neck dissection involves removal of all cervical lymph nodes from the mandible to the clavicle and removal of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve on one side of the neck. The associated complications include shoulder drop/dysfunction and poor cosmesis (visible neck depression). Because of the high mortality and known complications, a radical neck dissection is now only performed when the extent and growth pattern of the cancer require aggressive intervention. Modified radical neck dissection, which preserves one or more of the nonlymphatic structures (internal jugular vein, sternocleidomastoid muscle, and the spinal accessory nerve) is used more often. A selective neck dissection (in comparison to a radical neck dissection or modified radical neck dissection) preserves one or more of the lymph node groups that are typically removed in a radical neck dissection. The selective neck dissection is the treatment usually used in oral cavity cancer for patients who are infected with HPV (Sabatini & Chiocca, 2019; Stack & Moreno, 2019) (see Fig. 39-4).

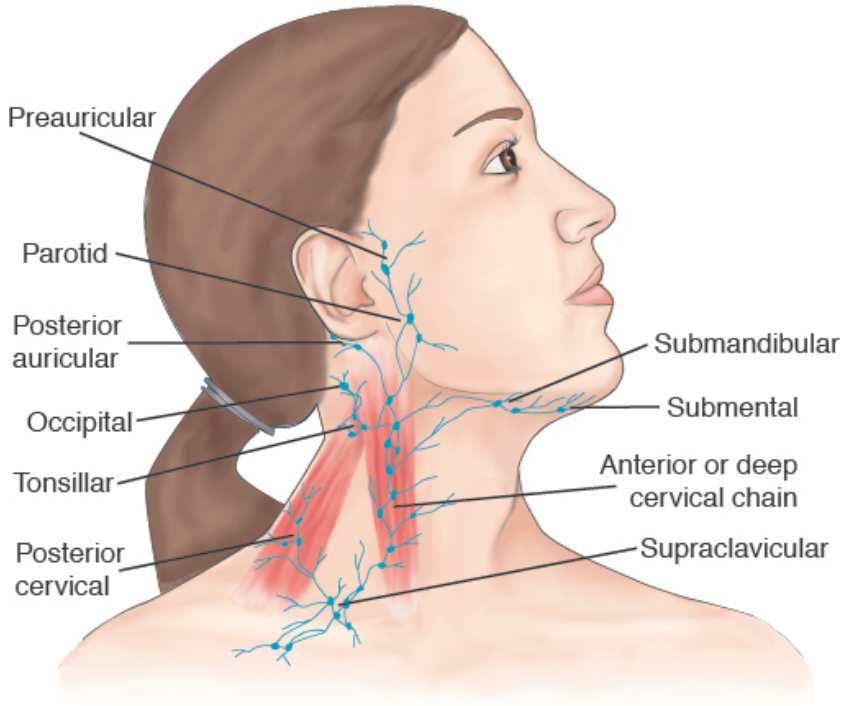

Figure 39-3 • Lymphatic drainage of the head and neck.

Reconstructive techniques may be performed with a variety of grafts. A cutaneous flap (skin and subcutaneous tissue), such as the deltopectoral flap, may be used. A myocutaneous platysma flap (subcutaneous tissue, muscle, and skin) is a more frequently used graft; the pectoralis major muscle is usually used. For large grafts, a microvascular free flap may be used. This involves the transfer of muscle, skin, or bone with an artery and vein to the area of reconstruction, using microinstrumentation. Areas used for a free flap include the scapula, the radial area of the forearm, or the anterolateral thigh (Stack & Moreno, 2019).

NURSING PROCESS

The Patient Undergoing a Neck Dissection

Assessment

Preoperatively, the patient's physical and psychological preparation for major surgery is assessed, along with the patient's knowledge of the preoperative and postoperative procedures. Postoperatively, the patient is assessed for complications such as altered respiratory status, wound infection, and hemorrhage. As healing occurs, nutritional support is provided and neck range of motion is assessed to determine whether there has been a decrease in range of motion due to nerve or muscle damage.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Lack of knowledge about preoperative and postoperative procedures
- Impaired airway clearance associated with obstruction by mucus, hemorrhage, or edema
- Acute pain associated with surgical incision
- Impaired tissue integrity secondary to surgery and grafting
- Impaired nutritional status associated with disease process or treatment
- Risk for situational low self-esteem associated with diagnosis or prognosis
- Risk for caregiver stress associated with physical and emotional effects of disease and related surgical procedure
- Impaired verbal communication secondary to surgical resection
- Impaired mobility secondary to nerve injury

Collaborative Problems/Potential Complications

Potential complications include the following (Stack & Moreno, 2019):

- Hemorrhage, including hematoma formation, and rupture ("blowout") of the internal jugular vein (IJV) or carotid artery
- Chyle leak, a lymphatic leak in the thoracic duct
- Neurologic complications, including stroke and nerve injury (spinal accessory, marginal mandibular, vagus, phrenic, hypoglossal, lingual, brachial plexus)

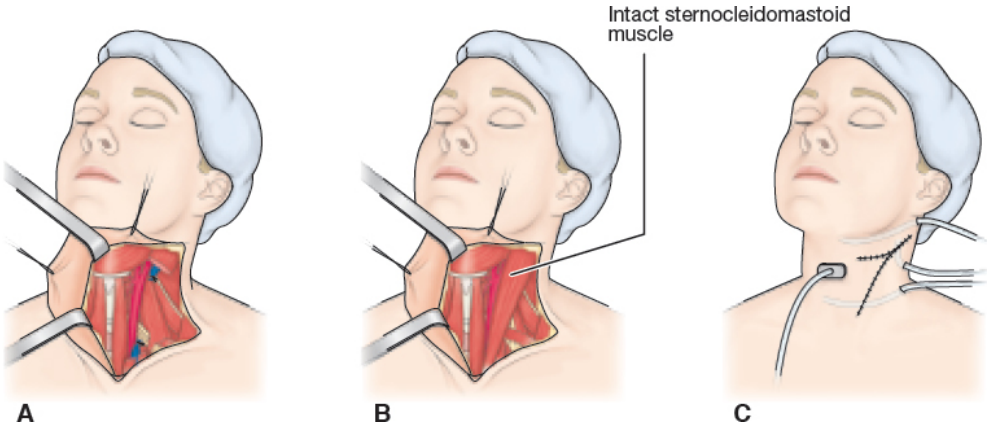

Figure 39-4 • **A.** A classic radical neck dissection in which the sternocleidomastoid and smaller muscles are removed. All tissue is removed, from the ramus of the jaw to the clavicle. The jugular vein has also been removed. **B.** The modified neck dissection is similar, but preserves the sternocleidomastoid muscle, internal jugular vein, and/or spinal accessory nerve. **C.** The wound is closed, and portable suction drainage tubes are in place.

Planning and Goals

The major goals for the patient include increased knowledge of surgical procedure and treatment plan, maintenance of respiratory status, decreased pain, viability of the graft, maintenance of adequate intake of food and fluids, effective coping strategies (for patient and caregivers), effective communication, maintenance of shoulder and neck motion, and absence of complications.

Nursing Interventions

Providing Preoperative Patient Education

Before surgery, the patient should be informed about the nature and extent of the surgery and what to expect in the postoperative period. Preoperative education addresses interventions that cover the entire perioperative period. As part of the informed consent process, the patient should be made aware of the potential/actual risks and benefits of the procedure as well as other treatment options, and the projected outcome if the procedure is not done. The patient is encouraged to ask questions and to express concerns about the upcoming surgery and the expected results. During this exchange, the nurse has an opportunity to assess the patient's coping abilities, answer questions, and develop a plan for offering assistance. A sense of mutual understanding and rapport make the postoperative experience less traumatic for the patient. The patient's expressions of concern, anxieties, and fears guide the nurse in providing support postoperatively.

Providing General Postoperative Care

The general postoperative nursing interventions are similar to those presented in Chapter 16 and are directed toward the identified nursing diagnoses and goals.

Maintaining Airway Clearance

After the endotracheal tube or airway has been removed and the effects of the anesthesia have worn off, the patient may be placed in the Fowler position to facilitate

breathing and promote comfort. This position also increases lymphatic and venous drainage, facilitates swallowing, decreases venous pressure on the skin flaps, and prevents regurgitation and aspiration of stomach contents. If the patient has a tracheostomy, the nurse performs focused assessment and care of the stoma (see Chapter 19). Signs of respiratory distress, such as dyspnea, cyanosis, changes in mental status, and changes in vital signs, are assessed because they may suggest edema, hemorrhage/hematoma formation, inadequate oxygenation, or inadequate drainage.

Quality and Safety Nursing Alert

In the immediate postoperative period, the nurse assesses for stridor (coarse, high-pitched sound on inspiration) by listening frequently over the trachea with a stethoscope. This finding must be reported immediately because it indicates obstruction of the airway.

Pneumonia may occur in the postoperative phase if pulmonary secretions are not removed. To aid in the removal of secretions, coughing and deep breathing are encouraged. With the nurse supporting the neck, the patient should assume a sitting position so that excessive secretions can be coughed up and expectorated. If this is ineffective, the patient's respiratory tract may have to be suctioned. Care is taken to protect the suture lines during suctioning. If a tracheostomy tube is in place, suctioning is performed through the tube. The patient may also be instructed on use of Yankauer suction (tonsil-tip suction) to remove oral secretions. Humidified air or oxygen is provided through the tracheostomy to keep secretions thin. Temperature should not be taken orally.

Relieving Pain

The nurse assesses and manages pain and the patient's fear of pain. Patients with head and neck cancer often report less pain than patients with other types of cancer; however, the nurse needs to be aware that each person's pain experience is different. The nurse works with the patient to establish reasonable pain goals and creates an interprofessional plan to meet those mutually defined goals. Patient-controlled analgesia may be prescribed for postoperative pain management (see Chapters 9 and 16).

Providing Wound Care

Wound drainage tubes are usually inserted during surgery to prevent the collection of fluid subcutaneously. The drainage tubes are connected to a portable suction device (e.g., Jackson-Pratt), and the container is emptied periodically. Between 80 and 120 mL of serosanguineous secretions may drain over the first 24 hours. Excessive drainage may be indicative of a chyle fistula or hemorrhage (see later discussion). Dressings are reinforced as needed and are observed for evidence of hemorrhage and constriction, which impair respiration and perfusion of the graft. A graft, if present, is assessed for color and temperature and for the presence of a pulse, if applicable, to determine viability. The graft should be pale pink and warm to the touch. The surgical incisions are also assessed for signs of infection (purulent, malodorous drainage), which are reported immediately. Prophylactic antibiotics may be prescribed in the early postoperative period. Aseptic technique is used when cleansing skin around the

drains; dressings are changed as prescribed by the surgeon, usually on the second through the fifth postoperative days. Care should be taken to not apply excessive pressure to the surgical site in order to not impair flap perfusion and viability (Hudson & Carr, 2020). If radiation is planned (either with or without chemotherapy), brachytherapy catheters are inserted intraoperatively (Stack & Moreno, 2019).

Maintaining Adequate Nutrition

The interprofessional team assesses the patient's nutritional status preoperatively; early intervention to correct nutritional imbalances may decrease the risk of postoperative complications. Frequently, nutrition is less than optimal because of inadequate intake and nutritional support is required before surgery or the start of radiation due to the psychological stress of the cancer diagnosis, the location of the tumor(s), and diagnostic procedures. Prophylactic nutritional support using a tube feeding is common and may prevent weight loss, reduce fluid imbalances, decrease hospitalizations, and increase treatment tolerance (Sandmæl et al., 2019). Supplements that are nutritionally dense may help reestablish a positive nitrogen balance. They may be taken enterally by mouth, by a nasogastric (NG) feeding tube, or by a gastrostomy feeding tube (see later discussion).

The patient who can chew may take food by mouth; the patient's chewing ability determines whether some diet modification (e.g., soft, puréed, or liquid foods) is necessary. Food preferences should also be discussed with the patient. Oral care before eating may enhance the patient's appetite, and oral care after eating is important to prevent infection and dental caries.

Supporting Patient Self-Esteem and the Needs of Caregivers

Preoperatively, information about the planned surgery is given to the patient and family. Any questions are answered as accurately as possible. Postoperatively, psychological nursing interventions are aimed at supporting the patient who has had a change in body image or who has major concerns related to the prognosis. The patient may have difficulty communicating and may be concerned about having the ability to breathe and swallow normally. Head and neck cancer recovery is unique in that the patient's behavioral issues (e.g., HPV infection status, alcohol, smoking) often directly relate to the underlying cause of the cancer. The psychological adaptation required after a disfiguring surgery, and the social complications inherent in swallowing and speech are profound. The *patient–caregiver dyad* is often considered a single unit, which reinforces the need to consider both entities, as well as their interrelationship (Dri, Bressan, Cadorin, et al., 2019).

The person who has had extensive neck surgery often is sensitive about their appearance. This can occur when the operative area is covered by bulky dressings, when the incision line is visible, or later after healing has occurred and the appearance of the neck and possibly the lower face has been significantly altered. If the nurse accepts the patient's appearance and expresses a positive, optimistic attitude, the patient is more likely to be encouraged. The patient also needs an opportunity to express fears and concerns regarding the success of the surgery and the prognosis. The American Cancer Society (ACS) may be a resource to provide a volunteer who meets with the patient either preoperatively or postoperatively and shares their own experience about the diagnosis, treatment, and recovery. The Look Good Feel Better programs of the ACS provide information about clothing and cosmetics that can be used to improve body image and self-esteem (see the Resources section at the end of this chapter).

People with cancer of the head and neck frequently have used alcohol or tobacco before surgery; postoperatively, they are encouraged to abstain from these substances. Alternative methods of coping need to be explored. A referral to Alcoholics Anonymous, a smoking cessation program, and family counseling may be appropriate.

Promoting Effective Communication

Communication plans begin preoperatively, when the patient and family determine which method of communication will be the best postoperatively. Useful communication methods for the patient who has undergone a laryngectomy include dry-erase boards, writing materials, pictorial guides, computer aids, smart phones, tablets, and hand signals. During the postoperative period, the call bell must be readily accessible to the patient at all times. For the patient who is intubated and mechanically ventilated postoperatively, not being able to communicate well can result in anxiety, depression, and frustration, which can lead to prolonged stress and increased hospitalization (Koszalinski, Heidel, & McCarthy, 2020). (See the Nursing Research Profile in Chart 39-3.)

The nurse obtains a consultation with a speech-language pathologist. Alternative speech techniques, such as a voice prosthesis or esophageal speech, may be taught by a speech-language pathologist (see Chapter 18).

Chart 39-3 NURSING RESEARCH PROFILE

Envisioning a Positive Future: Patients Who Are Communication Vulnerable

Koszalinski, R. S., Heidel, R. E., & McCarthy, J. (2020). Difficulty envisioning a positive future: Secondary analyses in patients in intensive care who are communication vulnerable. *Nursing & Health Sciences*, *22*(2), 374–380.

Purpose

This study explored the experience of patients who, for myriad reasons, find themselves unable to communicate in the intensive care unit (ICU) setting.

Design

This secondary analysis was based on an equivalent control group design. Data were analyzed with a mixed-effect analysis of variance (ANOVA; between and within groups), repeated measure to compare the control and treatment groups over time. The focus of this analysis was on considering the impact of a nurse-led electronic communication intervention, called *Speak for Myself Voice* (SFMV), on depression and anxiety. Data were collected using the Hospital Anxiety and Depression scale (HADS) from 36 participants in a trauma surgical ICU, neuro ICU, progressive care unit, medical ICU, and cardiovascular ICU at an academic medical center in rural Tennessee.

Findings

Although change was detected from preintervention to postintervention on several questions on the HADS, one item piqued the interest of the researchers: "I look forward with enjoyment to things." There was a statistically significant interaction (p = 0.017) from preintervention to postintervention. This indicates that patients who are mechanically ventilated or unable to communicate because of obstruction, trauma, or surgical resection (including head and neck procedures) may be silently suffering with depressive symptoms.

Nursing Implications

These results are supported by other studies in the literature. Nurses have the unique ability to make sure patients who are unable to communicate feel seen and heard. Intentional presence and honest interest in the patient as a person by the nurse opens the door to communication that extends beyond mere vocalizations and provides the patient comfort.

Maintaining Physical Mobility

Excision of the sternocleidomastoid muscle and spinal accessory nerve results in weakness at the shoulder that can cause shoulder drop, which is a forward curvature of the shoulder. Many problems can be avoided with a conscientious exercise program. These exercises are usually started in collaboration with a physical therapist after the drains have been removed and the neck incision is sufficiently healed. The purpose of the exercises depicted in Figure 39-5 is to promote maximal shoulder function and neck motion after surgery.

Monitoring and Managing Potential Complications

Hemorrhage. Hemorrhage may occur from carotid artery rupture as a result of necrosis of the graft or damage to the artery itself from tumor or infection. This can result in frank bleeding or the formation of a hematoma. The following measures are indicated:

- Vital signs are assessed frequently (every 1 to 2 hours or every 15 minutes if the patient is critical). Once the patient is stabilized, assessment is performed every 4 hours. Tachycardia, tachypnea, and hypotension may indicate hemorrhage and impending hypovolemic shock (see Chapter 11 for discussion of treatment of hypovolemic shock).

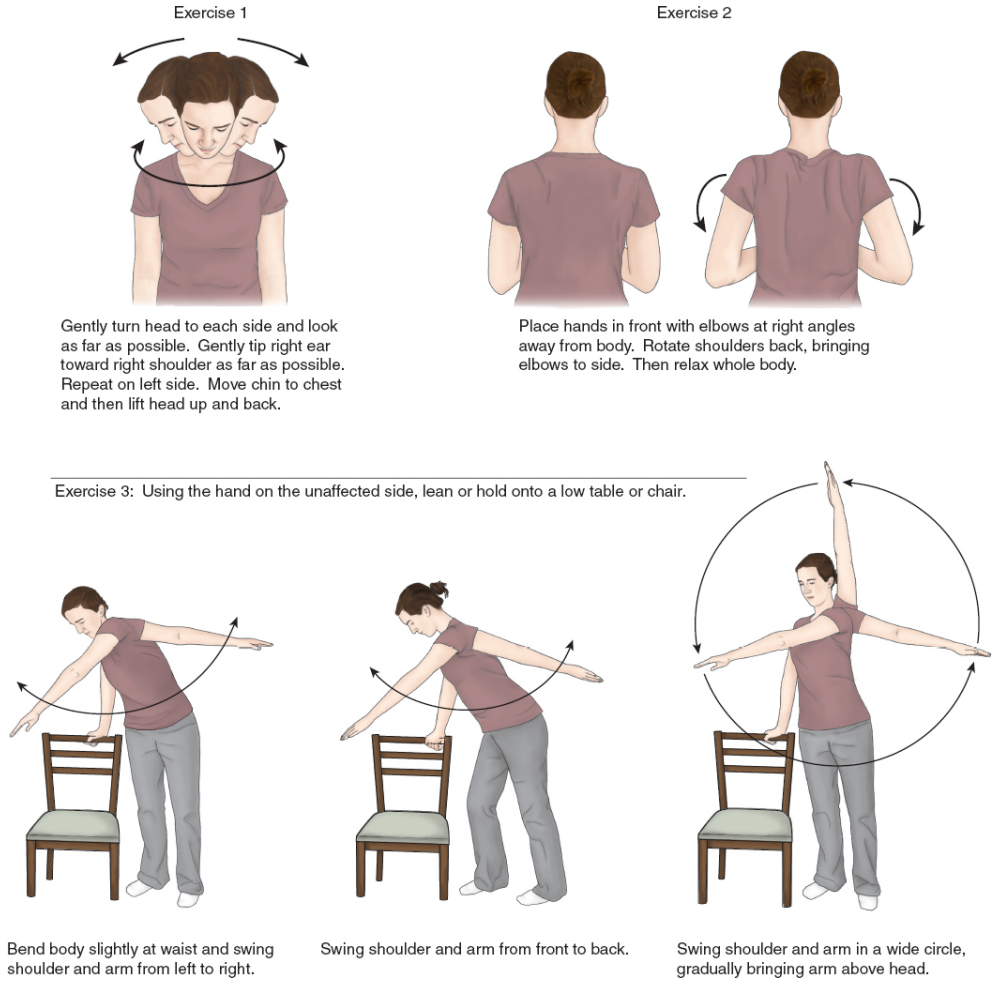

Figure 39-5 • Three rehabilitation exercises after head and neck surgery. The objective is to regain maximum shoulder function and neck motion after neck surgery. Adapted from Exercise for radical neck surgery patients. Head and Neck Service, Department of Surgery, Memorial Hospital, New York, NY.

- The patient is instructed to avoid the Valsalva maneuver to prevent stress on the graft and carotid artery.
- Signs of impending rupture, such as high epigastric pain or discomfort, are reported.
- Dressings and wound drainage are observed for excessive bleeding.
- If hemorrhage occurs, assistance is summoned immediately.
- Hemorrhage requires the continuous firm application of pressure to the bleeding site or major associated vessel.
- The head of the patient's bed should be elevated at least 30 degrees to maintain airway patency and prevent aspiration.

- A controlled, calm manner allays the patient's anxiety.
- The surgeon is notified immediately, because a vascular or ligature tear requires surgical intervention.

Chyle Leak. A chyle leak (milklike, lymphatic fluid drainage from the thoracic duct into the thoracic cavity) may develop as a result of damage to the thoracic duct during surgery. Although not very common (3% to 5.7% of cases), this leak may be recognized during surgery (where it can be repaired immediately) or in the postoperative setting, especially when oral intake begins. If a chyle leak is suspected postoperatively, conservative measures to limit increases in intrathoracic pressure will reduce the flow of chyle fluid in the thoracic duct. Recommended interventions include initiating enteral feeding or supporting a low fat diet focused on the intake of small- and medium-chain fatty acids (chylous fluid is formed from long-chain fatty acids). Medium-chain triglycerides/fats, like those found in coconut oil, are metabolized in the liver into ketones to provide energy without the formation of chyle. Other interventions include fluid and electrolyte replacement, activity restriction, head of bed elevation, stool softeners (to prevent straining), and occasionally, pressure dressings. Providers often prescribe octreotide, a synthetic analogue of the natural hormone somatostatin, that works primarily by inhibiting the release of gastrointestinal hormones that regulate digestion and absorption, thereby reducing lymph flow and decreasing the chyle flow (Rudrappa & Paul, 2019; Stack & Moreno, 2019).

Nerve Injury. Nerve injury can occur if the spinal accessory, marginal mandibular (branch of the facial nerve), vagus, phrenic, hypoglossal, lingual, or brachial plexus nerves are severed or injured during surgery. Because lower facial paralysis may occur as a result of injury to the facial nerve, this complication is observed for and reported. The patient with nerve damage may have difficulty swallowing liquids and food because of the partial lack of sensation of the glottis, impaired tongue movement, or vagus nerve injury. Speech therapy may be indicated to assist with the problems related to nerve injury. Shoulder dysfunction is most common in radical neck dissection and often requires extensive physical rehabilitation.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient and caregiver require instructions about management of the wound, the dressing, and any drains that remain in place. Patients who require oral suctioning or who have a tracheostomy may be very anxious about their care at home; the transition to home can be eased if the caregiver is given several opportunities to demonstrate the ability to meet the patient's needs (see Chart 39-4). The patient and caregiver are also instructed about possible complications, specifically bleeding and respiratory distress, and when to notify the primary provider.

Chart 39-4  **HOME CARE CHECKLIST**

The Patient Recovering from Neck Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in communication, ADLs, IADLs, roles, body image, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., utilizing durable medical equipment, employing a home health aide) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Describe ongoing therapeutic regimen, including diet and activities to perform (e.g., oral care, suctioning) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Identify foods or therapies necessary to meet caloric needs and dietary needs (e.g., change in consistency, seasoning limitations, supplements, enteral or parenteral therapy).
  - Participate in prescribed therapy (e.g., speech therapy, PT, OT) to promote recovery and rehabilitation.
  - Demonstrate the use of tracheostomy care and suctioning if indicated.
  - Demonstrate use of humidification if indicated.
  - Demonstrate effective oral hygiene.
  - Demonstrate care of incision and drains.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- Identify possible complications (e.g., bleeding, respiratory distress) and interventions.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical/dental appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, cancer support, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living; OT, occupational therapy; PT, physical therapy.

If the patient cannot take food by mouth, detailed instructions and demonstration of enteral or parenteral feedings will be required. Education in techniques of effective oral hygiene is also important.

Continuing and Transitional Care. A referral for home, community-based, or transitional care may be necessary in the early period after discharge. The nurse assesses healing, ensures that feedings are being given properly, and monitors for any complications. The patient's adjustment to changes in physical appearance and status and ability to communicate and eat normally is also assessed. Physical and speech therapy also are likely to be continued at home.

The patient is given information regarding local support groups such as "New Voice Club," if indicated. The local chapter of the ACS may be contacted for information and equipment needed for the patient (see the Resources section).

Evaluation

Expected patient outcomes may include:

1. Exhibits increased knowledge of course of treatment
2. Demonstrates adequate respiratory exchange
   a. Lungs are clear to auscultation
   b. Breathes easily with no shortness of breath
   c. Demonstrates ability to use suction effectively
3. Verbalizes comfort and relief of pain
4. Graft is pink and warm to touch
5. Maintains adequate intake of foods and fluids
   a. Accepts altered route of feeding
   b. Is well hydrated
   c. Maintains or gains weight
6. Demonstrates ability to cope (both patient and caregivers)
   a. Discusses emotional responses to the diagnosis
   b. Utilizes available support
7. Communicates effectively with caregivers and family members
8. Attains maximal mobility
   a. Adheres to physical therapy exercises
   b. Attains maximal range of motion
9. Exhibits no complications
   a. Vital signs stable
   b. No excessive bleeding or discharge
   c. Able to move muscles of lower face and shoulders

DELIVERING NUTRITION ENTERALLY

Feeding via the **enteric** route infers that the intestines are receiving nutrients. Thus, delivering **enteral nutrition** refers to infusing nutritional formula feedings through a tube directly into the GI tract. The nurse plays a key role in ensuring that patients prescribed this therapy achieve nutritional balance sufficient to meet their metabolic needs.

Nursing Management

Administering Tube Feedings

Tube feedings are given to meet nutritional requirements when oral intake is inadequate or not possible and the GI tract is functional. The feedings are delivered to the stomach, duodenum, or proximal jejunum and help preserve GI integrity by preserving normal intestinal and hepatic metabolism. Tube feedings have several advantages over parenteral nutrition: they are lower in cost, safer, usually well tolerated by the patient, and easier to

use in extended care facilities and in the patient's home. When possible, the physiological-based preference is to *feed the gut*.

TABLE 39-2 Conditions That May Require Enteral Therapy

Condition or Need	Examples
Alcoholism, chronic depression, anorexia nervosa[a]	Chronic illness, psychiatric or neurologic disorder
Cancer therapy	Radiation, chemotherapy
Coma, semiconsciousness[a]	Stroke, head injury, neurologic disorder, neoplasm
Convalescent care	Surgery, injury, severe illness
Debilitation[a]	Disease or injury
Gastrointestinal problems	Fistula, short-bowel syndrome, mild pancreatitis, Crohn's disease, ulcerative colitis, nonspecific maldigestion or malabsorption
Hypermetabolic conditions	Burns, trauma, multiple fractures, sepsis, acquired immune deficiency syndrome, organ transplantation
Maxillofacial or cervical surgery	Disease or injury
Oropharyngeal or esophageal paralysis[a]	Disease or injury, neoplasm, inflammation, trauma, respiratory failure
Preoperative bowel preparation	After administration of larger-volume cathartics

[a]Because some patients with these conditions are at risk for regurgitating or vomiting and aspirating administered formula, each condition must be considered individually.

Nasoduodenal or nasojejunal feeding is indicated when the esophagus and stomach need to be bypassed or when the patient is at risk for **aspiration** (i.e., inhalation of fluids or foods into the trachea and bronchial tree). For tube feedings longer than 4 weeks, gastrostomy or jejunostomy tubes are preferred for administration of medications or nutrition. Indications for enteral nutrition are summarized in Table 39-2.

Osmolality

The **osmolality** of normal body fluids (i.e., concentration) is approximately 300 mOsm/kg. The body attempts to keep the osmolality of the contents of the stomach and intestines at this level. Osmolality is an important consideration for patients receiving tube feedings through the duodenum or jejunum because feeding formulas with a high osmolality may lead to undesirable effects. For example, when a concentrated solution of high osmolality entering the stomach is taken in quickly or in large amounts, the small intestines expand and water moves rapidly into the intestinal lumen from fluid surrounding the organs and the vascular compartment. The patient may have feelings of fullness, nausea, cramping, dizziness, diaphoresis, and osmotic diarrhea, collectively termed **dumping syndrome**. Dumping syndrome can lead to dehydration, hypotension, and tachycardia. Patients fed by the small intestinal route vary in the degree to which they tolerate the effects of high osmolality; the nurse needs to be knowledgeable about the patient's formula and take steps to prevent this undesired effect. The small intestines may be able to adapt to a formula of high osmolality if it is initiated at a low hourly rate that is advanced slowly (Seres, 2019).

Formulas

The choice of formula to be delivered by tube feeding is influenced by the status of the GI tract and the nutritional needs of the patient. Formula characteristics that are considered include the chemical composition of the nutrient source (protein, carbohydrates, fat), caloric density, osmolality, fiber content, vitamins, minerals, electrolytes, and cost. Enteral formulas contain 70% to 85% free water and are not designed to meet total fluids needs (Seres, 2019). A wide variety of containers, delivery systems, and enteral pumps are available for use with tube feedings.

Various tube feeding formulas are available commercially. Polymeric formulas are the most common and are composed of protein (10% to 15%), carbohydrates (50% to 60%), and fats (30% to 35%). Standard polymeric formulas are undigested and require that the patient has relatively normal digestive function and absorptive capacity. Specialty formulas may be prescribed to treat disease-specific disorders (e.g., diabetes), organ-specific disorders (e.g., renal, pulmonary, or hepatic), sepsis, or trauma, or to support wound-healing or immune-modulation. Chemically defined or *predigested* formulas contain easier-to-absorb nutrients. Modular products contain only one major nutrient, such as protein, and are used to enhance commercially prepared products. Fiber, either premixed in or added to formulas, helps bulk the stool to decrease the occurrence of both diarrhea and constipation (McClave, Taylor, Martindale, et al., 2016).

Some feedings are given as supplements, and others are given to meet the patient's total nutritional needs. Registered dietitians (RD), registered dietitian nutritionists (RDN), and certified nutrition support clinicians collaborate with primary providers and nurses to determine the best formula for each patient. The volume of formula delivered varies depending on the caloric density of the formula and the energy needs of the patient. The overall goal is to achieve positive nitrogen balance and weight maintenance or gain without producing discomfort or diarrhea.

Administration Methods

The tube feeding method chosen depends on the location of the tube in the GI tract, patient tolerance, convenience, and cost. Large-bore (larger than 12-Fr) nasogastric (NG) tubes can be uncomfortable and their usefulness for tube feedings is limited; however, they may be used for administration of short-term feedings (Mueller, 2017). Small-bore (Dobhoff) tubes that are typically inserted into the jejunum with a guidewire and manufactured for tube feedings, are better tolerated for up to 6 weeks; however, they require diligent monitoring and frequent flushing to remain patent.

Bolus and intermittent drip tube feeding methods are practical and inexpensive options for the patient receiving tube feedings who resides at home or in a long-term care facility; however, these methods may be poorly tolerated in patients who are acutely ill. Bolus infusion requires dividing the total daily feeding volume into 4 to 6 feeds throughout the day. Boluses can be given into the stomach through a large (50-mL) syringe via gravity (see Fig. 39-6). The typical volume is 200 to 400 mL of feeding over a 15- to 60-minute period, but these parameters should be outlined in the provider's prescription (Bischoff et al., 2020; Boullata et al., 2017). Bolus feedings can be delivered as quickly as the patient can tolerate them, but are initiated slowly, increasing the rate as tolerated. With gravity feedings, raising or lowering the syringe above the abdominal wall regulates the rate of flow. The amount and flow rate is often determined by the patient's reaction. If the patient feels full, it may be desirable to slow the delivery time or give smaller volumes more frequently. The intermittent gravity drip feeding method requires administering

feedings over 30 minutes or longer at designated intervals by a reservoir enteral bag and tubing, with the flow rate regulated by a roller clamp or automated pump.

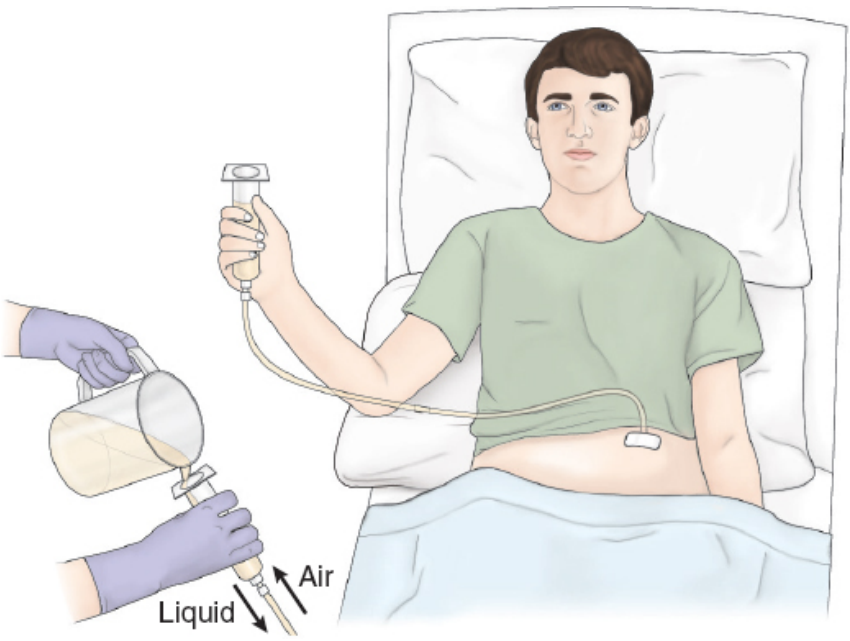

Figure 39-6 • Bolus gastrostomy feeding by gravity. Syringe is raised perpendicular to the abdomen so that feeding can enter by gravity.

Continuous feeding is the delivery of feedings incrementally by a slow infusion over long periods. Slow drip feedings are recommended for patients who are critically ill, patients at high risk for aspiration, patients at risk for intolerance (e.g., patients with pancreatitis), and for small bowel feedings (Boullata, Carrera, Harvey, et al., 2017). Enteral feeding pumps control the delivery rate of the formula (see Fig. 39-7). They allow for a constant flow rate and can infuse a viscous formula through a small-diameter feeding tube. However, they do not allow the patient as much flexibility as intermittent feedings. Portable lightweight enteral pumps are available for home use. In addition, feeding pumps have built-in alarms that signal when the bag is empty, the battery is low, or the tube is occluded. The patient and caregiver need to be aware of these alarms and know how to troubleshoot the pump.

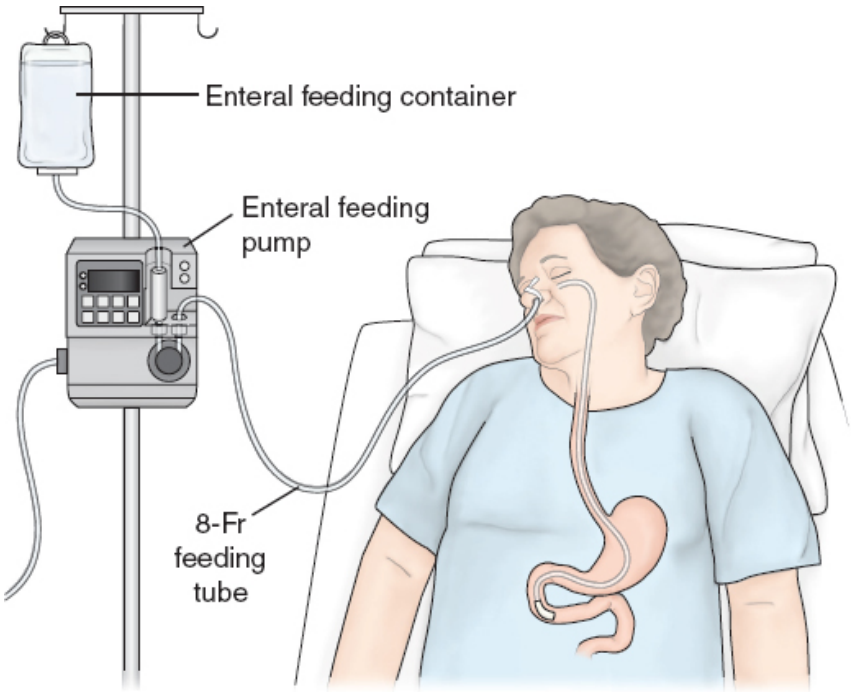

Figure 39-7 • Nasoenteric tube feeding by continuous controlled pump. The head of the bed should be elevated to prevent aspiration.

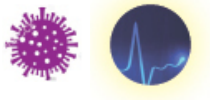
Chart 39-5 ASSESSMENT

Assessing Patients Receiving Tube Feedings



Be alert for the following assessment findings:

- Tube placement, patient's position (head of bed elevated > 30 degrees), and formula flow rate
- Patient's ability to tolerate the formula; observe for fullness, bloating, distention, nausea, vomiting, and stool pattern
- Clinical responses, as noted in laboratory findings (blood urea nitrogen, serum protein, prealbumin, electrolytes, kidney function, hemoglobin, hematocrit)
- Signs of dehydration (dry mucous membranes, thirst, decreased urine output)
- Amount of formula actually taken in by the patient
- Elevated blood glucose level, decreased urinary output, sudden weight gain, and periorbital or dependent edema
- Signs of infection (to avoid infection, replace any formula given by an open system every 4 to 8 hours with fresh formula; change tube feeding container and tubing every 24 hours)
- Signs of complications (if suspected, check gastric residual volume before each feeding or, in the case of continuous feedings, every 4 hours; return the aspirate to the stomach)
- Intake and output
- Weekly weights
- Recommendations made on dietitian consult

Adapted from McClave, S. A., Taylor, B. E., Martindale, R. G., et al. (2016). Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN). *Journal of Parenteral and Enteral Nutrition*, *40*(2), 159–211.

An alternative to the continuous infusion method is cyclic feeding, in which the infused feeding is given by an enteral feeding pump over 8 to 18 hours. Feedings may be infused at night to avoid interrupting the patient's lifestyle. Cyclic infusions may be appropriate for patients who are being weaned from tube feedings to an oral diet, for patients who cannot eat enough and need supplements, and for patients at home who need daytime hours free from the pump.

Key assessment findings for patients receiving tube feedings are noted in Chart 39-5.

COVID-19 Considerations

Patients hospitalized with severe coronavirus disease (COVID-19) pneumonia and respiratory failure necessitating intubation and mechanical ventilation may require the delivery of enteral nutrition (see Chapter 19 for further discussion of severe COVID-19 pneumonia). Guidelines developed by the American Society for Parenteral and Enteral Nutrition (ASPEN) stipulate that enteral nutrition should be initiated for these patients within 36 hours of admission to the intensive care unit (Martindale, Patel, Taylor, et al., 2020). These guidelines should be implemented unless the decision has been made that the patient receives end-of-life palliative care. Large-bore nasogastric tubes are the preferred route of delivery; these can be placed rapidly and are less prone to clogging

compared to small-bore nasoduodenal or nasojejunal feeding tube. Therefore, there is less risk of contamination for nurses and other providers responsible for inserting or manipulating the feeding tubes (Martindale et al., 2020).

However, inserting a nasogastric feeding tube still incurs risk. Placement of a nasogastric feeding tube can generate a cough, which can produce sputum; consequently, placing a nasogastric tube is considered an aerosol-generating procedure. When inserting a nasogastric tube in a patient with known or suspected COVID-19, whether for feeding or for decompression, the nurse should wear appropriate personal protective equipment (PPE) (see Chapter 66 for description of PPE) (Anderson, 2020). In addition, if possible, the patient's mouth should be covered with a mask during the procedure (Martindale et al., 2020). The feedings should be delivered as continuous rather than bolus infusions (Martindale et al., 2020).

Many patients with severe COVID-19 pneumonia who are intubated and mechanically ventilated experience an improvement in their respiratory status when they are placed in the prone position (see Chapter 19); however, if they are also receiving enteral nutrition, they are at greater risk for aspiration in this position. These patients should be placed in reverse Trendelenburg, with their heads elevated 10 to 25 degrees, to minimize this risk (Martindale et al., 2020). Some experts also advocate that feedings be held for 1 hour prior to the patient being moved into the prone position, to further reduce the risk of aspiration (Anderson, 2020; Arkin, Krishnan, & Chang, 2020).

Maintaining Feeding Equipment and Nutritional Balance

The temperature and volume of the feeding, the flow rate, and the patient's total fluid intake are important factors to consider when tube feedings are given. The schedule of tube feedings, including the correct quantity and frequency, is maintained. The nurse must carefully monitor the drip rate and avoid administering fluids too rapidly.

For patients receiving tube feedings, measuring gastric residual volumes (GRVs) by removing gastric contents with a large syringe at routine intervals has been a commonly prescribed practice. However, the usefulness of measuring GRVs has not been validated by research; furthermore, this practice may cause clogging of gastric tubes (Boullata et al., 2017). Previously, GRV in excess of 250 to 500 mL had been thought to indicate feeding intolerance. Other indicators of feeding tolerance that the nurse needs to consider include abdominal distention, patient reports of discomfort, vomiting, hypoactive bowel sounds, changes in passing flatus, and presence of diarrhea (McClave et al., 2016). The most recent guidelines for assessment and provision of nutrition in the patient who is critically ill, authored by the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN), do not advocate using GRVs to monitor tolerance of enteral feedings (McClave et al., 2016). Research findings show that GRVs between 250 and 500 mL did not increase the incidence of vomiting, aspiration, or pneumonia (McClave et al., 2016). Although feedings should not routinely be held if residuals are 250 to 500 mL, measures to decrease the risk of aspiration should be implemented (Boullata et al., 2017; McClave et al., 2016). If agency protocols and policies include assessing GRV as part of routine care, research and guidelines support holding the feeding for 2 hours only if the GRV is greater than 500 mL (Boullata et al., 2017; McClave et al., 2016). Growing evidence supports moving away from routine assessment of GRVs (Seres, 2019).

Maintaining tube function is an ongoing responsibility of the nurse, patient, primary provider, and caregiver. To ensure patency and to decrease the chance of bacterial growth,

sludge build-up, or occlusion of the tube, at least 30 mL of water flush is recommended for adults receiving tube feedings in each of the following instances (Bischoff, Austin, Boeykens, et al., 2020; Boullata et al., 2017):

- Before and after intermittent tube feeding
- Before and after medication administration (see later discussion)
- After checking for gastric residuals (if required by policy) and gastric pH
- Every 4 hours with continuous feedings
- When the tube feeding is discontinued or interrupted for any reason

Water used to flush these tubes must be recorded as fluid intake. Although distribution (i.e., tap) or drinking (i.e., distribution and bottled) water can be used for flushes, the likelihood of contamination with pathogens must be considered. Purified (contaminant free; distillation or ultrafiltration) or sterile (purified water free of microorganisms and pyrogens) should be used for medication preparation. The use of sterile water is considered best practice for patients who are immunocompromised and for reconstitution of powdered formula (Bischoff et al., 2020; Boullata et al., 2017).

Potential complications of enteral therapy are noted in Table 39-3.

Providing Medications by Tube

When different types of medications are prescribed, a bolus method is used for administration that is compatible with the medication's preparation. The feeding is paused, and the tube is flushed with at least 15 mL of water before and at least 15 mL of water after medication administration (30 mL total). Each medication should be prepared and administered separately, with a 15-mL flush provided between medications. When small-bore feeding tubes for continuous infusion are irrigated after administration of medications, a 20-mL or larger syringe is used because the pressure generated by smaller syringes could rupture the tube. Nursing judgment is required to individualize care; institutional protocols and pharmacist input should guide the primary provider's prescriptions regarding medication choices and route of delivery. Consideration needs to be given to preparations (tablets that can be crushed/dissolved; availability of elixirs), absorption (e.g., some medications bind to enteral feedings, location of distal end of tube in the stomach or jejunum), and the patient's fluid volume status (i.e., increased number of medications necessitates increases in the flush/water that is administered).

Quality and Safety Nursing Alert

Administering medications through postpyloric enteric tubes may adversely affect their absorption; therefore, this should be avoided if possible. In addition, to avoid nutrient and drug interactions, medications should not be mixed with the feeding formulas.

Maintaining Delivery Systems

Tube feeding formula is delivered to patients by either an open or a closed system. The open system is packaged as a liquid or a powder to be mixed with water that is either poured into a feeding container or given by a large syringe. The feeding container (which is hung on a pole) and the tubing used with the open system should be changed every 24 hours (Bischoff et al., 2020; Boullata et al., 2017). The open system can be used for bolus feedings, intermittent feedings, or continuous drip feedings and can be delivered by

push (with a syringe and plunger), gravity (syringe with plunger removed or gravity bag with roller clamp), or pump. To avoid bacterial contamination, the formula hang time in the bag at room temperature should never exceed what the formula manufacturer recommends, which is usually no more than 4 to 8 hours. Closed delivery systems use a prefilled, sterile container of about 1 L of formula that is spiked with enteral tubing and allows a typical hang time of 24 hours at room temperature. The closed delivery system must always use a pump to control formula rate in order to avoid dispensing a large formula volume in a short period of time. Closed systems lower the risk of infection from bacterial contamination (Boullata et al., 2017).

Maintaining Normal Bowel Elimination Pattern

Patients receiving gastric or enteric tube feedings can experience diarrhea or constipation. Possible causes of diarrhea include:

- Intolerance to enteral nutrition, related to underlying disease
- Malnutrition: A decrease in the intestinal absorptive area can cause diarrhea
- Medication therapy:
  - Elixir-based medications—often contain sorbitol, which can act as a cathartic
  - Magnesium—acts as a cathartic
  - Antibiotics—thought to alter normal intestinal flora, allowing pathogenic bacteria to flourish
- *Clostridium difficile* (*C. difficile*) colitis: Can result after antibiotic use alters normal intestinal flora and promotes the abnormal growth of this potentially dangerous microbe; *C. difficile* colitis occurs most commonly in patients who are hospitalized (Read, Olson, & Calderwood, 2020)
- Zinc deficiency: Zinc is lost with diarrhea, and zinc deficiency can then cause continued diarrhea
- Concomitant lactose intolerance
- Concomitant hyperthyroidism
- Dumping syndrome: Formula is infused into the small intestine quickly or formula bypasses the stomach too readily into the small intestine and causes expansion of the intestinal wall. This leads to bloating, cramping, diarrhea, dizziness, diaphoresis, and weakness. Measures for managing the GI symptoms associated with dumping syndrome are presented in Chart 39-6.
- Contamination of the formula and feeding equipment with diarrhea-causing pathogens (Boullata et al., 2017)

Possible causes of constipation include:

- Inadequate water intake: Tube feedings typically do not meet total fluid needs and additional water needs to be given.
- Administration of fiber-free tube feeding formulas
- Concomitant use of opioids

TABLE 39-3 Potential Complications of Enteral Therapy

Complications	Causes	Select Nursing Interventions	
		Therapeutic	Preventive
Gastrointestinal			
Constipation	Lack of fiber Inadequate fluid intake/dehydration Opioid use	Check fiber and water content; report findings.	Administer adequate amount of hydration as flushes. Consider cathartic.
Diarrhea	Hyperosmolar feedings Rapid infusion/bolus feedings Cold formula Medications, especially antibiotic therapy	Assess fluid balance and electrolyte levels; report findings. Implement changes in tube feeding formula or rate. Review medications.	Ensure appropriate rate of infusion and temperature of formula. Avoid multiple elixirs and prokinetic medications.
Gas/bloating/cramping	Air in tube Excess fiber	Notify primary provider if persistent.	Keep tubing free of air.
Nausea/vomiting	Change in formula or rate Inadequate gastric emptying	Review medications.	Check residuals; if ≥200 mL, reinstill and recheck; report if residual is consistently high.
Mechanical			
Aspiration pneumonia	Improper tube placement Vomiting with aspiration of tube feeding Flat in bed	Assess respiratory status and notify primary provider.	Implement reliable method for checking tube placement. Keep head of bed elevated 30 degrees.
Nasopharyngeal irritation	Tube position/improper taping Use of large tubes	Assess nasopharyngeal mucous membranes every 8 h.	Tape tube to prevent pressure on nares. Reposition tape.
Tube displacement	Excessive coughing/vomitus Tension on the tube or unsecured tube Tracheal suctioning Airway intubation	Stop feeding, and notify primary provider.	Check tube placement before administering feeding.

Tube obstruction	Inadequate flushing/formula rate Inadequate crushing of medications and flushing after administration	Follow policy for declogging feeding tubes (for the procedural guidelines for declogging a feeding tube, go to thepoint.lww.com/Brunner15e).	Obtain liquid medications when possible. Flush tube and crush medications adequately.
Metabolic			
Dehydration and azotemia (excessive urea in the blood)	Hyperosmolar feedings with insufficient fluid intake	Report signs and symptoms of dehydration. Implement changes in tube feeding formula, rate, or ratio to water.	Provide adequate hydration through flushes.
Hyperglycemia	Glucose intolerance High carbohydrate content of the feeding	Check blood glucose levels routinely. Dietary consult to reevaluate feeding regimen.	
Refeeding syndrome, caused by rapid shifts in intracellular and extracellular electrolytes	Inadequate nutritional intake for >2 wks/Anorexia Poorly controlled diabetes Cancer Short bowel syndrome/inflammatory bowel disease Older adult patient living alone Chronic infections	Monitor fluid balance, daily weight, electrolyte status, and metabolic/nutrition parameters	Initiate feedings at 25% of the estimated goal and advance slowly over 3–5 days with careful laboratory monitoring

Maintaining Adequate Hydration

The nurse carefully monitors hydration because in many cases the patient cannot communicate the need for water. Water flushes are given every 4 hours and after feedings to prevent hypertonic dehydration. The feeding may be initially given as a continuous drip in order to help the patient develop tolerance, especially for hyperosmolar solutions. Key nursing interventions include observing for signs of dehydration (e.g., dry mucous membranes, thirst, decreased urine output); administering water routinely; and monitoring intake and output, residual volume, and fluid balance.

Promoting Coping Ability

The psychosocial goal of nursing care is to support and encourage the patient to accept physical changes and to convey hope that daily progressive improvement is possible. If the patient is having difficulty adjusting to the treatment, the nurse intervenes by encouraging self-care within the parameters of the patient's activity level. In addition, the nurse reinforces an optimistic approach by identifying indicators of progress (daily weight trends, electrolyte balance, absence of nausea and diarrhea, improvement in plasma proteins).

Chart 39-6

Preventing Dumping Syndrome

The following strategies may help prevent some of the uncomfortable signs and symptoms of dumping syndrome related to tube feeding:

- Slow the formula instillation rate to provide time for carbohydrates and electrolytes to be diluted.
- Administer feedings at room temperature, because temperature extremes stimulate peristalsis.
- Administer feeding by continuous drip (if tolerated) rather than by bolus, to prevent sudden distention of the intestine.
- Advise the patient to remain in semi-Fowler position for 1 hour after the feeding; this position prolongs intestinal transit time by decreasing the effect of gravity.
- Instill the minimal amount of water needed to flush the tubing before and after a feeding, because fluid given with a feeding increases intestinal transit time.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patients who require long-term tube feedings may have had recent surgery, dysphagia due to a neuromuscular disease, head and neck cancer, radiation or other types of trauma to the throat, an obstruction of the upper GI tract, GI cancer and other malignancies, GI disease (including malabsorptive syndromes), or decreased level of consciousness. For a patient to be considered for tube feeding at home, the patient should:

- Be medically stable and successfully tolerating at least 60% to 70% of the feeding regimen
- Be capable of self-care or have a caregiver willing to assume the responsibility
- Have access to supplies and interest in learning how to administer tube feedings at home

Preparation of the patient for home administration of enteral feedings begins while the patient is still hospitalized. The nurse should educate the patient and caregiver while administering the feedings so that they can observe the mechanics and participate in the procedure, ask questions, and express any concerns. Before discharge, the nurse provides information about the equipment needed, formula purchase and storage, and administration of the feedings and water flushes (frequency, quantity, rate of instillation).

Family members who will be active in the patient's home care are encouraged to participate in education sessions. Available printed information about the equipment, the formula, and the procedure is reviewed. Arrangements are made to obtain the equipment and formula and have it ready for use before the patient's discharge.

Continuing and Transitional Care

Referral to home, community-based, or transitional care is important so that a nurse can supervise and provide support during the first tube feedings at home. Additional visits will depend on the skill and comfort of the patient or caregiver in administering the feedings. During all visits, the nurse monitors the patient's physical status (weight,

hydration status, vital signs, activity level) and the ability of the patient and family to administer the tube feedings correctly and assess the enteral access device and site. Enteral access devices require periodic replacement, and the nurse should be sure that the patient and caregiver have the necessary information to set up these tube replacement appointments. In addition, the nurse assesses for any complications. The patient or caregiver is encouraged to record times and amounts of feedings and water flushes, bowel patterns, and any symptoms that occur. The nurse can review the record with the patient and caregiver during home visits.

Gastrostomy and Jejunostomy

A **gastrostomy** is a procedure in which an opening is created into the stomach either for the purpose of administering nutrition, fluids, and medications via a feeding tube, or for gastric decompression in patients with gastroparesis, gastroesophageal reflux disease, or intestinal obstruction. A gastrostomy is preferred over a nasally inserted tube to deliver enteral nutrition support longer than 4 to 6 weeks (Bischoff et al., 2020; Boullata et al., 2017). Gastrostomy is also preferred over nasogastric or orogastric feedings in the patient who is comatose because the gastroesophageal sphincter remains intact, making regurgitation and aspiration less likely. Placement involves creation of a **stoma**, an artificially created opening, that houses the tube.

Insertion of a **percutaneous endoscopic gastrostomy (PEG)** requires the services of a provider skilled in endoscopy, utilizes moderate sedation, and takes approximately 15 to 20 minutes. A lighted endoscope is inserted through the mouth into the stomach. Once in the stomach, the light indicates the location for hollow needle and guidewire insertion into the stomach. The wire is pulled back through the mouth, then the PEG tube itself is attached to the wire to guide the PEG tube as it moves into the mouth, down the esophagus, into the stomach, and out the incision in the abdominal wall. An internal fixation bolster, often called a *bumper*, is pulled snug against the stomach wall. An external retention disc/phalange sits close to the abdominal surface. The tension between the external and internal fixation bolsters keeps the tube in place (see Fig. 39-8A). A radiologically inserted gastrostomy tube (RIG) can be placed fluoroscopically by a skilled provider when an endoscope cannot be passed through a strictured or obstructed esophagus. The RIG is internally sutured and held in place by an internal balloon that is inflated with a small amount of water (Anderson, 2019; Thompson, 2017).

Feeding can be initiated via PEG tubes within several hours (≤4 hours) of placement. The stomal tract will take 30 to 90 days to mature, so replacement should not occur until at least 30 days after placement. Manufacturer guidelines should be followed for replacement of tubes, but deterioration or dysfunction, a ruptured balloon, stomal tract disruption, nonhealing ulcers, or fistula formation may accelerate this recommended time frame. With optimal care, tubes may last 1 to 2 years; however, most policies encourage preventative maintenance that includes elective changing of the balloon gastrostomy tube every 3 to 6 months (Boullata et al., 2017). An alternative to standard gastrostomy tubes that are bulky are low-profile gastrostomy devices (see Fig. 39-8B). Specific types of low-profile gastrostomy devices include the MIC-KEY or the Bard Button. These devices are flush with the skin, eliminate the possibility of inward tube migration, have antireflux valves to prevent gastric leakage, and do not require tape or other securement devices (Boullata et al., 2017). Patients requiring enteral nutrition support can conceal the feeding tube access site under their clothing. Low-profile gastrostomy devices require special

connection tubing so they can be attached to the feeding container. Patients must be instructed to bring this connection tubing with them when traveling, going to the emergency department or hospital, or undergoing diagnostic procedures that require access into the GI tract.

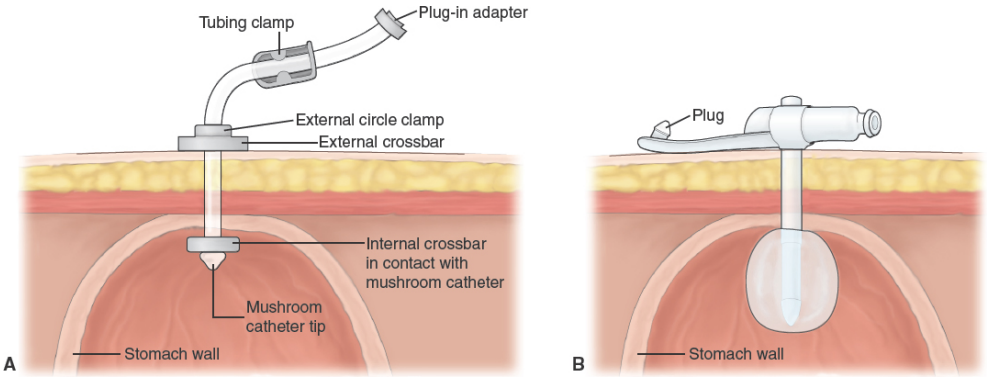

Figure 39-8 • **A.** A detail of the abdomen and the percutaneous endoscopic gastrostomy (PEG) tube showing catheter fixation. **B.** A detail of the abdomen and the nonobturated low-profile gastrostomy device showing balloon fixation.

A **jejunostomy** is a surgically, endoscopically (percutaneous gastrojejunostomy or jejunal; PEJ), or radiologically placed opening into the jejunum for the purpose of administering nutrition, fluids, and medications. A jejunostomy tube is indicated when the gastric route is not accessible, or to decrease aspiration risk when the stomach is not functioning adequately to process and empty food and fluids. These tubes either have an internal balloon or dacron cuff, or are sutured externally to secure them. Unlike the gastrostomy tubes, jejunostomy tubes should not be rotated and only last between 6 to 9 months (Anderson, 2019; Boullata et al., 2017). The small intestine can also be accessed by placing a jejunal extension tube through an existing gastrostomy tube and manipulating it through the pylorus into the small intestine endoscopically, fluoroscopically, or during a surgical procedure—this is referred to as a *gastrojejunostomy* tube.

NURSING PROCESS

The Patient with a Gastrostomy or Jejunostomy

Assessment

The focus of the preoperative assessment is to determine the patient's ability to understand and cooperate with the procedure. The nurse assesses the ability of both patient and family to adjust to a change in body image and to participate in self-care. There are multiple medical and ethical issues that the patient, the caregivers, and the primary provider should discuss together.

The purpose of the procedure and expected postoperative course should be explained. The patient needs to know that the feeding tube will bypass the mouth and esophagus so that liquid feedings can be given directly into the stomach or intestine. If the feeding tube is expected to be permanent, the patient should be made aware of this. If the procedure is being performed to relieve discomfort, prolonged vomiting, debilitation, or an inability to eat, the patient may find the feeding tube more acceptable.

In the postoperative period, the patient's fluid and nutritional needs are assessed to ensure proper intake and GI function. The nurse inspects the tube for proper maintenance and the incision for any drainage, skin breakdown, or signs of infection. As the nurse evaluates patients' responses to the change in body image and their understanding of the feeding methods, interventions are identified to help them cope with the tube and learn self-care measures.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired nutritional status
- Risk for infection associated with presence of wound and tube
- Risk for impaired skin integrity at tube insertion site
- Disturbed body image associated with presence of tube

Collaborative Problems/Potential Complications

Potential complications may include the following (Anderson, 2019):

- Wound infection, cellulitis, and leakage
- GI bleeding
- Premature dislodgement of the tube
- Tube obstruction/clogging

Planning and Goals

The major goals for the patient may include achieving nutritional requirements, preventing infection, maintaining skin integrity, adjusting to changes in body image, and preventing complications.

Nursing Interventions

Meeting Nutritional Needs

The first fluid nourishment is given soon after tube insertion and can consist of a sterile water or normal saline flush of at least 30 mL. Formula feeding can begin as

prescribed, typically within 4 hours post tube insertion. The infusion rate or bolus amount given is gradually increased.

If the tube has been placed for gastric drainage, it can be connected to either low intermittent suction or to a gravity drainage bag. This drainage should be measured and recorded because it is a significant indicator of GI function. A decrease in the amount of drainage may indicate that the tube can be clamped for periods of time, allowing greater freedom of movement. High output can result in significant fluid and electrolyte losses.

Preventing Infection and Providing Skin Care

For the first week after insertion, interventions are focused on prevention of stomal tract infection and promotion of incisional healing. The insertion site should be kept clean and dry using aseptic wound care daily and/or a glycerin hydrogel or glycogel dressing. It is normal to see scant serous drainage at the site for a few days post insertion. After approximately 1 week, the site (including under the external disc, if one is present) can be cleansed twice a week with soap and water and left open to air. Skin at the exit site is evaluated daily for signs of breakdown, irritation, excoriation, and the presence of drainage, bleeding or hypertrophic tissue growth or scattered, raised red papules that could indicate a yeast or candidal infection. Candida may appear in warm moist areas of the body; the area beneath the gastric tube external retention bolster is a common location for it to develop and spread. The nurse encourages the patient and family members to participate in this evaluation and in hygiene activities. If gastric contents leak and irritate the skin at the stoma site, zinc oxide–based protectants may be used. After the first week of healing, buried bumper syndrome, a severe, but rare complication, can be prevented by rotating the gastric tube (not done with jejunostomy tubes) daily and moving the tube inward 2 to 10 cm at least once a week (Bischoff et al., 2020; Boullata et al., 2017).

Enhancing Body Image

Eating is a major physiologic and social function, and the patient with a gastrostomy has experienced a major change in body image. The patient is also aware that gastrostomy as a therapeutic intervention is performed only in the presence of a major, chronic, or perhaps terminal illness. It is necessary to evaluate the existing family support system because adjustment takes time and is facilitated by family acceptance.

Monitoring and Managing Potential Complications

During the postoperative course, the most common complications are wound infection or cellulitis at the exit site, bleeding, leakage, excessive tightness of external retention bolster, and dislodgement. Because many patients who receive tube feedings are debilitated and have compromised nutritional status, any signs of infection are promptly reported to the primary provider so that appropriate therapy can be instituted. Bleeding from the insertion site in the stomach can also occur and should be reported promptly. The nurse closely monitors the patient's vital signs and observes all operative site drainage, vomitus, and stool for evidence of bleeding. If an external retention bolster, tape, securement device, or sutures are present, they are evaluated for adequate tension and securement. Excessive tension of the external retention bolster can cause excruciating pain and will lead to skin breakdown and ulceration. The nurse should notify the primary provider if excessive pain occurs at the incision site post insertion.

Dislodgement of a recently inserted tube requires immediate attention because the tract can close within 4 to 6 hours if the tube is not replaced promptly. Aspiration is a

potential risk with tube dislodgment, especially with nasally inserted tubes. The head of bed for the patient should be elevated to at least 30 degrees. Careful assessment of external tube markings that could suggest drift in placement, and of the patient for signs and symptoms of fullness or nausea that might lead to gastric reflux are important strategies that may prevent aspiration (Boullata et al., 2017).

Tube occlusion/clogging occurs in 23% to 35% of patients with feeding tubes and can lead to delays in feeding and medication administration (Boullata et al., 2017). Prevention is important and can be accomplished by administering adequate and frequent flushes as previously described. If a tube does become clogged, warm water may be instilled into the enteral nutrition device with a 30- to 60-mL syringe, followed by a gentle pulling and pushing on the plunger. If this method does not resolve the obstruction, an enzyme-containing commercially available declogging kit may be used or a combination of a pancreatic enzyme tablet and a bicarbonate tablet may be used (Boullata et al., 2017).

For the procedural guidelines for declogging a feeding tube, go to thepoint.lww.com/Brunner15e.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The patient with a gastrostomy or jejunostomy tube in the home setting must be capable of maintaining patency of the tube or have a caregiver who can do so. The nurse assesses the patient's level of knowledge and interest in learning about the tube, as well as an ability to understand how to flush, provide site care, and administer feedings or facilitate decompression and drainage. Education is similar to that described earlier. To facilitate self-care, the nurse encourages the patient to participate in flushing the tube, administering medications and tube feedings during hospitalization, and establishing as normal a routine as possible.

Adapters are available that can be secured to the end of the tube to create a "Y" site for ease of flushing, suction, or medication delivery. The flushing equipment is cleaned with warm, soapy water and rinsed after each use. The tube can be marked at skin level to provide the patient with a baseline for later comparison. The patient or caregiver should be advised to monitor the tube's length and to notify the primary provider or home care nurse if the segment of the tube outside the body becomes shorter or longer.

Chart 39-7  **HOME CARE CHECKLIST**

The Patient Receiving Tube Feeding

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- State what types of changes are needed (if any) to maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, and tube feeding supply vendor.
  - List emergency phone numbers.
- State how to obtain medical supplies and carry out dressing changes, site care, and other prescribed regimens.
- Demonstrate how to perform site care.
- Demonstrate how to prepare tube feeding.
- Demonstrate how to deliver tube feeding via prescribed method (e.g., bolus method, intermittent drip method, continuous feeding).
  - When indicated, demonstrate how to operate, disconnect, and clean the tube feeding pump.
  - When indicated, demonstrate tube maintenance functions.
    - Flush before and after bolus and intermittent feeding and medication administration
    - Flush every 4 hours with continuous feeding
    - Flush once daily if tube is not being used
- Demonstrate how to record all fluid intake and output.
- Identify a plan for operation of tube feeding pump during a power outage or other emergency.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate medication preparation and administration via bolus method, with flushing before, after and between medications.
- Identify possible tube feeding complications and interventions.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up appointments and testing.
- State understanding of community resources and referrals (if any).
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care. Referral to home, community-based, or transitional care is important to ensure initial supervision and support for the patient and caregiver. The nurse assesses the patient's status and progress and evaluates the care of the tube and healing status of the tube insertion site. Further instruction and supervision in the home setting may be required to help the patient and caregiver adapt to a physical environment and equipment that are different from the hospital setting (see Chart 39-7). The nurse also reviews with the patient and caregiver what

complications to report and assists the patient and family in establishing as normal a routine as possible.

Evaluation

Expected patient outcomes may include:

1. Achieves nutrition goals
   a. Attains weight goal
   b. Tolerates tube feeding prescription without nausea, emesis, cramping, abdominal pain, or feelings of early satiety
   c. Has acceptable bowel movements without constipation or large-volume liquid stools
   d. Has normal plasma protein, glucose, vitamin, and mineral levels
   e. Has normal electrolyte values
2. Is free of infection at enteral access site
   a. Is afebrile
   b. Has no induration, redness, pain, or purulent drainage
   c. Has no scattered papules indicative of a yeast infection
3. Has dry, intact skin surrounding enteral access site
   a. No evidence of excessive drainage or bleeding
   b. No skin breakdown or hypertrophic tissue growth
4. Adjusts to change in body image
   a. Is able to discuss expected changes
   b. Verbalizes concerns
5. Demonstrates skill in tube care
   a. Handles equipment competently
   b. Successfully maintains tube patency
   c. Keeps an accurate record of intake and output
   d. Demonstrates how to gently wash tube site daily and keep clean and dry
6. Avoids other complications
   a. Exhibits adequate wound healing
   b. Tube remains intact and is routinely replaced for the duration of therapy

DISORDERS OF THE ESOPHAGUS

The esophagus is a mucus-lined, muscular tube that carries food from the mouth to the stomach. It begins at the base of the pharynx and ends about 4 cm below the diaphragm. Its ability to transport food and fluid is facilitated by two sphincters. The upper esophageal sphincter, also called the *hypopharyngeal sphincter,* is located at the junction of the pharynx and the esophagus. The lower esophageal sphincter, also called the *gastroesophageal sphincter* or *cardiac sphincter,* is located at the junction of the esophagus and the stomach. An incompetent lower esophageal sphincter allows reflux (backward flow) of gastric contents. Because there is no serosal layer of the esophagus, if surgery is necessary, it is more difficult to perform suturing or anastomosis.

Disorders of the esophagus include motility disorders (achalasia, spasms), hiatal hernias, diverticula, perforation, foreign bodies, chemical burns, gastroesophageal reflux disease, Barrett esophagus (BE), benign tumors, and carcinoma. Dysphagia, the most

common symptom of esophageal disease, may vary from an uncomfortable feeling that a bolus of food is caught in the upper esophagus to acute **odynophagia** (pain on swallowing). Obstruction of food (solid and soft) and even liquids may occur anywhere along the esophagus. Often, the patient can indicate that the problem is located in the upper, middle, or lower third of the esophagus.

Achalasia

Achalasia is absent or ineffective peristalsis of the distal esophagus accompanied by failure of the esophageal sphincter to relax in response to swallowing. Narrowing of the esophagus just above the stomach results in a gradually increasing dilation of the esophagus in the upper chest. Achalasia is rare, may progress slowly, and occurs most often in people between ages 20 and 40 and ages 60 and 70 years (Swanström, 2019).

Clinical Manifestations

The main symptom is dysphagia, with the hallmark being difficulty with solid food. The patient has a sensation of food sticking in the lower portion of the esophagus. As the condition progresses, food is commonly regurgitated either spontaneously or intentionally by the patient to relieve the discomfort produced by prolonged distention of the esophagus by food that will not pass into the stomach. The patient may also report noncardiac chest or epigastric pain and **pyrosis** (heartburn) that may or may not be associated with eating. These symptoms mirror those of GERD, and patients are often misdiagnosed and treated for GERD (Swanström, 2019).

Assessment and Diagnostic Findings

X-ray studies show esophageal dilation above the narrowing at the lower gastroesophageal sphincter, which is called a *birds beak* deformity. Barium swallow, CT scan of the chest, and endoscopy may be used for diagnosis; however, high-resolution manometry, a process in which peristalsis, contraction amplitudes, and esophageal pressure is measured by a radiologist or gastroenterologist, confirms the diagnosis (Swanström, 2019).

Management

The patient is instructed to eat slowly and to drink fluids with meals. Injection of botulinum toxin into quadrants of the esophagus via endoscopy has been helpful because it inhibits the contraction of smooth muscle. However, because the benefits of these injections fade over time and there is a risk of submucosal fibrosis, botulinum toxin is only used in patients who cannot receive other definitive treatments (Swanström, 2019).

Achalasia may be treated conservatively by pneumatic dilation to stretch the narrowed area of the esophagus (see Fig. 39-9). Pneumatic dilation has a high success rate; however, typically two dilations are required and the long-term results are variable (Swanström, 2019). Although perforation is a potential complication, its incidence is low (see later discussion). The procedure can be painful; therefore, moderate sedation in the form of an analgesic or tranquilizer, or both, is given for the treatment.

Achalasia may be treated surgically by esophagomyotomy, called a Heller myotomy, which involves cutting the esophageal muscle fibers. A complete lower esophageal sphincter myotomy is usually performed laparoscopically, with or without a *fundoplication* (antireflux procedure that minimizes the incidence of GERD). A newer technique, an endoscopic myotomy (per-oral endoscopic myotomy [POEM]) provides an alternative procedure that has been adopted by many high-volume achalasia centers (Swanström, 2019).

Esophageal Spasm

The three types of esophageal spasm include jackhammer esophagus, diffuse esophageal spasm (DES), and type III (spastic) achalasia. In jackhammer esophagus, referred to as hypercontractile esophagus, spasms occur on more than 20% of swallows at a very high amplitude, duration, and length. In DES, the spasms are normal in amplitude but are premature/uncoordinated, move quickly, and occur at various places in the esophagus at once. Type III achalasia is characterized by lower esophageal sphincter obstruction with esophageal spasms (Clermont & Ahuja, 2018).

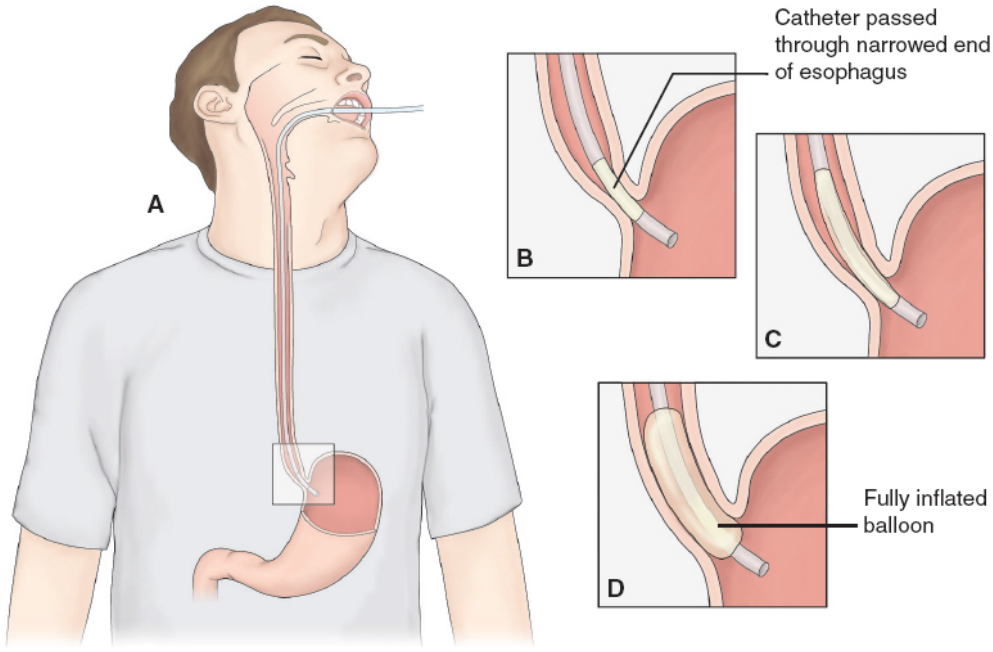

Figure 39-9 • Treatment of achalasia by pneumatic dilation. **A–C.** The dilator is passed, guided by a previously inserted guide wire. **D.** When the balloon is in proper position, it is distended by pressure sufficient to dilate the narrowed area of the esophagus.

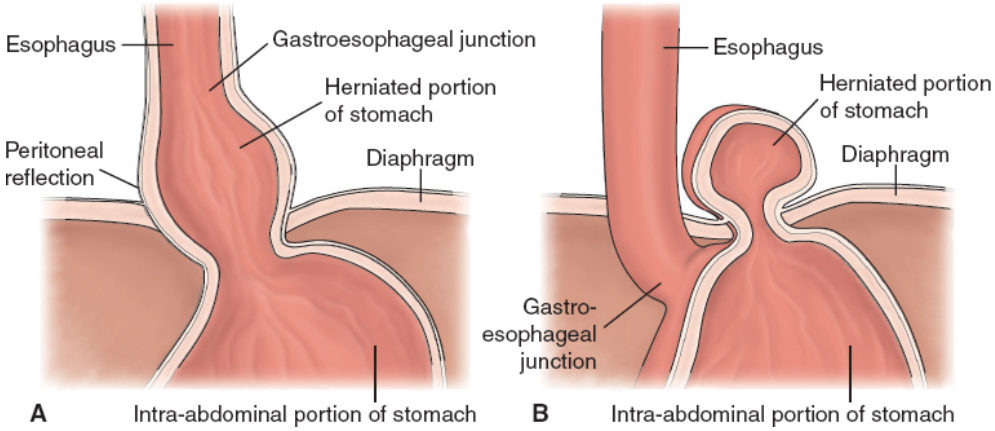

Figure 39-10 • **A.** Sliding esophageal hernia. The upper stomach and gastroesophageal junction have moved upward and slide in and out of the thorax. **B.** Paraesophageal hernia. All or part of the stomach pushes through the diaphragm next to the gastroesophageal junction.

Clinical Manifestations

All three forms of esophageal spasm are characterized by dysphagia, pyrosis, regurgitation, and chest pain similar to that of coronary artery spasm.

Assessment and Diagnostic Findings

Esophageal manometry, which measures the motility and internal pressure of the esophagus, remains the standard test for irregular and high-amplitude spasms.

Management

In all three spastic disorders, smooth muscle relaxants such as calcium channel blockers and nitrates may be used to reduce the pressure and amplitude of contractions. Like the treatment for achalasia, botulinum toxin may be used in specific frail patients who cannot tolerate other interventions. Proton pump inhibitors (PPIs) may also be indicated, especially if symptoms of GERD are present (Clermont & Ahuja, 2018). Small, frequent feedings and a soft diet are usually recommended to decrease the esophageal pressure and irritation that lead to spasm. If conservative therapies do not provide relief, Heller myotomy or POEM may be tried (Clermont & Ahuja, 2018). Since many patients also experience GERD, surgical procedures that also address GERD may be beneficial (see later discussion).

Hiatal Hernia

In the condition known as hiatal **hernia**, the opening in the diaphragm through which the esophagus passes becomes enlarged, and part of the upper stomach moves up into the lower portion of the thorax. Hiatal hernia occurs more often in women than in men. There are two main types of hiatal hernias: sliding and paraesophageal. Sliding, or type I, hiatal hernia occurs when the upper stomach and the gastroesophageal junction are displaced upward and slide in and out of the thorax (see Fig. 39-10A). Between 90% and 95% of

patients with esophageal hiatal hernia have a sliding hernia. A paraesophageal hernia occurs when all or part of the stomach pushes through the diaphragm beside the esophagus (see Fig. 39-10B). Paraesophageal hernias are further classified as types II, III, or IV, depending on the extent of herniation. Type IV has the greatest herniation, with other intra-abdominal viscera such as the colon, omentum, or small bowel present in the hernia sac that is displaced through the hiatus along with the stomach (Huerta, Plymale, Barrett, et al., 2019).

Clinical Manifestations

The patient with a sliding hernia may have pyrosis, regurgitation, and dysphagia, but many patients are asymptomatic. The patient may present with vague symptoms of intermittent epigastric pain or fullness after eating. Large hiatal hernias may lead to intolerance to food, nausea, and vomiting. Sliding hiatal hernias are commonly associated with GERD. Hemorrhage, obstruction, volvulus (bowel obstruction caused by a twist in the intestines and supporting mesentery), and strangulation can occur with any type of hernia but are more common with paraesophageal hernia (Huerta et al., 2019).

Assessment and Diagnostic Findings

Diagnosis is typically confirmed by x-ray studies; barium swallow; esophagogastroduodenoscopy (EGD), which is the passage of a fiberoptic tube through the mouth and throat into the digestive tract for visualization of the esophagus, stomach, and small intestine; esophageal manometry; or chest CT scan (Kohn, Price, Demeester, et al., 2013).

Management

Management for a hiatal hernia includes frequent, small feedings that can pass easily through the esophagus. The patient is advised not to recline for 1 hour after eating, to prevent reflux or movement of the hernia, and to elevate the head of the bed on 4- to 8-inch (10- to 20-cm) blocks to prevent the hernia from sliding upward. Surgical hernia repair is indicated in patients who are symptomatic, although the primary reason for the surgery is typically to relieve GERD symptoms and not repair the hernia. Current guidelines recommend a laparoscopic approach (Toupet or Nissen fundoplication procedures) (Huerta et al., 2019), with an open transabdominal or transthoracic approach reserved for patients with complications such as bleeding, dense adhesions, or injury to the spleen.

Up to 50% of patients may experience early postoperative dysphagia; therefore, the nurse advances the diet slowly from liquids to solids, while managing nausea and vomiting, tracking nutritional intake, and monitoring weight. The nurse also monitors for postoperative belching, vomiting, gagging, abdominal distention, and epigastric chest pain, which may indicate the need for surgical revision; these should be reported immediately to the primary provider. Surgical repair is often reserved for patients with more extreme cases that involve gastric outlet obstruction or suspected gastric strangulation, which may result in ischemia, necrosis, or perforation of the stomach (Kohn et al., 2013).

Diverticulum

An esophageal diverticulum is an out-pouching of mucosa and submucosa that protrudes through a weak portion of the musculature of the esophagus. Diverticula may occur in one of the three areas of the esophagus—pharyngoesophageal (upper), midesophageal (middle), or epiphrenic (lower).

The most common type of diverticulum is Zenker diverticulum (ZD). Located in the pharyngoesophageal area, ZD is caused by a dysfunctional sphincter that fails to open, which leads to increased pressure that forces the mucosa and submucosa to herniate through the esophageal musculature (called a pulsion diverticulum) (Smith, 2015) (see Fig. 39-11). It is usually seen in people older than 60 years of age.

Midesophageal diverticula are uncommon. Symptoms are less acute, and usually the condition does not require surgery. Epiphrenic diverticula are usually larger diverticula in the lower esophagus just above the diaphragm. They may be related to the improper functioning of the lower esophageal sphincter or to motor disorders of the esophagus. Intramural diverticulosis is the occurrence of numerous small diverticula associated with a stricture in the upper esophagus.

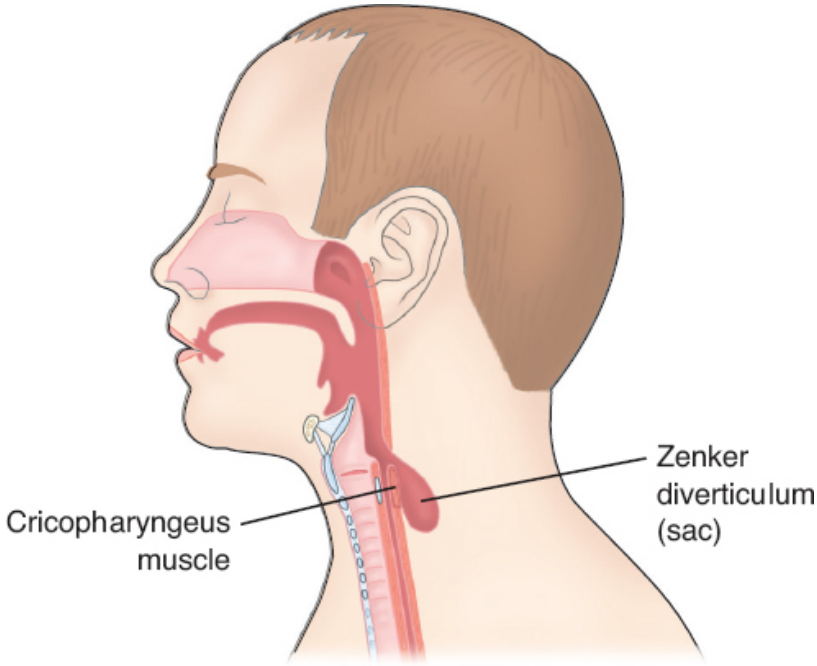

Figure 39-11 • Zenker diverticulum.

Clinical Manifestations

Symptoms experienced by the patient with a pharyngoesophageal pulsion diverticulum include dysphagia, fullness in the neck, belching, regurgitation of undigested food, and gurgling noises after eating. The diverticulum, or pouch, becomes filled with food or liquid. When the patient assumes a recumbent position, undigested food is regurgitated, and coughing may be caused by irritation of the trachea or aspiration. **Halitosis** (foul odor from the oral cavity) and a sour taste in the mouth are also common because of the decomposition of food retained in the diverticulum. Although less acute, dysphagia is the primary symptom in the other types of diverticula (Smith, 2015).

Assessment and Diagnostic Findings

A barium swallow may determine the exact nature and location of a diverticulum. Manometric studies may be performed for patients with epiphrenic diverticula to rule out a motor disorder. Esophagoscopy usually is contraindicated because of the danger of perforation of the diverticulum, with resulting mediastinitis (inflammation of the organs and tissues that separate the lungs). Blind insertion of an NG tube should be avoided.

Management

ZD can be treated by endoscopy (rigid or flexible) or open surgery. Endoscopic septotomy effectively treats ZD, with a recurrence rate of 11% to 30% of cases; POEM may be a better option as it is associated with a decreased risk of symptom recurrence (Gutierrez, Ichkhanian, Spadaccini, et al., 2019). If surgery is required, care is taken to avoid trauma to the common carotid artery and internal jugular veins. In addition to a diverticulectomy, a myotomy of the cricopharyngeal muscle is often performed to relieve spasticity of the musculature, which seems to contribute to a continuation of symptoms. An NG tube may be inserted at the time of surgery. Postoperatively, the nurse observes the incision for evidence of leakage from the esophagus and a developing fistula. Food and fluids are withheld until x-ray studies show no leakage at the surgical site. The diet begins with liquids and is progressed as tolerated.

Surgery is indicated for epiphrenic and midesophageal diverticula only if the symptoms are troublesome and becoming worse. Treatment consists of a diverticulectomy and long myotomy. Intramural diverticula usually regress after the esophageal stricture is dilated.

Perforation

Esophageal perforation is a surgical emergency. It may result from iatrogenic causes, such as endoscopy or intraoperative injury, or from spontaneous perforation associated with forceful vomiting or severe straining (Boerhaave syndrome), foreign-body ingestion, trauma, and malignancy. Immediate diagnosis and treatment are essential to minimize mortality. A delay of more than 24 hours is associated with higher mortality (20%) when compared to rapid recognition and treatment (7.4%). Perforation can occur at the cervical, thoracic, or abdominal portion of the esophagus (Olivero, 2019; Raymond, 2020).

Clinical Manifestations

The patient has excruciating retrosternal pain followed by dysphagia. Infection, fever, leukocytosis, and severe hypotension may be noted. In addition, mediastinal sepsis can occur with Boerhaave syndrome, which may be accompanied by pneumothorax and subcutaneous emphysema (see Chapter 19 for discussion of pneumothorax and subcutaneous emphysema).

Assessment and Diagnostic Findings

X-ray studies, fluoroscopy by either a barium swallow or esophagram (a noninvasive test), or a chest CT scan may be used to identify the site and scope of the injury.

Management

Esophageal perforation requires immediate treatment. Treatment includes having the patient remain NPO (*nil per os*; nothing by mouth), beginning IV fluid therapy, administering broad-spectrum antibiotics (ampicillin-sulbactam, piperacillin-tazobactam, or a carbapenem [e.g., imipenem]), considering the need for antifungal therapy (if the patient is immunosuppressed, has HIV infection, or shows no improvement with antibiotics), supportive monitoring and care (intensive care unit level-of-care often required), and evaluating and preparing the patient for surgery (Raymond, 2020). Surgical repair of the perforation site is performed in most cases, even if the diagnosis is made after 24 hours. If surgical repair of the perforation is not possible due to the clinical status of the patient, then drainage, diversion, stent placement, or an esophagostomy (removal of the esophagus) may be performed (Raymond, 2020).

Postoperative nutritional status is a major concern. The patient remains NPO for approximately 7 days, so enteral (e.g., jejunal feeding) or parenteral nutrition is started on postoperative day 2 or 3 (see Chapter 41 for further discussion of parenteral nutrition). The nurse uses water to moisten the patient's mouth for comfort measures only. A repeat esophagram is obtained on postoperative day 7 to verify there is no leak or ileus before the NG tube is removed and oral intake is permitted. It is common for broad-spectrum antibiotics to continue for 7 to 10 days postoperatively (Raymond, 2020).

Foreign Bodies

Many swallowed foreign bodies pass through the GI tract without the need for medical intervention. However, some swallowed foreign bodies (e.g., dentures, fish bones, pins, small batteries, items containing mercury or lead) may injure the esophagus or obstruct its lumen and must be removed. Pain and dysphagia may be present, and dyspnea may occur as a result of pressure on the trachea. The foreign body may be identified by x-ray. Perforation may have occurred (see earlier discussion).

Quality and Safety Nursing Alert

The nurse performs an initial and ongoing respiratory (airway-focused) assessment of a patient with a foreign body in the esophagus. Intubation may be required to protect the airway.

Glucagon, because of its relaxing effect on the esophageal muscle, may be injected IV (a 1-mg dose). A flexible endoscope and retrieval devices (e.g., forceps, graspers) may be used to remove the impacted food or object from the esophagus. Foreign bodies such as short-blunt objects, long objects, sharp-pointed objects, disc batteries, magnets, coins, or narcotic packets require special consideration (American Society for Gastrointestinal Endoscopy Standards of Practice Committee, 2011; Fung, Sweetser, Wong Kee Song, et al., 2019). Various devices can be used for endoscopic extraction (overtubes, forceps, snares, baskets, etc.) and dilation techniques can be used to facilitate the passage of foreign objects to the stomach. Decisions regarding the best course of action consider the likelihood of the object passing on its own (blunt, nontoxic objects), the patient's condition (airway maintenance), the length of time the obstruction has been present (typical intervention occurs within 24 hours), and the type of foreign object that is

impacted. For example, ingested drug packets are not removed by endoscopy for fear of packet rupture; no intervention or surgical intervention are recommended in these cases. The endoscopic procedure usually is performed in the endoscopy suite or clinic by the gastroenterologist under moderate sedation (Fung et al., 2019).

Chemical Burns

Chemical burns of the esophagus occur most often when a patient, either intentionally (67%; typically adults) or unintentionally (33%; typically children), swallows a strong acid or base, with alkaline agents being the most common (Byard, 2015). The patient is often emotionally distraught as well as in acute physical pain. Chemical burns of the esophagus may also be caused by undissolved medications in the esophagus, or they may occur after swallowing of a battery, which may release a caustic alkaline. The National Capital Poison Center (2018) provides an algorithm for button battery ingestion and triage (see Resources section). An acute chemical burn of the esophagus may be accompanied by severe burns of the lips, mouth, and pharynx, with pain on swallowing. Breathing difficulties due to either edema of the throat or a collection of mucus in the pharynx may occur. The patient needs to be closely monitored for tracheoesophageal fistula, perforation of large vessels, mediastinitis, vocal cord paralysis, tracheal stenosis or tracheomalacia, aspiration pneumonia, empyema, lung abscess, pneumothorax, spondylodiscitis, and strictures (National Capital Poison Center, 2018).

The patient, who may be profoundly toxic, febrile, and in shock, is treated immediately for shock, pain, and respiratory distress. Esophagoscopy and barium swallow are performed as soon as possible to determine the extent and severity of damage. Vomiting and gastric lavage are avoided to prevent further exposure of the esophagus to the caustic agent. Emergent esophagectomy (a total resection of the esophagus) or gastrectomy may be required (Byard, 2015). The patient remains NPO and IV fluids are given. The use of corticosteroids to reduce inflammation and minimize subsequent scarring and stricture formation is of questionable value. Antibiotics are prescribed if there is documented infection.

After the acute phase has subsided, the patient may need nutritional support via enteral or parenteral feedings. The patient may require further treatment to prevent or manage strictures of the esophagus. Dilation may be sufficient, but may need to be repeated periodically (see previous discussion). For strictures that do not respond to dilation, surgical management may be necessary. Reconstruction may be accomplished by esophagectomy and colon interposition to replace the portion of esophagus removed. This surgery is quite complex and should be considered only when other options have failed.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a fairly common disorder marked by backflow of gastric or duodenal contents into the esophagus that causes troublesome symptoms and/or mucosal injury to the esophagus. Excessive reflux may occur because of an incompetent lower esophageal sphincter, pyloric stenosis, hiatal hernia, or a motility disorder. The incidence of GERD seems to increase with aging and is seen in patients with irritable bowel syndrome and obstructive airway disorder exacerbations (e.g., asthma, COPD, cystic fibrosis) (Broers & Tack, 2017; Gabel, Galante, & Freedman,

2019), BE (see later discussion), peptic ulcer disease, and angina. GERD is associated with tobacco use, coffee drinking, alcohol consumption, and gastric infection with *Helicobacter pylori.*

Clinical Manifestations

Pyrosis (heartburn, specifically more commonly described as a burning sensation in the esophagus that is noncardiac in nature) and regurgitation are the hallmark symptoms, but patients may also experience dyspepsia (indigestion), dysphagia or odynophagia, hypersalivation, and esophagitis. GERD can result in dental erosion, ulcerations in the pharynx and esophagus, laryngeal damage, esophageal strictures, adenocarcinoma, and pulmonary complications (Kroch & Madanick, 2017; Patti, 2016).

Assessment and Diagnostic Findings

The patient's history aids in obtaining an accurate diagnosis. Diagnostic testing may include ambulatory pH monitoring, which is the gold standard for the diagnosis of GERD, or a PPI trial. Ambulatory pH monitoring involves transnasal catheter placement or endoscopic wireless capsule placement for approximately 24 hours. Endoscopy or barium swallow is used to evaluate damage to the esophageal mucosa and rule out strictures and hernias (Patti, 2016).

Management

Management begins with educating the patient to avoid situations that decrease lower esophageal sphincter pressure or cause esophageal irritation. Lifestyle modifications include tobacco cessation, limiting alcohol, weight loss, elevating the head of the bed, avoiding eating before bed, and altering the diet (Kroch & Madanick, 2017). See Table 39-4 for a list of medications commonly used to manage GERD.

If medical management is unsuccessful, surgical intervention may be necessary. Surgical management involves an open or laparoscopic Nissen fundoplication, which involves wrapping of a portion of the gastric fundus around the sphincter area of the esophagus (Huerta et al., 2019; Patti, 2016).

Barrett Esophagus

BE is a condition in which the lining of the esophageal mucosa is altered. It occurs predominantly in White men aged 50 or older, and occurs in association with family history of BE or esophageal adenocarcinoma (EAC), GERD, smoking, and obesity. The rate of BE was found to increase by 1.2% for each additional risk factor, indicating the additive effect of risk factors (Qumseya, Bukannan, Gendy, et al., 2019). BE is the only known precursor to EAC, one of the fastest rising cancers in Western populations (Qumseya et al., 2019). The 5-year survival rate for EAC does not exceed 20% (Iyer & Kaul, 2019; Qumseya et al., 2019).

Clinical Manifestations

The patient complains of symptoms of GERD, notably frequent heartburn. The patient may also complain of symptoms related to peptic ulcers or esophageal stricture, or both.

Assessment and Diagnostic Findings

An EGD provides screening in patients with multiple risk factors. This usually reveals an esophageal lining that is pink rather than pale white. Biopsies are performed, and BE is diagnosed when the squamous mucosa of the esophagus is replaced by columnar epithelium (columnar metaplasia) at least 1 cm above the gastric folds, and that area resembles that of the stomach or intestines (intestinal metaplasia) as evidenced by the presence of goblet cells (Iyer & Kaul, 2019).

Management

Monitoring varies depending on the extent of cell changes. When BE is caught and treated early, endoscopic ablation techniques have been shown to eliminate BE in up to 80% of patients, thereby preventing progression to **dysplasia**, the bizarre cell growth resulting in cells that differ in size, shape, or arrangement from other cells of the same tissue type. Such dysplasia is indicative of early EAC. Follow-up biopsies are recommended no sooner than 3 to 5 years after a biopsy shows no evidence of dysplasia (Iyer & Kaul, 2019; Sharma, Katzka, Gupta, et al., 2015). Treatment is individualized for each patient. Recommendations include surveillance with biopsies, the use of PPIs (see Table 39-4) to control reflux symptoms, followed by endoscopic resection and/or radiofrequency ablation (high-frequency heat/cold energy that kills surrounding cells and tissues) for progression of dysplasia (Iyer & Kaul, 2019; Sharma et al., 2015).

Benign Tumors of the Esophagus

Benign tumors are rare, but can arise anywhere along the esophagus. The most common lesion is a leiomyoma (tumor of the smooth muscle), which can occlude the lumen of the esophagus and cause dysphagia, pain, and pyrosis. Half of patients with benign tumors are asymptomatic and the other half present with multiple symptoms that have been present for a long period of time. The diagnosis may be made incidentally and is confirmed by endoscopy and needle biopsy. Due to the slow growth of most of these tumors, monitoring and minimally invasive techniques (endoscopic, thoracic, or laparoscopic resections) tend to be indicated rather than surgical resection (Ha, Regan, Cetindag, et al., 2015).

TABLE 39-4  Pharmacologic Management of GERD

Key Examples	Actions/Class	Key Nursing Considerations
Antacids/Acid neutralizing agents • Calcium carbonate • Aluminum hydroxide, magnesium hydroxide, and simethicone • Alginate	**Neutralize acid** *Therapeutic and Pharmacologic class*—Antacid	• Potential risk of gastric acid suppression is the loss of protective flora and an increased risk of infection, especially *Clostridium difficile*
Histamine-2 (H_2) receptor antagonists • Famotidine • Cimetidine	**Decrease gastric acid production** • *Therapeutic class*—Antiulcer drugs • *Pharmacologic class*—H_2-receptor antagonists	• Potential risk of gastric acid suppression is the loss of protective flora and an increased risk of infection, especially *Clostridium difficile* • For direct injection (IVP), dilute 2 mL (20 mg) with compatible solution to a total volume of either 5 or 10 mL; administer over at least 2 min • Monitor for QT-interval prolongation in patients with kidney injury
Prokinetic agents Metoclopramide	**Accelerate gastric emptying** *Therapeutic class*—GI stimulants *Pharmacologic class*—Dopamine antagonist	• May cause tardive dyskinesia • Typically used short term
Proton pump inhibitors (PPIs) **First-line drugs used** • Pantoprazole • Omeprazole • Esomeprazole • Lansoprazole • Rabeprazole • Dexlansoprazole	**Decrease gastric acid production** *Therapeutic class*—Antiulcer drugs *Pharmacologic class*—Proton pump inhibitors	• Potential risk of gastric acid suppression is the loss of protective flora and an increased risk of infection, especially *Clostridium difficile* • For a 2-min infusion (IVP), give the reconstituted vials (4 mg/mL) over at least 2 min • May increase the risk of hip fractures and interfere with some vitamin and mineral absorption (B_{12}, iron, magnesium) • Interact with commonly prescribed medications such as diuretics and clopidogrel
Reflux inhibitors Bethanechol chloride	**Stimulates parasympathetic**	• Primary use is for urinary retention

	Therapeutic and Pharmacologic class —Cholinergic	• Do not use with possible GI obstruction or peptic ulcer
Surface agents/Alginate-based barriers Sucralfate	**Preserve mucosal barrier** *Therapeutic class*—Antiulcer drugs *Pharmacologic class*—GI protectants	• Give on an empty stomach—either one hour before or two hours after meals • Separate from doses of antacid by 30 min
Inhibitors of transient lower esophageal sphincter relaxations (TLESRs) Baclofen	**Reducing TLESRs to reduce reflux** *Therapeutic class*—Muscle relaxant *Pharmacologic class*—gamma-aminobutyric acid (GABA) agonist	• Only approved GABA-B agonist that that reduces TLESRs • Used when PPI therapy fails

GI, gastrointestinal; IVP, intravenous push.

NURSING PROCESS

The Patient with a Noncancerous Disorder of the Esophagus

Assessment

Emergency disorders of the esophagus (perforation, chemical burns) usually occur in the home or away from medical help and require emergency medical care. The patient is treated for shock and respiratory distress and transported as quickly as possible to a health care facility. Foreign bodies in the esophagus do not pose an immediate threat to life unless pressure is exerted on the trachea, resulting in dyspnea or interfering with respiration, or unless there is leakage of caustic alkali from a battery or exposure to another corrosive agent.

For nonemergency symptoms, a complete health history may reveal the nature of the esophageal disorder. The nurse asks about the patient's appetite. Has it remained the same, increased, or decreased? Is there any discomfort with swallowing? If so, does it occur only with certain foods? Is it associated with pain? Does a change in position affect the discomfort? The patient is asked to describe the pain. Does anything aggravate it? Are there any other symptoms that occur regularly, such as regurgitation, nocturnal regurgitation, eructation (belching), pyrosis, substernal pressure, a sensation that food is sticking in the throat, a feeling of fullness after eating a small amount of food, nausea, vomiting, or weight loss? Are the symptoms aggravated by emotional upset? If the patient reports any of these symptoms, the nurse asks about when they occur, their relationship to eating, and factors that relieve or aggravate them (e.g., position change, belching, antacids, vomiting; Bickley, 2016).

This history also includes questions about past or present causative factors, such as infections and chemical, mechanical, or physical irritants; alcohol and tobacco use; and the amount of daily food intake. The nurse determines whether the patient appears emaciated and auscultates the patient's chest to assess for pulmonary complications (Bickley, 2016).

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Impaired nutritional intake associated with difficulty swallowing
- Risk for aspiration associated with difficulty swallowing or tube feeding
- Acute pain associated with difficulty swallowing, ingestion of an abrasive agent, tumor, or frequent episodes of gastric reflux
- Lack of knowledge about the esophageal disorder, diagnostic studies, medical management, surgical intervention, and rehabilitation

Planning and Goals

The major goals for the patient may include attainment of adequate nutritional intake, avoidance of respiratory compromise from aspiration, relief of pain, and increased knowledge level.

Nursing Interventions

Encouraging Adequate Nutritional Intake

The patient is encouraged to eat slowly and to chew all food thoroughly so that it can pass easily into the stomach. Small, frequent feedings of nonirritating foods are

recommended to promote digestion and to prevent tissue irritation. Sometimes liquid swallowed with food helps the food pass through the esophagus, but usually liquids should be consumed between meals. Food should be prepared in an appealing manner to help stimulate the appetite. Irritants such as tobacco and alcohol should be avoided. A baseline weight is obtained, and daily weights are recorded. The patient's intake of nutrients is assessed.

Decreasing Risk of Aspiration

The patient who has difficulty swallowing or difficulty managing secretions should be kept in at least a semi-Fowler position to decrease the risk of aspiration. The patient is instructed in the use of oral suction to decrease the risk of aspiration further.

Relieving Pain

Small, frequent feedings (6 to 8 per day) are recommended because large quantities of food overload the stomach and promote gastric reflux. The patient is advised to avoid any activities that increase pain and to remain upright for 1 to 4 hours after each meal to prevent reflux. The head of the bed should be placed on 4- to 8-inch (10- to 20-cm) blocks. Eating before bedtime is discouraged.

The patient is advised that excessive use of over-the-counter antacids can cause rebound acidity. Antacid use should be directed by the primary provider, who can recommend the daily, safe dose needed to neutralize gastric juices and prevent esophageal irritation. H_2-antagonists or PPIs (more commonly) are given as prescribed to decrease gastric acid irritation.

Providing Patient Education

The patient is prepared physically and psychologically for diagnostic tests, treatments, and possible surgery. Nursing interventions include reassuring the patient and explaining the procedures and their purposes. Some disorders of the esophagus evolve over time, whereas others are the result of trauma (e.g., chemical burns, perforation). In instances of trauma, the emotional and physical preparation for treatment is more difficult because of the short time available and the circumstances of the injury. Treatment interventions must be evaluated continually, and the patient is given sufficient information to participate in care and diagnostic tests. If endoscopic diagnostic methods are used, the patient is instructed regarding the moderate sedation that will be used during the procedure. If outpatient procedures are performed with the use of moderate sedation, someone must be available to drive the patient home after the procedure. If surgery is required, immediate and long-term evaluation is similar to that for a patient undergoing thoracic surgery.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The self-care required of the patient depends on the nature of the disorder and on the surgery or treatment measures used (e.g., diet, positioning, medications). If an ongoing condition exists, the nurse helps the patient plan for needed physical and psychological adjustments and for follow-up care (see Chart 39-8).

Special equipment, such as suction or enteral or parenteral feeding devices, may be required. The patient may need assistance in planning meals, using medications as prescribed, and resuming activities. Education about nutritional requirements and how to measure the adequacy of nutrition is important. Older adults and patients who are

debilitated in particular often need assistance and education about ways they can adjust to their limitations and resume activities that are important to them.

Continuing and Transitional Care. Patients with chronic esophageal conditions require an individualized approach to their management at home. Foods may need to be prepared in a special way (blenderized foods, soft foods), and the patient may need to eat more frequently (e.g., 6 to 8 small servings per day). The medication schedule is adjusted to the patient's daily activities as much as possible. Analgesic medications and antacids can usually be taken as needed every 3 to 4 hours.

Postoperative home health care focuses on nutritional support, management of pain, and respiratory function. Some patients are discharged from the hospital with enteral feeding by means of a gastrostomy or jejunostomy tube, or parenteral nutrition. The patient and caregiver need specific instructions regarding management of the equipment and treatments. Home care visits by a nurse may be necessary to assess the patient and the caregiver's ability to provide the necessary care. A multidisciplinary team that includes a dietitian, a social worker, and family members is helpful. Hospice care and consideration of end-of-life issues are appropriate for some patients.

Chart 39-8  **HOME CARE CHECKLIST**

The Patient with an Esophageal Disorder

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the esophageal disorder and treatment on physiologic functioning, ADLs, IADLs, body image, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., utilizing durable medical equipment, employing a home health aide) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Describe ongoing therapeutic regimen, including diet and activities to perform (e.g., suctioning) and to limit or avoid (e.g., oral foods if NPO).
  - Identify foods or therapies necessary to meet caloric needs and dietary needs (e.g., change in consistency, seasoning limitations, supplements, enteral or parenteral therapy).
  - Participate in prescribed therapy (e.g., speech therapy) to promote recovery and rehabilitation.
  - Demonstrate the use of suction equipment if indicated.
  - Demonstrate care of incision if indicated.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- Identify possible complications (e.g., difficulty swallowing, pain, respiratory distress) and interventions.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, cancer support, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living; NPO, nothing by mouth.

Evaluation

Expected patient outcomes may include:

1. Achieves an adequate nutritional intake
   a. Eats small, frequent meals
   b. Drinks small sips of water with small servings of food
   c. Avoids irritants (alcohol, tobacco, very hot beverages)
   d. Maintains optimal weight
2. Does not aspirate or develop pneumonia
   a. Maintains upright position during feeding
   b. Uses oral suction equipment effectively
3. Is free of pain or able to control pain within a tolerable level
   a. Avoids large meals and irritating foods

b. Takes medications as prescribed and with adequate fluids (at least 4 oz), and remains upright for at least 10 minutes after taking medications
c. Maintains an upright position after meals for 1 to 4 hours
d. Reports that there is less eructation (belching) and chest pain

4. Increases knowledge level of esophageal condition, diagnostic tests, treatment, and prognosis
   a. States cause of condition
   b. Discusses rationale for medical or surgical management and diet or medication regimen
   c. Describes treatment program
   d. Practices preventive measures so that injuries are avoided

Cancer of the Esophagus

In the United States, there are about 18,440 newly diagnosed cases of carcinoma of the esophagus annually; of these, 14,350 are men and 4,090 are women. Adenocarcinoma is more common among Whites, and squamous cell carcinoma is more frequently seen in African Americans. In the 1960s and 1970s, only about 5% of patients diagnosed with esophageal cancer survived at least 5 years. Today, survival rates are approximately 20% at the 5-year mark (ACS, 2021a).

Pathophysiology

Esophageal cancer can be of two cell types: adenocarcinoma and squamous cell carcinoma. The rate of adenocarcinoma is rapidly increasing in the United States as well as in other Western countries. It is found primarily in the distal esophagus and gastroesophageal junction (ACS, 2021a).

Risk factors for esophageal cancer include chronic esophageal irritation or GERD. In the United States, cancer of the esophagus has been associated with ingestion of alcohol and the use of tobacco. There is an apparent association between GERD and adenocarcinoma of the esophagus. Patients with BE (see previous discussion of risks) have a higher incidence of esophageal cancer (Iyer & Kaul, 2019; Sharma et al., 2015). Risk factors for squamous cell carcinoma of the esophagus include chronic ingestion of hot liquids or foods, nutritional deficiencies, poor oral hygiene, exposure to nitrosamines in the environment or food, cigarette smoking or chronic alcohol exposure (especially in Western cultures), and some esophageal medical conditions such as caustic injury.

Early stages of esophageal cancer are limited to the mucosa or submucosa; these stages of cancer have a 5-year survival rate of about 90% (Levine & Rubesin, 2012). In later stages, tumor cells of adenocarcinoma and of squamous cell carcinoma may spread beneath the esophageal mucosa or directly into, through, and beyond the muscle layers into the lymphatics. Obstruction of the esophagus is noted, with possible perforation into the mediastinum and erosion into the great vessels (Levine & Rubesin, 2012).

Clinical Manifestations

Many patients have an advanced ulcerated lesion of the esophagus before symptoms manifest. Symptoms include dysphagia, initially with solid foods and eventually with

liquids; a sensation of a mass in the throat; painful swallowing; substernal pain or fullness; and, later, regurgitation of undigested food with halitosis and hiccups. The patient first becomes aware of intermittent and increasing difficulty in swallowing. As the tumor grows and the obstruction becomes nearly complete, even liquids cannot pass into the stomach. Regurgitation of food and saliva occurs, hemorrhage may take place, and progressive loss of weight and strength occurs from inadequate nutrition. Later symptoms include substernal pain, persistent hiccup, respiratory difficulty, and halitosis.

The delay between the onset of early symptoms and the patient seeking medical advice is often 12 to 18 months. Any person having swallowing difficulties should be encouraged to consult the primary provider immediately.

Assessment and Diagnostic Findings

Several imaging techniques may provide useful diagnostic information. A CT scan of the chest and abdomen is beneficial for detecting any anatomic evidence of metastatic disease, especially of the lungs, liver, and kidney. A PET scan may also help detect metastasis. Endoscopic ultrasound is used to determine whether the cancer has spread to the lymph nodes and other mediastinal structures; it can also determine the size and invasiveness of the tumor. Exploratory laparoscopy is the best method for finding positive lymph nodes in patients with distal lesions (Cools-Lartigue, Molena, & Gerdes, 2018).

Future diagnostic techniques that may serve as predictors for dysplastic progression in patients with BE involve molecular markers. Some data have shown that a small percentage of people may have a genetic predisposition to esophageal cancer. Researchers have identified several biomarkers with strong potential to predict outcomes in esophageal cancer, but none of these biomarkers are currently recommended or clinically available (Iyer & Kaul, 2019). The usefulness of molecular markers in treating esophageal cancer continues to be researched.

Medical Management

If esophageal cancer is detected at an early stage, treatment goals may be directed toward cure; however, it is often detected in late stages, making relief of symptoms the only reasonable goal of therapy. Treatment may include surgery, radiation, chemotherapy, or a combination of these modalities, depending on the type of cancer cell, the extent of the disease, and the patient's condition. A standard treatment plan for a patient who is newly diagnosed with esophageal cancer will vary depending on the staging but may include: endoscopic resection, chemoradiation followed by surgery, chemotherapy followed by surgery, surgery alone, definitive chemoradiation, or palliative measures (NCI, 2021a).

Although minimally invasive surgery may be possible in some cases, standard surgical management includes esophagectomy with removal of the tumor plus a wide tumor-free margin of the esophagus and the lymph nodes in the area. Variations on the original esophagectomy preserve nerves, employ less invasive techniques, and target specific areas of the esophagus (Schlottmann, Molena, & Patti, 2018). The surgical approach may be through the neck, thorax and/or the abdomen, depending on the location of the tumor. When tumors occur in the cervical or upper thoracic area, and the stomach cannot be mobilized, pulled up, and anastomosed to the esophagus, esophageal continuity may be maintained by performing a colon graft transfer, in which the tumor is removed and the area is replaced with a portion of the colon (see Fig. 39-12). In many of these cases, a feeding tube is placed in the jejunum during surgery for feeding (Schlottman et al., 2018).

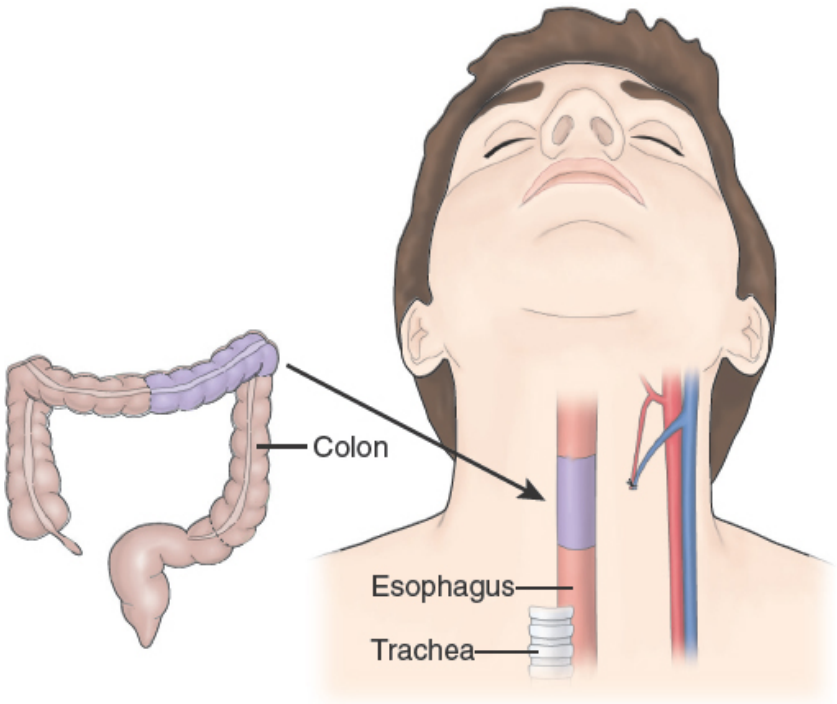

Figure 39-12 • Esophageal reconstruction with colonic interposition. A portion of the colon is grafted between the esophagus and pharynx to replace the abnormal portion of the esophagus. The vascular structures are also anastomosed.

Tumors of the lower thoracic esophagus are more amenable to surgery than are tumors located higher in the esophagus. GI tract integrity is maintained by anastomosing the lower esophagus to the stomach (see Fig. 39-13).

Surgical resection of the esophagus has a relatively high mortality rate because of infection, pulmonary complications, or leakage through the anastomosis. Postoperatively, the patient has an NG tube in place that should not be manipulated. The patient remains NPO until x-ray studies that confirm that the anastomosis is free from an esophageal leak, there is no obstruction, and that there is no evidence of pulmonary aspiration.

Palliative treatment may be necessary to keep the esophagus open, to assist with nutrition, and to control saliva. Palliation may be accomplished with dilation of the esophagus, laser therapy, placement of an endoprosthesis (stent) via EGD, radiation, or chemotherapy.

Nursing Management

Preoperative nursing management is directed toward improving the patient's nutritional and physical status in preparation for surgery, radiation therapy, and/or chemotherapy. A program to promote weight gain based on a high-calorie and high-protein diet, in liquid or soft form, is provided if adequate food can be taken by mouth. If this is not possible, parenteral or enteral nutrition is initiated. Nutritional status is monitored throughout treatment. The patient is informed about the nature of the postoperative equipment that will be used, including that required for closed chest drainage, NG suction, parenteral fluid therapy, and gastric intubation.

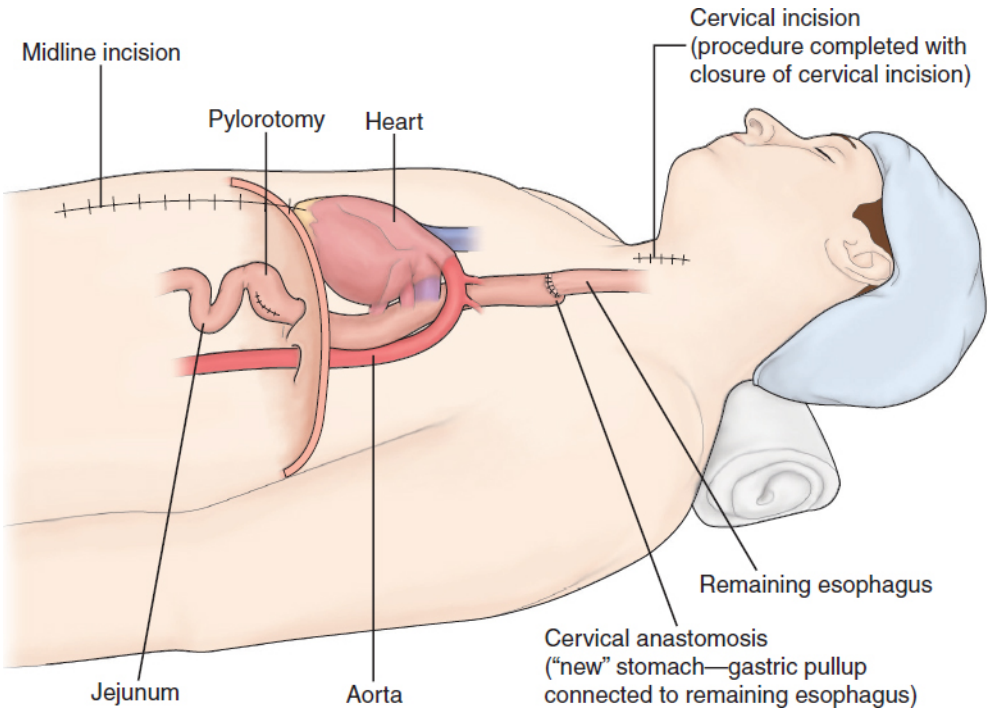

Figure 39-13 • Transhiatal esophagectomy. Surgical removal of tumor of the lower esophagus with anastomosis of the remaining esophagus to the stomach. Redrawn from Heitmiller, R. F. (1999). Closed chest esophageal resection, 252–265. *Operative Techniques in Thoracic and Cardiovascular Surgery*, *4*(3). © 1999, with permission from Elsevier. doi: 10.1016/S1522-2942(07)70121-6.

Immediate postoperative care is similar to that provided for patients undergoing thoracic surgery. It is not uncommon for patients to have a tracheostomy and be placed in an intensive care unit or step-down unit. After recovering from the effects of anesthesia, the patient is placed in a low Fowler position, and later in a Fowler position, to help prevent reflux of gastric secretions. The patient is observed carefully for regurgitation and dyspnea. A common postoperative complication is aspiration pneumonia (Brownlee & Ferguson, 2018). Therefore, the patient is placed on a vigorous pulmonary plan of care that includes incentive spirometry, sitting up in a chair, and, if necessary, nebulizer treatments. Chest physiotherapy is avoided due to the risk of aspiration. The patient's temperature is monitored to detect any elevation that may indicate aspiration or seepage of fluid through the operative site into the mediastinum, which would indicate an esophageal leak. Drainage from the cervical neck wound, usually saliva, is evidence of an early esophageal leak. Typically, no treatment other than maintaining NPO status and parenteral or enteral support is warranted. The patient is also monitored for a postoperative chylothorax (accumulation of chyle/lymphatic fluid in the pleural cavity), which would require pleural drainage (Brownlee & Ferguson, 2018; Rudrappa & Paul, 2019).

Cardiac complications include atrial fibrillation, which occurs due to irritation of the vagus nerve at the time of surgery. Typical medical management includes digitalization or the use of beta-blockers, calcium channel blockers, amiodarone, and/or cardioversion depending on the patient's hemodynamic status (Brownlee & Ferguson, 2018).

Esophageal anastomotic leak is managed by facilitating adequate drainage, initiating broad-spectrum antibiotics (often including antifungal agents), and optimizing nutrition

via enteral or parenteral feeding (Brownlee & Ferguson, 2018). During surgery, an NG tube is inserted and taped in place. It is connected to low intermittent suction. The NG tube is not manipulated; if displacement occurs, it is not replaced because damage to the anastomosis may occur. The NG tube is typically removed 5 days after surgery; before the patient is allowed to eat, a barium swallow is performed to assess for any anastomotic leak.

Once feeding begins, the nurse encourages the patient to swallow small sips of water. Eventually, the diet is advanced as tolerated to a soft, mechanical diet. When the patient can increase food and fluid intake to an adequate amount, parenteral fluids are discontinued. After each meal, the patient remains upright for at least 2 hours to allow the food to move through the GI tract. It is a challenge to encourage the patient to eat because the appetite is usually poor. Family involvement and home-cooked favorite foods may help the patient to eat. Antacids may help patients with gastric distress. Erythromycin, metoclopramide, or domperidone are useful in promoting gastric emptying (Brownlee & Ferguson, 2018).

If chemotherapy and radiation are part of the therapy, the patient's appetite will be further depressed, and esophagitis may occur, causing pain when food is eaten. Liquid supplements may be more easily tolerated. Surgical adjuncts to esophagectomy that address delayed gastric emptying (a major complication in 15% to 39% of patients after esophagectomy) may promote **vagotomy syndrome** (dumping syndrome), which can occur with each meal or approximately 20 minutes to 2 hours after eating (Zhang & Zhang, 2019). Vagotomy syndrome occurs due to interruption of vagal nerve fibers, which in turn causes an alteration in the storage function of the stomach and the pyloric emptying mechanism. As a result, large amounts of solids and liquids rapidly "dump" into the duodenum. The patient experiences severe abdominal cramping, followed by a liquid bowel movement that may or may not be associated with diaphoresis, rapid heart rate or rapid respirations, or both. It can be quite disabling but typically resolves without incident, and the patient is left feeling extremely tired. As the patient's recovery progresses and the patient begins to eat soft foods and remains in an upright position for 2 hours after eating, the frequency and severity of episodes decrease.

Often, in either the preoperative or the postoperative period, an obstructed or nearly obstructed esophagus causes difficulty with excess saliva, and drooling becomes a problem. Oral suction may be used if the patient cannot manage oral secretions, or a wick-type gauze may be placed at the corner of the mouth to direct secretions to a dressing or emesis basin. The possibility that the patient may aspirate saliva into the tracheobronchial tree and develop pneumonia is a concern.

When the patient is ready to go home, the family is instructed about how to promote nutrition, what observations to make, what measures to take if complications occur, how to keep the patient comfortable, and how to obtain needed physical and emotional support.

CRITICAL THINKING EXERCISES

1 ebp A 63-year-old female patient presents to a primary care clinic where you work reporting a slightly sore throat and a red patch on the side of her mouth that bleeds easily and simply will not heal. What questions should you ask? What are the primary risk factors for oral cancer? How should you frame assessment questions regarding actual and potential HPV exposure? What guidelines and evidence should inform this conversation?

2 ipc You are a nurse working on an inpatient oncology unit and have been assigned a postoperative patient who has had a classic, radical neck resection due to head and neck cancer. What nerve and muscular changes do you expect with this specific procedure? Based on this information, what are the key priority nursing interventions that will prevent short-term postoperative and long-term complications in this patient? What interprofessional consults should you plan to facilitate? What is the role of each of these interprofessional team members?

3 pq A patient diagnosed with stage III esophageal cancer undergoes the standard treatment of chemoradiation prior to an esophagostomy, and is admitted postoperatively to the surgical unit where you work. You notice on your first postoperative assessment that the NG tube that was placed in the OR has been pulled out 5 cm. What should you do *first*? What is the rationale for this NG tube? What are the risks (if any) with it being dislodged? For what other esophagostomy-specific postoperative complications should you monitor (*list four*)?

40 Management of Patients with Gastric and Duodenal Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Compare the etiology, pathophysiology, clinical manifestations, and management of acute gastritis, chronic gastritis, and peptic ulcer disease.
2. Use the nursing process as a framework for care of the patient with acute or chronic gastritis, or peptic ulcer.
3. Discuss the etiology, pathophysiology, clinical manifestations, and management of gastric cancer and tumors of the small intestine.
4. Use the nursing process as a framework for care of the patient with gastric cancer or tumors of the small intestine.

NURSING CONCEPT

Nutrition

GLOSSARY

achlorhydria: lack of hydrochloric acid in digestive secretions of the stomach

antrectomy: removal of the pyloric (antrum) portion of the stomach with anastomosis (surgical connection) either to the duodenum (gastroduodenostomy or Billroth I) or to the jejunum (gastrojejunostomy or Billroth II)

dumping syndrome: physiologic response to rapid emptying of gastric contents into the small intestines, manifested by nausea, weakness, sweating, palpitations, syncope, and diarrhea (*synonym:* vagotomy syndrome)

duodenum: first portion of the small intestine, between the stomach and the jejunum

dyspepsia: indigestion; upper abdominal discomfort associated with eating

gastric: refers to the stomach

gastric outlet obstruction: any condition that mechanically impedes normal gastric emptying; there is obstruction of the channel of the pylorus and duodenum through which the stomach empties; also called pyloric obstruction

gastritis: inflammation of the stomach

***Helicobacter pylori* (*H. pylori*):** a spiral-shaped gram-negative bacterium that colonizes the gastric mucosa; is involved in most cases of peptic ulcer disease

hematemesis: vomiting of blood

hematochezia: bright red, bloody stools

melena: tarry or black stools; indicative of occult blood in stools

omentum: fold of the peritoneum that surrounds the stomach and other organs of the abdomen

peritoneum: thin membrane that lines the inside of the wall of the abdomen and covers all of the abdominal organs

pyloroplasty: surgical procedure to increase the opening of the pyloric orifice

pylorus: opening between the stomach and the duodenum

pyrosis: a burning sensation in the stomach and esophagus that moves up to the mouth (*synonym:* heartburn)

serosa: thin membrane that covers the outer surface of the stomach; visceral peritoneum covering the outer surface of the stomach

steatorrhea: fatty stool; typically malodorous with an oily appearance and floats in water

stenosis: narrowing or tightening of an opening or passage in the body

A person's nutritional status depends not only on the type and amount of intake, but also on the functioning of the **gastric** (stomach) and intestinal portions of the gastrointestinal (GI) system. The scope of disorders that may affect a person's nutritional status is of particular note. Given the prevalence of Americans who have gastric and duodenal disorders, nurses will encounter adults and older adults with these disorders in virtually every inpatient and outpatient clinical setting. This chapter

describes disorders of the stomach and small intestine, their etiology, pathophysiology, clinical manifestations, management, and related nursing care.

Gastritis

Gastritis (inflammation of the gastric or stomach mucosa) is a common GI problem, accounting for approximately two million visits to outpatient clinics annually in the United States, with increasing prevalence occurring in adults older than 60 years of age (Wehbi, Dacha, Sarver, et al., 2019). It affects women and men about equally. Gastritis may be acute, lasting several hours to a few days, or chronic, resulting from repeated exposure to irritating agents or recurring episodes of acute gastritis.

Acute gastritis may be classified as erosive or nonerosive, based on pathologic manifestations present in the gastric mucosa (Wehbi et al., 2019). The erosive form of acute gastritis is most often caused by local irritants such as aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen); corticosteroids; alcohol consumption; and gastric radiation therapy (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2020a; Norris, 2019; Wehbi et al., 2019). The nonerosive form of acute gastritis is most often caused by an infection with a spiral-shaped gram-negative bacterium, ***Helicobacter pylori* (*H. pylori*)** (Wehbi et al., 2019). It is estimated that 50% of individuals globally are infected with *H. pylori* (Santacroce & Bhutani, 2019).

A more severe form of acute gastritis is caused by the ingestion of strong acid or alkali, which may cause the mucosa to become gangrenous or to perforate (see Chapter 67). Scarring can occur, resulting in pyloric **stenosis** (narrowing or tightening) or obstruction. Acute gastritis also may develop in acute illnesses, especially when the patient has had major traumatic injuries, burns, severe infection, lack of perfusion to the stomach lining, or major surgery. This type of acute gastritis is often referred to as *stress-related gastritis or ulcer* (Clarke, Ferraro, Gbadehan, et al., 2020; Norris, 2019).

Chronic gastritis is often classified according to the underlying causative mechanism, which most often includes an infection with *H. pylori*. Chronic *H. pylori* gastritis is implicated in the development of peptic ulcers, gastric adenocarcinoma (cancer), and gastric mucosa–associated lymphoid tissue lymphoma (Akiva & Greenwald, 2019; Lloyd & Leiman, 2019). Chronic gastritis may also be caused by a chemical gastric injury (gastropathy) as the result of long-term drug therapy (e.g., aspirin and other NSAIDs) or reflux of duodenal contents into the stomach, which most often occurs after gastric surgery (e.g., gastrojejunostomy, gastroduodenostomy). Autoimmune disorders such as Hashimoto thyroiditis, Addison disease, and Graves disease are also associated with the development of chronic gastritis (see Chapter 45) (Akiva & Greenwald, 2019; Norris, 2019).

Pathophysiology

Gastritis is characterized by a disruption of the mucosal barrier that normally protects the stomach tissue from digestive juices (e.g., hydrochloric acid [HCl] and pepsin). The impaired mucosal barrier allows corrosive HCl, pepsin, and other irritating agents

(e.g., alcohol, NSAIDs, *H. pylori*) to come in contact with the gastric mucosa, resulting in inflammation. In acute gastritis, this inflammation is usually transient and self-limiting in nature. Inflammation causes the gastric mucosa to become edematous and hyperemic (congested with fluid and blood) and to undergo superficial erosion (Fig. 40-1). Superficial ulceration may occur as a result of erosive disease and may lead to hemorrhage. In chronic gastritis, persistent or repeated insults lead to chronic inflammatory changes, and eventually atrophy (or thinning) of the gastric tissue (Norris, 2019).

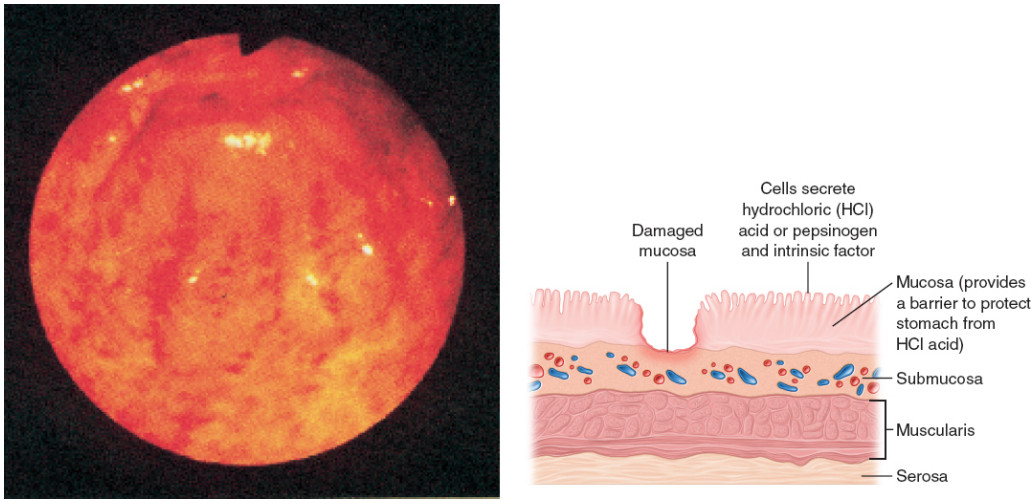

Figure 40-1 • Endoscopic view of erosive gastritis (**left**). Damage from irritants (**right**) results in increased intracellular pH, impaired enzyme function, disrupted cellular structures, ischemia, vascular stasis, and tissue death. Image at left reproduced with permission from Strayer, D. S., Saffitz, J. E., & Rubin, E. (2015). *Rubin's pathology: Mechanisms of human disease* (8th ed., Fig. 19-15). Philadelphia, PA: Lippincott Williams & Wilkins.

Clinical Manifestations

The patient with acute gastritis may have a rapid onset of symptoms, such as epigastric pain or discomfort, **dyspepsia** (indigestion; upper abdominal discomfort associated with eating), anorexia, hiccups, or nausea and vomiting, which can last from a few hours to a few days. Erosive gastritis may cause bleeding, which may manifest as blood in vomit or as **melena** (black, tarry stools; indicative of occult blood in stools) or **hematochezia** (bright red, bloody stools) (Wehbi et al., 2019).

The patient with chronic gastritis may complain of fatigue, **pyrosis** (a burning sensation in the stomach and esophagus that moves up to the mouth; heartburn) after eating, belching, a sour taste in the mouth, halitosis, early satiety, anorexia, or nausea and vomiting. Some patients may have only mild epigastric discomfort or report intolerance to spicy or fatty foods or slight pain that is relieved by eating (Akiva & Greenwald, 2019). Patients with chronic gastritis may not be able to absorb vitamin B_{12} because of diminished production of intrinsic factor by the stomach's parietal cells due to atrophy, which may lead to pernicious anemia (see Chapter 29) (Zayouna

& Piper, 2018). Some patients with chronic gastritis have no symptoms (Marcus & Greenwald, 2019) (Table 40-1).

Assessment and Diagnostic Findings

The definitive diagnosis of gastritis is determined by an endoscopy and histologic examination of a tissue specimen obtained by biopsy (Akiva & Greenwald, 2019; Wehbi et al., 2019). A complete blood count (CBC) may be drawn to assess for anemia as a result of hemorrhage or pernicious anemia. Diagnostic measures for detecting *H. pylori* infection may be used and are discussed later in this chapter in the Peptic Ulcer Disease section.

TABLE 40-1 Clinical Manifestations of Acute and Chronic Gastritis

	Acute Gastritis	Chronic Gastritis
Gastrointestinal Manifestations	• Anorexia • Epigastric pain (rapid onset) • Hematemesis • Hiccups • Melena or hematochezia • Nausea and vomiting	• Belching • Early satiety • Intolerance of spicy or fatty foods • Nausea and vomiting • Pyrosis • Sour taste in mouth • Vague epigastric discomfort relieved by eating
Systemic Manifestations	• Possible signs of shock	• Anemia • Fatigue

Adapted from Marcus, A. J., & Greenwald, D. (2019). Chronic gastritis. *Medscape*. Retrieved on 2/25/2020 at: www.emedicine.medscape.com/article/176156; Wehbi, M., Dacha, S., Sarver, G., et al. (2019). Acute gastritis. *Medscape*. Retrieved on 2/25/2020 at: www.emedicine.medscape.com/article/175909

Medical Management

The gastric mucosa is capable of repairing itself after an episode of acute gastritis. As a rule, the patient recovers in about 1 day, although the patient's appetite may be diminished for an additional 2 or 3 days. Acute gastritis is also managed by instructing the patient to refrain from alcohol and food until symptoms subside. When the patient can take nourishment by mouth, a nonirritating diet is recommended. If the symptoms persist, intravenous (IV) fluids may need to be given. If bleeding is present, management is similar to the procedures used to control upper GI tract hemorrhage discussed later in this chapter.

Therapy is supportive and may include nasogastric (NG) intubation, antacids, histamine-2 receptor antagonists (H_2 blockers) (e.g., famotidine, cimetidine), proton pump inhibitors (e.g., omeprazole, lansoprazole), and IV fluids (Wehbi et al., 2019). Fiberoptic endoscopy may be necessary. In extreme cases, emergency surgery may be required to remove gangrenous or perforated tissue. A gastric resection or a

gastrojejunostomy (anastomosis of jejunum to stomach to detour around the pylorus) may be necessary to treat **gastric outlet obstruction,** also called *pyloric obstruction,* a narrowing of the pyloric orifice, which cannot be relieved by medical management.

Chronic gastritis is managed by modifying the patient's diet, promoting rest, reducing stress, recommending avoidance of alcohol and NSAIDs, and initiating medications that may include antacids, H_2 blockers, or proton pump inhibitors (Akiva & Greenwald, 2019). *H. pylori* may be treated with select drug combinations which typically include a proton pump inhibitor, antibiotics, and sometimes bismuth salts (Table 40-2).

Nursing Management

Reducing Anxiety

If the patient has ingested acids or alkalis, emergency measures may be necessary (see Chapter 67). The nurse offers supportive therapy to the patient and family during treatment and after the ingested acid or alkali has been neutralized or diluted. In some cases, the nurse may need to prepare the patient for additional diagnostic studies (endoscopies) or surgery. The patient may be anxious because of pain and planned treatment modalities. The nurse uses a calm approach to assess the patient and to answer all questions as completely as possible.

Promoting Optimal Nutrition

For acute gastritis, the nurse provides physical and emotional support and helps the patient manage the symptoms, which may include nausea, vomiting, and pyrosis. The patient should take no foods or fluids by mouth—possibly for a few days—until the acute symptoms subside, thus allowing the gastric mucosa to heal. If IV therapy is necessary, fluid intake and output are monitored, along with serum electrolyte values. After the symptoms subside, the nurse may offer the patient ice chips followed by clear liquids. Introducing solid food as soon as possible may provide adequate oral nutrition, decrease the need for IV therapy, and minimize irritation to the gastric mucosa. As food is introduced, the nurse evaluates and reports any symptoms that suggest a repeat episode of gastritis.

The nurse discourages the intake of caffeinated beverages, because caffeine is a central nervous system stimulant that increases gastric activity and pepsin secretion. The nurse also discourages alcohol use. Discouraging cigarette smoking is important. The level of nicotine measured in gastric acid can be 10 times greater than arterial blood and 80 times greater than venous blood. Nicotine will increase secretion of gastric acid and will also interfere with the mucosal barrier in the GI tract (Berkowitz, Schultz, Salazar, et al., 2018). When appropriate, the nurse initiates and refers the patient for alcohol counseling and smoking cessation programs.

TABLE 40-2  Select Pharmacotherapy for Peptic Ulcer Disease and Gastritis

Pharmacologic Agent	Major Action	Key Nursing Considerations
Antibiotics		
Amoxicillin	A bactericidal antibiotic that assists with eradicating *H. pylori* bacteria in the gastric mucosa	• May cause abdominal pain and diarrhea • Should not be used in patients allergic to penicillin
Clarithromycin	Exerts bactericidal effects to eradicate *H. pylori* bacteria in the gastric mucosa	• May cause GI upset, headache, altered taste • Many drug–drug interactions (e.g., colchicine, lovastatin, warfarin); interacts with grapefruit juice
Metronidazole	A synthetic antibacterial and antiprotozoal agent that assists with eradicating *H. pylori* bacteria in the gastric mucosa when given with other antibiotics and proton pump inhibitors	• Should be given with meals to decrease GI upset; may cause anorexia and metallic taste • Patient should avoid alcohol; increases blood-thinning effects of warfarin
Tetracycline	Exerts bacteriostatic effects to eradicate *H. pylori* bacteria in the gastric mucosa	• May cause photosensitivity reaction; advise patient to use sunscreen • May cause GI upset • Must be used with caution in patients with renal or hepatic impairment • Milk or dairy products may reduce effectiveness
Antidiarrheal		
Bismuth subsalicylate	Suppresses *H. pylori* bacteria in the gastric mucosa and assists with healing of mucosal ulcers	• Given concurrently with antibiotics to eradicate *H. pylori* infection • Should be taken on empty stomach • May darken the bowel movements
H_2 Receptor Antagonists		
Cimetidine	Decreases amount of HCl produced by stomach by blocking action of histamine on histamine receptors of parietal cells in the stomach	• Least expensive of H_2 receptor antagonists • May cause confusion, agitation, or coma in older

		adults or those with renal or hepatic insufficiency • Long-term use may cause diarrhea, dizziness, and gynecomastia • Many drug–drug interactions (e.g., amiodarone, amitriptyline, benzodiazepines, metoprolol, nifedipine, phenytoin, warfarin)
Famotidine	Same as for cimetidine	• Best choice for patient who is critically ill because it is known to have the least risk of drug–drug interactions; does not alter liver metabolism • Prolonged half-life in patients with renal insufficiency • Short-term relief for GERD
Nizatidine	Same as for cimetidine	• Used for treatment of ulcers and GERD • Prolonged half-life in patients with renal insufficiency • May cause headache, dizziness, diarrhea, nausea/vomiting, GI upset, and urticaria
Proton Pump Inhibitors of Gastric Acid		
Esomeprazole	Decreases gastric acid secretion by slowing the H^+,K^+-ATPase pump on the surface of the parietal cells of the stomach	• Used mainly for treatment of duodenal ulcer disease and *H. pylori* infection • A delayed-release capsule that is to be swallowed whole and taken before meals
Lansoprazole	Same as for esomeprazole	• A delayed-release capsule that is to be swallowed whole and taken before meals
Omeprazole	Same as for esomeprazole	• A delayed-release capsule that is to be swallowed whole and taken before meals • May cause diarrhea, nausea, constipation, abdominal pain, vomiting, headache, or dizziness

Pantoprazole	Same as for esomeprazole	• A delayed-release tablet that is to be swallowed whole and taken before meals • May cause diarrhea and hyperglycemia, headache, abdominal pain, and abnormal liver function tests
Rabeprazole	Same as for esomeprazole	• A delayed-release tablet that is to be swallowed whole and taken without regard to meals; however, if used for duodenal ulcers give after meals and when used for *H. pylori* treatment, give with food. • May cause abdominal pain, diarrhea, nausea, and headache • Drug–drug interactions with digoxin, iron, and warfarin
Prostaglandin E_1 Analogue		
Misoprostol	Synthetic prostaglandin; protects the gastric mucosa from agents that cause ulcers; also increases mucus production and bicarbonate levels	• Used to prevent ulceration in patients using NSAIDs • Administer with food • May cause diarrhea and cramping (including uterine cramping) • Used mainly for the treatment of duodenal ulcers • Pregnancy category X (i.e., should not be taken by a pregnant woman as it can soften the cervix and result in miscarriage or premature labor.)
Sucralfate	Creates a viscous substance in the presence of gastric acid that forms a protective barrier, binding to the surface of the ulcer, and prevents digestion by pepsin	• Should be taken without food but with water 1 h prior to meals • Other medications should be taken 2 h before or after this medication • Many drug–drug interactions (e.g., digoxin, phenytoin, warfarin)

	• May cause constipation or nausea

CNS, central nervous system; GERD, gastroesophageal reflux disease; GI, gastrointestinal; H_2, histamine-2; HCl, hydrochloric acid; H^+,K^+-ATPase, hydrogen–potassium adenosine triphosphatase; NSAIDs, nonsteroidal anti-inflammatory drugs.

Adapted from Karch, A. M. (2018). *Lippincott nursing drug guide*. Philadelphia, PA: Lippincott Williams & Wilkins.

Chart 40-1 HOME CARE CHECKLIST

The Patient with Gastritis

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of gastritis on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the need for vitamin B_{12} injections if patient has pernicious anemia.
- Explain the importance of and necessity for adherence with prescribed medication regimen.
- Demonstrate methods of keeping track of the medication regimen and storage of the prescribed medications and use reminders such as beepers and/or pillboxes.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify foods and other substances that may cause gastritis (e.g., spicy, highly seasoned foods, caffeine, nicotine, alcohol).
- Identify side effects and complications (e.g., increased or return of abdominal discomfort, inability to ingest adequate solids and liquids) that should be reported to primary provider.
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments and testing.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Promoting Fluid Balance

Daily fluid intake and output are monitored to detect early signs of dehydration (minimal fluid intake of 1.5 L/day, urine output of less than 1 mL/kg/h). If food and oral fluids are withheld, IV fluids (3 L/day) usually are prescribed and a record of fluid intake plus caloric value (1 L of 5% dextrose in water = 170 calories of carbohydrate) needs to be maintained. Electrolyte values (sodium, potassium, chloride) are assessed every 24 hours to detect any imbalance (see Chapter 10).

The nurse must always be alert to any indicators of hemorrhagic gastritis, which include **hematemesis** (vomiting of blood), tachycardia, and hypotension. All stools should be examined for the presence of frank or occult bleeding. If these occur, the primary provider should be notified, and the patient's vital signs are monitored as the

patient's condition warrants. Guidelines for managing upper GI tract bleeding are discussed later in this chapter.

Relieving Pain

Measures to help relieve pain include instructing the patient to avoid foods and beverages that may irritate the gastric mucosa as well as the correct use of medications to relieve chronic gastritis. The nurse must regularly assess the patient's level of pain and the extent of comfort achieved through the use of medications and avoidance of irritating substances.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse evaluates the patient's knowledge about gastritis and develops an individualized education plan that includes information about stress management, diet, and medications (see Table 40-2). Dietary instructions take into account the patient's daily caloric needs as well as cultural aspects of food preferences and patterns of eating. The nurse and patient review foods and other substances to be avoided (e.g., spicy, irritating, or highly seasoned foods; caffeine; nicotine; alcohol). Consultation with a dietitian may be recommended (Chart 40-1).

Providing information about prescribed medications, which may include antacids, H_2 blockers, or proton pump inhibitors, may help the patient to better understand why these medications assist in recovery and prevent recurrence. The importance of completing the medication regimen as prescribed to eradicate *H. pylori* infection must be reinforced to the patient and caregiver (see later discussion).

Continuing and Transitional Care

The nurse reinforces previous education and conducts ongoing assessment of the patient's symptoms and progress. Patients with malabsorption of vitamin B_{12} need information about lifelong vitamin B_{12} injections; the nurse may instruct a family member or caregiver how to administer the injections or make arrangements for the patient to receive the injections from the primary provider. Finally, the nurse emphasizes the importance of keeping follow-up appointments with the primary provider.

Peptic Ulcer Disease

Peptic ulcer disease affects approximately 4.6 million Americans annually, with the peak onset between 30 and 60 years of age (Anand, 2020; Norris, 2019). A peptic ulcer may be referred to as a gastric, duodenal, or esophageal ulcer, depending on its location. A peptic ulcer is an excavation (hollowed-out area) that forms in the mucosa of the stomach, in the **pylorus** (the opening between the stomach and duodenum), in the **duodenum** (the first portion of the small intestine, between the stomach and the jejunum), or in the esophagus. Erosion of a circumscribed area of mucosa is the cause

(Fig. 40-2). This erosion may extend as deeply as the muscle layers or through the muscle to the **peritoneum** (thin membrane that lines the inside of the wall of the abdomen) (Norris, 2019).

Peptic ulcers are more likely to occur in the duodenum than in the stomach. As a rule, they occur alone but they may occur in multiples. Chronic gastric ulcers tend to occur in the lesser curvature of the stomach, near the pylorus. Esophageal ulcers occur as a result of the backward flow of HCl from the stomach into the esophagus (gastroesophageal reflux disease [GERD]).

Figure 40-2 • Deep peptic ulcer. Reprinted with permission from Strayer, D. S., Saffitz, J. E., & Rubin, E. (2015). *Rubin's pathology: Mechanisms of human disease* (8th ed., Fig. 19-23). Philadelphia, PA: Lippincott Williams & Wilkins.

Women have 8% to 11% and men have an 11% to 14% lifetime risk of developing peptic ulcers (Anand, 2020). The rates of peptic ulcer disease among middle-age men have diminished over the past several decades, whereas the rates among older adults have increased, particularly among women (Anand, 2020). Those who are 65 years and older present to both outpatient and inpatient settings for treatment of peptic ulcers more than any other age group. This trend may be explained, at least in part, by higher rates of NSAID use and *H. pylori* infections in older adult populations (Anand, 2020).

In the past, stress and anxiety were thought to be causes of peptic ulcers, but research has documented that most peptic ulcers result from infection with *H. pylori,* which may be acquired through ingestion of food and water. Person-to-person transmission of the bacteria also occurs through close contact and exposure to emesis. Although *H. pylori* infection is common in the United States, most infected people do not develop ulcers. It is not known why *H. pylori* infection does not cause ulcers in all people, but most likely the predisposition to ulcer formation depends on certain factors, such as the type of *H. pylori* and other as yet unknown factors (Anand, 2020; Norris, 2019; Santacroce & Bhutani, 2019).

The use of NSAIDs, such as ibuprofen and aspirin, represents a major risk factor for peptic ulcers. Studies report that both NSAIDs and *H. pylori* impair the protective gastric mucosa, and the failure of the GI tract to repair the mucosa may result in ulceration (Anand, 2020; Norris, 2019). It is believed that smoking and alcohol consumption may be risks, although the evidence is inconclusive (Anand, 2020; NIDDK, 2020c).

Familial tendency also may be a significant predisposing factor. People with blood type O are more susceptible to the development of peptic ulcers than are those with blood type A, B, or AB. There also is an association between peptic ulcer disease and chronic obstructive pulmonary disease, cirrhosis of the liver, chronic kidney disease, and autoimmune disorders (Anand, 2020).

Peptic ulcer disease is also associated with Zollinger-Ellison syndrome (ZES). ZES is a rare condition in which benign or malignant tumors form in the pancreas and duodenum that secrete excessive amounts of the hormone gastrin (NIDDK, 2020d; Roy, 2019). The excessive amount of gastrin results in extreme gastric hyperacidity and severe peptic ulcer disease. While the exact cause of ZES is unknown, 25% to 30% of cases are linked to an inherited, genetic condition called multiple endocrine neoplasia, type 1 (MEN-1) (NIDDK, 2020b; Norris, 2019).

Pathophysiology

Peptic ulcers occur mainly in the gastroduodenal mucosa because this tissue cannot withstand the digestive action of gastric acid (HCl) and pepsin. The erosion is caused by the increased concentration or activity of acid–pepsin or by decreased resistance of the normally protective mucosal barrier. A damaged mucosa cannot secrete enough mucus to act as a barrier against normal digestive juices. Exposure of the mucosa to gastric acid (HCl), pepsin, and other irritating agents (e.g., NSAIDs or *H. pylori*) leads to inflammation, injury, and subsequent erosion of the mucosa. Patients with duodenal ulcers secrete more acid than normal, whereas patients with gastric ulcers tend to secrete normal or decreased levels of acid. When the mucosal barrier is impaired, even normal or decreased levels of HCl may result in the formation of peptic ulcers.

The use of NSAIDs inhibits prostaglandin synthesis, which is associated with a disruption of the normally protective mucosal barrier. Damage to the mucosal barrier also results in decreased resistance to bacteria, and thus infection from *H. pylori* bacteria may occur (Anand, 2020; Norris, 2019).

ZES is suspected when a patient has several peptic ulcers or an ulcer that is resistant to standard medical therapy. It is identified by the following: hypersecretion of gastrin, duodenal ulcers, and gastrinomas (islet cell tumors) in the pancreas or duodenum. More than 80% of gastrinomas are found in the “gastric triangle,” which encompasses the cystic and common bile ducts, the second and third portions of the duodenum, and the junction of the head and body of the pancreas. Most gastrinomas tend to grow slowly; however, more than 50% of these tumors are malignant (Bonheur & Nachimuthu, 2019). The patient with ZES may experience epigastric pain, pyrosis, diarrhea, and **steatorrhea** (fatty stools). Patients with ZES associated with MEN-1 syndrome may have coexisting pituitary or parathyroid tumors. ZES-associated MEN-1 syndrome is diagnosed with hyperparathyroidism; therefore,

patients may exhibit signs of hypercalcemia for several years before MEN-1 is diagnosed (NIDDK, 2020b).

Stress ulcer is the term given to the acute mucosal ulceration of the duodenal or gastric area that occurs after physiologically stressful events, such as burns, shock, sepsis, and multiple organ dysfunction syndrome (Clarke et al., 2020). Stress ulcers, which are clinically different from peptic ulcers, are most common in patients following significant burn injuries, traumatic brain injury, or who require mechanical ventilation. Stress ulcers are believed to be a result of ischemia to gastric mucosa and alterations in the mucosa barrier (Clarke et al., 2020; Norris, 2019). When the patient recovers, the lesions are reversed. This pattern is typical of stress ulceration.

Differences of opinion exist as to the actual cause of mucosal ulceration in stress ulcers. Usually, the ulceration results from a disruption of the normally protective mucosal barrier and decreased mucosal blood flow (ischemia). Mucosal ischemia results in the reflux of duodenal contents into the stomach, which increases exposure of the unprotected gastric mucosa to the digestive effects of gastric acid (HCl) and pepsin (Anand, 2020; Clarke et al., 2020; Norris, 2019). The combination of mucosal ischemia and increased gastric acid and pepsin exposure creates an ideal climate for ulceration.

Specific types of ulcers that result from stressful conditions include Curling ulcers and Cushing ulcers. Curling ulcer is frequently observed after extensive burn injuries and often involves the antrum of the stomach or the duodenum (Anand, 2020). Cushing ulcer is common in patients with a traumatic head injury, stroke, brain tumor, or following intracranial surgery. Cushing ulcer is thought to be caused by increased intracranial pressure, which results in overstimulation of the vagal nerve and an increased secretion of gastric acid (HCl) (Norris, 2019). Cushing ulcers are typically deep, single ulcerations and have increased risk of perforation (Anand, 2020).

Clinical Manifestations

Symptoms of peptic ulcer disease may last for a few days, weeks, or months and may disappear only to reappear, often without an identifiable cause. Many patients with peptic ulcers have no signs or symptoms. These s*ilent peptic ulcers* most commonly occur in older adults and those taking aspirin and other NSAIDs (Anand, 2020).

As a rule, the patient with an ulcer complains of dull, gnawing pain or a burning sensation in the mid epigastrium or the back. There are few clinical manifestations that differentiate gastric ulcers from duodenal ulcers; however, classically, the pain associated with gastric ulcers most commonly occurs immediately after eating, whereas the pain associated with duodenal ulcers most commonly occurs 2 to 3 hours after meals. In addition, approximately 50% to 80% of patients with duodenal ulcers awake with pain during the night, whereas 30% to 40% of patients with gastric ulcers voice this type of complaint. Patients with duodenal ulcers are more likely to express relief of pain after eating or after taking an antacid than patients with gastric ulcers (Anand, 2020).

Other nonspecific symptoms of either gastric ulcers or duodenal ulcers may include pyrosis, vomiting, constipation or diarrhea, and bleeding. These symptoms are often accompanied by sour eructation (burping), which is common when the patient's stomach is empty.

Although vomiting is rare in an uncomplicated peptic ulcer, it may be a symptom of a complication of an ulcer. It results from gastric outlet obstruction, caused by either muscular spasm of the pylorus or mechanical obstruction from scarring or acute swelling of the inflamed mucous membrane adjacent to the ulcer. Vomiting may or may not be preceded by nausea; usually, it follows a bout of severe pain and bloating, which is relieved by vomiting. Emesis may contain undigested food eaten many hours earlier. Constipation or diarrhea may occur, probably as a result of diet and medications.

The patient with bleeding peptic ulcers may present with evidence of GI bleeding, such as hematemesis or the passage of melena (Anand, 2020). Approximately 20% of patients with bleeding peptic ulcers do not experience abdominal pain at the time of diagnosis (Norris, 2019). Peptic ulcer perforation results in the sudden onset of signs and symptoms. The patient often reports severe, sharp upper abdominal pain, which may be referred to the shoulder; extreme abdominal tenderness; and nausea or vomiting. Hypotension and tachycardia may occur, indicating the onset of shock (Azer, 2018).

Assessment and Diagnostic Findings

A physical examination may reveal pain, epigastric tenderness, or abdominal distention. Upper endoscopy is the preferred diagnostic procedure because it allows direct visualization of inflammatory changes, ulcers, and lesions. Through endoscopy, a biopsy of the gastric mucosa and any suspicious lesions can be obtained. Endoscopy may reveal lesions that, because of their size or location, are not evident on x-ray studies. *H. pylori* infection may be determined by endoscopy and histologic examination of a tissue specimen obtained by biopsy, or a rapid urease test of the biopsy specimen. Other less invasive diagnostic measures for detecting *H. pylori* include serologic testing for antibodies against the *H. pylori* antigen, stool antigen test, and urea breath test (Anand, 2020).

The patient who has a bleeding peptic ulcer may require periodic CBCs to determine the extent of blood loss and whether or not blood transfusions are advisable (see Chapter 28). Stools may be tested periodically until they are negative for occult blood. Gastric secretory studies are of value in diagnosing ZES and **achlorhydria** (lack of HCl), hypochlorhydria (low levels of HCl), or hyperchlorhydria (high levels of HCl).

Medical Management

Once the diagnosis is established, the patient is informed that the condition can be managed. Recurrence may develop; however, peptic ulcers treated with antibiotics to eradicate *H. pylori* have a lower recurrence rate than those not treated with antibiotics. The goals are to eradicate *H. pylori* as indicated and to manage gastric acidity. Methods used include medications, lifestyle changes, and surgical intervention.

Pharmacologic Therapy

Currently, the most commonly used therapy for peptic ulcers is a combination of antibiotics, proton pump inhibitors, and sometimes bismuth salts that suppress or

eradicate *H. pylori*. Recommended combination drug therapy is typically prescribed for 10 to 14 days and may include triple therapy with two antibiotics (e.g., metronidazole or amoxicillin and clarithromycin) plus a proton pump inhibitor (e.g., lansoprazole, omeprazole, or rabeprazole), or quadruple therapy with two antibiotics (metronidazole and tetracycline) plus a proton pump inhibitor and bismuth salts (Anand, 2020; Marcus & Greenwald, 2019). Research is currently being conducted to develop a vaccine against *H. pylori* (Liu, Zhong, Chen, et al., 2020).

H_2 blockers and proton pump inhibitors that reduce gastric acid secretion are used to treat ulcers not associated with *H. pylori* infection. Table 40-3 provides information about the medication regimens for peptic ulcer disease.

TABLE 40-3 Drug Regimens for Peptic Ulcer Disease

Indications	Drug Regimen	Nursing Considerations
Ulcer healing	**H_2 receptor antagonist** Cimetidine 400 mg bid or 800 mg at bedtime Famotidine 20 mg bid or 40 mg at bedtime Nizatidine 150 mg bid or 300 mg at bedtime	Should be used for 6–8 wks for complete peptic ulcer healing; patients who are at high risk require a maintenance dose for 1 yr
	PPIs: Esomeprazole 40 mg daily Lansoprazole 30 mg daily Omeprazole 20 mg daily Pantoprazole 40 mg daily Rabeprazole 20 mg daily	Should be used for 4–8 wks for complete peptic ulcer healing; patients who are at high risk require a maintenance dose for 1 yr
***H. pylori* infection**	*Quadruple therapy* with bismuth subsalicylate 525 mg qid, plus tetracycline 500 mg qid, plus metronidazole 500 mg bid, plus a PPI daily for 10–14 days *Alternate therapy* with clarithromycin 500 mg bid, amoxicillin 1 g bid, metronidazole 500 mg bid, plus PPI for 10–14 days	Efficacy of therapy is approximately 85% qid dosing may decrease adherence to the regimen
Prophylactic therapy for NSAID ulcers	Peptic ulcer healing doses of PPIs (above) Misoprostol 100–200 mcg qid	Prevents recurrent ulceration in approximately 80–90% of patients; qid dosing may decrease adherence to the regimen Pregnancy category X (i.e., should not be taken by a pregnant woman as it can soften the cervix and result in miscarriage or premature labor.)

bid, two times a day; H_2, histamine-2; NSAID, nonsteroidal anti-inflammatory drug; PPIs, proton pump inhibitors; qid, four times a day.

Adapted from Anand, B. S. (2020). Peptic ulcer disease. *Medscape*. Retrieved on 4/29/2020 at: www.emedicine.medscape.com/article/181753

The patient is advised to adhere to and complete the medication regimen to ensure complete healing of the ulcer. The patient also is advised to avoid the use of NSAIDs. Because most patients become symptom free within a week, the nurse stresses to the patient the importance of following the prescribed regimen so that the healing process can continue uninterrupted and the return of chronic ulcer symptoms can be prevented. Maintenance dosages of H_2 blockers are usually recommended for 1 year.

For patients with ZES, hypersecretion of gastrin stimulates the release of gastric acid (HCl), which may be controlled with proton pump inhibitors. Octreotide, a medication that suppresses gastrin levels, also may be prescribed (Daniels, Khalili, Morano, et al., 2019). Patients with ZES will require periodic endoscopy to evaluate the effectiveness of medication therapy.

Patients at high risk for stress ulcers (e.g., patients who are mechanically ventilated for more than 48 hours) may be treated prophylactically with either H_2 blockers or proton pump inhibitors, and cytoprotective agents (e.g., misoprostol, sucralfate) because of the increased risk of upper GI tract hemorrhage (Clarke et al., 2020; Young, Bagshaw, Forbes, et al., 2020).

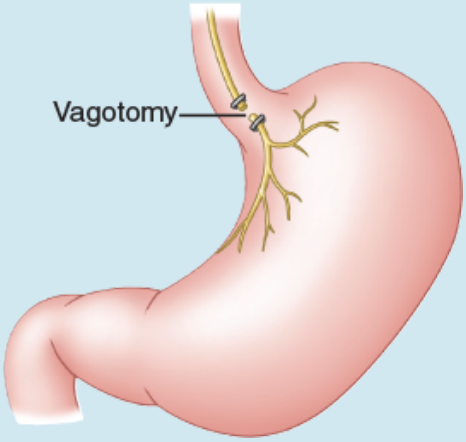
Quality and Safety Nursing Alert

Misoprostol should not be taken by a pregnant woman as it can soften the cervix and result in miscarriage or premature labor. The nurse should be aware of this risk when caring for women of childbearing age.

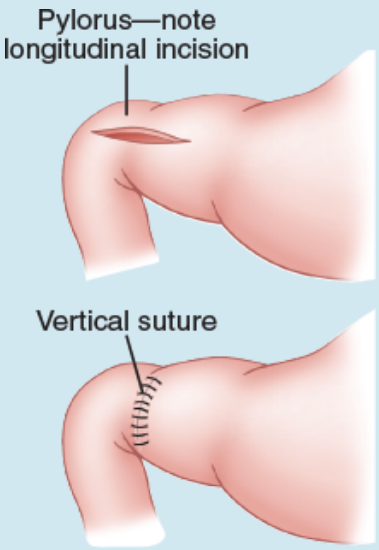
Smoking Cessation

Smoking decreases the secretion of bicarbonate from the pancreas into the duodenum, resulting in increased acidity of the duodenum. Continued smoking is also associated with delayed healing of peptic ulcers (Berkowitz et al., 2018; Kennedy & Winter, 2017). Therefore, the patient is encouraged to stop smoking. Refer to Chapter 23 for information on how the nurse may promote cessation of tobacco use.

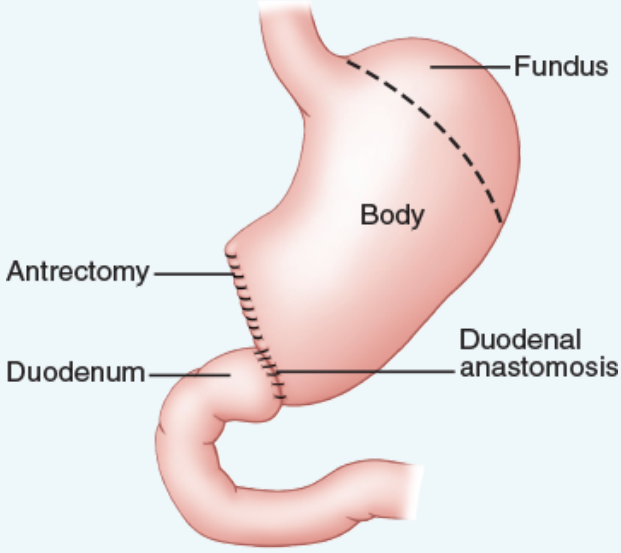
Dietary Modification

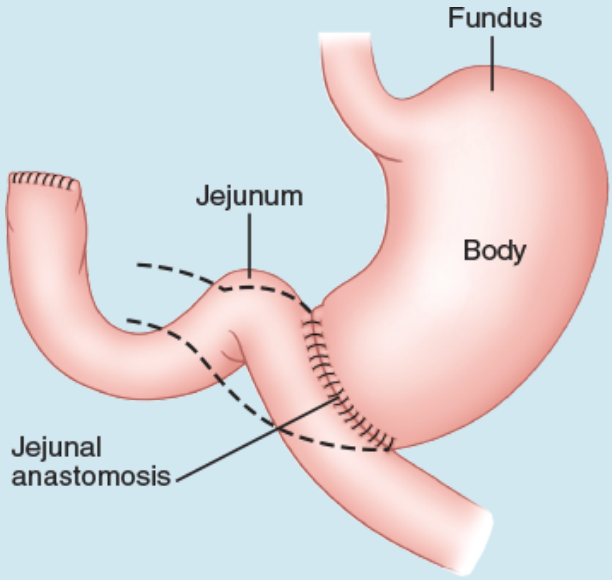


The intent of dietary modification for patients with peptic ulcers is to avoid oversecretion of acid and hypermotility in the GI tract. These can be minimized by avoiding extremes of temperature in food and beverages and overstimulation from the consumption of alcohol, coffee (including decaffeinated coffee, which also stimulates acid secretion), and other caffeinated beverages. In addition, an effort is made to neutralize acid by eating three regular meals a day. Small, frequent feedings are not necessary as long as an antacid or an H_2 blocker is taken. Diet compatibility becomes an individual matter: The patient eats foods that are tolerated and avoids those that produce pain.



Surgical Management





The introduction of antibiotics to eradicate *H. pylori* and of proton pump inhibitors as treatment for ulcers results in ulcer healing in approximately 85% to 90% of patients (Anand, 2020). However, surgery is usually recommended for patients with

intractable ulcers (those failing to heal after 12 to 16 weeks of medical treatment), life-threatening hemorrhage, perforation, or obstruction and for those with ZES that is unresponsive to medications (Anand, 2020; Bonheur & Nachimuthu, 2019; Upchurch, 2019). Surgical procedures include vagotomy, with or without **pyloroplasty** (transecting nerves that stimulate acid secretion and opening the pylorus), and **antrectomy**, which is removal of the pyloric (antrum) portion of the stomach with anastomosis (surgical connection) to either the duodenum (gastroduodenostomy or Billroth I) or jejunum (gastrojejunostomy or Billroth II) (Table 40-4).

TABLE 40-4 Surgical Procedures for Peptic Ulcer Disease

Operation	Description	Adverse Effects
Vagotomy 	Severing of the vagus nerve. Decreases gastric acid by diminishing cholinergic stimulation to the parietal cells, making them less responsive to gastrin. May be performed via an open surgical approach or laparoscopy. May be performed to reduce gastric acid secretion. A drainage type of procedure (see pyloroplasty) is usually performed to assist with gastric emptying (because there is total denervation of the stomach).	Some patients experience problems with feeling of fullness, dumping syndrome, diarrhea, and gastritis.
Truncal vagotomy	Severs the right and left vagus nerves as they enter the stomach at the distal part of the esophagus; most commonly used to decrease acid secretions.	Some patients experience problems with feeling of fullness, dumping syndrome, diarrhea, or constipation.
Selective vagotomy	Severs vagal	Fewer associated

	innervation to the stomach but maintains innervation to the rest of the abdominal organs.	adverse effects than with truncal vagotomy.
Proximal (parietal cell) gastric vagotomy without drainage	Denervates acid-secreting parietal cells but preserves vagal innervation to the gastric antrum and pylorus.	No associated dumping syndrome.
Pyloroplasty  	Longitudinal incision is made into the pylorus and transversely sutured closed to enlarge the outlet and relax the muscle; usually accompanies truncal and selective vagotomies.	See adverse effects associated with truncal and selective vagotomies, as appropriate.
Antrectomy Billroth I (gastroduodenostomy)	Removal of the lower portion of the antrum of the stomach (which contains the cells that secrete gastrin) as well as a small portion of the duodenum and pylorus.	Patients may have problems with feeling of fullness, dumping syndrome, and diarrhea.

	The remaining segment is anastomosed to the duodenum. May be performed in conjunction with a truncal vagotomy.		
Billroth II (gastrojejunostomy) 	Removal of lower portion (antrum) of stomach with anastomosis to jejunum. *Dotted lines* show portion removed (antrectomy). A duodenal stump remains and is oversewn.	Patients frequently have associated dumping syndrome, anemia, weight loss, and malabsorption.	

Surgery may be performed using a traditional open abdominal approach (requiring a long abdominal incision) or through the use of laparoscopy (only requiring small abdominal incisions). Laparoscopy is a type of minimally invasive surgery that involves the indirect visualization of the abdominal cavity through the use of a laparoscope (a thin flexible tube) attached to a camera. The laparoscope is placed into the abdomen through small "keyhole" incisions (0.5 to 1.5 cm in length). Laparoscopy has been associated with decreased postoperative bleeding, pain, infection, respiratory complications, and recovery time (Davenport, Ueland, Kumar, et al., 2019). The choice of using an open abdominal approach or laparoscopy is determined by the surgeon's preference and expertise as well as clinical factors, such as the patient's current health status; the presence of coexisting medical conditions; and a history of previous abdominal surgery.

Follow-Up Care

Recurrence of peptic ulcer disease within 1 year may be prevented with the prophylactic use of H_2 blockers taken at a reduced dose. Not all patients require maintenance therapy; it may be prescribed only for those with two or three recurrences per year, those who have had a complication such as bleeding or gastric outlet obstruction, or those for whom gastric surgery poses too high a risk. The likelihood of recurrence is reduced if the patient avoids smoking, coffee (including decaffeinated coffee) and other caffeinated beverages, alcohol, and ulcerogenic medications (e.g., NSAIDs).

NURSING PROCESS

The Patient with Peptic Ulcer Disease

Assessment

The nurse asks the patient to describe the pain, its pattern and whether or not it occurs predictably (e.g., after meals, during the night), and strategies used to relieve it (e.g., food, antacids). If the patient reports a recent history of vomiting, the nurse determines how often emesis has occurred and notes important characteristics of the vomitus: Is it bright red, does it resemble coffee grounds, or is there undigested food from previous meals? Has the patient noted any bloody or tarry stools?

The nurse also asks the patient to list their usual food intake for a 72-h period. Lifestyle and other habits are a concern as well. For example, do they smoke cigarettes? If yes, how many? Do they use any type of electronic nicotine delivery systems (ENDS)? If yes, what type and how often? Does the patient ingest alcohol? If yes, how much and how often? Are NSAIDs used? Is there a family history of ulcer disease?

The nurse assesses the patient's vital signs and reports tachycardia and hypotension, which may indicate anemia from GI bleeding. The stool is tested for occult blood, and a physical examination, including palpation of the abdomen for localized tenderness, is performed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Acute pain associated with the effect of gastric acid secretion on damaged tissue
- Anxiety associated with an acute illness
- Impaired nutritional intake associated with changes in diet

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- Perforation
- Penetration
- Gastric outlet obstruction

Planning and Goals

The goals for the patient may include relief of pain, reduced anxiety, maintenance of nutritional requirements, and absence of complications.

Nursing Interventions

Relieving Pain

Pain relief can be achieved with prescribed medications. The patient should avoid NSAIDs, aspirin in particular, as well as alcohol. In addition, meals should be eaten at regularly paced intervals in a relaxed setting. Medications prescribed to

treat the peptic ulcer should provide relief of ulcer-associated pain. Some patients benefit from learning relaxation techniques to help manage stress and pain.

Reducing Anxiety

The nurse assesses the patient's level of anxiety. Explaining diagnostic tests and administering medications as scheduled help reduce anxiety. The nurse interacts with the patient in a relaxed manner; helps identify stressors; and explains various coping techniques and relaxation methods, such as biofeedback, hypnosis, or behavior modification. The patient's family is also encouraged to participate in care and to provide emotional support.

Maintaining Optimal Nutritional Status

The nurse assesses the patient for malnutrition and weight loss. After recovery from an acute phase of peptic ulcer disease, the patient is advised about the importance of adhering to the medication regimen and dietary restrictions.

Monitoring and Managing Potential Complications

Hemorrhage. Gastritis and hemorrhage from peptic ulcer are the two most common causes of upper GI tract bleeding (which may also occur with esophageal varices, as discussed in Chapter 43). Hemorrhage in patients with duodenal ulcers is associated with an approximately 5% mortality rate (Anand, 2020). Bleeding peptic ulcers account for 27% to 40% of all upper GI bleeds and it may be manifested by hematemesis or melena (Anand, 2020; Upchurch, 2019). The vomited blood can be bright red, or it can have a dark coffee grounds appearance from the oxidation of hemoglobin to methemoglobin. When the hemorrhage is large (2000 to 3000 mL), most of the blood is vomited. Because large quantities of blood may be lost quickly, immediate correction of blood loss may be required to prevent hemorrhagic shock. When the hemorrhage is small, much or all of the blood is passed in the stools, which appear tarry black because of the digested hemoglobin. Management depends on the amount of blood lost and the rate of bleeding.

The nurse assesses the patient for faintness or dizziness and nausea, which may precede or accompany bleeding. The nurse must monitor vital signs frequently and evaluate the patient for tachycardia, hypotension, and tachypnea. Other nursing interventions include monitoring the hemoglobin and hematocrit, testing the stool for gross or occult blood, and recording hourly urinary output to detect anuria or oliguria (absence of or decreased urine production).

Many times, the bleeding from a peptic ulcer stops spontaneously; however, the incidence of recurrent bleeding is high. Because bleeding can be fatal, the cause and severity of the hemorrhage must be identified quickly, and the blood loss treated to prevent hemorrhagic shock. The nurse monitors the patient carefully so that bleeding can be detected quickly. Patients suspected of having an ulcer who present with symptoms of acute GI bleeding should undergo evaluation with endoscopy within 12 h to confirm the diagnosis and allow targeted endoscopic interventions (Upchurch, 2019). These endoscopic interventions may include injecting the bleeding site with epinephrine or alcohol, or cauterizing the site, or clipping the ulcer, all in efforts to stop the bleeding (Anand, 2020; Upchurch, 2019). Arteriography with embolization may be needed if therapeutic endoscopy fails to control the bleeding (Spiliopoulos, Inchingolo, Lucatelli, et al., 2018). If

bleeding cannot be managed by these methods, surgery may be indicated, in which the area of the ulcer is removed, or the bleeding vessels are ligated. Many patients also undergo procedures (e.g., vagotomy and pyloroplasty, gastrectomy) aimed at controlling the underlying cause of the ulcers (see Table 40-4).

For patients who are not candidates for surgery or for those with persistent, severe bleeding despite medical and endoscopic treatment, arteriography with embolization may be indicated (Spiliopoulos et al., 2018). Arteriography with embolization is more commonly referred to as *Transcatheter Arterial Embolization* (TAE). TAE is an interventional radiologic procedure in which a catheter is placed percutaneously (through the skin) into an artery (e.g., femoral or brachial artery) and is advanced under use of fluoroscopy to the site of the bleeding peptic ulcer. An embolic agent is then delivered via the catheter, which selectively occludes blood flow to the bleeding vessel(s), and thus stops bleeding of the peptic ulcer. Common embolic agents used include metallic coils (a small metal device) and ethylene vinyl alcohol copolymer (Loffroy, Midulla, Falvo, et al., 2018; Spiliopoulos et al., 2018).

The patient with GI bleeding may require treatment for hemorrhagic shock. If that is the case, then the collaborative treatment guidelines described in Chapter 11 must be followed (e.g., hemodynamic monitoring, IV line insertion for fluid resuscitation, blood component therapy). In addition, other related nursing and collaborative interventions may include inserting an NG tube to distinguish fresh blood from material resembling coffee grounds, to aid in the removal of clots and acid through administering a saline lavage, to prevent nausea and vomiting through suction decompression of gastric contents, and to provide a means of monitoring further bleeding.

Perforation and Penetration. Perforation is the erosion of the ulcer through the gastric **serosa** (thin membrane covering the outer surface of the stomach) into the peritoneal cavity without warning. It is an abdominal emergency and requires immediate surgery. Perforation occurs more commonly with duodenal ulcers than it does with gastric ulcers; however, in both cases, it is a very serious complication that can result in sepsis or multiorgan failure (Azer, 2018; Norris, 2019). Penetration is erosion of the ulcer through the gastric serosa into adjacent structures such as the pancreas, biliary tract, or gastrohepatic **omentum** (membranous fold of the peritoneum). Symptoms of penetration include back and epigastric pain not relieved by medications that were effective in the past. Like perforation, penetration usually requires surgical intervention.

Signs and symptoms of perforation include the following:

- Sudden, severe upper abdominal pain (persisting and increasing in intensity); pain may be referred to the shoulders, especially the right shoulder, because of irritation of the phrenic nerve in the diaphragm
- Vomiting
- Collapse (fainting)
- Extremely tender and rigid (boardlike) abdomen
- Hypotension and tachycardia, indicating shock

Because chemical peritonitis develops within a few hours of perforation and is followed by bacterial peritonitis, the perforation must be closed as quickly as possible and the abdominal cavity lavaged of stomach or intestinal contents. In

some patients, it may be safe and advisable to perform surgery to treat the ulcer disease in addition to suturing the perforation.

During surgery and postoperatively, the stomach contents are drained by means of an NG tube. The nurse monitors fluid and electrolyte balance and assesses the patient for localized infection or peritonitis (increased temperature, abdominal pain, paralytic ileus, increased or absent bowel sounds, abdominal distention). Antibiotic therapy is given as prescribed.

Gastric Outlet Obstruction. Peptic ulcer disease is the leading benign (noncancerous) cause of gastric outlet obstruction (Castellanos & Podolsky, 2020). Gastric outlet obstruction occurs when the area distal to the pyloric sphincter becomes scarred and stenosed from spasm or edema or from scar tissue that forms when an ulcer alternately heals and breaks down. The patient may have nausea and vomiting, constipation, epigastric fullness, anorexia, and, later, weight loss.

In treating the patient with gastric outlet obstruction, the first consideration is to insert an NG tube to decompress the stomach. Confirmation that obstruction is the cause of the discomfort is accomplished by assessing the amount of fluid aspirated from the NG tube. A residual of more than 400 mL suggests obstruction. Usually, an upper GI study or endoscopy is performed to confirm gastric outlet obstruction. Decompression of the stomach and management of extracellular fluid volume and electrolyte balances may improve the patient's condition and avert the need for surgical intervention. Balloon dilation of the pylorus via endoscopy may be beneficial. If the obstruction is unrelieved by medical management, surgery (in the form of a vagotomy and antrectomy or gastrojejunostomy and vagotomy) may be required.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The nurse educates the patient about the factors that relieve and those that aggravate the condition. The nurse reviews information about medications to be taken at home, including name, dosage, frequency, and possible side effects, stressing the importance of continuing to take medications even after signs and symptoms have decreased or subsided (Chart 40-2). The patient is instructed to avoid medications and foods that exacerbate symptoms (e.g., NSAIDs, alcohol). If relevant, the nurse also informs the patient about the irritant effects of smoking on the ulcer and provides information about smoking cessation programs.

Continuing and Transitional Care. The nurse reinforces the importance of follow-up care; the need to report recurrence of symptoms; and the need for treating possible problems that occur after surgery, such as intolerance to specific foods. The patient and family are reminded of the importance of participating in health promotion activities and recommended health screening.

Evaluation

Expected patient outcomes may include:

1. Reports freedom from pain between meals and at night
2. Reports feeling less anxious
3. Maintains weight
4. Demonstrates knowledge of self-care activities

a. Avoids irritating foods and beverages (alcohol) and medications such as NSAIDs, particularly aspirin
b. Takes medications as prescribed

5. No evidence of complications (e.g., hemorrhage, perforation or penetration, gastric outlet obstruction)

Gastric Cancer

According to the American Cancer Society (ACS, 2020b), an estimated 27,000 Americans were expected to be diagnosed with gastric cancer in 2020, and an estimated 11,000 deaths from the disease were expected to occur that year. Gastric cancer is a more common diagnosis among older adults, with the mean age at diagnosis of 68 years (ACS, 2020b). Men have a higher incidence of gastric cancer than women. Hispanic Americans, African Americans, and Asian/Pacific Islanders are at higher risk of developing gastric cancer than Caucasian Americans.

Chart 40-2  **HOME CARE CHECKLIST**

The Patient with Peptic Ulcer Disease

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of peptic ulcer disease on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Explain the importance of and necessity for adherence with prescribed medication regimen.
- Demonstrate methods of keeping track of the medication regimen and storage of the prescribed medications and use reminders such as beepers and/or pillboxes.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify foods and other substances to avoid (e.g., food and drinks with extreme temperatures, coffee and other caffeinated beverages, alcohol, foods that were not tolerated in the past).
- Identify side effects and complications that should be reported to primary provider:
  - Hemorrhage—cool skin, confusion, increased heart rate, labored breathing, blood in stool (either bright red or tarry black)
  - Penetration and perforation—severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, increased heart rate
  - Gastric outlet obstruction—nausea and vomiting, distended abdomen, abdominal pain
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments and testing.
- Identify the need for health promotion (e.g., cessation of use of tobacco products, stress management), disease prevention and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Worldwide, gastric cancer is the fifth most common cancer diagnosis, with the highest incidence in Eastern and Central Asia (e.g., Republic of Korea, Mongolia, and Japan) and Latin America (Rawla & Barsouk, 2019). Countries with high incidence of gastric cancer, such as Japan, have implemented mass screening programs, which resulted in earlier diagnosis (at a more curable stage of disease), and may have reduced the number of deaths from gastric cancer (ACS, 2020b).

Diet appears to be a significant risk factor for the development of gastric cancer. A diet high in smoked, salted, or pickled foods and low in fruits and vegetables may increase the risk of gastric cancer (ACS, 2020b). *H. pylori* infection is a major risk factor for the development of gastric cancer. Other factors related to the incidence of gastric cancer include gastritis, pernicious anemia, smoking, obesity, achlorhydria, gastric ulcers, previous partial gastrectomy (more than 20 years ago), and genetics (ACS, 2020b; National Cancer Institute [NCI], 2020).

The vast majority of gastric cancers are sporadic or occurring as a result of acquired, not inherited, gene mutations. However, it is understood that gastric cancers may have a familial component (e.g., blood type A and those with another first-degree

relative [parent, sibling, or child] with gastric cancer) and are associated with inherited cancer predisposition syndromes (ACS, 2020b; Cabebe, 2020; NCI, 2020). Inherited cancer predisposition syndromes associated with increased risk of developing gastric cancer include hereditary diffuse gastric cancer, Lynch syndrome (i.e., hereditary non-polyposis colorectal cancer), juvenile polyposis syndrome, familial adenomatosis polyposis, and Peutz–Jeghers syndrome (ACS, 2020b; Cabebe, 2020; NCI, 2020).

The prognosis for patients with gastric cancer is generally poor. The 5-year survival rate for all patients with gastric cancer is about 32% (NCI, 2020). One reason for the poor survival rate is that the diagnosis is usually made late because most patients are asymptomatic during the early stages of the disease. Most cases of gastric cancer are discovered only after the cancer has spread from the stomach to involve the lymph nodes or has metastasized to distant organs.

Pathophysiology

Ninety to 95% of gastric cancers are adenocarcinomas, which arise from the mucus-producing cells of the innermost lining of the stomach (ACS, 2020b). Gastric cancer begins with a lesion involving cells on the top layer of the stomach mucosa. The lesion then penetrates cells in the deeper layers of the mucosa, submucosa, and stomach wall. Eventually the lesion infiltrates the stomach wall and extends to organs or structures adjacent to the stomach. Lymph node involvement and metastasis tend to occur early due to the abundant lymphatic and vascular networks of the stomach. Common sites of metastasis include the liver, peritoneum, lungs, and brain (ACS, 2020b).

Clinical Manifestations

Gastric cancer is associated with few if any symptoms in the early stages of the disease (ACS, 2020b; Cabebe, 2020). Symptoms of early-stage disease may include pain that is relieved by antacids, resembling those of benign ulcers, and are seldom definitive. Symptoms of advanced disease are similar to those of peptic ulcer disease, such as dyspepsia, early satiety, weight loss, abdominal pain just above the umbilicus, loss or decrease in appetite, bloating after meals, and nausea or vomiting. Fatigue often occurs as a result of the cancer itself or blood loss from the lesion infiltrating the stomach or surrounding tissue (ACS, 2020b; Cabebe, 2020).

Assessment and Diagnostic Findings

The physical examination is usually not helpful in detecting the cancer because most early gastric tumors are not palpable. Advanced gastric cancer may be palpable as a mass. Ascites and hepatomegaly (enlarged liver) may be apparent if the cancer cells have metastasized to the liver. Palpable nodules around the umbilicus, called *Sister Mary Joseph's nodules,* are a sign of a GI malignancy, usually a gastric cancer (Cabebe, 2020).

Esophagogastroduodenoscopy for biopsy and cytologic washings is the diagnostic study of choice, and a barium x-ray examination of the upper GI tract may also be

performed (ACS, 2020b; Cabebe, 2020; Li, Chung, & Mullen, 2019; Norris, 2019). Endoscopic ultrasound is an important tool to assess tumor depth and any lymph node involvement. Computed tomography (CT) scanning completes the diagnostic studies, particularly to assess for surgical resectability of the tumor before surgery is scheduled. CT scans of the chest, abdomen, and pelvis are valuable in staging gastric cancer.

A CBC may be used to evaluate for the presence of anemia. Assessment of tumor markers (blood analysis for antigens indicative of cancer), such as carcinoembryonic antigen (CEA), carbohydrate antigen (CA 19-9), and CA 50 are monitored to determine the effectiveness of treatment(s). Tumor marker values are usually elevated in the presence of gastric cancer before treatment and decrease if the tumor is responding to the treatment (Cabebe, 2020).

Medical Management

The treatment of gastric cancer is multimodal, often involving surgery, chemotherapy, targeted therapy, and radiation therapy. In general, the patient with a resectable tumor undergoes a surgical procedure to remove the tumor and appropriate lymph nodes. If the tumor can be removed while it is still localized to the stomach, the patient may be cured. In patients with a tumor that is not surgically resectable or those with advanced disease, cure is less likely. Treatment may include surgery to control the cancer growth or for the palliation of symptoms, chemotherapy, targeted therapy, and radiation therapy.

Surgical Management

A total gastrectomy may be performed for a resectable cancer in the midportion or body of the stomach. The entire stomach is removed along with the duodenum, the lower portion of the esophagus, supporting mesentery, and lymph nodes. Reconstruction of the GI tract is performed by anastomosing the end of the jejunum to the end of the esophagus, a procedure called an *esophagojejunostomy.* A radical partial (subtotal) gastrectomy is performed for a resectable tumor in the middle and distal portions of the stomach. A Billroth I or a Billroth II operation (see Table 40-4) is performed. The Billroth I involves a limited resection and offers a lower cure rate than the Billroth II. The Billroth II procedure is a wider resection that involves removing approximately 75% of the stomach and decreases the possibility of lymph node spread or metastatic recurrence. A proximal partial (subtotal) gastrectomy may be performed for a resectable tumor located in the proximal portion of the stomach or cardia. A total gastrectomy or an esophagogastrectomy is usually performed in place of this procedure to achieve a more extensive resection (Chisti & Willner, 2020; Norris, 2019).

Surgery may be also required to treat common complications of advanced gastric cancer, which may include gastric outlet obstruction, bleeding, and severe pain. Gastric perforation is an emergency situation requiring surgical intervention. A gastric resection may be the most effective palliative procedure for advanced gastric cancer. Palliative procedures such as gastric or esophageal bypass, gastrostomy, or jejunostomy may temporarily alleviate symptoms such as nausea and vomiting.

Palliative rather than radical surgery may be performed if there is metastasis to other vital organs, such as the liver, or to achieve a better quality of life.

Complications of Gastric Surgery

The patient undergoing gastric surgery may experience complications, including hemorrhage, dumping syndrome, bile reflux, and gastric outlet obstruction. Postoperative bleeding from the surgical site is a common complication of gastric surgery. Bleeding may be severe (hemorrhage) and manifest as vomiting large amounts of bright red blood, which may result in hemorrhagic shock (see Chapter 11). The medical management and nursing care of the patient experiencing hemorrhage is discussed in the Peptic Ulcer Disease section of this chapter.

Dumping syndrome may occur as a result of any surgical procedure that involves the removal of a significant portion of the stomach or includes resection or removal of the pylorus (see Table 40-4). The rapid bolus of hypertonic food from the stomach to the small intestines draws extracellular fluid into the lumen of the intestines to dilute the high concentrations of electrolytes and sugars, which results in intestinal dilation, increased intestinal transit, hyperglycemia, and the rapid onset of GI and vasomotor symptoms (Kanth & Roy, 2019; NIDDK, 2019). It is estimated that 25% to 50% of all patients who have undergone gastric surgery experience at least some symptoms of dumping syndrome (Kanth & Roy, 2019). Early symptoms tend to occur within 10 to 30 minutes after a meal and often include early satiety, cramping abdominal pain, nausea, vomiting, and diarrhea. Vasomotor symptoms may manifest as a headache, flushing and feelings of warmth, diaphoresis, dizziness, palpations, drowsiness, faintness, or syncope. Early symptoms tend to resolve within 1 hour or with bowel evacuation (defecation) (NIDDK, 2019). Later, the rapid elevation in blood glucose is followed by the increased secretion of insulin, which results in hypoglycemia 2 to 3 hours after eating. Manifestations of hypoglycemia may include irritability, anxiety, shakiness, weakness, fatigue, diaphoresis, palpitations, and hunger. Dumping syndrome typically lasts for a few months after surgery, although in some patients, symptoms may persist on a long-term basis.

Bile reflux may occur with any gastric surgery that involves manipulation or removal of the pylorus, which acts as a barrier to prevent reflex of duodenal contents back into the stomach. Prolonged exposure of bile acid from the duodenum results in irritation and damage to the gastric mucosa, which may lead to gastritis, esophagitis, and possibly peptic ulcer formation. The patient with bile reflux may experience burning epigastric pain that may increase after meals. Vomiting usually does not provide relief from pain. Pharmacologic management of bile reflux includes the administration of proton pump inhibitors and ursodiol. Ursodiol changes the composition of bile, reducing acidity and promoting gastric healing (Kumar & Thompson, 2017; Li, Zhang, Yao, et al., 2020).

Gastric outlet obstruction may occur as a complication of gastric surgery. Postoperative gastric outlet obstruction may be caused by stenosis (narrowing) or stricture (scar tissue) formation at the surgical anastomosis site. Typical clinical manifestations and management of gastric outlet obstruction were previously discussed (see the Peptic Ulcer Disease section of this chapter).

Chemotherapy and Targeted Therapy

In instances where the gastric tumor is not resectable, treatment with chemotherapy may offer further control of the disease or palliation. Chemotherapy may also be used in addition to surgery as adjuvant treatment of gastric cancer. Chemotherapeutic agents often include fluorouracil, carboplatin, capecitabine, cisplatin, docetaxel, epirubicin, irinotecan, oxaliplatin, and paclitaxel. For improved tumor response rates, it is more common to administer combination chemotherapy, primarily fluorouracil-based therapy, with other agents (e.g., fluorouracil plus cisplatin or oxaliplatin) (ACS, 2020b; National Comprehensive Cancer Network [NCCN], 2020).

Targeted therapies have become an important addition to the treatment of advanced gastric cancers (NCCN, 2020). Trastuzumab (a recombinant humanized anti–HER-2 monoclonal antibody) prescribed in combination with fluorouracil or capecitabine and cisplatin has shown an improvement in survival of patients with advanced gastric cancer who are HER-2 positive (Miura, Sukawa, Hironaka, et al., 2018). Other targeted therapies are currently being investigated for the treatment of advanced gastric cancers. For example, ramucirumab is currently in clinical trial studies in combination with olaparib for tumors considered to be inoperable (NCI, 2020). Ramucirumab works by blocking VEGFR2, which reduces the blood supply to the tumor to decrease tumor growth (NCCN, 2020; Ramurcirumab, 2020) (Chart 40-3).

Radiation Therapy

Radiation therapy is primarily used for advanced gastric cancers to slow the rate of tumor growth or for the palliation of symptoms related to obstruction, bleeding, and significant pain (ACS, 2020b). Radiation therapy may also be used alone or along with chemotherapy before surgery to decrease the size of the tumor or after surgery to destroy any remaining cancer cells and to delay or prevent reoccurrence of the cancer (ACS, 2020b; NCCN, 2020). Common approaches to radiation therapy for gastric cancer include traditional external-beam radiation therapy or newer specialized approaches to external-beam radiation therapy, such as three-dimensional conformal radiation therapy (3D-CRT), intraoperative radiotherapy, and intensity-modulated radiation therapy (IMRT). These specialized approaches to external radiation therapy precisely direct the radiation beam to the site of the tumor, thus limiting damage to the healthy surrounding tissue (ACS, 2020b; Cabebe, 2020).

Chart 40-3  **ETHICAL DILEMMA**

Should Patients at the End-of-Life Be Enrolled in Clinical Trials?

Case Scenario

You are a nurse who works in an outpatient oncology treatment center. R.K. is a 68-year-old woman who was diagnosed with advanced gastric adenocarcinoma 13 months ago. She had a gastrectomy and peritonectomy last year, and finished six cycles of chemotherapy 2 months ago. Her most recent postchemotherapy positron emission tomography (PET) scans reveal metastatic disease to her liver, lungs, and pelvis. The oncologist discusses her options with R.K. and her husband, and tells them that R.K. should make preparations for end of life. The oncologist tells them that R.K. can elect to receive palliative chemotherapy, which is associated with good quality of life and extended survival by 2 months in most patients like R.K. who take this option. Another option R.K. might pursue is to enroll in a phase I clinical trial with a novel immunotherapeutic agent. The oncologist is clear that the aim of this treatment would be not to extend R.K.'s life, but to test the safety of the new immunotherapy, and that any potential benefits could only be reaped by future patients with gastric cancer. R.K. and her husband decide to go home and discuss her options between themselves. A few days later, they return to the oncology center to tell the oncologist that they wish for R.K. to enroll in the clinical trial. After you finish checking them into an examination room in preparation to see the oncologist, R.K.'s husband turns to you with tears in his eyes and says "I want my wife to have the very best treatments possible. I will take any chance of a cure for her and this new drug might be the right ticket."

Discussion

Phase I of a clinical trial is one of the very earliest steps in testing a new therapy. This step in the research process aims to find if the new therapy is safe in humans. The effectiveness of the new therapy in treating a disease is not subject to testing at this early juncture. R.K.'s oncologist noted this during discussions with R.K. and her husband. However, it is not uncommon for patients and family members who face a life-threatening diagnosis to misunderstand the aims of an intervention or of enrolling in a research study, and falsely assume that there is indeed a therapeutic aim that does not exist. For this reason, most researchers who conduct clinical trials will give patients written information about the nature of the research to read at home and to give them time to digest and discuss their enrollment in the research study with their friends and family members so that they may make a fully informed decision.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Do you believe that R.K. is making a well-informed decision should she go through with enrolling in the clinical trial?
- Is it just to not invite patients who are near end of life to participate in research? Is it morally defensible to offer a patient with a terminal diagnosis the option to enroll in a clinical trial when there is no clear potential benefit to them?
- What if R.K. turns to you, after her husband voices his hopes for a cure, and says "I agree with my husband and I will take any chance I can get!" On the other hand, what if she turns to you and says "My husband is having a difficult

time letting go right now, and I am trying to do my best to support him. I want to do this because I want my death to have some meaning. I want to help future patients with my type of cancer."

- What resources might be mobilized to be of assistance to you and to R.K. and her husband so that they make the decision that is in R.K.'s best interests?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

Gerontologic Considerations

Gastric cancer mostly affects older adults. It is estimated that 6 of every 10 patients diagnosed with gastric cancer each year are 65 years old or older (ACS, 2020c). According to most recent Surveillance, Epidemiology, and End Results (SEER) data, 65.9% of all deaths from gastric cancer occur in patients 65 years old or older (NCI, 2020). Confusion, agitation, and restlessness may be the only symptoms seen in older adult patients, who may have no gastric symptoms until their tumors are well advanced. At this time, they present with reduced functional ability and other signs and symptoms of malignancy.

Surgery is more hazardous for the older adult, and the risk increases proportionately with increasing age. Nonetheless, gastric cancer should be treated with surgery in older patients. Patient education is important to prepare older patients with cancer for treatment, to help them manage adverse effects, and to face the challenges that cancer and aging present.

NURSING PROCESS

The Patient with Gastric Cancer

Assessment

The nurse obtains a dietary history from the patient, focusing on recent nutritional intake and status. Has the patient lost weight? If so, how much and over what period of time? Can the patient tolerate a full diet? If not, what foods can they eat? What other changes in eating habits have occurred? Does the patient have an appetite? Does the patient feel full after eating a small amount of food? Is the patient in pain? Do foods, antacids, or medications relieve the pain, make no difference, or worsen the pain? Is there a history of infection with *H. pylori*? Other health information to obtain includes the patient's tobacco use and alcohol history and family history (e.g., any first- or second-degree relatives with gastric or other cancer). A psychosocial assessment, including questions about social support, individual and family coping skills, and financial resources, helps the nurse plan for care in acute and community settings.

After the interview, the nurse performs a complete physical examination, carefully assesses the patient's abdomen for tenderness or masses, and palpates and percusses the abdomen to detect ascites.

Nursing Diagnosis

Based on the assessment data, major nursing diagnoses may include the following:

- Anxiety associated with the disease and anticipated treatment
- Impaired nutritional intake associated with early satiety or anorexia
- Acute pain associated with tumor mass
- Grief associated with the diagnosis of cancer
- Lack of knowledge regarding self-care activities

Planning and Goals

The major goals for the patient may include reduced anxiety, optimal nutrition, relief of pain, and adjustment to the diagnosis and anticipated lifestyle changes.

Nursing Interventions

Reducing Anxiety

A relaxed, nonthreatening atmosphere is provided so the patient can express fears, concerns, and possibly anger about the diagnosis and prognosis. The nurse encourages the family or significant other to support the patient, offering reassurance and supporting positive coping measures. The nurse educates the patient about any procedures and treatments so that the patient knows what to expect.

Promoting Optimal Nutrition

The nurse encourages the patient to eat small, frequent portions of nonirritating foods to decrease gastric irritation. Food supplements should be high in calories, as well as vitamins A and C and iron, to enhance tissue repair. Because the patient may develop dumping syndrome when enteral feeding resumes after gastric resection, the nurse explains ways to prevent and manage it and informs the patient

that symptoms often resolve after several months. Management of dumping syndrome includes encouraging six small feedings daily that are low in carbohydrates and sugar and the consumption of fluids between meals rather than with meals. If a total gastrectomy is performed, injection of vitamin B_{12} will be required for life, because intrinsic factor, secreted by parietal cells in the stomach, binds to vitamin B_{12} so that it may be absorbed in the ileum. This deficiency in vitamin B_{12} metabolism can result in decreased production of red blood cells, or pernicious anemia. If the patient is unable to eat adequately prior to surgery to meet nutritional requirements, parenteral nutrition may be necessary. Weight loss is a common occurrence in the postoperative period following gastric surgery. Chemotherapy treatment can contribute to ongoing weight loss. Research suggests that a multidisciplinary approach is necessary to manage symptoms that may contribute to ongoing weight loss such as early satiety, dysphagia, reflux and regurgitation, and elimination issues (Aoyama, Sato, Maezawa, et al., 2017; Grace, Shaw, Lalji, et al., 2018). The nurse monitors the IV therapy and nutritional status and records intake, output, and daily weights to ensure that the patient is maintaining or gaining weight. The nurse assesses for signs of dehydration (thirst, dry mucous membranes, poor skin turgor, tachycardia, decreased urine output) and reviews the results of daily laboratory studies to note any metabolic abnormalities (sodium, potassium, glucose, BUN). Antiemetic agents are given as prescribed.

Relieving Pain

The nurse administers analgesic agents as prescribed. A continuous IV infusion of an opioid or a patient-controlled analgesia (PCA) pump set to infuse an opioid may be necessary to mitigate postoperative pain. The frequency, intensity, and duration of the pain are routinely assessed to determine the effectiveness of the analgesic agent. The nurse works with the patient to help manage pain by suggesting nonpharmacologic methods for pain relief, such as position changes, imagery, distraction, relaxation exercises (using relaxation apps and online videos), backrubs, massage, and periods of rest and relaxation. See Chapter 9 for further discussion of pain management.

Providing Psychosocial Support

The nurse helps the patient express fears, concerns, and grief about the diagnosis. The nurse answers the patient's questions honestly and encourages the patient to participate in treatment decisions. Some patients mourn the loss of a body part and perceive their surgery as a type of mutilation. Some express disbelief and need time and support to accept the diagnosis (see the Nursing Research Profile in Chart 40-4 for more discussion).

The nurse offers emotional support and involves family members and significant others whenever possible. This includes recognizing mood swings and defense mechanisms (e.g., denial, rationalization, displacement, regression) and reassuring the patient, family members, and significant others that emotional responses are normal and expected. The services of clergy, psychiatric clinical nurse specialists, psychologists, social workers, and psychiatrists are made available, if needed. The nurse projects an empathetic attitude and spends time with the patient. Many patients may begin to participate in self-care activities after they have acknowledged their loss.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. Self-care activities depend on the type of treatments used—surgery, chemotherapy, radiation, or palliative care. Patient and family education include information about diet and nutrition, treatment regimens, activity and lifestyle changes, pain management, and possible complications (Chart 40-5). Consultation with a dietitian is essential to determine how the patient's nutritional needs can best be met at home. The nurse instructs the patient or caregiver about administration of enteral or parenteral nutrition. If chemotherapy or radiation is prescribed, the nurse provides explanations to the patient and family about what to expect, including the length of treatments, the expected side effects (e.g., nausea, vomiting, anorexia, fatigue, neutropenia), and the need for transportation to appointments for treatment. Psychological counseling may also be helpful (see Chapter 12).

Chart 40-4  **NURSING RESEARCH PROFILE**

Understanding Uncertainty and Care Needs in Patients with Gastric Cancer

Lee, J. Y., Jang, Y., Kim, S., et al. (2020). Uncertainty and unmet care needs before and after surgery in patients with gastric cancer: A survey study. *Nursing & Health Sciences*, *22*(2), 427–435.

Purpose

Patients diagnosed with cancer often experience uncertainty and a variety of other physical, psychological, emotional, and educational needs throughout their illness course. Little is known about unmet care needs across the illness trajectory in patients who have gastric cancer. Gastric cancer is frequently preceded by nonspecific symptoms that patients often attribute to less serious causes; symptom ambiguity at time of diagnosis may contribute to high levels of uncertainty. Varying symptom clusters and levels of symptom intensity and frequency after surgical intervention for gastric cancer may also increase uncertainty. Understanding how uncertainty and needs change over time may help improve the effectiveness of nursing interventions. The purpose of this study was to assess levels of uncertainty and unmet care needs before and after surgery in patients with gastric cancer.

Design

This was a descriptive study using a before and after design to evaluate uncertainty and unmet care needs at time of diagnosis and after gastrectomy in patients with a diagnosis of gastric cancer. Purposeful sampling was used to recruit participants 20 years of age or older with a new diagnosis of gastric cancer; patients receiving chemotherapy or with other types of cancer were excluded. Demographic and clinical data were collected at baseline. Uncertainty was measured using the *Uncertainty in Illness Scale* and unmet care needs were examined using the *Supportive Care Needs Survey-Short Form 34* at two time points; time 1 (day of admission after diagnosis) and time 2 (first postoperative outpatient follow-up). Both scales were translated to Korean and validated. Data were analyzed using descriptive statistics and differences in uncertainty and unmet needs from time 1 to time 2 were examined using a dependent *t*-test.

Findings

Eighty-six participants with a mean age of 58.5 years completed the study; the majority were male (58.1%), married (83.7%), and educated at or above a high school level (74.4%). Most had a diagnosis of early gastric cancer (93%), with no family history of cancer (61.6%), or no cancer-related symptoms prior to their diagnosis (59.3%); the majority (81.4%) had sought out information about gastric cancer after their diagnosis. Patients reported moderate levels of uncertainty at time of diagnosis and after surgery; however, total uncertainty scores and the subscales of ambiguity, inconsistency, and unpredictability were significantly higher at time of diagnosis. Needs related to patient care support, psychological status, and health care system information (e.g., disease progression, testing, recovery, self-management) were also significantly higher at time of diagnosis compared to follow-up. However, physical needs (e.g., tiredness, pain, ability to do usual activities/work at home, and feeling unwell) were significantly higher at follow-up. Needs related to sexuality were low at both time points and there were

no significant differences in scores from time of diagnosis to postoperative follow-up.

Nursing Implications

This study demonstrates that patients who have gastric cancer experience moderate levels of uncertainty related to symptoms, prognosis, and treatment duration that are higher at time of diagnosis. Patient care needs varied across the course of treatment, which suggests that nurses should perform ongoing assessments in various domains and individualize interventions based on patients' priority concerns.

Chart 40-5  HOME CARE CHECKLIST

The Patient with Gastric Cancer

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of cancer and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify modification of home environment, interventions, and strategies (e.g., utilizing durable medical equipment, employing a home health aide) used in safely adapting to changes in structure or function and promote effective recovery and rehabilitation.
- Identify foods or therapies necessary to meet caloric needs and dietary needs (e.g., change in consistency, seasoning limitations or other dietary restrictions, supplements, enteral or parenteral therapy).
- Demonstrate safe management of enteral or parenteral feedings, if applicable.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe approaches to controlling pain (e.g., take antispasmodic agents as prescribed; use nonpharmacologic interventions).
- When indicated, list possible side effects of chemotherapeutic agents and suggested management approaches.
- When indicated, list possible side effects of radiation therapy and suggested management approaches.
- Identify possible complications (e.g., infection, bleeding, obstruction, perforation or worsening pain or other symptoms) and interventions.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, cancer support, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.
- Make decisions about end-of-life care as appropriate.

Resources

See Chapter 39, Chart 39-5 for additional information on The Patient Receiving Tube Feeding, and Chapter 41, Chart 41-7 The Patient Receiving Parenteral Nutrition.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care. The need for ongoing care in the home depends on the patient's condition and treatment. The nurse reinforces nutritional counseling and supervises the administration of any enteral or parenteral feedings; the patient or caregiver must become skillful in administering the feedings and in detecting and preventing untoward effects or complications related to the feedings (see Chapter 39). The nurse instructs the patient or caregiver to record the patient's

daily intake, output, and weight and explains strategies to manage pain, nausea, vomiting, or other symptoms. Education is provided on how to recognize and report signs and symptoms of complications that require immediate attention, such as bleeding, obstruction, perforation, or any symptoms that become progressively worse. The nurse must explain the chemotherapy or radiation therapy regimen and ensure that the patient and family or significant other understand the care that will be needed during and after treatments (see Chapter 12). Because the prognosis for gastric cancer is poor, the patient, family, or significant other may need assistance with decisions regarding end-of-life care; the nurse should provide support and make referrals as needed.

Evaluation

Expected patient outcomes may include the following:

1. Reports less anxiety
   a. Expresses fears and concerns about surgery
   b. Seeks emotional support
2. Attains optimal nutrition
   a. Eats small, frequent meals high in calories, iron, and vitamins A and C
   b. Adheres to enteral or parenteral nutrition as needed
3. Has decreased pain
4. Performs self-care activities and adjusts to lifestyle changes
   a. Resumes typical activities within 3 months
   b. Alternates periods of rest and activity
   c. Manages enteral feedings
5. Verbalizes knowledge of disease management
   a. Acknowledges disease process
   b. Reports control of symptoms
   c. Verbalizes fears and concerns about dying; involves family/caregiver in discussions
   d. Completes advance directives and other appropriate documents

Tumors of the Small Intestine

Benign or malignant tumors of the small intestine are rare. Approximately 64% of all tumors of the small intestines are malignant (Somasundar, Fisichella, & Espat, 2019). Malignant tumors of the small intestine account for only about 1% to 2% of all GI cancers (Somasundar et al., 2019); it was estimated that in 2020, approximately 11,000 new cases of cancer of the small intestine would be diagnosed in the United States (ACS, 2020a). Rates are higher among older adults (mean age at diagnosis of 60 years) and are also higher among African Americans and men (ACS, 2020c). Malignant tumors are often not discovered until they have metastasized to distant sites. Benign tumors may place patients at an increased risk for malignancy (Terry & Santora, 2019). The relative rarity of tumors of the small intestine, the diversity of tumor types (that may include adenocarcinomas, carcinoid tumors, lymphomas, or

sarcomas), and the nonspecific nature of their manifestations complicate their diagnosis and treatment. Multiple factors, including preexisting GI disorders, can increase the risk of tumors in the small intestine and often contribute to advanced metastatic disease at the time of diagnosis. The lack of surveillance for multiple risk factors can contribute to a delay in treatment (Chen & Vaccaro, 2018; Somasundar et al., 2019).

Clinical Manifestations

Tumors of the small intestine often present insidiously with vague, nonspecific symptoms. Most benign tumors are discovered incidentally on an x-ray study, during surgery, or at autopsy. When the patient is symptomatic, benign tumors often present with intermittent pain. The next most common presentation is occult bleeding. Malignant tumors often result in symptoms that lead to their diagnosis, although these symptoms may reflect advanced disease. Most patients have sustained weight loss and may be malnourished at the time of diagnosis. Occult GI bleeding is less common than is found in patients with benign tumors, and complaints of pain are common. The patient also frequently presents with complaints of weakness, fatigue, nausea, vomiting, and intestinal obstruction (ACS, 2020a). Intestinal perforation is rare and associated with a poorer overall prognosis (ACS, 2020a; Somasundar et al., 2019). Clinical manifestations and management of the patient experiencing an intestinal obstruction and intestinal perforation are discussed in Chapter 41.

Assessment and Diagnostic Findings

A CBC may reveal a low hematocrit and hemoglobin level that is consistent with anemia if the patient has an occult source of GI bleeding. The bilirubin may also be elevated if tumor mass has caused biliary obstruction. CEA levels may also be elevated, consistent with a malignant mass.

An upper GI x-ray series with small bowel follow-through using oral water-insoluble contrast with frequent and detailed x-rays to follow the contrast through the small bowel is the traditional approach to diagnosis. A more sensitive examination is an enteroclysis, in which an NG tube is advanced into the small bowel to a position above the area in question; the area is then studied by single- and double-contrast techniques. Abdominal CT scan is used to determine the extent of disease (Somasundar et al., 2019).

Management

Benign tumors of the small intestine include adenomas, lipomas, hemangiomas, and hamartomas (a focal malformation that resembles a neoplasm, but unlike a neoplasm does not result in compression of adjacent tissue). These tumors may be treated endoscopically by excision/resection or electrocautery if the patient is symptomatic. Routine monitoring is recommended to assess for malignant transformation (Terry & Santora, 2019).

The most common primary malignant tumor of the small intestine is adenocarcinoma; the second and third portions of the duodenum are most often

involved. These tumors may present with obstruction. If the tumor is located at the ampulla of Vater, obstructive jaundice is likely. Other rare malignant tumors of the small intestine include carcinoid tumors, lymphoma, and GI stromal tumors (Chen & Vaccaro, 2018; Terry & Santora, 2019). Abdominal surgery may be required to remove these rare tumors. Chemotherapy and radiation therapy are commonly part of the treatment regimen.

The nursing process related to the care of the patient with a tumor of the small intestine is similar to that of the patient with gastric cancer. Each patient requires specialized care, astute assessment for complications, prompt interventions, and individualized education for self-care.

CRITICAL THINKING EXERCISES

1 ebp A 65-year-old woman is diagnosed with a peptic ulcer after experiencing fatigue, epigastric pain associated with meals, and coffee ground emesis. She is started on treatment with omeprazole and sucralfate. The patient asks you if taking these medications will be successful in treating her ulcer. How would you respond to this patient? On what evidence do you base your response?

2 pq A 55-year-old female patient arrives in the emergency department with the onset of melena, abdominal pain, and weight loss of 18 lb. Upon admission, she is awake, alert, and oriented. Her pain level is 8 (on a 0 to 10 numeric pain scale). Her blood pressure is 90/60 mm Hg, heart rate is 126 bpm, respiratory rate is 16 breaths/min and regular, and temperature is 36.7°C (98.1°F). Her abdomen is hard and rigid and no bowel sounds are assessed upon auscultation. What is your first nursing action? Describe the priorities of care for this patient.

3 ipc You are caring for a 67-year-old man who was recently diagnosed with peptic ulcer disease and was admitted with melena. The dietitian met with the patient to discuss changes in his diet. Prior to discharge, you are reviewing a 7-day diet plan with the patient. Describe food selections that would necessitate follow-up with the dietitian prior to the patient's discharge.

41 Management of Patients with Intestinal and Rectal Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the pathophysiology, clinical manifestations, and management of patients with constipation, diarrhea, fecal incontinence, and irritable bowel syndrome.
2. Identify celiac disease as a disorder of malabsorption; describe its pathophysiology, clinical manifestations, and management.
3. Discuss the nursing management of the patient with appendicitis, diverticular disease, and intestinal obstruction.
4. Compare Crohn's disease and ulcerative colitis with regard to their pathophysiology; clinical manifestations; diagnostic evaluation; and medical, surgical, and nursing management.
5. Identify the purposes, indications for, types, and administration techniques of parenteral nutrition access devices and formulas.
6. Use the nursing process as a framework for care of the patient with inflammatory bowel disease, or receiving parenteral nutrition, or with colorectal cancer.
7. Explain the nursing management of the patient with an anorectal disorder.

NURSING CONCEPTS

Elimination
Inflammation
Nutrition

GLOSSARY

abscess: localized collection of purulent material surrounded by inflamed tissues

central venous access device (CVAD): a device designed and used for administration of sterile fluids, nutrition formulas, and medications into central veins

colostomy: surgical opening into the colon by means of a stoma to allow drainage of bowel contents; one type of fecal diversion

constipation: fewer than three bowel movements weekly or bowel movements that are hard, dry, small, or difficult to pass

diarrhea: an increased frequency of bowel movements or an increased amount of stool with altered consistency (i.e., increased liquidity) of stool

diverticulitis: inflammation of a diverticulum from obstruction by fecal matter resulting in abscess formation

diverticulosis: presence of several diverticula in the intestine

diverticulum: saclike out-pouching of the lining of the bowel protruding through the muscle of the intestinal wall

fecal incontinence: involuntary passage of feces

fissure: normal or abnormal fold, groove, or crack in body tissue

fistula: anatomically abnormal tract that arises between two internal organs or between an internal organ and the body surface

gastrocolic reflex: peristaltic movements of the large bowel occurring five to six times daily that are triggered by distention of the stomach

hemorrhoids: dilated portions of the anal veins

ileostomy: surgical opening into the ileum by means of a stoma to allow drainage of bowel contents; one type of fecal diversion

inflammatory bowel disease (IBD): group of chronic disorders (ulcerative colitis and Crohn's disease) that result in inflammation or ulceration (or both) of the bowel lining

irritable bowel syndrome (IBS): chronic functional disorder characterized by recurrent abdominal pain that affects frequency of defecation and consistency of stool; is associated with no specific structural or biochemical alterations

lipid injectable emulsion (ILE): an oil-in-water emulsion of oils, egg phospholipids, and glycerin (*synonym:* intravenous fat emulsion [IVFE] or lipid)

malabsorption: impaired transport across the mucosa

parenteral nutrition: method of supplying nutrients to the body by an intravenous route

peripherally inserted central catheter (PICC): a device inserted into a peripheral vein and designed and used for administration of sterile fluids, nutrition formulas, and medications into central veins

peritonitis: inflammation of the lining of the abdominal cavity

steatorrhea: excess of fatty wastes in the feces

tenesmus: ineffective and sometimes painful straining and urge to eliminate feces

total nutrient admixture (TNA): an admixture of lipid emulsions, proteins, carbohydrates, electrolytes, vitamins, trace minerals, and water

Between 60 and 70 million people in the United States are diagnosed with some type of disease of the gastrointestinal (GI) tract. These diseases account for more than 48.3

million office visits to health care facilities and clinics and approximately 21.7 million hospital admissions annually. GI diseases cost the American public more than $141.8 billion and account for approximately 246,000 deaths each year (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2014b). The types of diseases and disorders that affect the lower GI tract are many and varied; examples include constipation, diarrhea, diverticulitis, and inflammatory bowel disease (IBD).

In all age groups, a fast-paced lifestyle, high levels of stress, irregular eating habits, insufficient intake of fiber and water, and lack of daily exercise contribute to GI disorders. There is a growing understanding of the biopsychosocial implications of GI disease. The mind and emotions can have a profound impact on the GI system. Nurses can influence these GI disorders by identifying behavior patterns that put patients at risk, by educating the public about prevention and management, and by helping those affected to improve their condition and prevent complications.

ABNORMALITIES OF FECAL ELIMINATION

Changes in patterns of fecal elimination are symptoms of functional disorders or diseases of the GI tract. The most common changes seen are constipation, diarrhea, and fecal incontinence.

Constipation

Constipation is defined as fewer than three bowel movements weekly or bowel movements that are hard, dry, small, or difficult to pass (Simren, Palsson, & Whitehead, 2017). Approximately 63 million Americans have chronic constipation, making it a very common GI disorder. People more likely to become constipated are women, particularly pregnant women, patients who recently had surgery, older adults, non-Caucasians, and people with a history of irritable bowel syndrome (NIDDK, 2018). Notably, constipation is a symptom and not a disease; however, constipation can indicate an underlying disease or motility disorder of the GI tract. Perceived constipation can also be an issue. This subjective problem occurs when a person's bowel elimination pattern is not consistent with what they consider normal (Dimidi, Cox, Grant, et al., 2019; Mari, Mahamid, Amara, et al., 2020).

Constipation can be caused by certain medications, such as anticholinergic agents, antidepressants, anticonvulsants, antispasmodics (muscle relaxants), calcium channel antagonists, diuretic agents, opioids, aluminum- and calcium-based antacids, and iron preparations. Other causes of constipation may include weakness, immobility, debility, fatigue, celiac disease, and an inability to increase intra-abdominal pressure to facilitate the passage of stools, as may occur in patients with emphysema or spinal cord injury, for instance. Many people develop constipation because they do not take the time to defecate or ignore the urge to defecate. Constipation is also a result of dietary habits (i.e., low consumption of fiber and inadequate fluid intake), lack of regular exercise, and a stress-filled life (NIDDK, 2018). Fiber is particularly important to bowel health because it increases the bulk of stool, generally easing its passage. One of the most significant benefits of dietary fiber, most of which is derived from plant cell walls, is its fermentability, which affects the diversity of microbes in the GI tract and promotes good bowel wall health (Williams, Grant, Gidley, et al., 2017).

Pathophysiology

The pathophysiology of constipation is poorly understood, but it is thought to include interference with one of three major functions of the colon: mucosal transport (i.e., mucosal secretions facilitate the movement of colon contents), myoelectric activity (i.e., mixing of the rectal mass and propulsive actions), or the processes of defecation (e.g., pelvic floor dysfunction). There are four classes of constipation, based upon their underlying pathophysiologic mechanisms (Basson, 2019a):

- Functional constipation, which involves normal transit mechanisms of mucosal transport. This type of constipation is most common and can be successfully treated by increasing intake of fiber and fluids.
- Slow-transit constipation, which is caused by inherent disorders of the motor function of the colon (e.g., Hirschsprung disease), and is characterized by infrequent bowel movements.
- Defecatory disorders, which are caused by dysfunctional motor coordination between the pelvic floor and anal sphincter. Dyssynergic constipation is a common cause of chronic constipation and is caused by an inability to coordinate the abdominal, pelvic floor, and rectoanal muscles to defecate. *Anismus* is a term used to describe pelvic floor dysfunction and constipation. This can cause not only constipation but also fecal incontinence (see later discussion).
- Opioid-induced constipation, which includes new or worsening symptoms that occur when opioid therapy is initiated, changed, or increased and must include two or more symptoms of functional constipation (see later discussion).

The urge to defecate is stimulated normally by rectal distention that initiates a series of four actions: stimulation of the inhibitory rectoanal reflex, relaxation of the internal sphincter muscle, relaxation of the external sphincter muscle and muscles in the pelvic region, and increased intra-abdominal pressure. Interference with any of these processes can lead to constipation.

When the urge to defecate is ignored, the rectal mucous membrane and musculature become insensitive to the presence of fecal masses, and consequently a stronger stimulus is required to produce the necessary peristaltic rush for defecation. The initial effect of fecal retention is to produce irritability of the colon, which at this stage frequently goes into spasm, especially after meals, giving rise to colicky midabdominal or low abdominal pains. After several years of this process, the colon loses muscular tone and becomes essentially unresponsive to normal stimuli (similar to an overstretched balloon). Atony or decreased muscle tone occurs with aging. This may lead to constipation because the stool is retained for longer periods.

Clinical Manifestations

Clinical manifestations of constipation include fewer than three bowel movements per week; abdominal distention; abdominal pain and bloating; a sensation of incomplete evacuation; straining at stool; and the elimination of small-volume, lumpy, hard, dry stools. The patient may report **tenesmus** (i.e., ineffective and sometimes painful straining and urge to eliminate feces) or low back pain. Chronic constipation, often associated with psychological disorders, is the presence of these symptoms for at least 12 weeks during the previous year (Basson, 2019a).

Assessment and Diagnostic Findings

The diagnosis of constipation is based on the patient's history, physical examination, possibly the results of a barium enema or sigmoidoscopy, and stool testing for occult blood. These tests are used to determine whether this symptom results from spasm or narrowing of the bowel. Anorectal manometry (i.e., pressure studies such as a balloon expulsion test) may be performed to assess malfunction of the sphincter. Defecography and colonic transit studies can also assist in the diagnosis because they permit assessment of active anorectal function. X-ray, colonoscopy, and lower GI endoscopy can be used to evaluate the patient with constipation (Basson, 2019a).

As noted previously, the majority of patients with constipation have functional constipation. The Rome IV Diagnostic Criteria provide the framework to make this determination (Simren, Palsson, & Whitehead, 2017) (see Chart 41-1).

Secondary causes of constipation should be evaluated. Neurologic diseases that can impact bowel function include stroke, Parkinson's disease, diabetes, spinal cord injury, and traumatic brain injury. Other causes of secondary constipation include colonic obstruction, rectal or vaginal prolapse, effects of some medications, hemorrhoids, anal fissures, and diverticular disease. Diagnostic testing is usually indicated for patients who fail to respond to conservative treatment (e.g., increasing fluids, fiber, physical activity) after 3 to 6 months (Basson, 2019a).

Complications

Increased arterial pressure can occur with defecation. Straining at stool, which results in the Valsalva maneuver (i.e., forcibly exhaling with the glottis closed), has a striking effect on arterial blood pressure. During active straining, the flow of venous blood in the chest is temporarily impeded because of increased intrathoracic pressure. This pressure tends to collapse the large veins in the chest. The atria and the ventricles receive less blood, and consequently less blood is ejected by the left ventricle. Cardiac output is decreased, and there is a transient drop in arterial pressure, which may cause orthostasis, dizziness, or syncope (Norris, 2019).

Chart 41-1  **ASSESSMENT**

Rome IV Diagnostic Criteria for Functional Constipation

Reported signs and symptoms must be present for the past 3 months with onset at least 6 months prior to diagnosis; these must include two or more of the following:

- Straining during at least 25% of bowel movements
- Lumpy or hard stools from at least 25% of bowel movements
- Sensation of incomplete evacuation during at least 25% of bowel movements
- Sensation of anorectal obstruction or blockage during at least 25% of bowel movements
- Manual maneuvers (e.g., digital stimulation, support of pelvic floor) needed to facilitate at least 25% of bowel movements
- Less than three spontaneous bowel movements weekly

In addition to these, loose stools are rarely present without the use of laxatives, and there must be insufficient suspicion of irritable bowel syndrome.

Adapted from Lacy, B. E., Mearin, F., Chang, L., et al. (2016). Bowel disorders. Gastroenterology, *150*(6), 1393–1407.

Additional complications of constipation include fecal impaction, which may lead to fecal incontinence, **hemorrhoids** (dilated portions of anal veins), **fissures** (normal or abnormal folds, grooves, or cracks in body tissue), rectal prolapse, and megacolon (see later discussion of disorders of the anorectum, which includes hemorrhoids and fissures). Fecal impaction occurs when an accumulated mass of dry feces, called a *fecalith*, cannot be expelled. The mass may be palpable on digital examination, may produce pressure on the colonic mucosa that results in ulcer formation, most typically in the rectosigmoid colon, and may cause fecal incontinence, with seepage of liquid stools. Treatment can be embarrassing and also painful, because impaction removal usually involves digital dislodgement and enema administration. An ulcer also has the potential to perforate the colon wall, leading to **peritonitis** (i.e., inflammation of the lining of the abdominal cavity) (Basson, 2019a).

Hemorrhoids develop as a result of perianal vascular congestion caused by straining. Anal fissures may result from the passage of the hard stool through the anus, tearing the lining of the anal canal. The rectum may prolapse through the anal canal, causing seepage of mucus (NIDDK, 2018).

Megacolon is a dilated and atonic colon caused by a fecal mass that obstructs the passage of colon contents. Symptoms include constipation, liquid fecal incontinence, and abdominal distention. Megacolon can lead to perforation of the bowel and peritonitis (Norris, 2019).

Gerontologic Considerations

Visits to primary providers for treatment of constipation are common in people 65 years and older. The most common complaint they voice is the need to strain at stool. The aging process inevitably generates changes in the colon; but the extent and physiologic implications for defecation remain unclear. The clinical situation is made more complex by ubiquitous factors among the aged (Eliopoulos, 2018). For instance, older adults who have loose-fitting dentures or have lost their teeth have difficulty chewing and frequently choose soft, processed foods that are low in fiber. Older adults tend to have decreased

food intake, reduced mobility, and weak abdominal and pelvic muscles, and they are more likely to have multiple chronic illnesses requiring multiple medications (polypharmacy) that often cause constipation. Low-fiber convenience foods are widely used by people who have lost interest in eating. Some older adults reduce their fluid intake if they are not eating regular meals. Depression, weakness, and prolonged bed rest also contribute to constipation by decreasing intestinal motility and anal sphincter tone. Nerve impulses are dulled, and there is a decreased urge to defecate. Many older adults overuse laxatives in an attempt to have a daily bowel movement and become dependent on them. Chronic constipation profoundly impairs quality of life comparable to other conditions such as diabetes, rheumatoid arthritis, and osteoarthritis (Eliopoulos, 2018).

Medical Management

Treatment targets the underlying cause of constipation and prevention of recurrence. It includes education, exercise, bowel habit training, increased fiber and fluid intake, and judicious use of laxatives. Management may also include discontinuing laxative use or replacing medications that could cause or exacerbate constipation with other nonconstipating medications (Lacy, Mearin, Chang, et al., 2016). Patients can be educated to sit on the toilet with legs supported and to utilize the **gastrocolic reflex** (peristaltic movements of the large bowel occurring five to six times daily that are triggered by distention of the stomach) by attempting to defecate following a meal and a warm drink. Routine exercise to strengthen abdominal muscles is encouraged. Biofeedback is a technique that can be used to help patients learn to relax the sphincter mechanism to expel stool. Biofeedback is an effective therapy for patients with dyssynergic defecation and is considered first-line therapy once anorectal structural lesions have been excluded as the cause for constipation (Rao & Patcharatrakul, 2016; Rao, Valestin, Xiang, et al., 2018). Daily dietary intake of 25 to 30 g/day of fiber (soluble and bulk forming) is recommended, especially for the treatment of constipation in the older adult. It is important to add fiber to the diet slowly in order to avoid adverse effects such as abdominal cramping and bloating. Fiber is increased daily in 5 g increments, along with encouraging fluid intake (Mari et al., 2020). If laxative use is necessary, one of the following may be prescribed: bulk-forming agents (fiber laxatives), saline and osmotic agents, lubricants, stimulants, or emollient stool softeners. The physiologic action and patient education information related to these laxatives are presented in Table 41-1. Enemas and rectal suppositories are generally not recommended for treating constipation unless other medications have failed.

Nursing Management

The nurse elicits information about the onset and duration of constipation, current and past elimination patterns, the patient's expectation of normal bowel elimination, and lifestyle information (e.g., exercise and activity level, occupation, food and fluid intake, and stress level) during the health history interview. Past medical and surgical history, current medications, and laxative and enema use are important, as is information about the sensation of rectal pressure or fullness, abdominal pain, excessive straining at defecation, and flatulence.

Chart 41-2 PATIENT EDUCATION

Preventing Constipation

The nurse instructs the patient to:

- Recognize the physiology of defecation and the importance of responding to the urge to defecate.
- Understand the normal variations in patterns of defecation.
- Establish a bowel routine, and be aware that having a regular time for defecation (e.g., best time is after a meal) may aid in initiating the reflex.
- Ensure proper dietary habits, such as eating high-residue, high-fiber foods (e.g., fruits, vegetables); adding fiber to the diet slowly with adequate fluid intake; choosing dietary sources of fiber, which are preferred over fiber supplements; adding bran daily (must be introduced gradually); and increasing fluid intake (unless contraindicated) to help prevent constipation.
- Increase muscle strength through an exercise regimen, increased ambulation, and abdominal muscle toning to help propel colon contents.
- Perform abdominal toning exercises, including contracting abdominal muscles 4 times daily and leg-to-chest lifts 10 to 20 times each day.
- Use the normal position (semisquatting) to maximize the use of abdominal muscles and force of gravity.
- Avoid overuse or long-term use of stimulant laxatives.

After the health history is obtained, the nurse sets specific goals for patient education (see Chart 41-2). Goals for the patient include restoring or maintaining a regular pattern of elimination by responding to the urge to defecate, ensuring adequate intake of fluids and high-fiber foods, learning about methods to avoid constipation, relieving anxiety about bowel elimination patterns, and avoiding complications.

Diarrhea

Diarrhea is an increased frequency of bowel movements (more than 3 per day) with altered consistency (i.e., increased liquidity) of stool. It can be associated with urgency, perianal discomfort, incontinence, nausea, or a combination of these factors (NIDDK, 2016b). Any condition that causes increased intestinal secretions, decreased mucosal absorption, or altered motility can produce diarrhea.

Diarrhea can be classified as acute, persistent, or chronic. Acute diarrhea is self-limiting, lasting 1 or 2 days; persistent diarrhea typically lasts between 2 and 4 weeks; and chronic diarrhea persists for more than 4 weeks and may return sporadically. Acute and persistent diarrheas are frequently caused by viral infections (e.g., norovirus). In addition, some drugs can cause acute or persistent diarrhea, including some antibiotics (e.g., erythromycin) and magnesium-containing antacids (e.g., magnesium hydroxide). Chronic diarrhea may be caused by adverse effects of chemotherapy, antiarrhythmic agents, antihypertensive agents, metabolic and endocrine disorders (e.g., diabetes, Addison disease, thyrotoxicosis), malabsorptive disorders (e.g., lactose intolerance, celiac disease), anal sphincter defect, Zollinger-Ellison syndrome, acquired immune

deficiency syndrome (AIDS), and by parasitic or *Clostridium difficile* infections (NIDDK, 2016b).

TABLE 41-1  Select Laxative Medications

Classification/Medications	Action	Patient Education
Bulk Forming methylcellulose, psyllium, wheat dextrin	Polysaccharides and cellulose and wheat derivatives mix with intestinal fluids, swell, and stimulate peristalsis.	Take with 8-oz water and follow with 8-oz water; do not take dry. Report abdominal distention or unusual amount of flatulence.
Saline Agent magnesium hydroxide	Nonabsorbable magnesium ions alter stool consistency by drawing water into the intestines by osmosis; peristalsis is stimulated. Action occurs within 2 h.	Be aware that the liquid preparation is more effective than the tablet form. Note that only short-term use is recommended because of toxicity (central nervous system or neuromuscular depression, electrolyte imbalance). Do not take magnesium laxatives with renal insufficiency.
Lubricant mineral oil, glycerin suppository	Nonabsorbable hydrocarbons soften fecal matter by lubricating the intestinal mucosa; the passage of stool is facilitated. Action occurs within 6–8 h for mineral oil and within 30 min for glycerin suppository.	Do not take mineral oil with meals, because it can impair the absorption of fat-soluble vitamins and delay gastric emptying. Swallow carefully, because drops of oil that gain access to the pharynx can produce a lipid pneumonia. Insert glycerin suppositories fully and retain.
Stimulant bisacodyl, senna	Irritates the colonic epithelium by stimulating sensory nerve endings and increasing mucosal secretions and decreasing large intestinal water absorption. Action occurs within 6–8 h.	Be aware that catharsis may cause fluid and electrolyte imbalance, especially in the older adult. Do not swallow, crush, or chew tablets. Avoid milk or antacids within 1 h of taking medication, because the enteric coating may dissolve prematurely. Note that stimulant laxatives are *not* indicated for long-term use.
Emollient Stool Softener docusate	Hydrates the stool by its surfactant action on the colonic epithelium (increases the wetting efficiency of intestinal water); aqueous and fatty substances are mixed. Does *not* exert a laxative action.	Note that this can be used safely by patients who should avoid straining (cardiac patients, patients with anorectal disorders). Be aware that this will not evacuate hard stool because it is not a true laxative. Best for short-term use; decreased effectiveness with long-term use.
Osmotic Agent polyethylene glycol and electrolytes (sodium and potassium)	Attracts water and electrolytes, increasing intraluminal pressure, shorten colonic transit time, and increase bowel motility.	Polyethylene glycol-based agents originally used for bowel cleansing prior to colonoscopy; now available in powder-base daily dose, which is generally safe and effective. Monitor electrolyte levels with long-term use. Effects of long-term therapy not well known.
Chloride Channel Activator lubiprostone	Stimulates chloride channels in the colonic mucosa, causing passive	Approved for opioid-induced constipation in people with chronic, non-cancer pain. Avoid pregnancy during treatment, keep

	passage of sodium and fluid into the colon.	in mind that it may cause increased flatulence and loose stools. Do not use for more than 4 wks.
Serotonin-4 Receptor Agonist prucalopride	Prokinetic, stimulates selective serotonin receptors in gastrointestinal tract, causing release of acetylcholine, stimulating gastrointestinal motility.	Approved for chronic idiopathic constipation. Selective action reduces cardiovascular adverse effects of other nonselective serotonin receptor agonists.

Adapted from Mari, A., Mahamid, M., Amara, H., et al. (2020). Chronic constipation in the elderly patient: Updates in evaluation and management. *Korean Journal of Family Medicine*, *41*(3), 139–145. doi.org/10.4082/kjfm.18.0182

C. difficile is a gram-positive anaerobic organism and the most commonly identified bacterium in antibiotic-associated diarrhea (Mada & Alam, 2019). Approximately half a million patients are infected annually, causing 15,000 deaths. Antibiotic use, including penicillins, cephalosporins, fluoroquinalones, and clindamycin are known risk factors. More than half of patients admitted to the hospital will receive an antibiotic during their stay, and the Centers for Disease Control and Prevention (CDC) estimates that 30% to 50% of those antibiotics are either unnecessary or incorrectly prescribed (Mada & Alam, 2019). Other risk factors for *C. difficile* infection include advanced age, the use of proton pump inhibitors or chemotherapy, and a history of chronic liver disease, kidney disease, or malnutrition.

Pathophysiology

Acute and persistent diarrheas are classified as either noninflammatory (large-volume) or inflammatory (small-volume). Enteric pathogens that are noninvasive (e.g., *S. aureus, Giardia*) do not cause inflammation but secrete toxins that disrupt colonic fluid transport. They cause noninflammatory diarrhea, which is characterized by a large volume of loose, watery stools. Other pathogens that invade the intestinal mucosa and cause inflammatory changes typically result in smaller volumes of stool that is bloody (e.g., dysentery). Organisms implicated may include *Shigella, Salmonella,* and *Yersinia* species (Norris, 2019).

Types of chronic diarrhea include secretory, osmotic, malabsorptive, infectious, and exudative. Secretory diarrhea is usually high-volume diarrhea. Often associated with bacterial toxins and chemotherapeutic agents used to treat neoplasms, it is caused by increased production and secretion of water and electrolytes by the intestinal mucosa into the intestinal lumen. Osmotic diarrhea occurs when water is pulled into the intestines by the osmotic pressure of unabsorbed particles, slowing the reabsorption of water. It can be caused by lactase deficiency, pancreatic dysfunction, or intestinal hemorrhage. Malabsorptive diarrhea combines mechanical and biochemical actions, inhibiting effective absorption of nutrients. Low serum albumin levels lead to intestinal mucosa swelling and liquid stool. Infectious diarrhea results from infectious agents invading the intestinal mucosa. Exudative diarrhea is caused by changes in mucosal integrity, epithelial loss, or tissue destruction by radiation or chemotherapy. Diarrhea may also be caused by laxative misuse (Norris, 2019).

Clinical Manifestations

In addition to the increased frequency and fluid content of stools, the patient usually has abdominal cramps, distention, borborygmus (i.e., a rumbling noise caused by the movement of gas through the intestines), anorexia, and thirst. Painful spasmodic contractions of the anus and tenesmus may occur with defecation. Other symptoms depend on the cause and severity of the diarrhea but are related to dehydration and to fluid and electrolyte imbalances.

Voluminous, greasy stools suggest intestinal **malabsorption** (i.e., impaired transport across the mucosa), and the presence of blood, mucus, and pus in the stools suggests inflammatory enteritis or colitis. Oil droplets on the toilet water may be suggestive of pancreatic insufficiency. Nocturnal diarrhea may be a manifestation of diabetic neuropathy (NIDDK, 2016b; Weber & Kelley, 2018). The possibility of *C. difficile* infection should be considered in all patients with unexplained diarrhea who are taking or have recently taken antibiotics.

Assessment and Diagnostic Findings

When the cause of the diarrhea is not obvious, the following diagnostic tests may be performed: complete blood cell count (CBC); serum chemistries; urinalysis; routine stool examination; and stool examinations for infectious or parasitic organisms, bacterial toxins, blood, fat, electrolytes, and white blood cells. Endoscopy or barium enema may assist in identifying the cause.

Complications

The most common complication of diarrhea is dehydration. Dehydration with electrolyte loss (especially loss of potassium) may cause cardiac arrhythmias. Loss of bicarbonate with diarrhea can also lead to metabolic acidosis. Urinary output less than 0.5 mL/kg/h for 2 to 3 consecutive hours, muscle weakness, paresthesia, hypotension, anorexia, and drowsiness with a potassium level less than 3.5 mEq/L (3.5 mmol/L) must be reported. Chronic diarrhea can also result in skin care issues related to irritant dermatitis (NIDDK, 2016b). Cleansing with a wet wipe and applying barrier cream can prevent dermatitis.

Gerontologic Considerations

Older patients can become dehydrated quickly and develop hypokalemia (low potassium levels) as a result of diarrhea. The nurse observes for clinical manifestations of muscle weakness, arrhythmias, or decreased peristaltic motility that may lead to paralytic ileus. The older patient taking digitalis (e.g., digoxin) must be aware of how quickly dehydration and hypokalemia can occur with diarrhea. The nurse educates the patient to recognize the symptoms of hypokalemia, because low levels of potassium potentiate the action of digitalis, leading to digitalis toxicity (Eliopoulos, 2018).

The skin of an older person is more sensitive to excoriation due to decreased turgor and reduced subcutaneous fat layers. Gentle cleansing with a perineal cleansing solution (i.e., wet wiping method) and the use of a barrier cream or a liquid skin sealant will prevent or treat the excoriation (Eliopoulos, 2018).

Medical Management

Management is directed at controlling symptoms, preventing complications, and eliminating or treating the underlying disease. Until the definitive cause is discovered, infection control measures that restrict the transmission of infectious organisms (e.g., *C. difficile*–associated diarrhea) are warranted (see Chapter 66 for further discussion of *C. difficile* infection). Certain medications (e.g., antibiotics, anti-inflammatory agents) and antidiarrheal agents (e.g., loperamide, diphenoxylate with atropine) may be prescribed to reduce the severity of the diarrhea and treat the underlying disease. In most cases, loperamide is the medication of choice because it has fewer side effects than diphenoxylate with atropine. Findings from a systematic review supported the use of probiotics (live organisms given to a host) in some forms of diarrhea (Jones & Cantor, 2019). The specific organisms used were *Saccharomyces boulardii* (yeast) or lactic acid bacteria such as *Lactobacillus* and *Enterococcus lactic acid bacterium* species. Benefits include shortened duration of symptoms and early improvement of symptoms; there were no serious adverse effects reported (Jones & Cantor, 2019).

Nursing Management

The nurse assesses and monitors the characteristics and pattern of diarrhea. A health history should address the patient's medication therapy, medical and surgical history, and dietary patterns and intake. Reports of recent acute illness or recent travel to another geographic area are important. Assessment includes abdominal auscultation and palpation for tenderness. Inspection of the abdomen, mucous membranes, and skin is important to determine hydration status. Stool samples are obtained for testing. The perianal area should also be assessed for skin excoriation.

During an episode of diarrhea, the patient is encouraged to increase intake of liquids and foods low in bulk until the symptoms subside. When the patient is able to tolerate food intake, the patient should avoid caffeine, alcoholic beverages, dairy products, and fatty foods for several days (NIDDK, 2016b). Antidiarrheal medications such as diphenoxylate with atropine or loperamide may be taken as prescribed. Intravenous (IV) fluid therapy may be necessary for rapid rehydration in some patients, especially in older adults and in patients with preexisting GI conditions (e.g., IBD). It is important to monitor serum electrolyte levels closely. The nurse immediately reports evidence of arrhythmias or a change in a patient's level of consciousness.

The perianal area may become excoriated because diarrheal stool contains digestive enzymes that can irritate the skin. The patient should follow a perianal skin care routine to decrease irritation and excoriation (see Chapter 56).

Fecal Incontinence

Fecal incontinence or inadvertent bowel leakage describes the recurrent involuntary passage of stool from the rectum for at least 3 months. Factors that influence this disorder include the ability of the rectum to sense and accommodate stool, the amount and consistency of stool, the integrity of the anal sphincters and musculature, and rectal motility. Fecal incontinence is a widespread problem, affecting at least 7 out of 100 nonhospitalized adults and at least half of adults who reside in long-term care facilities

(i.e., nursing homes) (NIDDK, 2017b). Fecal incontinence can have a substantially negative impact on quality of life (NIDDK, 2017b).

Pathophysiology

Fecal incontinence has many causes and risk factors and may be a symptom of an underlying condition. In general, it results from conditions that interrupt or disrupt the structure or function of the anorectal unit. Common causes include anal sphincter weakness, both traumatic (e.g., after surgical procedures involving the rectum) and nontraumatic (e.g., scleroderma); neuropathies, both peripheral (e.g., pudendal) and generalized (e.g., diabetes); disorders of the pelvic floor (e.g., rectal prolapse); inflammation (radiation proctitis, IBD); central nervous system disorders (e.g., dementia, stroke, spinal cord injury, multiple sclerosis); diarrhea; fecal impaction with overflow; and behavioral disorders. It is less commonly a long-term consequence of vaginal childbirth injuries than in years past, most likely because of improved delivery methods. It is more common with advancing age (i.e., weakness or loss of anal or rectal muscle tone) (Emmanuel, 2019; Rao, Bharucha, Chiaroni, et al., 2016).

Clinical Manifestations

Patients may have minor soiling, occasional urgency and loss of control, or complete incontinence. Patients may also experience poor control of flatus, diarrhea, or constipation. Passive incontinence occurs without warning; whereas, patients with urge incontinence have the sensation of the urge to defecate but cannot reach the toilet in time (Rao et al., 2016).

Assessment and Diagnostic Findings

Assessing the patient's medical history is helpful in identifying the most likely etiology. Diagnostic studies are necessary because the treatment of fecal incontinence depends on the cause. A rectal examination and an endoscopic examination such as a flexible sigmoidoscopy are performed to rule out tumors, inflammation, fissures, or impaction. Anorectal manometry, defecography, electromyography, anal endosonography, pelvic MRI scan, and transit studies may be helpful in identifying alterations in intestinal mucosa and muscle tone or in detecting other structural or functional problems (NIDDK, 2017b).

Medical Management

Medical management of fecal incontinence is directed at correcting the underlying cause. If fecal incontinence is related to diarrhea, the incontinence may disappear when diarrhea is successfully treated. Fecal incontinence secondary to a fecal impaction may cease after the impaction is removed and the rectum is cleansed. If the fecal incontinence is related to the use of contributory drugs (e.g., laxatives, antacids containing magnesium), the incontinence may improve or cease when the drug regimen is altered. When fecal incontinence is related to other disorders, treatments targeted at correcting the underlying disorder are initiated. Some patients benefit from the addition of psyllium as a fiber supplement. In addition, administering loperamide 30 minutes prior to meals can be an effective intervention in some patients. Biofeedback therapy with pelvic floor muscle

training can be of assistance if the problem is decreased sensory awareness or sphincter control. Transanal irrigation and bowel training programs, including techniques to assist evacuation such as abdominal massage, Valsalva maneuver, and digital rectal stimulation can also be effective (Emmanuel, 2019; Rao et al., 2016). Sacral nerve stimulation, provided by implanting a subcutaneous stimulator that delivers low amplitude electrical stimulation to the sacral nerve, may be an option for some patients refractory to other interventions (Emmanuel, 2019). Surgical procedures include surgical reconstruction or repair of anal sphincter, artificial sphincter implantation, anal sphincter bulking by injection of synthetic agents, sacral nerve stimulation, or fecal diversion (Emmanuel, 2019).

Nursing Management

The nurse obtains a thorough health history, including information about previous surgical procedures, chronic illnesses, dietary patterns, bowel habits and problems, and current medication regimen. A bowel diary covering a 1- to 2-week period may be helpful in identifying elimination patterns and factors affecting bowel function (Emmanuel, 2019). Stool charts (e.g., Bristol Stool Form, see later discussion) may help with identifying frequency, volume, and consistency of the feces. The nurse also completes an examination of the rectal area. If a fecal impaction is noted, it must be removed before instituting any preventive therapies (Gump & Schmelzer, 2016; Taylor, Lynn, & Bartlett, 2019).

The nurse initiates a bowel training program that involves setting a schedule to establish bowel regularity. The goal is to help the patient achieve fecal continence. If this is not possible, the goal should be to manage the problem so the patient can have predictable, planned elimination. Sometimes it is necessary to use suppositories to stimulate the anal reflex. After the patient has achieved a regular schedule, the suppository can be discontinued. Biofeedback in conjunction with pelvic floor exercises can be used to help the patient improve sphincter contractility and rectal sensitivity. Bowel regulation also involves the therapeutic use of diet and fiber. Foods that thicken stool (e.g., applesauce) and fiber supplements help improve continence (Gump & Schmelzer, 2016). Conversely, foods that loosen stool (e.g., rhubarb, figs, prunes, plums) should be avoided. Some patients with fecal incontinence may benefit from the use of antidiarrheal medications (Gump & Schmelzer, 2016). Loperamide and diphenoxylate with atropine can be used; loperamide is the preferred medication because it does not cause central nervous system adverse effects (Comerford & Durkin, 2020; Rao et al., 2016).

Fecal incontinence can disrupt perineal skin integrity. Maintaining skin integrity is a priority, especially in the debilitated or older adult patient. Incontinence briefs or adult diapers, although helpful in containing the fecal material, permit increased skin contact with feces and may cause skin excoriation. In general, incontinence briefs are to be used only for brief periods of time. The nurse encourages and instructs about meticulous skin hygiene and uses perineal skin cleansers and skin protection products to protect perineal skin. Some patients may benefit from occasional use of foam anal plugs. However, many people find them unacceptable (Gump & Schmelzer, 2016).

Continence sometimes cannot be achieved, and the nurse assists the patient and family to accept and cope with this chronic situation. Patients with dementia may benefit from toileting assistance, including prompted or timed voiding and habit training, which is the setting of a regular time to go to the bathroom (e.g., after breakfast to have a bowel

movement) (Gump & Schmelzer, 2016). The patient can use fecal incontinence devices, which include external collection devices and internal drainage systems. External devices are special rectal pouches (called *fecal incontinence collectors*) that are drainable. They are attached to a synthetic adhesive skin barrier specially designed to conform to the buttocks. Designed for patients with chronic, debilitating illnesses (e.g., in long-term care facilities) or acute illnesses, fecal management systems (e.g., Flexi-Seal Fecal Management System) can be used to eliminate fecal skin contact and are especially useful when there is extensive excoriation or skin breakdown. These systems, which consist of a tube with a low-pressure balloon that conforms to the internal rectal area, may be used for short-term management of liquid stools (no more than 4 consecutive weeks) (see Fig. 41-1).

Figure 41-1 • Flexi-Seal Fecal Management System. Reprinted with permission from ConvaTec, Inc.

Irritable Bowel Syndrome (IBS)

Irritable bowel syndrome (IBS) is a chronic functional disorder characterized by recurrent abdominal pain associated with disordered bowel movements, which may include diarrhea, constipation, or both, without an identifiable cause (Lehrer, 2019; NIDDK, 2017c; Pacheco, Roizenblatt, Góis, et al., 2019). Global prevalence is estimated at 11%; its prevalence among American adults is estimated to be 12%. It is typically diagnosed in adults younger than 45 years of age (NIDDK, 2017c). Women are affected more often than men, with twice as many women diagnosed with IBS in the United States than men. A complex interplay of genetic, environmental, and psychosocial factors is thought to be associated with the onset of IBS. It is believed that some triggers can

either herald the initial onset of IBS or exacerbate symptoms in those with diagnosed IBS; these may include chronic stress, sleep deprivation, neurohormonal deregulation, bacterial overgrowth, genetics, surgery, infections (e.g. *Giardia*), inflammation, and food intolerance (Pacheco et al., 2019).

Pathophysiology

IBS results from a functional disorder of intestinal motility. The change in motility may be related to neuroendocrine dysregulation, especially changes in serotonin signaling, infection, irritation, or a vascular or metabolic disturbance. The peristaltic waves are affected at specific segments of the intestine and in the intensity with which they propel the fecal matter forward. There is no evidence of inflammation or tissue changes in the intestinal mucosa (Norris, 2019).

Clinical Manifestations

Symptoms can vary widely, ranging in intensity and duration from mild and infrequent to severe and continuous. The main symptom is an alteration in bowel patterns: constipation (classified as IBS-C), diarrhea (classified as IBS-D), or a combination of both (classified as IBS-M for "mixed"). The few patients with IBS who do not fit any of these three categories of IBS-C, IBS-D, or IBS-M, are classified as IBS-U for "unclassified." Pain, bloating, and abdominal distention often accompany changes in bowel pattern. The abdominal pain is sometimes precipitated by eating and is frequently relieved by defecation. IBS frequently occurs concomitant with other GI disorders, including gastroesophageal reflux disease (GERD) and with a variety of non-GI functional disorders, including chronic fatigue syndrome, chronic pelvic pain, fibromyalgia, interstitial cystitis, migraine headaches, anxiety, and depression (NIDDK, 2017c).

Assessment and Diagnostic Findings

The Rome IV criteria define IBS as recurrent abdominal pain occurring at least once daily during the last 3 months, associated with two or more of the following (Lehrer, 2019):

- Abdominal pain related to defecation;
- Abdominal pain associated with a change in frequency of stool;
- Abdominal pain associated with a change in form/appearance of stool.

Recording the quality and quantity of bowel movements in a stool diary such as the Bristol Stool Form Scale can be useful in determining the category of IBS (Lacy et al., 2016) (see Fig. 41-2).

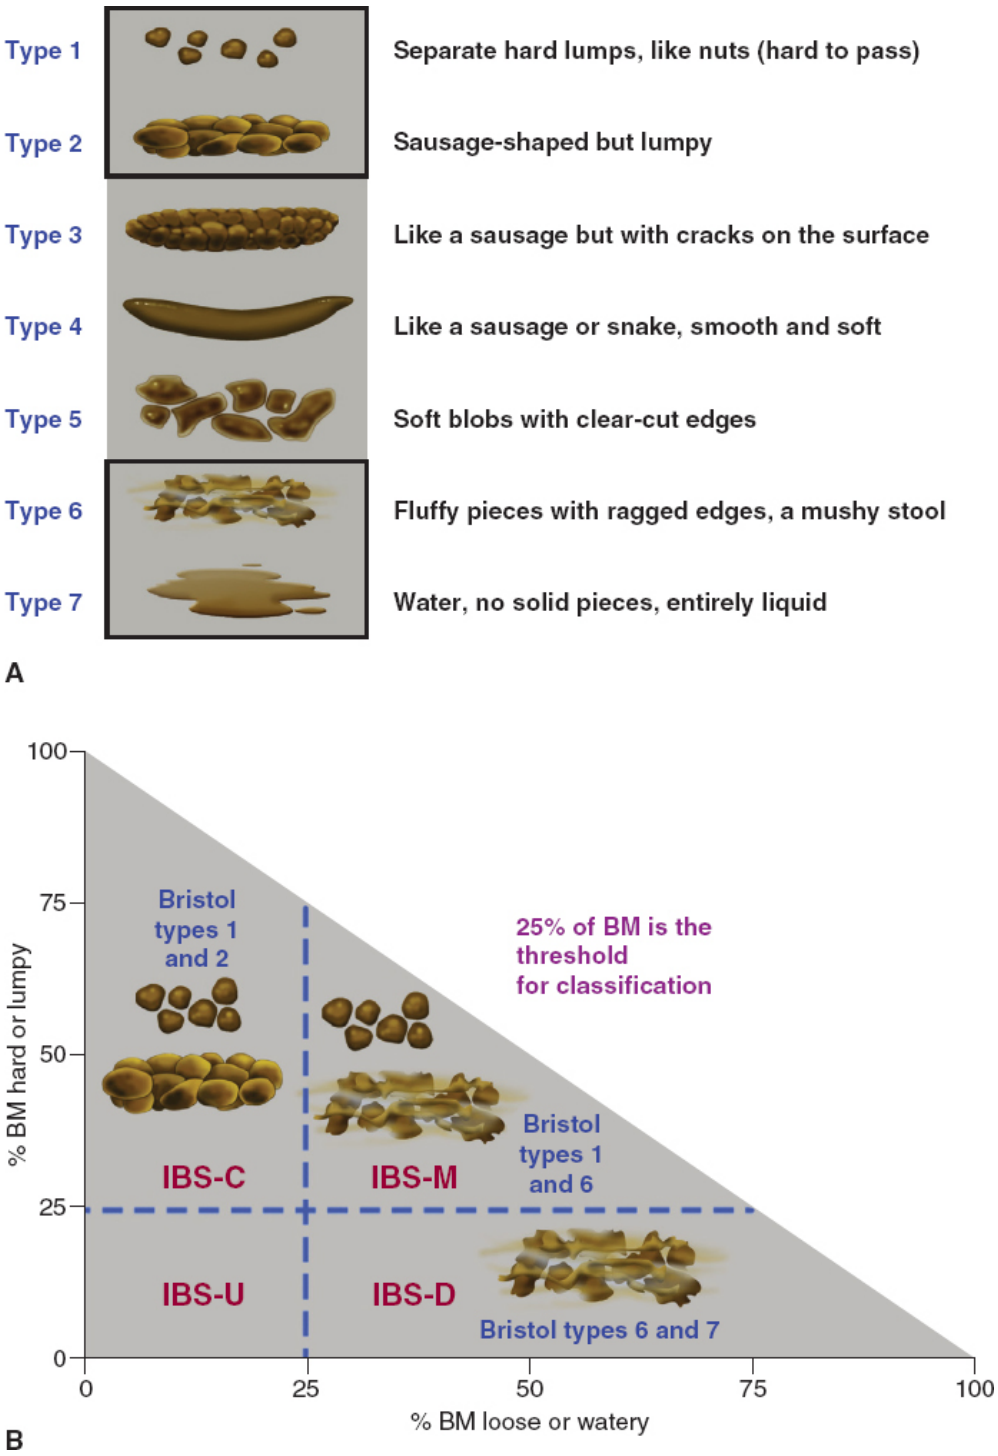

Figure 41-2 • **A.** The Bristol Stool Form Scale (BSFS) is used to evaluate bowel movement (BM) habit. **B.** Characteristics of stools as recorded on the BSFS are then used to determine category of irritable bowel syndrome (IBS), where IBS-C (constipation), IBS-D (diarrhea), IBS-M (mixed), and IBS-U (unclassified). Reprinted with permission from Lacy, B. E., Mearin, F., Chang, L., et al. (2016). Bowel disorders. *Gastroenterology*, *150*(6), 1393–1407.

A definite diagnosis of IBS also necessitates testing to confirm the absence of structural or other disorders. Results from a CBC and C-reactive protein or fecal calprotectin can rule out IBD (see later discussion) for patients who may have IBS-D or

IBS-M, as well as serologic tests for celiac disease (see later discussion). Stool studies and colonoscopy may be performed to rule out other colon diseases (e.g., colorectal cancer, colitis) (Lacy et al., 2016).

Medical Management

The goals of treatment are to relieve abdominal pain and control diarrhea or constipation. Lifestyle modification, including stress reduction, ensuring adequate sleep, and instituting an exercise regimen, can result in symptom improvement. The introduction of soluble fiber (e.g., psyllium) to the diet is important to IBS management. Restriction and then gradual reintroduction of foods that are possibly irritating may help determine what types of food are acting as irritants. Low-FODMAP diets, which restrict intake of the following types of foods, might improve symptoms for some patients (Pacheco et al., 2019):

- ***F***ermentable ***O***ligosaccharides (e.g., wheat, rye, asparagus, legumes, garlic, onions),
- ***D***isaccharides (lactose-containing foods such as milk, yogurt),
- ***M***onosaccharides (fructose-containing foods such as honey, agave nectar, figs, mangoes), ***A***nd
- ***P***olyols (e.g., blackberries, lychee, and low-calorie sweeteners)

For patients with IBS-D, antidiarrheal agents (e.g., loperamide) may be given to control the diarrhea and fecal urgency. Women with severe IBS-D that persists for more than 6 months that does not respond to other therapies may be prescribed alosetron, a highly selective 5-HT_3 antagonist that slows colonic motility. Other drugs that can mitigate IBS-D symptoms include rifaximin, a nonabsorbable oral antibiotic, and eluxadoline, a mu-receptor agonist/delta-receptor antagonist that neuromodulates colonic motility (Pacheco et al., 2019). Lubiprostone, a chloride channel regulator in the gut, can be prescribed for patients with IBS-C (Lacy et al., 2016).

Patients with all types of IBS complain of abdominal pain. This symptom may be mitigated by prescribing smooth muscle antispasmodic agents (e.g., dicyclomine). Antidepressants can assist in treating underlying anxiety and depression but also have secondary benefits. Antidepressants may affect serotonin levels, thus modulating intestinal transit time and improving abdominal comfort. Peppermint oil, a complementary medication, has proven effective in diminishing abdominal discomfort (Lacy et al., 2016). Other alternatives for IBS management include probiotics. Probiotics are bacteria that include *Lactobacillus* and *Bifidobacterium* that can be given to help decrease abdominal bloating and gas (Lacy et al., 2016).

Nursing Management

The nurse's role is to provide patient and family education and encourage self-care activities. The nurse may provide education on the appropriate use of a bowel habit diary, such as the Bristol Stool Form Scale (see Fig. 41-2A). The nurse emphasizes and reinforces good sleep habits and good dietary habits (e.g., avoidance of food triggers). A good way to identify problem foods is to keep a 1- to 2-week food diary and correlate symptoms with food intake. Patients are encouraged to eat at regular times and to avoid food triggers. They should understand that although adequate fluid intake is necessary, fluid should not be taken with meals because this results in abdominal distention.

Alcohol use and cigarette smoking are discouraged. Stress management via relaxation techniques, cognitive-behavioral therapy, yoga, and exercise can be recommended.

DISORDERS OF MALABSORPTION

The inability of the digestive system to absorb one or more of the major vitamins (especially A and B_{12}), minerals (i.e., iron and calcium), and nutrients (i.e., carbohydrates, fats, and proteins) occurs in disorders of malabsorption. Interruptions in the complex digestive process may occur anywhere in the digestive system and cause decreased absorption (Norris, 2019). The conditions that cause malabsorption can be grouped into the following categories (Norris, 2019):

- Mucosal (transport) disorders causing generalized malabsorption (e.g., celiac disease, Crohn's disease, radiation enteritis)
- Luminal disorders causing malabsorption (e.g., bile acid deficiency, Zollinger-Ellison syndrome, pancreatic insufficiency, small bowel bacterial overgrowth, or chronic pancreatitis)
- Lymphatic obstruction, interfering with transport of fat by products of digestion into the systemic circulation (e.g., neoplasms, surgical trauma).

Chart 41-3 PATIENT EDUCATION

Managing Lactose Intolerance

The nurse instructs the patient to:

- Recognize that deficiency of lactase, a digestive enzyme essential for the digestion and absorption of lactose ("milk sugar") from the intestines, results in an intolerance to milk.
- Prevent symptoms by eliminating milk and milk substances.
- Eliminate processed foods that have fillers, such as dried milk, added to them; recognizing this can help determine which foods may need to be eliminated.
- Reduce symptoms by pretreating foods with lactase preparations (e.g., Lactaid drops) before ingestion or by ingesting lactase enzyme tablets with the first bite of food.
- Understand that most people can tolerate 1 to 2 cups of milk or milk products daily without major problems; they are best tolerated if ingested in small amounts during the day.
- Be aware that lactase activity of yogurt with "active cultures" helps the digestion of lactose within the intestine better than lactase preparations.
- Recognize that milk and milk products are rich sources of calcium and vitamin D; elimination of milk from the diet may result in calcium and vitamin D deficiencies; decreased intake without supplements can lead to osteoporosis.

Table 41-2 lists the clinical and pathologic aspects of select malabsorptive disorders. Chart 41-3 provides an education plan for a patient with lactose intolerance, a common malabsorptive disorder caused by a deficiency in lactase.

Celiac Disease

Celiac disease is a disorder of malabsorption caused by an autoimmune response to consumption of products that contain the protein gluten. Gluten is most commonly found in wheat, barley, rye, and other grains, malt, dextrin, and brewer's yeast. Celiac disease has become more common in the past decade, with an estimated prevalence of 1% in the United States. Women are afflicted twice as often as men. This disease is more common among Caucasians, although the rates of celiac disease are on the rise among non-Caucasians. Celiac disease also has a familial risk component, particularly among first-degree relatives. Others at heightened risk include those with type 1 diabetes, Down syndrome, and Turner syndrome. Celiac disease may manifest at any age in a person who is genetically predisposed (NIDDK, 2016a).

Pathophysiology

Nearly 30% of the population in the United States may be genetically predisposed to developing celiac disease. Individuals who are predisposed share a major histocompatibility complex (MHC) class II allele human leukocyte antigen (HLA), HLA-DQ2 or HLA-DQ8. Those who develop celiac disease exhibit an autoimmune response to gluten products that is both humoral and cell mediated. It is not known what trigger or triggers may incite this autoimmune response, although it cannot occur if gluten is not ingested. As a result of this response, the epithelial cells that line the small intestines become inflamed, particularly the proximal portion, where most absorption of nutrients occurs. Eventually, the mucosal villi of the small intestine become denuded and cannot function. This results in loss of ability to absorb both micronutrients and macronutrients, causing systemic nutritional deficits (Norris, 2019).

TABLE 41-2 Select Disorders of Malabsorption

Diseases/Disorders	Pathophysiology	Clinical Features
Gastric resection with gastrojejunostomy	Decreased pancreatic stimulation because of duodenal bypass; poor mixing of food, bile, pancreatic enzymes; decreased intrinsic factor	Weight loss, moderate steatorrhea, anemia (combination of iron deficiency, vitamin B_{12} malabsorption, folate deficiency)
Pancreatic insufficiency (chronic pancreatitis, pancreatic carcinoma, pancreatic resection, cystic fibrosis)	Reduced intraluminal pancreatic enzyme activity, with maldigestion of lipids and proteins	History of abdominal pain followed by weight loss; marked steatorrhea, azotorrhea (excess of nitrogenous matter in the feces or urine); also frequent glucose intolerance (70% in pancreatic insufficiency)
Ileal dysfunction (resection or disease)	Loss of ileal absorbing surface leads to reduced bile salt pool size and reduced vitamin B_{12} absorption; bile in colon inhibits fluid absorption	Diarrhea, weight loss with steatorrhea, especially when >100-cm resection, decreased vitamin B_{12} absorption
Stasis syndromes (surgical strictures, blind loops, enteric fistulas, multiple jejunal diverticula, scleroderma)	Overgrowth of intraluminal intestinal bacteria, especially anaerobic organisms, to $>10^6$/mL results in deconjugation of bile salts, leading to decreased effective bile salt pool size, also bacterial utilization of vitamin B_{12}	Weight loss, steatorrhea; low vitamin B_{12} absorption; may have low D-xylose absorption
Zollinger-Ellison syndrome	Hyperacidity in duodenum inactivates pancreatic enzymes	Ulcer diathesis, steatorrhea
Lactose intolerance	Deficiency of intestinal lactase results in high concentration of intraluminal lactose with osmotic diarrhea	Varied degrees of diarrhea and cramps after ingestion of lactose-containing foods; positive lactose intolerance test, decreased intestinal lactase
Celiac disease (gluten-sensitive enteropathy)	Toxic response to a gluten fraction gliadin by surface epithelium results in destruction of absorbing surface of intestine	Weight loss, diarrhea, bloating, anemia (low iron, folate), osteomalacia, steatorrhea, azotorrhea, low D-xylose absorption; folate and iron malabsorption
Tropical sprue	Unknown toxic factor results in mucosal inflammation, partial villous atrophy	Weight loss, diarrhea, anemia (low folate, vitamin B_{12}); steatorrhea; low D-xylose absorption, low vitamin B_{12} absorption
Whipple disease	Bacterial invasion of intestinal mucosa	Arthritis, hyperpigmentation, lymphadenopathy, serous effusions, fever, weight loss, steatorrhea, azotorrhea
Certain parasitic diseases (giardiasis, strongyloidiasis, coccidiosis, capillariasis)	Damage to or invasion of surface mucosa	Diarrhea, weight loss; steatorrhea; organism may be seen on jejunal biopsy or recovered in stool
Immunoglobulinopathy	Decreased local intestinal defenses, lymphoid hyperplasia, lymphopenia	Frequent association with *Giardia:* hypogammaglobulinemia or

	isolated immunoglobulin A deficiency

Adapted from Hammami, M. B. (2019). Malabsorption. *Medscape*. Retrieved on 2/29/2019 at: emedicine.medscape.com/article/180785-overview; Norris, T. L. (2019). *Porth's pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Clinical Manifestations

The most common GI clinical manifestations of celiac disease include diarrhea, steatorrhea, abdominal pain, abdominal distention, flatulence, and weight loss. However, these manifestations are more common among children than adults. Adults can present with non-GI signs and symptoms of celiac disease, which are highly variable and can include fatigue, general malaise, depression, hypothyroidism, migraine headaches, osteopenia, anemia, seizures, paresthesias in the hands and feet, and a red, shiny tongue. Some adults and children may evidence ridges in the enamel of their adult teeth, as well as discoloration or yellowing. Dermatitis herpetiformis is a rash that is frequently associated with celiac disease in adults; it manifests as clusters of erythematous macules that develop into itchy papules and vesicles on the forearms, elbows, knees, face, or buttocks (NIDDK, 2016a).

Assessment and Diagnostic Findings

A comprehensive assessment of the patient's presenting signs and symptoms, as well as a family history and risk factor assessment, may provide the first clues that the patient may have celiac disease. The definitive diagnosis is based upon a series of serologic tests and endoscopic biopsy. It is important that the patient continues to consume gluten products during testing, or there could be a false-negative serologic finding. The first serologic test is the immunoglobulin A (IgA) anti-tissue transglutaminase (tTG), which is 90% sensitive and 95% specific to celiac disease. Findings are confirmed with upper endoscopy with biopsies of the proximal small intestine (Goebel, 2019).

Medical Management

Celiac disease is a chronic, noncurable, lifelong disease. There are no drugs that induce remission; the treatment is to refrain from exposure to gluten in foods and other products (see later discussion). A consultation with a dietician may be advisable. The patient should be advised that it will likely take time before bothersome signs and symptoms resolve; it will take a full year before the integrity of the intestinal villi can be restored. The patient should be cautioned that despite adhering to a gluten-free diet, symptoms can still occur and can have an impact on quality of life (Roos, Liedberg, Hellström, et al., 2019). Other manifestations of celiac disease may require specific, targeted treatment. For instance, patients who present with anemia may require folate, cobalamin, or iron supplements (see Chapter 29). Patients with osteopenia may require treatment for osteoporosis (see Chapter 36).

Nursing Management

The nurse provides patient and family education regarding adherence to a gluten-free diet (see Chart 41-4), and how to avoid other gluten products. For instance, oats are not

contraindicated in gluten-free diets; however, many oat products are produced in facilities that are cross-contaminated with wheat or other contraindicated grains. Likewise, gluten-free foods prepared in restaurants or dining areas that share preparatory space can become gluten-contaminated. For instance, gluten-free toast prepared in a toaster that is also used for wheat-based toast can become gluten-contaminated. Patients must become vigilant in asking restaurant and dining hall staff about how gluten-free foods are prepared.

Chart 41-4 PATIENT EDUCATION

How to Avoid Gluten

The nurse instructs the patient to choose foods that are naturally gluten-free such as:

- Fresh fruits and vegetables
- Meat and poultry
- Fish and seafood
- Dairy
- Beans, legumes, and nuts
- Corn, rice, soy, quinoa, and potato

The nurse instructs the patient to avoid foods that commonly contain gluten, including the following:

- Wheat (wheat-free does not mean gluten-free), barley, bran, durum, spelt, faro, rye, bulgur, graham, semolina, farina, emmer, and triticale; these are generally used in:
  - Cakes, pastries, cookies
  - Breads, pastas, rolls, pizza, crackers
- Brewer's yeast; this generally includes beer, ale, and porter
- Malt, malt extract, and malt flavoring
- Modified food starch made from wheat (commonly contained in sour cream)

The nurse instructs the patient to exercise caution and carefully read labels on foods,[a] particularly before consuming the following:

- Candies (gluten-free candy list is available on Celiac Disease Foundation site)
- Caramel-colored foods
- Cornflakes and puffed rice cereals (these often contain malt flavoring or extract, which contains gluten)
- Oat products not specifically labeled as produced in gluten-free facilities
- Processed lunch meats and "shaped" foods (e.g., cheese sticks)
- Salad dressings, condiments, soy sauce, seasonings
- Sauces (wheat is often used as thickening agent)
- Soft drinks

[a]The U.S. Food and Drug Administration (FDA) standard for "gluten-free" is that the product must contain less than 200 parts per million (ppm) of gluten.

Adapted from Celiac Disease Foundation. Gluten-Free Living. Retrieved on 2/29/2020 at: celiac.org/gluten-free-living/gluten-free-foods/

Products that are not foods can also contain gluten. Many generic and over-the-counter drugs can be prepared with gluten gels. Toothpastes, communion wafers, and some cosmetics (e.g., lipsticks) and art supplies (e.g., modeling clay) can also contain gluten. Patients must understand how to carefully read labels on both foods and nonfood products to determine if they contain gluten. The U.S. Food and Drug Administration (FDA) regulates and monitors the appropriate application of gluten-free labels.

ACUTE ABDOMEN

An acute abdomen, sometimes called a *surgical abdomen* is characterized by an acute onset of abdominal pain that does not have a traumatic etiology and that most typically requires swift surgical intervention to prevent peritonitis, sepsis, and septic shock. Disorders of the lower GI tract that may cause similar initial presenting clinical manifestations, causing acute abdominal pain and an acute abdomen include appendicitis, severe diverticulitis, and intestinal obstruction, all of which may lead to peritonitis.

Peritonitis

Peritonitis is inflammation of the peritoneum, which is the serous membrane lining the abdominal cavity and covering the viscera. Usually, it is a result of bacterial infection but may occur secondary to a fungal or mycobacterial infection; the organisms come from diseases or disorders of the GI tract or, in women, from the internal reproductive organs (e.g., fallopian tube). The most common bacteria implicated are *Escherichia coli* and *Klebsiella, Proteus, Pseudomonas,* and *Streptococcus* species. Peritonitis can also result from external sources such as abdominal surgery or trauma (e.g., gunshot wound, stab wound) or an inflammation that extends from an organ outside the peritoneal area, such as the kidney, or from continuous ambulatory peritoneal dialysis (CAPD) (see Chapter 48). Peritonitis can be categorized as (Daley, 2019):

- Primary peritonitis, also called *spontaneous bacterial peritonitis (SBP),* occurs as a spontaneous bacterial infection of ascitic fluid. This occurs most commonly in adult patients with liver failure (see Chapter 43).
- Secondary peritonitis occurs secondary to perforation of abdominal organs with spillage that infects the serous peritoneum. The most common causes include a perforated appendix (see later discussion), perforated peptic ulcer (see Chapter 40), perforated sigmoid colon caused by severe diverticulitis (see later discussion), volvulus of the colon (see later discussion), and strangulation of the small intestine (see later discussion). The major focus of this section is on secondary peritonitis.
- Tertiary peritonitis occurs as a result of a superinfection in a patient who is immunocompromised. Tuberculous peritonitis in a patient with AIDS is an example of tertiary peritonitis; these are rare causes of peritonitis.

Pathophysiology

Secondary peritonitis is caused by leakage of contents from abdominal organs into the abdominal cavity, usually as a result of inflammation, infection, ischemia, trauma, or tumor perforation. Bacterial proliferation occurs. Edema of the tissues results, and exudation of fluid develops in a short time. Fluid in the peritoneal cavity becomes turbid

with increasing amounts of protein, white blood cells, cellular debris, and blood. The immediate response of the intestinal tract is hypermotility, soon followed by paralytic ileus with an accumulation of air and fluid in the bowel (Daley, 2019; Norris, 2019).

Clinical Manifestations

Symptoms depend on the location and extent of the inflammation. The early clinical manifestations of peritonitis frequently are the signs and symptoms of the disorder causing the condition (e.g., manifestations of infection). At first, pain is diffuse but then becomes constant, localized, and more intense over the site of the pathologic process (site of maximal peritoneal irritation). Movement usually aggravates the pain. The affected area of the abdomen becomes extremely tender and distended, and the muscles become rigid. Rebound tenderness may be present. Usually, anorexia, nausea, and vomiting occur and peristalsis is diminished, followed by paralytic ileus. An initial temperature of 37.8° to 38.3°C (100° to 101°F) can be expected, along with an increased pulse rate. With progression of the condition, patients may become hypotensive and oliguric or anuric. Without swift and decisive intervention, clinical manifestations will mirror those of sepsis and septic shock (Daley, 2019) (see Chapter 11).

Assessment and Diagnostic Findings

The white blood cell count is elevated (> 11,000/mm^3) and may demonstrate a relative increase in the bands (i.e., immature neutrophils), consistent with bacterial infection (Daley, 2019). The hemoglobin and hematocrit levels may be low if blood loss has occurred. Serum electrolyte studies may reveal altered levels of potassium, sodium, and chloride. Blood chemistry panels and arterial blood gases may reveal dehydration and acidosis.

An abdominal x-ray may show free air and fluid as well as distended bowel loops. Abdominal ultrasound may reveal **abscesses** (localized collection of purulent material surrounded by inflamed tissues) and fluid collections, and ultrasound-guided aspiration may assist in easier placement of drains. A computed tomography (CT) scan of the abdomen may show abscess formation. Peritoneal aspiration and culture and sensitivity studies of the aspirated fluid may reveal infection and identify the causative organisms. Ultrasound-guided paracentesis may be indicated for the patient with ascites. MRI may be used for diagnosis of intra-abdominal abscesses (Daley, 2019).

Medical Management

Fluid, colloid, and electrolyte replacement is the major focus of medical management. The administration of several liters of an isotonic solution is prescribed. Hypovolemia occurs because massive amounts of fluid and electrolytes move from the intestinal lumen into the peritoneal cavity and deplete the fluid in the vascular space.

Analgesic medications are prescribed for pain. Antiemetic agents are given as prescribed for nausea and vomiting. Intestinal intubation and suction assist in relieving abdominal distention and in promoting intestinal function. Fluid in the abdominal cavity can cause pressure that restricts expansion of the lungs and causes respiratory distress. Oxygen therapy by nasal cannula or mask generally promotes adequate oxygenation, but airway intubation and ventilatory assistance occasionally are required.

Antibiotic therapy is initiated early in the treatment of peritonitis. Large doses of a broad-spectrum antibiotic are given IV until the specific organism causing the infection is identified and appropriate antibiotic therapy can be initiated.

The main focus of treatment in secondary peritonitis is to identify and control the source of infection, maintain organ function, and prevent complications (Daley, 2019). Treatment is multidisciplinary and involves hemodynamic support, fluid and electrolyte replacement, systemic broad-spectrum antibiotics, and nutritional support. Control of the source of infection can be treated surgically and nonsurgically depending on the patient's condition and underlying pathology. Nonsurgical treatment includes percutaneous drainage of abscesses and endoscopic stent placement. In select instances, ultrasound-guided and CT-guided peritoneal drainage of abdominal and extraperitoneal abscesses has allowed for avoidance or delay of surgical therapy until the acute septic process has subsided (Daley, 2019). Surgical treatment is directed toward excision (e.g., appendix), resection with or without anastomosis (e.g., intestine), repair (e.g., perforation), and drainage (e.g., abscess). With extensive sepsis, a fecal diversion may need to be created (see later discussions). Antibiotic therapy is continued postoperatively.

Nursing Management

Intensive care is needed for the patient with septic shock (see Chapter 11). Signs indicating that peritonitis is subsiding include a decrease in temperature and pulse rate, softening of the abdomen, return of peristaltic sounds, passing of flatus, and bowel movements. The nurse increases fluid and food intake gradually and reduces parenteral fluids as prescribed. A worsening clinical condition may indicate a complication, and the nurse must prepare the patient for emergency surgery. The nursing management of a patient treated for secondary peritonitis is based upon the patient's primary diagnosis and treatment (see later discussions of Nursing Management of Patients with Appendicitis, Diverticular Disease, and Intestinal Obstruction).

Appendicitis

The appendix is a small, vermiform (i.e., wormlike) appendage about 8 to 10 cm (3 to 4 inches) long that is attached to the cecum just below the ileocecal valve. The appendix fills with byproducts of digestion and empties regularly into the cecum. Because it empties inefficiently and its lumen is small, the appendix is prone to obstruction and is particularly vulnerable to infection (i.e., appendicitis). Appendicitis, the most frequent cause of acute abdomen in the United States, is the most common reason for emergency abdominal surgery. Although it can occur at any age, it typically occurs between the ages of 10 and 30 years. Its incidence is slightly higher among males and there is a familial predisposition (Craig, 2018; NIDDK, 2014a).

Pathophysiology

The appendix becomes inflamed and edematous as a result of becoming kinked or occluded by a fecalith, lymphoid hyperplasia (secondary to inflammation or infection), or rarely, foreign bodies (e.g., fruit seeds) or tumors. The inflammatory process increases

intraluminal pressure, causing edema and obstruction of the orifice. Once obstructed, the appendix becomes ischemic, bacterial overgrowth occurs, and eventually gangrene or perforation occurs (Craig, 2018).

Clinical Manifestations

Vague periumbilical pain (i.e., visceral pain that is dull and poorly localized) with anorexia progresses to right lower quadrant pain (i.e., parietal pain that is sharp, discrete, and well localized) and nausea in approximately 50% of patients with appendicitis (Craig, 2018). A low-grade fever may be present. Local tenderness may be elicited at McBurney's point when pressure is applied (see Fig. 41-3). Rebound tenderness (i.e., production or intensification of pain when pressure is released) may be present. Rovsing's sign may be elicited by palpating the left lower quadrant; this paradoxically causes pain to be felt in the right lower quadrant (see Fig. 41-3). If the appendix has ruptured, the pain becomes consistent with peritonitis (see previous discussion); abdominal distention develops as a result of paralytic ileus, and the patient's condition worsens (Craig, 2018).

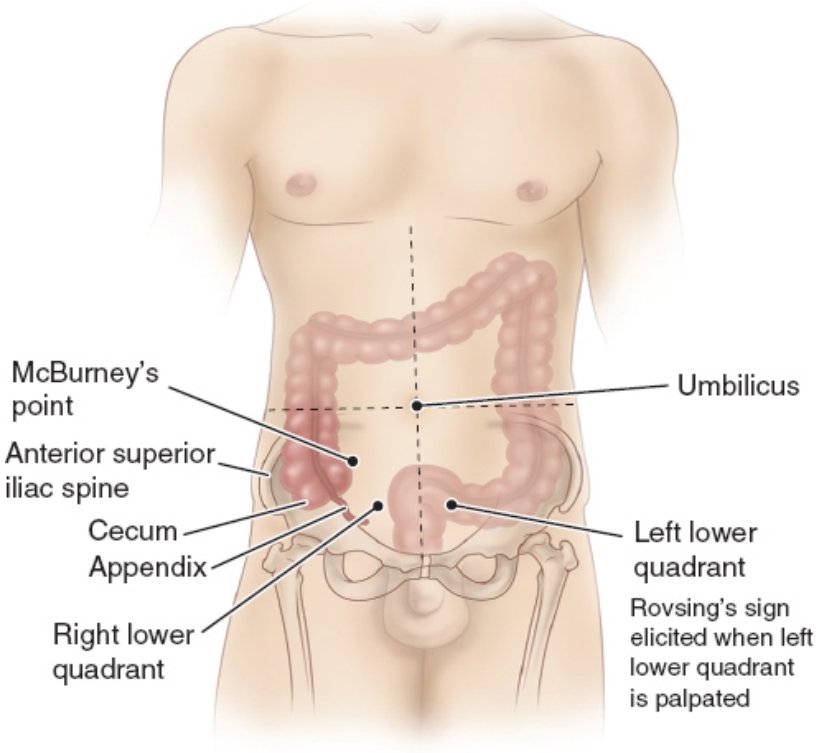

Figure 41-3 • When the appendix is inflamed, tenderness can be noted in the right lower quadrant at McBurney's point, which is between the umbilicus and the anterior superior iliac spine. Rovsing's sign is pain felt in the right lower quadrant after the left lower quadrant has been palpated.

Constipation can also occur with appendicitis. Laxatives given in this instance may result in perforation of the inflamed appendix. In general, a laxative or cathartic should not be given when a person has fever, nausea, and abdominal pain.

Assessment and Diagnostic Findings

Diagnosis is based on the results of a complete history and physical examination, laboratory findings, and imaging studies. The white blood cell (WBC) count is useful when determining diagnosis; between 80% and 85% of adults with appendicitis will have a WBC count >10,500/mm^3; 78% of patients have neutrophilia, where neutrophils comprise >75% of the WBCs (Daley, 2019). C-reactive protein levels are typically elevated, especially within the first 12 hours of symptoms, but may return to normal in patients who are symptomatic longer than 24 hours (Daley, 2019). A CT scan or ultrasound is used to confirm the diagnosis. A pregnancy test may be ordered for women of childbearing age to rule out ectopic pregnancy and before radiologic studies are done. As an alternative, a transvaginal ultrasound may be used to confirm the diagnosis (Craig, 2018). A urinalysis is usually obtained to rule out urinary tract infection or renal calculi.

Complications

The major complications of appendicitis are gangrene or perforation of the appendix, which can lead to peritonitis, abscess formation, or portal pylephlebitis, which is septic thrombosis of the portal vein caused by vegetative emboli that arise from septic intestines. Perforation generally occurs within 6 to 24 hours after the onset of pain and leads to peritonitis (Craig, 2018; Spelman, 2019).

Gerontologic Considerations

Acute appendicitis is uncommon in older adults. When appendicitis does occur, classic signs and symptoms are altered and may vary greatly. Pain may be absent or minimal. Symptoms may be vague, suggesting bowel obstruction or another process. Fever and leukocytosis may not be present. As a result, diagnosis and prompt treatment may be delayed, causing complications and mortality. The patient may have no symptoms until the appendix becomes gangrenous or perforates. The incidence of complications is higher in older adults because many of these patients do not seek health care as quickly as younger patients (Craig, 2018; Eliopoulos, 2018).

Medical Management

Immediate surgery is typically indicated if appendicitis is diagnosed (Craig, 2018). To correct or prevent fluid and electrolyte imbalance, dehydration, and sepsis, antibiotics, and IV fluids are given until surgery is performed. Appendectomy (i.e., surgical removal of the appendix) is performed as soon as possible to decrease the risk of perforation. Appendectomy has traditionally been performed under general anesthesia with an open technique via transverse incision in the right lower quadrant (laparotomy). The laparoscopic approach is becoming the procedure of choice; it allows the patient an earlier return to normal activities (Santacroce, 2019). Both laparotomy and laparoscopy are safe and effective in the treatment of appendicitis with or without perforation. Antibiotic prophylaxis is recommended for less than 24 hours for nonperforated appendicitis and for <5 days for perforated appendicitis (Daley, 2019). Antibiotic selection should follow guidelines outlined by the CDC to prevent surgical site infections (CDC, 2017a).

Some patients may have abscess formation that involves the cecum or terminal ileum. In these select cases, appendectomy may be deferred until the mass is drained. Most

commonly, these abscesses are drained percutaneously or surgically. The patient continues to receive treatment with antibiotics. After the abscess is drained and there is no further evidence of infection, an appendectomy is then performed (Craig, 2018).

Nursing Management

Goals include relieving pain, preventing fluid volume deficit, reducing anxiety, preventing or treating surgical site infection, preventing atelectasis, maintaining skin integrity, and attaining optimal nutrition.

The nurse prepares the patient for surgery, which includes an IV infusion to replace fluid loss and promote adequate renal function, antibiotic therapy to prevent infection, and administration of analgesic agents for pain. An enema is not given because it can lead to perforation.

After surgery, the nurse places the patient in a high Fowler position. This position reduces the tension on the incision and abdominal organs, helping to reduce pain. It also promotes thoracic expansion, diminishing the work of breathing, and decreasing the likelihood of atelectasis. The patient is educated on the use of an incentive spirometer and encouraged to use it at least every 2 hours while awake (see Chapter 19 for discussion on atelectasis and incentive spirometry). A parenteral opioid (e.g., morphine) is typically prescribed to relieve pain; this is switched to an oral agent when the patient is able to tolerate oral fluids and foods. Any patient who was dehydrated before surgery receives IV fluids. When tolerated, oral fluids are given. Food is provided as desired and tolerated on the day of surgery when bowel sounds are present. The nurse auscultates for the return of bowel sounds and queries the patient for passing of flatus. Urine output is monitored to ensure that the patient is not hampered by postoperative urinary retention and to ensure that hydration status is adequate. The patient is encouraged to ambulate the day of surgery to reduce risks of atelectasis and venous thromboembolism (VTE) formation.

The patient may be discharged on the day of surgery if the temperature is within normal limits, there is no undue discomfort in the operative area, and the appendectomy was performed laparoscopically. Discharge instruction for the patient and family is imperative. The nurse instructs the patient to make an appointment to have the surgeon remove any sutures and inspect the wound between 1 and 2 weeks after surgery. Incision care and activity guidelines are discussed; heavy lifting is to be avoided postoperatively, although normal activity can usually be resumed within 2 to 4 weeks.

Patients with a gangrenous or perforated appendix are at greater risk for infection and peritonitis; therefore, they may be kept in the hospital for several days. Secondary abscesses may form in the pelvis, under the diaphragm, or in the liver, causing elevation of the temperature, pulse rate, and white blood cell count. When the patient is ready for discharge, the patient and family are educated about how to care for the incision and perform dressing changes and irrigations as prescribed. A home health nurse may be needed to assist with this care and to monitor the patient for complications and wound healing.

Diverticular Disease 

A **diverticulum** is a saclike herniation of the lining of the bowel that extends through a defect in the muscle layer. True diverticula are herniations of all layers of the GI wall (mucosa, muscularis propria, and adventitia), while pseudo-diverticula only involve the mucosa and submucosa (Ghoulam, 2019). Diverticula may occur anywhere in the GI tract, from the esophagus to the colon, but occur most commonly in the colon. In the colon there is only one complete muscle layer, in contrast to the small intestine and rectum which have two muscular layers. People with Asian ancestry are more likely to develop diverticula in the right colon, while people of European descent are more prone to diverticular disease in the sigmoid colon (Ghoulam, 2019).

Diverticulosis is defined by the presence of multiple diverticula without inflammation or symptoms. Diverticular disease of the colon is very common in developed countries, and its prevalence increases with increasing age; it is present in half of all adults over 65 years of age, and 70% of adults over 80 years of age (Krzyzak & Mulrooney, 2019). Diverticulosis is the most common pathologic incidental finding on colonoscopy. Approximately 80% of patients with diverticulosis never develop any complications or symptoms of disease. Risk factors include low intake of dietary fiber, slow colonic transit time, obesity, a history of cigarette smoking, regular use of nonsteroidal anti-inflammatory drugs (NSAIDs), and a positive family history. Dietary factors such as high intake of red meat, fat, particularly dairy fat, and refined sugar are strongly associated with diverticular disease (Ghoulam, 2019; Krzyzak & Mulrooney, 2019).

Diverticulitis is inflammation of one or more diverticula and is a common reason for elective colectomy (Ghoulam, 2019). Approximately 1% to 4% of people with diverticulosis develop diverticulitis; of those, 20% will have another episode within 10 years (Ghoulam, 2019).

Pathophysiology

Diverticula form when the mucosal and submucosal layers of the colon herniate through the muscular wall because of high intraluminal pressure, low volume in the colon (i.e., fiber-deficient contents), and decreased muscle strength in the colon wall (i.e., muscular hypertrophy from hardened fecal masses). The etiology of diverticulitis is not completely understood. One theory is the cause due to an altered immune response in the gut microbiome (Krzyzak & Mulrooney, 2019). Other explanations are feces or food particles become trapped in diverticula, resulting in bacterial overgrowth, distention, increased intraluminal pressure, muscle spasms, vascular compromise, and subsequent micro- or macroperforation. Complications include intra-abdominal abscesses, peritonitis, **fistula** (abnormal tract formation), and hemorrhage (Krzyzak & Mulrooney, 2019). Repeated bouts of diverticulitis can result in scar tissue formation, which may lead to narrowing of the colonic lumen and bowel obstruction.

Bowel contents can accumulate in a diverticulum and decompose, causing inflammation and infection. The diverticulum can also become obstructed and then inflamed if the obstruction continues. The inflammation of the weakened colonic wall of the diverticulum can cause it to perforate, giving rise to irritability and spasticity of the colon (i.e., diverticulitis). In addition, abscesses may develop and may eventually perforate, leading to peritonitis and erosion of the arterial blood vessels, resulting in bleeding. When a patient develops symptoms of diverticulitis, microperforation of the colon has occurred.

Clinical Manifestations

Chronic constipation sometimes precedes the development of diverticulosis by many years. Most commonly, no problematic symptoms occur with diverticulosis. Some patients may have mild signs and symptoms that include bowel irregularity with intervals of alternating constipation and diarrhea, with nausea, anorexia, and bloating or abdominal distention.

With diverticulitis, up to 70% of patients report an acute onset of mild to severe cramping pain in the left lower quadrant (Ghoulam, 2019). This may be accompanied by a change in bowel habits, most typically constipation or obstipation (i.e., severe constipation) and bloating, with nausea, fever, and leukocytosis. Acute complications of diverticulitis may include abscess formation, bleeding, and peritonitis. If an abscess develops, the associated findings are tenderness, a palpable mass, fever, and leukocytosis. Inflamed diverticula may erode areas adjacent to arterial branches, causing massive rectal bleeding. An inflamed diverticulum that perforates results in abdominal pain localized over the involved segment, usually the sigmoid; local abscess or peritonitis follows (see previous discussion).

Recurrent episodes of diverticulitis may cause chronic complications that include fistula formation, including colovesicular fistulas (i.e., between the colon and bladder) and, in women, colovaginal fistulas (i.e., between the colon and vagina). As a response to repeated inflammation, the colon may narrow with scar tissue and fibrotic strictures, leading to cramps, narrow stools, and increased constipation, or, at times, intestinal obstruction (see later discussion).

Assessment and Diagnostic Findings

Diverticulosis is typically diagnosed by colonoscopy, which permits visualization of the extent of diverticular disease. Laboratory tests that assist in diagnosis of diverticulitis include a CBC; if the patient has frank blood in the stool, the hemoglobin level should be analyzed. The WBC is frequently elevated; however, a normal WBC count does not rule out diverticulitis. Up to 40% of patients with diverticulitis have a normal WBC count (Ghoulam, 2019). Urinalysis and urine cultures should be analyzed in patients with suspected colovesicular fistulas.

An abdominal CT scan with contrast agent is the diagnostic test of choice to confirm diverticulitis; it can also reveal perforation and abscesses. Abdominal x-rays may demonstrate free air under the diaphragm if a perforation has occurred from the diverticulitis. Results from these radiologic tests confirm whether or not the patient has uncomplicated diverticulitis or complicated diverticulitis that could require surgical intervention. The Modified Hinchey Classification System is used as a guide to determine treatment (Hinchey, Schaal, & Richards, 1978; Krzyzak & Mulrooney, 2019) (see Table 41-3).

Gerontologic Considerations

The incidence of diverticular disease increases with age because of degeneration and structural changes in the circular muscle layers of the colon and because of cellular hypertrophy. The symptoms are less pronounced in the older adult than in other adults. Older adults may not have abdominal pain until infection occurs. They may delay

reporting symptoms because they fear surgery or are afraid that they may have cancer (Eliopoulos, 2018).

Medical Management

Medical management is guided by the severity of disease and the presence of comorbid diagnoses and complications. Treatment for patients with uncomplicated diverticulitis is on an outpatient basis with diet and medication. This is the typical treatment for most patients with diagnosed diverticulitis. Rest, oral fluids, and analgesic medications are recommended. Initially, a clear liquid diet is consumed until the inflammation subsides; then a high-fiber, low-fat diet is recommended. This type of diet helps increase stool volume, decrease colonic transit time, and reduce intraluminal pressure. The American Gastroenterology Association recommends selective use of antibiotics for patients with acute, uncomplicated diverticulitis (Ghoulam, 2019).

TABLE 41-3 Modified Hinchey Classification: Staging of Acute, Complicated Diverticulitis

Modified Hinchey Classification Stage	Description	Category
0	Mild diverticulitis or diverticula with colonic thickening on CT	Uncomplicated
Ia	Colonic reaction with inflammatory reaction in the pericolic fate	Uncomplicated
Ib	Localized pericolic or mesenteric abscess	Complicated
II	Intra-abdominal, pelvic, or retroperitoneal abscess	Complicated
III	Perforated diverticulitis causing generalized purulent peritonitis	Complicated
IV	Rupture of diverticula into the peritoneal cavity with generalized fecal peritonitis	Complicated

Adapted from Ghoulam, E. M. (2019). Diverticulitis. *Medscape*. Retrieved on 2/29/2020 at: emedicine.medscape.com/article/173388-overview; Krzyzak, M., & Mulrooney, S. (2019). Diverticulitis: A review of diagnosis, treatment, and prevention. *Consultant*, *59*(2), 35–37, 44.

In acute cases of diverticulitis with significant symptoms, hospitalization is required. Hospitalization is often indicated for those who are older, immunocompromised, taking corticosteroids, or unable to tolerate oral fluids. Patients with complicated disease (see Table 41-3) can require hospitalization; those with higher stages require surgery and hospitalization (see later discussion). Withholding oral intake, administering IV fluids, and instituting nasogastric (NG) suctioning if vomiting or distention occurs are used to rest the bowel. Broad-spectrum antibiotics (e.g., ampicillin/sulbactam, ticarcillin/clavulanate) are prescribed. An opioid or other analgesic agent may be prescribed for pain relief. Oral intake is increased as symptoms subside. A low-fiber diet may be necessary until signs of infection decrease.

Surgical Management

Although acute diverticulitis usually subsides with medical management, immediate surgical intervention is necessary if complications (e.g., perforation, peritonitis, hemorrhage, obstruction) occur. In cases of abscess formation without peritonitis,

hemorrhage, or obstruction, CT-guided percutaneous drainage may be performed to drain the abscess, and IV antibiotics are given. After the abscess is drained and the acute episode of inflammation has subsided (after approximately 6 weeks), surgery may be recommended to prevent repeated episodes. Two types of surgery are typically considered either to treat acute complications or prevent further episodes of inflammation:

- One-stage resection, in which the inflamed area is removed and a primary end-to-end anastomosis is completed
- Multiple-stage procedures for complications such as obstruction or perforation (see Fig. 41-4)

The type of surgery performed depends on the extent of complications found during the procedure. When possible, the area of diverticulitis is resected and the remaining bowel is joined end to end (i.e., primary resection and end-to-end anastomosis). This is performed using traditional surgical or laparoscopically assisted colectomy with lavage. A two-stage resection may be performed in patients with Hinchey Stage IV diverticulitis; the diseased colon is resected (as in a one-stage procedure) but no anastomosis is performed. In this procedure, one end of the bowel is brought out to the abdominal wall and the distal end is closed over and left in the abdomen (Hartmann procedure), or if the blood supply to the distal colon is questionable, both ends of the bowel are brought out to the abdominal wall (double-barrel). Both Hartmann procedures and double-barrel colostomies usually can be reanastomosed at a later time.

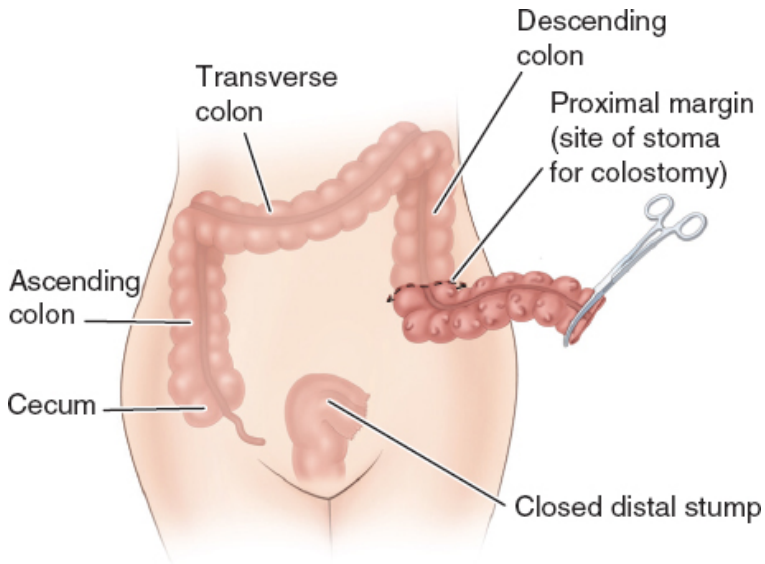

Figure 41-4 • Hartmann procedure for diverticulitis: primary resection for diverticulitis of the colon. The affected segment (*clamp attached*) has been divided at its distal end. In a primary anastomosis, the proximal margin (*dotted line*) is transected and the bowel attached end to end. In a two-stage procedure, a colostomy is constructed at the proximal margin with the distal stump oversewn (Hartmann procedure, as shown) and the stump is left in the pelvis. The distal stump may be brought to the surface as a mucous fistula if there is concern about blood supply. The second stage consists of colostomy takedown and anastomosis.

Nursing Management

The nurse recommends a fluid intake of 2 L/day (within limits of the patient's cardiac and renal reserve) and suggests foods that are soft but have increased fiber, such as prepared cereals or soft-cooked vegetables, to increase the bulk of the stool and facilitate peristalsis, thereby promoting defecation. An individualized exercise program is encouraged to improve abdominal muscle tone. It is important to review the patient's daily routine to establish a schedule for meals and a set time for defecation and to assist in identifying habits that may have suppressed the urge to defecate. The nurse encourages daily intake of bulk laxatives such as psyllium, which helps propel feces through the colon. Some people with diverticulosis may have food triggers such as nuts and popcorn that bring on a diverticulitis attack, whereas others may not report food triggers. If triggers are identified, patients should be urged to avoid them.

For the patient who has had a colostomy placed, refer to the later section on Nursing Management of the Patient Requiring an Ostomy.

Intestinal Obstruction

Intestinal obstruction exists when blockage prevents the normal flow of intestinal contents through the intestinal tract. Two types of processes can impede this flow (Norris, 2019; Ramnarine, 2017):

- *Mechanical obstruction: Extrinsic* lesions from outside the intestines or *intrinsic* lesions within the intestines can obstruct flow. Examples of extrinsic lesions include adhesions, hernias, and abscesses. Examples of intrinsic lesions include intestinal tumors (benign and cancerous), strictures (from prior surgery or radiation), or *intraluminal* lesions due to a defect in the bowel lumen (e.g., intussusception).
- *Functional or paralytic obstruction:* The intestinal musculature cannot propel the contents along the bowel either due to interruption of innervation or vascular supply to the bowel. Examples are amyloidosis, muscular dystrophy, endocrine disorders such as diabetes, or neurologic disorders such as Parkinson's disease. The blockage also can be temporary and the result of the manipulation of the bowel during surgery (i.e., ileus).

Obstruction can occur in the large or small intestine and can be partial or complete. Severity depends on the region of bowel affected, the degree to which the lumen is occluded, and especially the degree to which the vascular supply to the bowel wall is disturbed. Most obstructions occur in the small intestine. Adhesions, hernia, and tumor account for 90% of obstructions in the small intestines (Bordeianou & Yeh, 2019). Other causes of small bowel obstruction include Crohn's disease, intussusception, volvulus, and paralytic ileus. Most obstructions in the large intestines occur in the sigmoid colon. The most common causes of large bowel obstruction are cancer (60%), diverticular disease (20%), and volvulus (5%). Other causes of large bowel obstruction include benign tumors, strictures, and obstipation or fecal impaction (Hopkins, 2017). Table 41-4 and Figure 41-5 list mechanical causes of obstruction and describe how they occur.

TABLE 41-4 Mechanical Causes of Intestinal Obstruction

Cause	Description	Result
Adhesions	Loops of intestine become adherent to areas that heal slowly or scar after abdominal surgery; occurs most commonly in small intestine	After surgery, adhesions produce a kinking of an intestinal loop.
Intussusception (see Fig. 41-5A)	One part of the intestine slips into another part located below it (like a telescope shortening); occurs more commonly in infants than adults	The intestinal lumen becomes narrowed, and blood supply becomes strangulated.
Volvulus (see Fig. 41-5B)	Bowel twists and turns on itself and occludes the blood supply	Intestinal lumen becomes obstructed. Gas and fluid accumulate in the trapped bowel.
Hernia (see Fig. 41-5C)	Protrusion of intestine through a weakened area in the abdominal muscle wall	Intestinal flow may be completely obstructed. Blood flow to the area may be obstructed as well.
Tumor	A tumor that exists within the wall of the intestine extends into the intestinal lumen, or a tumor outside the intestine causes pressure on the wall of the intestine. Most common type is colorectal adenocarcinoma	Intestinal lumen becomes partially obstructed; if the tumor is not removed, complete obstruction results.

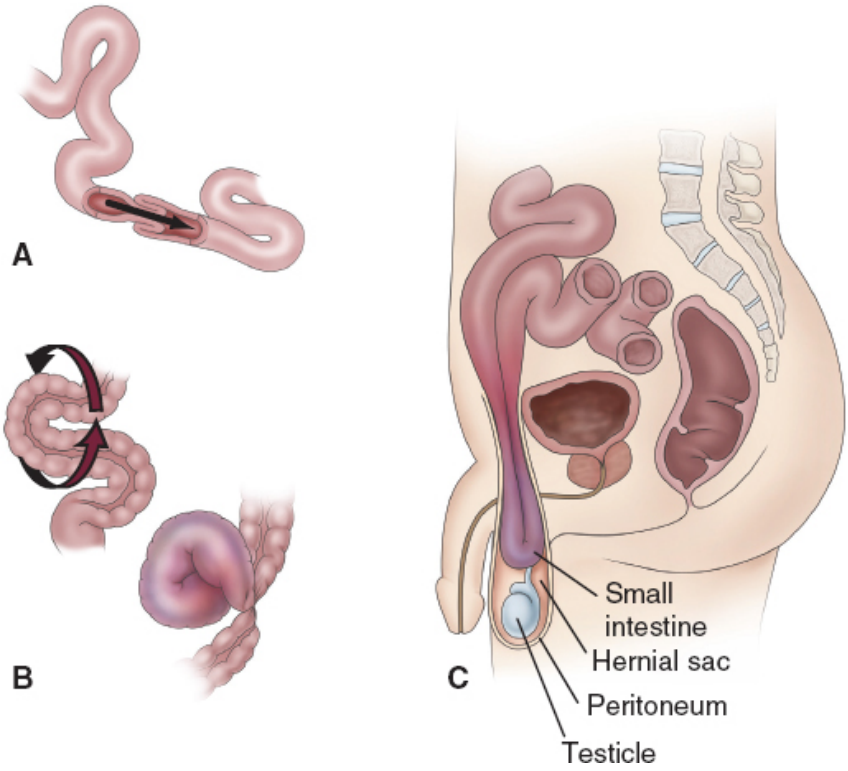

Figure 41-5 • Three causes of intestinal obstruction. **A.** Intussusception; invagination or shortening of the colon caused by the movement of one segment of bowel into another. **B.** Volvulus of the sigmoid colon; the twist is counterclockwise in most cases. Note the edematous bowel. **C.** Hernia (inguinal). The sac of the hernia is a continuation of the peritoneum of the abdomen. The hernial contents are intestine, omentum, or other abdominal contents that pass through the hernial opening into the hernial sac.

Small Bowel Obstruction

Pathophysiology

Intestinal contents, fluid, and gas accumulate proximal to the intestinal obstruction. The abdominal distention and retention of fluid reduce the absorption of fluids and stimulate more gastric secretion. With increasing distention, pressure within the intestinal lumen increases, causing a decrease in venous and arteriolar capillary pressure. Third-spacing of fluids, electrolytes, and proteins into the intestinal lumen occurs, resulting in decreased circulating fluid volume and dehydration. With continued intestinal distention and edema, perfusion to the affected intestinal segment can be compromised, leading to ischemia, necrosis, and eventual rupture or perforation of the intestinal wall, with resultant peritonitis (Bordeianou & Yeh, 2019; Ramnarine, 2017).

Clinical Manifestations

The initial symptom is usually crampy pain that is wavelike and colicky due to persistent peristalsis both above and below the blockage. The patient may pass blood and mucus but no fecal matter and no flatus. Vomiting occurs. If the obstruction is complete, the peristaltic waves initially become extremely vigorous and eventually assume a reverse

direction, with the intestinal contents propelled toward the mouth instead of toward the rectum. The signs of dehydration become evident: intense thirst, drowsiness, oliguria, generalized malaise, aching, and a parched tongue and mucous membranes. The patient may continue to have flatus and stool early in the process due to distal peristalsis. The abdomen becomes distended. The lower the obstruction in the GI tract, the more marked the abdominal distention; this may cause reflux vomiting. Vomiting results in loss of hydrogen ions and potassium from the stomach, leading to reduction of chloride and potassium in the blood and to metabolic alkalosis. Dehydration and acidosis develop from loss of water and sodium. With acute fluid losses, hypovolemic shock may occur; septic shock may also occur (Bordeianou & Yeh, 2019; Ramnarine, 2017) (see Chapter 11).

Assessment and Diagnostic Findings

Diagnosis is based on the symptoms, physical assessment findings, and the results of imaging studies. Early in the process, bowel sounds are high-pitched and hyperactive in an attempt to pass the obstruction; later, bowel sounds will be hypoactive. Changes in the pattern (constant) or increased intensity of bowel sounds may also be indicative of strangulation or ischemic bowel (Bordeianou & Yeh, 2019; Ramnarine, 2017). Abdominal x-ray and CT scan findings include abnormal quantities of gas, fluid, or both in the intestines and sometimes collapsed distal bowel. Laboratory studies (i.e., electrolyte studies and a CBC) reveal a picture of dehydration, loss of plasma volume, and possible infection. The approach to small bowel obstruction focuses on confirming the diagnosis, identifying the etiology, and determining the likelihood of strangulation.

Medical Management

Decompression of the bowel through insertion of an NG tube is necessary for all patients with small bowel obstruction; this may be tried for up to 3 days for patients with partial obstructions, as resting the bowel in this manner can result in resolution of the obstruction (Ramnarine, 2017). For patients with adhesions, administration of hypertonic water-soluble GI contrast media (Gastrografin) may be of benefit in stimulating peristalsis and determining the probability of needing surgical intervention. The dye is administered via NG tube, the tube is clamped for 2 to 4 hours, then an abdominal x-ray is taken within 6 to 24 hours; evidence of the dye in the large intestine is predictive of resolution of obstruction without surgical intervention (Bordeianou & Yeh, 2019).

Surgical Management

Approximately 25% of patients with obstruction will need surgical intervention (Bordeianou & Yeh, 2019). When the bowel is completely obstructed, the possibility of strangulation and tissue necrosis warrants surgical intervention. Before surgery, IV fluids are necessary to replace the depleted water, sodium, chloride, and potassium.

The surgical treatment of intestinal obstruction depends on the cause of the obstruction. For the most common causes of obstruction, such as hernia and adhesions, the surgical procedure involves repairing the hernia or dividing the adhesion to which the intestine is attached. In some instances, the portion of affected bowel may be removed and an anastomosis performed. The complexity of the surgical procedure depends on the

duration of the intestinal obstruction and the condition of the intestine. Open or laparoscopic technique can be used.

Nursing Management

Nursing management of the patient with a small bowel obstruction who does not require surgery includes maintaining the function of the NG tube, assessing and measuring the NG output, assessing for fluid and electrolyte imbalance, monitoring nutritional status, and assessing for manifestations consistent with resolution (e.g., return of normal bowel sounds, decreased abdominal distention, subjective improvement in abdominal pain and tenderness, passage of flatus or stool).

Quality and Safety Nursing Alert

Maintaining fluid and electrolyte balance is a priority to monitor in the patient with a small bowel obstruction. The presence of the NG tube in conjunction with the patient's nothing-by-mouth (NPO) status places the patient at significant risk of fluid imbalance. Thus, measures to promote fluid balance are critically important.

The nurse reports discrepancies in the patient's intake and output, worsening of pain or abdominal distention, and increased NG output. If the patient's condition does not improve, the nurse prepares them for surgery. This preparation includes preoperative education as the patient's condition indicates. Nursing care of the patient after surgical repair of a small bowel obstruction is similar to that for other abdominal surgeries (see Chapter 16).

Unfolding Patient Stories: Stan Checketts • Part 2

Recall from Chapter 9 **Stan Checketts**, who arrived in the emergency department with severe abdominal pain. He is diagnosed with a small bowel obstruction. He is NPO and has an NG tube placed to low intermittent suction. Describe the steps of a focused GI assessment performed by the nurse. How would the nurse explain the rationale for an NG tube and NPO status? What are specific assessments and nursing care responsibilities for an NG tube?

Care for Stan and other patients in a realistic virtual environment: ***vSim** for Nursing* (**thepoint.lww.com/vSimMedicalSurgical**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Large Bowel Obstruction

Pathophysiology

A large bowel obstruction results in an accumulation of intestinal contents, fluid, and gas proximal to the obstruction. It can lead to severe distention and perforation unless some

gas and fluid can flow back through the ileocecal valve. Large bowel obstruction, even if complete, may be undramatic if the blood supply to the colon is not disturbed. However, if the blood supply is cut off, intestinal strangulation and necrosis occur; this condition is life threatening. In the large intestine, dehydration occurs more slowly than in the small intestine because the colon can absorb its fluid contents and can distend to a size considerably beyond its normal full capacity. Similar to small bowel obstruction, complications include perforation, peritonitis, and sepsis.

Clinical Manifestations

Large bowel obstruction differs clinically from small bowel obstruction in that the symptoms develop and progress relatively slowly. In patients with obstruction in the sigmoid colon or the rectum, constipation may be the only symptom for weeks. The shape of the stool is altered as it passes the obstruction that is gradually increasing in size. Blood loss in the stool may result in iron deficiency anemia. The patient may experience weakness, weight loss, and anorexia. Eventually, the abdomen becomes markedly distended, loops of large bowel become visibly outlined through the abdominal wall, and the patient has crampy lower abdominal pain (Hopkins, 2017).

Assessment and Diagnostic Findings

Diagnosis is based on symptoms, physical assessment findings, and on imaging studies. The abdomen may be distended, bowel sounds may be normal early in the obstruction, but later hypoactive to absent, and the abdomen hyperresonant (Hopkins, 2017).

Abdominal x-ray and abdominal CT or MRI findings reveal a distended colon and pinpoint the site of the obstruction (Hopkins, 2017).

Medical Management

Restoration of intravascular volume, correction of electrolyte abnormalities, and NG aspiration and decompression are instituted immediately. A colonoscopy may be performed to untwist and decompress the bowel. A rectal tube may be used to decompress an area that is lower in the bowel. As an alternative, a metal colonic stent may be used as either a palliative intervention or as a bridge to definitive surgery. The colonic stent is placed endoscopically with the assistance of an image intensifier, which creates a fluoroscopic image (Hopkins, 2017). The usual treatment is surgical resection to remove the obstructing lesion. A temporary or permanent colostomy may be necessary. An ileoanal anastomosis may be performed if removal of the entire large bowel is necessary (Hopkins, 2017).

Nursing Management

The nurse's role is to monitor the patient for symptoms indicating that the intestinal obstruction is worsening or resolving and to provide emotional support and comfort. The nurse administers IV fluids and electrolytes as prescribed. If the patient's condition does not respond to nonsurgical treatment, the nurse prepares the patient for surgery. This preparation includes preoperative education as the patient's condition indicates. After surgery, routine postoperative nursing care is provided, including abdominal wound care (see Chapter 16).

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is a group of chronic disorders: Crohn's disease and ulcerative colitis that result in inflammation or ulceration (or both) of the bowel. Both disorders have striking similarities but also several differences. Approximately 10% to 15% of patients with IBD have characteristics of both disorders and cannot be definitively diagnosed with either disorder and are classified as having indeterminate colitis (Rowe, 2020). Table 41-5 compares Crohn's disease and ulcerative colitis.

The prevalence of IBD in the United States has increased in the past century; it is estimated that 1.3% of adults are diagnosed with IBD (CDC, 2019). Prevalence is highest in Europe (particularly in Germany and Norway), the United States, and Canada, although the incidence has been increasing in South America, Africa, and Asia (Piovani, Danese, Peyrin-Biroulet, et al., 2019).

Family history predisposes people to IBD, particularly if a first-degree relative has the disease (Rowe, 2020). Other risk factors for IBD include being Caucasian, of Ashkenazi Jewish descent, living in a northern climate, and living in an urban area (Rowe, 2020). Both diseases are commonly diagnosed in people 15 to 40 years of age, with a second peak incidence in adults 55 to 65 years of age (Rowe, 2020). Current smokers are at risk for Crohn's disease, but those who are ex-smokers or nonsmokers are at risk for ulcerative colitis (Piovani et al., 2019).

Despite extensive research, the cause of IBD is still unknown. Three underlying factors are genetic predisposition, altered immune response, and an altered response to gut microorganisms (Rowe, 2020). Researchers theorize that environmental triggers (e.g., exposure to air pollutants), food, tobacco, and viral illnesses in people genetically predisposed to developing an IBD can trigger the cell-mediated immune response that results in the inflammatory changes that characterize IBDs (Rowe, 2020). Inflammatory cytokines have been identified in the pathologic and clinical characteristics of both disorders (Rowe, 2020; Walfish, 2019). Both disorders have extra-intestinal manifestations; systemic symptoms common to both include fever, arthralgias, malaise, and episodes of diaphoresis (Rowe, 2020).

Crohn's Disease (Regional Enteritis)

Crohn's disease, also called regional enteritis, is characterized by a subacute and chronic inflammation of the GI tract wall that extends through all layers (i.e., transmural lesion). Although its characteristic histopathologic changes can occur anywhere in the GI tract, it most commonly occurs in the distal ileum and the ascending colon. Approximately 35% of patients have ileitis (only ileal involvement); 45% have ileocolitis (diseased ileum and colon); and 20% have granulomatous colitis (only colon involvement) (Rowe, 2020).

Pathophysiology

The inflammatory process in Crohn's disease begins with crypt inflammation and abscesses, which develop into small, focal ulcers. These initial lesions then deepen into longitudinal and transverse ulcers, separated by edematous patches, creating a characteristic *cobblestone* appearance in the affected bowel. Fistulas, fissures, and abscesses form as the inflammation extends into the peritoneum. Granulomas can occur in lymph nodes, the peritoneum, and through the layers of the bowel in about half of patients. Diseased bowel segments are sharply demarcated by adjoining areas of normal

bowel tissue. These are called *skip* lesions, from which the label *regional enteritis* is derived. As the disease advances, the bowel wall thickens and becomes fibrotic, and the intestinal lumen narrows. Diseased bowel loops sometimes adhere to other loops surrounding them (Rowe, 2020).

TABLE 41-5 Comparison of Crohn's Disease and Ulcerative Colitis

	Crohn's Disease	Ulcerative Colitis
Course	Prolonged, variable	Exacerbations, remissions
Pathology		
Early	Transmural thickening	Mucosal ulceration
Late	Deep, penetrating granulomas	Minute, mucosal ulcerations
Clinical Manifestations	Ileum, ascending colon (usually)	Rectum, descending colon
Location	Usually not, but if it occurs, it tends to be mild	Common—severe
Bleeding	Common	Rare—mild
Perianal involvement	Common	Rare
Fistulas	Less severe	Severe
Diarrhea	Common	Rare
Abdominal mass		
Diagnostic Study Findings		
Barium studies	Regional, discontinuous skip lesions Narrowing of colon Thickening of bowel wall Mucosal edema Stenosis, fistulas May be unremarkable unless accompanied by perianal fistulas	Diffuse involvement No narrowing of colon No mucosal edema Stenosis rare Shortening of colon Abnormal inflamed mucosa
Sigmoidoscopy Colonoscopy	Distinct ulcerations separated by relatively normal mucosa in ascending colon	Friable mucosa with pseudopolyps or ulcers in descending colon
Therapeutic Management	Corticosteroids, aminosalicylates (sulfasalazine) Immunomodulators (e.g., azathioprine) or monoclonal antibodies (e.g., infliximab, adalimumab) may be tried if refractory to corticosteroids and aminosalicylates Antibiotics Parenteral nutrition Partial or complete colectomy, with ileostomy or anastomosis Rectum can be preserved in some patients Recurrence common	Corticosteroids, aminosalicylates (sulfasalazine) useful in preventing recurrence Immunomodulators (e.g., azathioprine) or monoclonal antibodies (e.g., infliximab, adalimumab) may be tried if refractory to corticosteroids and aminosalicylates Bulk hydrophilic agents Antibiotics Proctocolectomy, with ileostomy Rectum can be preserved in only a few patients "cured" by colectomy
Systemic Complications	Small bowel obstruction Right-sided hydronephrosis Nephrolithiasis Colon cancer Cholelithiasis Arthritis Uveitis Erythema nodosum	Toxic megacolon Perforation Hemorrhage Colon cancer Pyelonephritis Nephrolithiasis Cholangiocarcinoma Arthritis Uveitis Erythema nodosum

Adapted from Walfish, A. E. (2019). Inflammatory bowel disease. *Merck Manual: Professional Version*. Retrieved on 3/1/2020 at: www.merckmanuals.com/professional/gastrointestinal-disorders/inflammatory-bowel-disease-ibd/overview-of-inflammatory-bowel-disease

Clinical Manifestations

The onset of symptoms is usually insidious in Crohn's disease, with diarrhea and prominent right lower quadrant abdominal pain unrelieved by defecation. Scar tissue and the formation of granulomas interfere with the ability of the intestine to transport products of upper intestinal digestion through the constricted lumen, resulting in crampy abdominal pain. There is abdominal tenderness and spasm. Because eating stimulates intestinal peristalsis, the crampy pains occur after meals. To avoid these bouts of crampy pain, the patient tends to limit food intake, reducing the amounts and types of food to such a degree that normal nutritional requirements are often not met. As a result, weight loss, malnutrition, and secondary anemia occur. Ulcers in the membranous lining of the intestine and other inflammatory changes result in a weeping, edematous intestine that continually empties an irritating discharge into the colon. Disrupted absorption causes chronic diarrhea and nutritional deficits, which can lead to significant weight loss and dehydration. In some patients, the inflamed intestine may perforate, leading to intra-abdominal and anal abscesses. Fever and leukocytosis occur. Chronic symptoms include diarrhea, abdominal pain, **steatorrhea** (i.e., excessive fat in the feces), anorexia, weight loss, and nutritional deficiencies.

Manifestations may extend beyond the GI tract and can include joint disorders (e.g., arthritis), skin lesions (e.g., erythema nodosum), ocular disorders (e.g., uveitis), and oral ulcers. The clinical course and symptoms can vary; in some patients, periods of remission and exacerbation occur, but in others, the disease follows a fulminating course. When intestinal symptoms worsen, some extraintestinal manifestations can worsen, whereas the clinical course of some extraintestinal manifestations seems independent of the clinical course of the Crohn's disease (Walfish, 2019).

Assessment and Diagnostic Findings

CT scan is indicated to find bowel wall thickening and mesenteric edema, as well as obstructions, abscesses, and fistulas, and may help specify abscess formation and location, guiding percutaneous access and drainage. MRI is both highly sensitive and specific in terms of identifying pelvic and perianal abscesses and fistulas (Rowe, 2020).

A CBC is performed to assess hematocrit and hemoglobin levels (which may be decreased) as well as the WBC count (may be elevated). The erythrocyte sedimentation rate (ESR) is usually elevated. Albumin and protein levels may be decreased, indicating malnutrition (Rowe, 2020).

Complications

Complications of Crohn's disease include intestinal obstruction or stricture formation, perianal disease, fluid and electrolyte imbalances, malnutrition from malabsorption, and fistula and abscess formation. The most common type of small bowel fistula caused by Crohn's disease is the enterocutaneous fistula (i.e., an abnormal opening between the small bowel and the skin). Abscesses can be the result of an internal fistula that results in fluid accumulation and infection. Patients with colonic Crohn's disease are also at increased risk of colon cancer (NIDDK, 2017d).

Ulcerative Colitis

Ulcerative colitis is a chronic ulcerative and inflammatory disease of the mucosal and submucosal layers of the colon and rectum that is characterized by unpredictable periods of remission and exacerbation with bouts of abdominal cramps and bloody or purulent diarrhea. The inflammatory changes typically begin in the rectum and progress proximally through the colon (Basson, 2019b).

Pathophysiology

Ulcerative colitis affects the superficial mucosa of the colon and is characterized by multiple ulcerations, diffuse inflammations, and desquamation or shedding of the colonic epithelium. Bleeding occurs as a result of the ulcerations. The mucosa becomes edematous and inflamed. The lesions are contiguous, occurring one after the other. Eventually, the bowel narrows, shortens, and thickens because of muscular hypertrophy and fat deposits. Because the inflammatory process is not transmural (i.e., it affects the inner lining only), abscesses, fistulas, obstruction, and fissures are uncommon in ulcerative colitis (Walfish, 2019).

Clinical Manifestations

The clinical course is usually one of remissions and exacerbations. The predominant symptoms of ulcerative colitis include diarrhea, with passage of mucus, pus, or blood; left lower quadrant abdominal pain; and intermittent tenesmus. The bleeding may be mild or severe, and pallor, anemia, and fatigue result. The patient may have anorexia, weight loss, fever, vomiting, and dehydration, as well as cramping, and the passage of six or more liquid stools each day. The disease is classified as mild, severe, or fulminant, depending on the severity of the symptoms. Hypoalbuminemia, electrolyte imbalances, and anemia frequently develop. Extraintestinal manifestations include skin lesions (e.g., erythema nodosum), eye lesions (e.g., uveitis), joint abnormalities (e.g., arthritis), and liver disease (Basson, 2019b).

Assessment and Diagnostic Findings

Abdominal x-ray studies are useful for determining the cause of symptoms. Free air in the peritoneum and bowel dilation or obstruction should be excluded as a source of the presenting symptoms. Colonoscopy is the definitive screening test that can distinguish ulcerative colitis from other diseases of the colon with similar symptoms. It may reveal friable, inflamed mucosa with exudate and ulcerations. Biopsies are typically taken to determine histologic characteristics of the colonic tissue and extent of disease. CT scanning, MRI, and ultrasound studies can identify abscesses and perirectal involvement (Basson, 2019b).

The stool is positive for blood, and laboratory test results reveal low hematocrit and hemoglobin levels in addition to an elevated WBC count, low albumin levels (indicating malabsorptive disorders), and an electrolyte imbalance. C-reactive protein levels are elevated. Elevated antineutrophil cytoplasmic antibody levels are common. Careful stool examination for parasites and other microbes is performed to rule out dysentery caused by common intestinal organisms, especially *Entamoeba histolytica, C. difficile* and *Campylobacter, Salmonella, Shigella,* and *Cryptospora* species (Basson, 2019b).

Complications

Complications of ulcerative colitis include toxic megacolon, perforation, and bleeding as a result of ulceration. In toxic megacolon, the inflammatory process extends into the muscularis, inhibiting its ability to contract and resulting in colonic distention. Symptoms include fever, abdominal pain and distention, vomiting, and fatigue. If the patient with toxic megacolon does not respond within 72 hours to medical management with NG suction, IV fluids with electrolytes, corticosteroids, and antibiotics, surgery is required. A subtotal colectomy may be performed if bowel perforation has not occurred. Otherwise, colectomy is indicated; it is ultimately needed in up to one third of patients with severe ulcerative colitis (Walfish, 2019). For many patients, surgery becomes necessary to relieve the effects of the disease and to treat these serious complications; an ileostomy usually is performed. The surgical procedures involved and the care of patients with this type of fecal diversion are discussed later in this chapter.

Patients with ulcerative colitis also have a significantly increased risk of osteoporotic fractures due to decreased bone mineral density. Corticosteroid therapy may also contribute to the diminished bone density. Patients with ulcerative colitis are also at increased risk for colon cancer. Approximately 20 years post diagnosis, an estimated 7% to 10% of patients with extensive ulcerative colitis (i.e., not contained to the rectum) will have colon cancer (Walfish, 2019).

Management of Inflammatory Bowel Disease

Most patients with either Crohn's disease or ulcerative colitis have long periods of well-being interspersed with short intervals of illness. Medical treatment for both of these types of IBD is aimed at inducing disease remission, using a management process called induction therapy, and preventing flare-ups of the disease process while maximizing quality of life, using a management process called maintenance therapy (Basson, 2019b; Rowe, 2020; Rubin, Ananthakrishnan, Siegel, et al., 2019; Walfish, 2019). Pharmacologic therapy is indicated to meet the goals of inducing and maintaining remission of IBD.

Medical Management

Pharmacologic Therapy

Aminosalicylates such as sulfasalazine are typically the first pharmacologic agents selected to induce and maintain remission of mild to moderate IBD (Rowe, 2020; Wilhelm & Love, 2017). Sulfa-free aminosalicylates (e.g., mesalamine, olsalazine, balsalazide) are indicated for patients with sulfa allergies; these drugs tend to be better tolerated by most patients, including those without sulfa allergies, and are effective in preventing and treating recurrence of inflammation. Aminosalicylates tend to be more effective agents in treating ulcerative colitis than Crohn's disease, although they are indicated as first-line agents for both types of IBDs (Wilhelm & Love, 2017). These drugs are administered orally or topically (by enema or rectal suppository) for patients with more distal disease involvement (Rowe, 2020). Common adverse effects of aminosalicylates include headaches, nausea, and diarrhea (Comerford & Durkin, 2020).

Some select patients with perianal fistulas or inflammatory abdominal masses that occur from flare-ups of Crohn's disease may be prescribed antibiotics as first line agents,

rather than aminosalicylates. The most commonly prescribed antibiotics include a combination therapy of both metronidazole and ciprofloxacin, taken orally. These drugs are not prescribed long-term, however. Therefore, another medication regimen must be selected for maintenance therapy. These antibiotics are associated with adverse effects that include nausea and diarrhea, and increased risk of *Clostridium difficile* infection. Furthermore, metronidazole can cause peripheral neuropathy that, if present, can warrant its discontinuance (Rowe, 2020; Walfish, 2019).

Tapering dosages of corticosteroids may be prescribed for patients who are refractory to inducing remission with other drugs such as aminosalicylates, or who are experiencing an exacerbation of the disease process (i.e., a flare-up or acute episode). These medications have potent anti-inflammatory effects (Rowe, 2020). Corticosteroids can be given orally (e.g., prednisone) in outpatient treatment or parenterally (e.g., hydrocortisone) in patients who are hospitalized. Topical (i.e., rectal administration) corticosteroids (e.g., budesonide) are widely used in the treatment of proctitis and colon disease associated with IBD. Because corticosteroids can adversely affect intestinal wound healing, they are only indicated for short-term use. Other adverse effects of corticosteroids are discussed in Chapter 45 and summarized in Table 45-3 (Walfish, 2019).

Immunomodulators (e.g., azathioprine, mercaptopurine, methotrexate, cyclosporine) alter the pathologic immune response present in IBD. The exact mechanism of action of these medications in treating IBD is unclear. These agents have demonstrated effectiveness in reducing inflammation and decreasing the need for corticosteroids, hospitalization, and surgery. Because it takes at least 2 months before they are effective, these agents tend to not be used to induce remission, but are useful as maintenance therapy, particularly for patients intolerant to aminosalicylates or in those who would otherwise require long-term use of corticosteroids to maintain remission (Rowe, 2020; Wilhelm & Love, 2017). These agents depress bone marrow function; therefore, the CBC must be periodically monitored for neutropenia (i.e., low WBC counts) and pancytopenia (i.e., generally low blood cells counts) that may warrant reducing the dosage or changing to a different agent (Rowe, 2020). Liver function should also be monitored periodically as these agents can be toxic to the liver (see Chapter 43, Table 43-1 for Common Laboratory Tests to Assess Liver Function). These agents can be immunosuppressive, placing patients at increased risk for pneumonia and cancers. Because of these risks, adults receiving these agents should be advised to receive pneumococcal vaccination with both PCV13 and PPSV23 (see Chapter 19 for further discussion of PCV13 and PPSV23); women should be screened for cervical cancer annually (i.e., Papanicolaou [Pap] Smear; see Chapter 50 for further discussion). Patients taking azathioprine or mercaptopurine should be screened annually for squamous cell carcinoma, particularly if they are over 50 years of age (Farraye, Melmed, Lichtenstein, et al., 2017).

Anti-tumor necrosis factor (TNF) medications incorporate monoclonal antibodies that inhibit the inflammatory effects of the cytokine TNF in the gut. These agents are indicated for use in patients with moderate to severe IBD that is refractory to treatment with immunomodulators (Wilhelm & Love, 2017). The first drug in this class that was approved for treatment of both types of IBD is infliximab. Infliximab has proven to be effective at inducing and maintaining remission of IBD, especially Crohn's disease. However, it must be administered by IV infusion. Infliximab is generally well tolerated by most patients, although it can rarely be associated with flulike symptoms. For those patients who experience these symptoms, premedication with diphenhydramine and acetaminophen seems to mitigate those unpleasant effects. Newer alternative anti-TNF

medications include adalimumab (for both types of IBD), certolizumab (for Crohn's disease only), and golimubab (for ulcerative colitis only). Each of these agents may be administered by subcutaneous injections (Walfish, 2019). Since all of these anti-TNF agents can potentially reactivate latent viral infections, patients must be tested for tuberculosis and hepatitis B before treatment commences (Rowe, 2020; Wilhelm & Love, 2017). Furthermore, all age-appropriate immunizations should be up to date prior to commencing treatment with these medications (Farraye et al., 2017) (see Chapter 3, Table 3-3 for adult immunizations). Patients prescribed these medications over the long-term need to be educated that they are at higher risk for cancers, particularly lymphomas and melanomas (Farraye et al., 2017; Rowe, 2020; Wilhelm & Love, 2017).

Nutritional Therapy

During induction therapy, oral fluids and a low-residue, high-protein, high-calorie diet with supplemental vitamin therapy and iron replacement are prescribed to meet nutritional needs, reduce inflammation, and control pain and diarrhea (Rowe, 2020). Patients prescribed corticosteroids may require supplemental calcium and vitamin D to prevent osteopenia (Rowe, 2020). Fluid and electrolyte imbalances from dehydration caused by diarrhea are corrected by IV therapy as necessary if the patient is hospitalized, or by oral fluids if the patient is managed at home. Any foods that cause or exacerbate bothersome symptoms, such as bloating or diarrhea, are avoided. Cold foods and smoking are avoided because both increase intestinal motility. Some patients may experience an improvement in symptoms if they follow the FODMAP diet that is commonly indicated for patients with IBS (see previous discussion), while others experience symptomatic improvement by restricting intake of milk and treating lactose intolerance (see Chart 41-3) (DeLegge, 2020).

Once remission is induced, patients with IBD are educated to avoid food triggers and maintain a diet that best meets their nutritional needs. Probiotic supplements (e.g., *Escherichia coli Nissle, Lactobacillus rhamnosus*) might be indicated to maintain remission in patient with ulcerative colitis, but have not been found to be similarly effective in patients with Crohn's disease (Bischoff, Escher, Hebuterne, et al., 2020). Most patients who achieve remission need not restrict fiber during maintenance therapy (DeLegge, 2020). A consultation with a dietician may be indicated (Bischoff et al., 2020).

Patients with IBD are at risk for becoming malnourished. Fewer patients with IBD are malnourished and require intensive nutritional therapy than was the case 30 years ago (DeLegge, 2020). In general, patients with IBD who have lost more than 10% of their lean body mass are considered malnourished, and are at risk for increased morbidity (e.g., infections, poor wound healing). These patients may require intensive nutritional therapy, which might include enteral nutrition (see Chapter 39) or parenteral nutrition (DeLegge, 2020). Oral nutrition or enteral nutrition is generally preferable to parenteral nutrition. However, parenteral nutrition may be indicated for patients intolerant of oral and enteral nutrition, or those with bowel obstruction or short bowel syndrome, or in patients with Crohn's disease and proximal fistula formation (see later discussion of parenteral nutrition) (Bischoff et al., 2020).

Surgical Management

When nonsurgical measures fail to relieve severe symptoms of IBD, surgery may be necessary. Nearly one third of patients with severe ulcerative colitis and between 60%

and 70% of patients with Crohn's disease require surgery (Walfish, 2019). Common indications for surgery in patients with ulcerative colitis include the presence of colon cancer or colonic dysplasia/polyps (see later discussion); megacolon; severe, intractable bleeding; or perforation (Walfish, 2019). The most common indication for surgery in patients with Crohn's disease is small bowel obstruction, which occurs in 30% to 50% of patients; other indications for surgery include abscess, perforation, hemorrhage, or fistula formation (Ghazi, 2019; Walfish, 2019).

Patients with either ulcerative colitis or Crohn's disease may require surgery to relieve strictures. A common procedure performed for strictures of the small bowel is laparoscope-guided strictureplasty, in which blocked or narrowed sections of the intestines are widened, leaving the intestines intact. In some cases, a small bowel resection is performed; diseased segments of the small intestines are resected, and the remaining portions of the intestines are anastomosed. Surgical removal of up to 80% of the small bowel usually can be tolerated (Gilroy, 2018).

Some patients with severe Crohn's disease may benefit from an intestinal transplant. This technique is now available to children and to young and middle-aged adults who have lost intestinal function from disease. It may improve quality of life for some patients. The associated technical and immunologic problems remain formidable, and the costs and mortality rates continue to be high (Gilroy, 2018).

Proctocolectomy and Total Colectomy with Ileostomy

Proctocolectomy (i.e., surgical excision of the colon and rectum) with **ileostomy** (i.e., a surgical opening into the ileum by means of a stoma to allow drainage of bowel contents) is recommended in the patient with IBD with a severely diseased colon and rectum that is refractory to medical therapy. This surgery cures the disease in patients with ulcerative colitis; however surgical cure is not possible with Crohn's disease (Ghazi, 2019; Walfish, 2019).

An ileostomy is a type of fecal diversion that allows for drainage of fecal matter, called *effluent*, from the ileum to the outside of the body. The drainage is liquid to unformed and occurs at frequent intervals. Nursing management of the patient with an ileostomy is discussed later in this chapter.

An ileostomy is indicated after a proctocolectomy or a total colectomy (i.e., surgical excision of the entire colon) and is either temporary or permanent. For patients with severe ulcerative colitis, restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) is the procedure of choice. This option is not generally recommended for patients with Crohn's disease, however, as the surgically formed ileal pouch frequently becomes diseased in these patients. A permanent ileostomy is typically indicated for the patient with Crohn's disease who must have a total colectomy.

Restorative Proctocolectomy with Ileal Pouch Anal Anastomosis

A restorative proctocolectomy with IPAA is the surgical procedure of choice in cases where the rectum can be preserved because it eliminates the need for a permanent ileostomy. It establishes an ileal reservoir that functions as a "new" rectum, and anal sphincter control of elimination is retained. The procedure involves connecting the ileum to the anal pouch (made from a small intestine segment), and the surgeon connects the pouch to the anus in conjunction with removing the colon and the rectal mucosa (i.e., total abdominal colectomy and mucosal proctectomy) (see Fig. 41-6). A temporary

diverting loop ileostomy that promotes healing of the surgical anastomoses is constructed at the time of surgery and closed about 3 months later.

With IPAA or restorative proctocolectomy, the diseased colon and rectum are removed, voluntary defecation is maintained, and anal continence is preserved. The ileal reservoir decreases the number of bowel movements significantly. Nighttime elimination is gradually reduced to one bowel movement. Complications of ileoanal anastomosis include irritation of the perianal skin from leakage of fecal contents, stricture formation at the anastomosis site, pelvic abscess, fistula, small bowel obstruction, and *pouchitis* (i.e., inflammation of the ileoanal pouch) (Wu, Ke, Kiran, et al., 2020). This procedure involves pelvic dissection; therefore, it is also associated with the risk of infertility in women. Women wanting to become pregnant may want to consider other treatment options (Rowe, 2020). Dietary intolerances may persist after the IPAA is formed. Increased stool output, flatulence, and perineal irritation are associated with consumption of nuts, corn, chocolate, spicy foods, onions, and citrus fruits. Consequently, some patients may need to alter their diet to avoid complications and perineal breakdown.

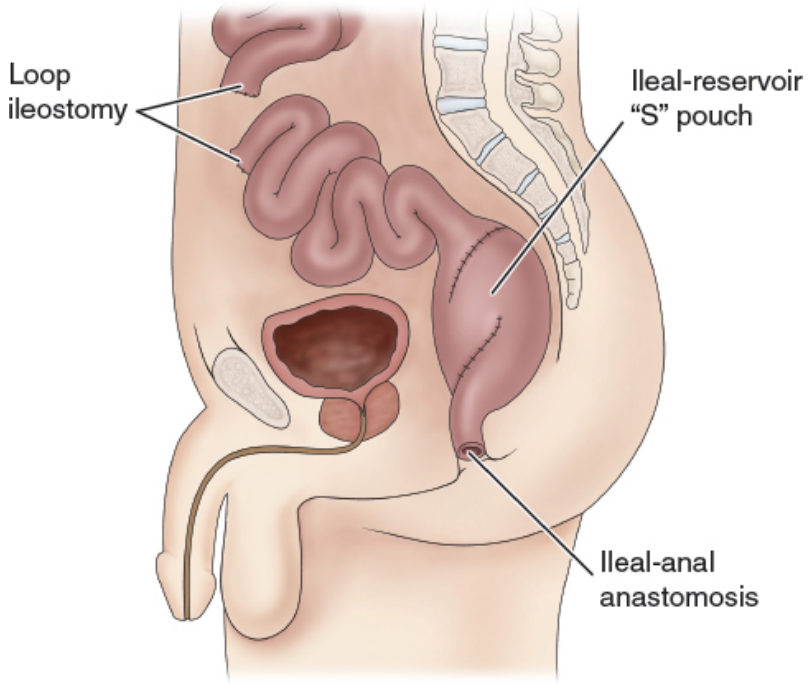

Figure 41-6 • A mucosal proctectomy precedes anastomosis of the ileal reservoir. A temporary loop ileostomy diverts effluent for several months to allow healing.

Continent Ileostomy

The procedure consists of a proctocolectomy, with 30 to 45 cm of the terminal ileum used to create a J- or S-shaped continent ileal reservoir (i.e., Kock pouch) by diverting a portion of the distal ileum to the abdominal wall and creating a stoma. This procedure eliminates the need for an external fecal collection bag. A nipple valve is created by pulling a portion of the terminal ileal loop back into the ileum. GI effluent can accumulate in the pouch for several hours and then be removed by means of a catheter inserted through the nipple valve. Possible indications for a total colectomy with Kock pouch placement (rather than a restorative proctocolectomy with IPAA) include a badly diseased rectum, lack of rectal sphincter tone, or inability to achieve fecal continence

post IPAA (Wu et al., 2020). Variations on the Kock pouch include the Barnett continent intestinal reservoir and T-pouch (Wu et al., 2020).

The major challenge with the Kock pouch is malfunction of the nipple valve, which often requires additional corrective surgery. Other potential postoperative complications include fistulas, stoma-related problems (strictures, parastomal hernia, difficulty with catheterization), pouchitis, and short-bowel syndrome (i.e., nutritional deficits that occur from loss of part of the small intestines). Kock pouches are used less commonly because they have greater complication rates than does restorative proctocolectomy with IPAA (Wu et al., 2020). A major advantage of the procedure is potential improved body image and lack of external drainage appliance (Wu et al., 2020).

NURSING PROCESS

Management of the Patient with Inflammatory Bowel Disease

Assessment

The nurse obtains a health history to identify the onset, duration, and characteristics of abdominal pain; the presence of diarrhea, fecal urgency, or tenesmus; nausea, anorexia, or weight loss; and family history of IBD. It is important to discuss dietary patterns and smoking habits. The nurse asks about patterns of bowel elimination, including character, frequency, and presence of blood, pus, fat, or mucus. Allergies and food intolerance, especially milk (lactose) intolerance, must be noted. The patient may identify sleep disturbances if diarrhea or pain occurs at night.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Diarrhea associated with the inflammatory process
- Acute pain associated with increased peristalsis and GI inflammation
- Hypovolaemia associated with anorexia, nausea, and diarrhea
- Impaired nutritional status associated with dietary restrictions, nausea, and malabsorption
- Activity intolerance associated with generalized weakness
- Anxiety associated with impending surgery
- Difficulty coping associated with repeated episodes of diarrhea
- Risk for impaired skin integrity associated with malnutrition and diarrhea
- Lack of knowledge concerning the process and management of the disease

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Electrolyte imbalance
- Cardiac arrhythmias related to electrolyte imbalances
- GI bleeding with fluid volume loss
- Perforation of the bowel

Planning and Goals

The major goals for the patient include attainment of normal bowel elimination patterns, relief of abdominal pain and cramping, prevention of fluid volume deficit, maintenance of optimal nutrition and weight, avoidance of fatigue, reduction of anxiety, promotion of effective coping, absence of skin breakdown, increased knowledge about the disease process and self-health management, and avoidance of complications.

Nursing Interventions

Maintaining Normal Elimination Patterns

The nurse assists the patient in determining if there is a relationship between diarrhea and certain foods, activities, or emotional stressors. Identifying precipitating factors, the frequency of bowel movements, and the character, consistency, and amount of stool passed is important. The nurse provides ready access to a bathroom, commode,

or bedpan and keeps the environment clean and odor free. It is important to administer antidiarrheal medications as prescribed. Loperamide may be prescribed 30 minutes before meals (see previous discussion on interventions for diarrhea). The nurse should record the frequency and consistency of stools after therapy is initiated.

Relieving Pain

The character of the pain is described as dull, burning, or crampy. It is important to ask about its onset. Does it occur before or after meals, during the night, or before elimination? Is the pattern constant or intermittent? Is it relieved with medications? The nurse administers analgesic agents as prescribed for pain. Position changes, local application of heat (as prescribed), diversional activities, and prevention of fatigue also are helpful for reducing pain.

Maintaining Fluid Intake

To detect fluid volume deficit, the nurse keeps an accurate record of intake and output. The nurse monitors daily weights for fluid gains or losses and assesses the patient for signs of fluid volume deficit (i.e., dry skin and mucous membranes, decreased skin turgor, oliguria, fatigue, decreased temperature, increased hematocrit, elevated urine specific gravity, and hypotension). It is important to encourage oral intake of fluids and to monitor the flow rate of any IV fluids. The nurse initiates measures to decrease diarrhea (e.g., dietary restrictions, stress reduction, antidiarrheal agents).

Maintaining Optimal Nutrition

Nursing interventions focus on optimizing the patient's nutritional status and include ensuring that the patient maintains adequate intake of fluids and nutrients and recognizes and avoids foods that exacerbate symptoms (DeLegge, 2020). The nurse assesses the patient's nutrition, including usual dietary habits, changes in appetite and body mass index (BMI) and trends in weight loss or gain (see Chapter 4 for further discussion of nutritional assessment). Laboratory studies to detect vitamin and mineral deficiencies may help identify the need for supplementation, especially vitamin D and B_{12} (Rowe, 2020). During the induction therapy, if oral foods are tolerated, small, frequent, low-residue feedings are given to avoid overdistending the stomach and stimulating peristalsis. For the patient with IBD who is malnourished and hospitalized, enteral nutrition or parenteral nutrition may be prescribed (see Chapter 39 for further discussion of enteral nutrition). Parenteral nutrition is indicated in patients who have short-bowel syndrome, bowel obstruction, or Crohn's disease with severe malnutrition and intolerance to enteral nutrition and who are expected to likely remain intolerant to enteral nutrition for more than 1 to 2 weeks (DeLegge, 2020) (see later discussion on parenteral nutrition in this chapter).

Promoting Rest

The nurse recommends intermittent rest periods during the day and schedules or restricts activities to conserve energy and reduce the metabolic rate. It is important to encourage activity within the limits of the patient's capacity. The nurse suggests naps and periods of bed rest for a patient who is febrile, has frequent diarrheal stools, or is bleeding. However, the patient should perform active exercises to maintain muscle tone and prevent venous thromboembolic complications. If the patient cannot perform these active exercises, the nurse performs passive exercises and joint range of motion. Activity restrictions are modified as needed on a day-to-day basis.

Reducing Anxiety

Anxiety is nearly twice as prevalent in individuals with IBD than in the general population. The prevalence of anxiety in patients with IBD is not dependent upon whether or not the disease is active or in remission (Farraye et al., 2017). Therefore, the nurse must recognize that the patient with IBD may experience anxiety throughout the spectrum of disease; that is, during periods of remission as well as exacerbation. Rapport can be established by being attentive and displaying a calm, confident manner. The nurse allows time for the patient to ask questions and express feelings. Careful listening and sensitivity to nonverbal indicators of anxiety (e.g., restlessness, tense facial expressions) are helpful. The patient may be emotionally labile because of the consequences of the disease and the uncertainty of exacerbations with complications. The nurse tailors information about possible impending surgery to the patient's level of understanding and desire for detail. If surgery with placement of a stoma is planned, photographs, illustrations, websites, and blogs help explain the surgical procedure and help the patient visualize what a stoma looks like.

Enhancing Coping Measures

Because the patient may feel isolated, helpless, and out of control, understanding and emotional support are essential. The patient may respond to stress in a variety of ways that may alienate others (e.g., anger, denial, social self-isolation).

The nurse needs to recognize that the patient's behavior may be affected by a number of factors. Any patient suffering the discomforts of frequent bowel movements and rectal soreness is anxious, discouraged, and unhappy. It is important to develop a relationship with the patient that supports their attempts to cope with these stressors. It is also important to communicate that the patient's feelings are understood by encouraging the patient to talk and express their feelings and to discuss any concerns. Stress reduction measures that may be used include relaxation techniques, visualization, breathing exercises, and biofeedback. Professional counseling may be needed to help the patient and family manage issues associated with chronic illness and resulting disability.

Preventing Skin Breakdown

The nurse examines the patient's skin frequently, especially the perianal skin. Perianal care, including the use of a skin barrier (e.g., petroleum ointment), is important after each bowel movement. The nurse gives immediate attention to reddened or irritated areas over bony prominences and uses pressure-relieving devices to prevent skin breakdown. Consultation with a wound-ostomy-continence (WOC) nurse (or WOCN; a nurse specially educated in the management of a variety of fecal and urinary diversions) is often helpful.

Monitoring and Managing Potential Complications

Serum electrolyte levels are monitored daily, and electrolyte replacements are given as prescribed. Evidence of arrhythmias or changes in level of consciousness must be reported immediately.

The nurse closely monitors rectal bleeding and administers blood component therapy and volume expanders as prescribed to prevent hypovolemia. It is important to monitor the blood pressure for hypotension and to obtain coagulation profiles and hemoglobin and hematocrit levels frequently. Vitamin K may be prescribed to increase clotting factors.

The nurse closely monitors the patient for indications of perforation (i.e., acute increase in abdominal pain, rigid abdomen, vomiting, or hypotension) and obstruction and toxic megacolon (i.e., abdominal distention, decreased or absent bowel sounds, change in mental status, fever, tachycardia, hypotension, dehydration, and electrolyte imbalances).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. The nurse assesses the patient's understanding of the disease process and their need for additional information about medical management (e.g., medications, diet) and surgical interventions. The nurse provides information about nutritional management and foods that might relieve symptoms and decrease diarrhea (e.g., FODMAP diet). It is important to explain the rationale for the use of corticosteroids and anti-inflammatory, antibacterial, and antidiarrheal medications. The nurse emphasizes the importance of taking medications as prescribed and not abruptly discontinuing them (especially corticosteroids) to avoid development of serious medical problems (see Chart 41-5). Patients over the age of 50 should be educated about the importance of receiving the herpes zoster vaccination; all patients should receive the influenza vaccination annually (Farraye et al., 2017). Patient education information can be obtained from the Crohn's and Colitis Foundation of America (CCFA) and from a patient skills education program developed by the American College of Surgeons (see Resources section).

Continuing and Transitional Care. For patients who have been hospitalized to treat IBD, readmission rates are as high as 18% at 30 days, and as high as 36% at 90 days (Nguyen, Koola, Dulai, et al., 2020). Overall, readmission rates were higher for patients with Crohn's disease than for those with ulcerative colitis. The most common reasons for rehospitalization were IBD flare-ups, infections, postoperative complications, pain management, or need for parenteral nutrition or surgery (Nguyen et al., 2020). Risk factors for readmission include history of chronic disease, psychiatric comorbidities, smoking, and opioid dependence (Cohen-Mekekburg, Rosenblatt, Wallace, et al., 2019; George, Martin, Gupta, et al., 2019; Micic, Gaetano, Rubin, et al., 2017; Nguyen et al., 2020). Patients treated at large centers with IBD specialty departments tend to have lower rates of readmission (George et al., 2019).

Patients with IBD are managed at home with follow-up care by their primary provider or through an outpatient clinic. Those whose nutritional status is compromised and who are receiving enteral or parenteral nutrition need the home health or transitional care nurse to consult and ensure that their nutritional requirements are being met and that they or their caregivers can follow through with the instructions for maintaining the nutrition plan. Patients who are undergoing medical treatment need to understand that their disease can be controlled and that they can lead a healthy life between exacerbations. Control implies management based on an understanding of the disease and its treatment. Patients in the home or transitional setting need information about their medications (i.e., name, dose, side effects, and frequency of administration) and need to take medications on schedule. Medication reminders such as containers that separate pills according to day and time or daily checklists are helpful.

During a flare-up, the nurse encourages the patient to rest as needed and to modify activities according to their energy level. Patients should limit tasks that impose strain on the lower abdominal muscles. They should sleep in a room close to the bathroom

because of the frequent diarrhea; quick access to a toilet helps alleviate worry about having an "accident." Room deodorizers help control odors.

Dietary modifications can control but do not cure the disease; the nurse recommends a low-residue, high-protein, high-calorie diet, especially during an acute phase. It is important to encourage the patient to keep a record of the foods that irritate the bowel and to avoid them and to drink at least eight glasses of water each day.

The prolonged nature of the disease has an impact on the patient and often strains their family life and financial resources. Family support is vital; however, some family members may be resentful or feel guilty, tired, or unable to cope with the emotional demands of the illness and the physical demands of providing care. Some patients with IBD do not socialize for fear of being embarrassed. Because they have lost control over elimination, they may fear losing control over other aspects of their lives. They need time to express their fears and frustrations. Individual and family counseling may be helpful.

Chart 41-5  HOME CARE CHECKLIST

The Patient with Inflammatory Bowel Disease

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of inflammatory bowel disease on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Discuss nutritional management: high-protein, high-vitamin diet; identify foods to include and foods to be avoided.
- Explain the importance of and necessity for adherence with prescribed medication regimen.
- Demonstrate methods of keeping track of the medication regimen, storing the prescribed medications, and using reminders such as beepers and/or pillboxes.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify measures to be used to treat exacerbation of symptoms, to include rest, dietary modifications, and medications.
- Identify measures to be used to promote fluid and electrolyte balance during acute exacerbations.
- Demonstrate management of enteral or parenteral nutrition therapy, if applicable; identify possible complications and interventions.
- State how to reach primary provider with questions or complications.
  - State time and date of follow-up appointments, testing.
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- Identify the need for health promotion (e.g., cessation of use of tobacco products), disease prevention and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Evaluation

Expected patient outcomes may include:

1. Reports a decrease in the frequency of diarrheal stools
   a. Adheres to dietary restrictions; maintains bed rest
   b. Takes medications as prescribed
2. Has reduced pain
3. Maintains fluid volume balance
   a. Drinks 1 to 2 L of oral fluids daily
   b. Has normal body temperature
   c. Displays adequate skin turgor and moist mucous membranes
4. Attains optimal nutrition; tolerates small, frequent feedings without diarrhea
5. Avoids fatigue
   a. Rests periodically during the day
   b. Adheres to activity restrictions
6. Is less anxious
   a. Seeks emotional support as appropriate

b. Verbalizes fewer feelings of anxiety and concern

7. Copes successfully with diagnosis
   a. Verbalizes feelings freely
   b. Uses appropriate stress reduction behaviors
8. Maintains skin integrity
   a. Cleans perianal skin after defecation
   b. Uses appropriate skin barrier
9. Acquires an understanding of the disease process
   a. Modifies diet appropriately to decrease diarrhea
   b. Adheres to medication regimen as prescribed
   c. Recognizes signs and symptoms of complications
10. Recovers without complications
   a. Electrolytes within normal ranges
   b. Normal sinus or baseline cardiac rhythm
   c. Maintains fluid balance
   d. Experiences no perforation or rectal bleeding

DELIVERING NUTRITION PARENTERALLY

Parenteral nutrition is a method of providing nutrients to the body by an IV route. The nutrients are a complex admixture containing proteins, carbohydrates, fats, electrolytes, vitamins, trace minerals, and sterile water in a single container. The goals of parenteral nutrition are similar to the goals of enteral feedings (see Chapter 39); namely, to improve nutritional status, establish a positive nitrogen balance, maintain muscle mass, promote weight maintenance or gain, and enhance the healing process (Seres, 2020). Parenteral nutrition is indicated in adults who are malnourished or at risk for becoming malnourished and who cannot tolerate receiving nutrition orally or by the enteral route (Worthington, Balint, Bechtold, et al., 2017).

Nursing Management

Establishing Positive Nitrogen Balance

Most IV fluids do not provide sufficient calories or protein to meet the body's daily requirements. Parenteral nutrition solutions can provide enough calories and nitrogen to meet the patient's daily nutritional needs. The patient with fever, trauma, burns, major surgery, or hypermetabolic disease requires additional daily calories (Norris, 2019). When highly concentrated dextrose is given, caloric requirements are satisfied and the body uses amino acids for protein synthesis rather than for energy. Additionally, electrolytes such as calcium, phosphorus, magnesium, and sodium chloride are added to the solution to maintain proper electrolyte balance and to transport glucose and amino acids across cell membranes.

The volume of fluid necessary to provide these calories peripherally can surpass fluid tolerance. To provide the required calories in a smaller volume, it is necessary to increase the concentration of nutrients and use a route of administration that rapidly dilutes incoming nutrients to the proper levels of body tolerance. Typically, a large, high-flow

vein such as the superior vena cava (at the right atriocaval junction) is the preferred site (Worthington et al., 2017).

Recognizing Clinical Indications

The indications for parenteral nutrition include an inability to ingest at least 50% of the daily required calories and nutrients within a 7-day timeframe for adults who are physiologically stable and well nourished, and within a 3- to 5-day time frame for adults who are malnourished. Enteral nutrition should be considered before parenteral support because it assists in maintaining gut mucosal integrity and improved immune function and is typically associated with fewer complications (Worthington et al., 2017). In both the home and hospital setting, parenteral nutrition is indicated in the situations listed in Table 41-6.

TABLE 41-6 Indications for Parenteral Nutrition

Condition or Need	Examples
Insufficient oral or enteral intake	Severe burns, malnutrition, short-bowel syndrome, acquired immune deficiency syndrome, sepsis, cancer
Impaired ability to ingest or absorb food orally or enterally	Paralytic ileus, Crohn's disease, short-bowel syndrome, postradiation enteritis, high-output enterocutaneous fistula
Patient unwilling or unable to ingest adequate nutrients orally or enterally	Major psychiatric illness (e.g., severe anorexia nervosa)
Prolonged preoperative and postoperative nutritional needs	Extensive bowel surgery, acute pancreatitis

Adapted from McClave, S. A., Taylor, B. E., Martindale, R. G., et al. (2016). Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN). *Journal of Parenteral and Enteral Nutrition*, *40*(2), 159–211.

Administering Formulas

A total of 1 to 3 L of solution is given over a 24-hour period. The label of the solution is verified by at least two identifiers and compared with the prescription (Guenter, Worthington, Ayers, et al., 2018). When parenteral nutrition is delivered as a *2-in-1* admixture of dextrose and amino acids, they are typically supplemented with a **lipid injectable emulsion (ILE**; also called intravenous fat emulsions [IVFE] or lipid). The dextrose and amino acid solution should be administered using a 0.22-micron in-line filter, and the ILE should be administered using a 1.2-micron in-line filter. The ILE may be administered in the same IV line as the 2-in-1 solution; however, a Y-connector should be used for the ILE, and the connector should be placed closer to the patient so that it bypasses the 0.22-micron filter. The 2-in-1 solution is not to be piggybacked into the ILE. As an alternative, the ILE may be delivered via a separate IV line from the 2-in-1 solution (Guenter et al., 2018). Usually, 500 mL of a 10% ILE or 250 mL of 20% ILE is given over 6 to 12 hours, one to three times a week. ILEs can provide up to 30% of the total daily calorie intake.

Quality and Safety Nursing Alert

Before a parenteral nutrition infusion is administered, the solution must be inspected for separation, oily appearance (also known as a "cracked solution"), or any precipitate (which appears as white crystals). If any of these are present, the solution is not used.

ILEs can be mixed by the pharmacy staff with other components of parenteral nutrition to create a *3-in-1* admixture commonly called a **total nutrient admixture (TNA)**. TNA is delivered using a 1.2-micron filter to prevent the administration of a precipitate (i.e., calcium, phosphorus, incompatibilities) that cannot be seen due to the opacity of the solution (Guenter et al., 2018). Advantages of TNA over parenteral nutrition are cost savings in preparation and equipment, decreased risk of catheter or nutrient contamination, decreased nursing time, and increased patient convenience and satisfaction (Gervasio, 2015). Ideally, the pharmacist, nutritionist, and primary provider should collaborate to determine the specific formula needed.

Initiating Therapy

Parenteral nutrition solutions are initiated slowly and advanced gradually each day to the desired rate as the patient's fluid and dextrose tolerance permits. The patient's laboratory test results and response to parenteral nutrition therapy are monitored on an ongoing basis by the primary provider. These parameters include the patient's weight, intake and output, blood glucose, CBC, and chemistry panel, including serum carbon dioxide, magnesium, phosphorus, and triglycerides. A 24-hour urine collection for nitrogen may be done to analyze nitrogen balance. In most hospitals, admixture solutions are prescribed on a daily standard parenteral nutrition form. The formulation of the parenteral nutrition solutions is calculated carefully each day to meet the complete nutritional needs of the individual patient.

Providing Parenteral Nutrition

Various vascular access devices are used to administer parenteral nutrition solutions in clinical practice. Parenteral nutrition may be given through either peripheral or central IV lines, depending on the patient's condition and the anticipated length of therapy.

Peripheral Method

To supplement oral intake, peripheral parenteral nutrition (PPN) may be prescribed. PPN is given through a peripheral vein; this is possible because the solution is less hypertonic than a full-calorie parenteral nutrition solution. PPN formulas are not nutritionally complete because of their low dextrose content. ILEs are given simultaneously to buffer the PPN and to protect the peripheral vein from irritation. The usual length of therapy using PPN is 5 to 7 days.

Quality and Safety Nursing Alert

Formulations with dextrose concentrations of more than 10% should not be given through peripheral veins because they irritate the intima (innermost walls) of small veins, causing chemical phlebitis.

Central Method

Because central parenteral nutrition solutions have at least five times the solute concentration of blood (and exert an osmotic pressure of about 2000 mOsm/L), they are given into the vascular system through a catheter inserted into a high-flow, large blood vessel, ideally at the superior vena cava/right atriocaval junction (Worthington et al., 2017). Concentrated solutions are then very rapidly diluted to isotonic levels by the blood in this vessel.

Several types of **central venous access devices (CVADs)** are available: percutaneous (or nontunneled), peripherally inserted central catheters (PICCs), surgically placed (or tunneled) catheters, and implanted vascular access ports.

Percutaneous (Nontunneled) Central Catheters

Percutaneous central catheters are used for short-term (less than 6 weeks) IV therapy in acute care settings. The subclavian vein is the most common vessel accessed because the subclavian area provides a stable insertion site to which the catheter can be anchored, is easily compressible (facilitating control of hemorrhage), allows the patient freedom of movement, and provides easy access to the dressing site. The subclavian access site should be avoided in patients with advanced kidney disease and those on hemodialysis to prevent subclavian vein stenosis. The second most common access sites include the basilic, brachial, or cephalic veins in the arm followed by the jugular vein. The femoral vein should be avoided for this purpose and should only be used as a last resort because of concerns about infection (Gorski, Hadaway, Hagle, et al., 2016). For a patient with limited IV access, a triple-lumen catheter can be used because it offers three ports for various uses (see Fig. 41-7). The use of a single-lumen catheter dedicated for the administration of parenteral nutrition is not typically feasible, because most patients require administration of medications and fluids in addition to parenteral nutrition, and the line used to administer parenteral nutrition cannot be used for other purposes (Gorski et al., 2016).

When a patient requires IV access for parenteral nutrition, the insertion procedure is first explained so that the patient is aware of what to expect. The patient is placed supine in the Trendelenburg position to produce dilation of neck and shoulder vessels, which makes insertion easier and decreases the risk of air embolus. The skin is cleansed with 2% chlorhexidine to remove surface oils. To afford maximal accuracy in the placement of the catheter, the patient is instructed to turn their head away from the site of venipuncture and to remain motionless while the catheter is inserted and the wound is dressed. The nurse maintains the sterile field and supports the patient throughout the procedure. Maximal barrier precautions mandate that full-body sterile drapes are applied and sterile gloves, cap, gown, and masks are donned to reduce risk of central line–associated bloodstream infection (CLABSI) (The Society for Healthcare Epidemiology of America [SHEA] Guideline Central, 2015) (see Chapter 11, Chart 11-2). Lidocaine is injected to anesthetize the skin and underlying issues. A large-bore needle on a syringe is inserted and moved parallel to and beneath the clavicle until it enters the vein. A radiopaque wire is inserted through the needle into the vein. The catheter is then advanced over the wire, the needle is withdrawn, and the hub of the catheter is attached to the IV tubing. Until the syringe is detached from the needle and the catheter is inserted, the patient may be asked to perform the Valsalva maneuver. The patient is instructed to take a deep breath, hold it, and bear down with the mouth closed to produce a positive phase in central venous pressure, thereby lessening the possibility of air being drawn into the circulatory system (air embolism). The catheter is sutured to the skin. A

chlorhexidine-impregnated disc or gel with a semipermeable transparent dressing is applied using sterile technique (Gorski et al., 2016).

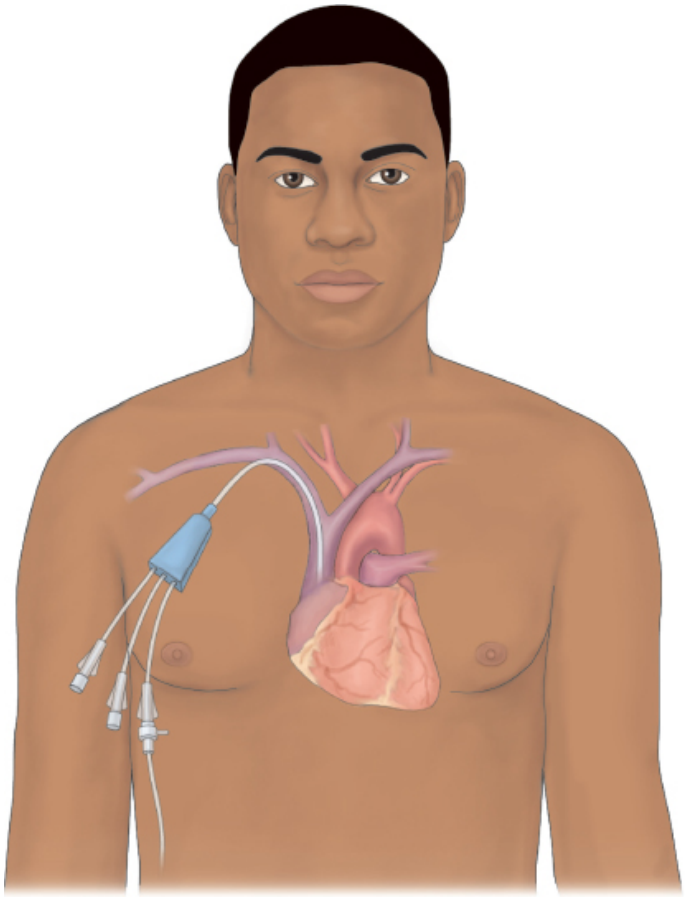

Figure 41-7 • Subclavian triple-lumen catheter used for parenteral nutrition and other adjunctive therapy. The catheter is threaded through the subclavian vein into the vena cava/right atriocaval junction. Each lumen is an avenue for solution administration. The lumens are secured with threaded needleless adapters or Luer lock–type caps when the device is not in use.

The position of the tip of the catheter is verified with x-ray or fluoroscopy to confirm its location in the superior vena cava at the junction of the right atrium and to rule out a pneumothorax resulting from inadvertent puncture of the pleura. Once the catheter's position is confirmed, the prescribed central parenteral nutrition solution can be started. The initial rate of infusion is usually low, and the rate is gradually increased to the target rate.

An injection cap is attached to the end of each central catheter lumen, creating a closed system. IV infusion tubing is connected to the insertion cap of the central catheter with a threaded needleless adapter or Luer lock device. To ensure patency, all lumens are initially flushed according to institution policy with a 10-mL syringe. Smaller-volume syringes are not to be used because the pressure from smaller syringes is potentially harmful to the catheter. Lumens are flushed with normal saline or diluted heparin (10 U/mL) after each intermittent infusion and after blood drawing; this flushing is necessary daily when the catheter is not in use. Force is never used to flush the catheter (Gorski et al., 2016). If resistance is met, aspiration may restore lumen patency; if this is not effective, the primary provider is notified. Low-dose tissue plasminogen activator may be

prescribed to dissolve a clot or fibrin sheath. If attempts to clear the lumen are ineffective, the catheter should be changed.

Peripherally Inserted Central Catheters

Peripherally inserted central catheters (PICCs) are used for intermediate-term (several days to months) IV therapy in the hospital, long-term care, or home setting. These catheters may be inserted at the bedside or in the outpatient setting by a primary provider or specially trained nurse. The basilic, brachial, or cephalic vein is accessed above the antecubital space, and the catheter is threaded to the superior vena cava/right atriocaval junction (see Chapter 12, Fig. 12-6). Taking of blood pressure and blood specimens from the extremity with the PICC is avoided.

Surgically Placed (Tunneled) Central Catheters

Surgically placed central catheters are for long-term use and may remain in place for many years. These catheters are cuffed and can have single or double lumens; examples are the Power line (Power injectable), Hickman, Groshong, and Permacath. These catheters are inserted surgically. They are threaded (or tunneled) under the skin (reducing the risk of ascending infection) to the subclavian vein and advanced into the superior vena cava.

Implanted Vascular Access Ports

Implanted vascular access ports are also used for long-term IV therapy; examples include the Power injectable Port-A-Cath, Mediport, Hickman Port, and P.A.S. Port. Instead of exiting from the skin, the end of the catheter is attached to a small chamber that is placed in a subcutaneous pocket, either on the anterior chest wall or on the forearm. The port requires minimal care and allows the patient complete freedom of activity. Implanted ports are more expensive than the external catheters, and access requires passing a special noncoring needle (Huber tipped) through the skin into the chamber to initiate IV therapy (see Chapter 12, Fig. 12-3).

Discontinuing Parenteral Nutrition

The parenteral nutrition solution is discontinued gradually to allow the patient to adjust to decreased levels of glucose. If the parenteral nutrition solution is abruptly terminated, isotonic dextrose can be given at the same rate the parenteral nutrition solution was infusing for 1 to 2 hours to prevent rebound hypoglycemia. Symptoms of rebound hypoglycemia include weakness, faintness, sweating, shakiness, feeling cold, confusion, and increased heart rate. Once IV therapy is completed, the percutaneous central venous catheter or PICC is removed, pressure is held until hemostasis is achieved, and an occlusive dressing is applied to the exit site. Surgically placed central catheters and implanted vascular access ports are removed only by the primary provider.

NURSING PROCESS

The Patient Receiving Parenteral Nutrition

Assessment

The nurse assists in identifying patients unable to tolerate oral or enteral feedings who may be candidates for parenteral nutrition. Indicators include significant weight loss (10% or more of usual weight), a decrease in oral food intake for more than 1 week, muscle wasting, decreased tissue healing, abnormal urea nitrogen excretion, and persistent vomiting and diarrhea (McClave et al., 2016). The nurse carefully monitors the patient's hydration status, electrolyte levels, and calorie intake.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired nutritional intake associated with inadequate oral intake of nutrients
- Risk for infection associated with contamination of the central catheter site or infusion line
- Fluid imbalance associated with altered infusion rate
- Risk for activity intolerance associated with restrictions because of the presence of IV access device

Collaborative Problems/Potential Complications

The most common complications are pneumothorax, air embolism, a clotted or displaced catheter, sepsis, hyperglycemia, fluid overload, and rebound hypoglycemia. These problems and the associated collaborative interventions are described in Table 41-7.

Planning and Goals

The major goals for the patient receiving parenteral nutrition may include optimal level of nutrition, absence of infection, adequate fluid volume, optimal level of activity (within individual limitations), knowledge of and skill in self-care, and absence of complications.

Nursing Interventions

Maintaining Optimal Nutrition

A continuous, uniform infusion of parenteral nutrition solution over a 24-hour period is desired. However, in some cases (e.g., home care patients), cyclic parenteral nutrition may be appropriate. Cyclic parenteral nutrition is infused during a set period of time. The time periods for infusion are sufficient to meet the patient's nutritional and pharmacologic needs. Ideally, cyclic parenteral nutrition is infused over a 10- to 14-hour period that continues through the night (Worthington et al., 2017). The cyclic parenteral nutrition is titrated up during the beginning of the infusion cycle and down at the conclusion of the infusion to prevent hyperglycemia and hypoglycemia, respectively.

The patient is initially weighed daily (this may be decreased to 2 or 3 times per week once stable) at the same time of the day under the same conditions for accurate comparison. Under the parenteral nutrition regimen, satisfactory weight maintenance or gain can usually be achieved. It is important to keep accurate intake and output

records and calculations of fluid balance. A calorie count is kept of any oral nutrients. Trace elements (copper, zinc, chromium, manganese, and selenium) are included in parenteral nutrition solutions and are individualized for each patient.

Preventing Infection

The high dextrose and fat content of parenteral nutrition solutions makes them an ideal culture medium for bacterial and fungal growth, and CVADs provide a port of entry. Gram-positive cocci, gram-negative bacilli, and *Candida* species are frequently isolated as causes of CLABSI. Common organisms include *Staphylococcus aureus, Staphylococcus epidermidis, Pseudomonas aeruginosa, Acinetobacter* species, and *Klebsiella pneumoniae*.

Quality and Safety Nursing Alert

Meticulous aseptic technique is essential to prevent infection any time the IV line setup is manipulated.

The skin and the catheter hub are the major sources for CLABSIs. The catheter site is covered with a chlorhexidine disc or gel and semipermeable transparent film dressing. The semipermeable transparent dressing allows frequent examination of the catheter site, adheres well to the skin, and is more comfortable for the patient. The transparent semipermeable membrane CVAD dressing is changed every 7 days unless the dressing is damp, bloody, loose, or soiled. Alternatively, an occlusive gauze dressing may be used and is changed every 48 hours or as needed (Gorski et al., 2016). During dressing changes, the nurse and patient wear masks to reduce the possibility of airborne contamination. Sterile technique is used (e.g., the nurse wears sterile gloves). The area is checked for leakage; bloody or purulent drainage; a kinked catheter; and skin reactions such as inflammation, redness, swelling, or tenderness. If chlorhexidine is used for skin asepsis, it is important to allow it to completely dry before applying the new dressing to avoid skin irritation.

The catheter is another major source of colonization and infection. The use of chlorhexidine/silver sulfadiazine- or minocycline/rifampin-impregnated catheters is recommended for a patient whose catheter is expected to remain in place for longer than 5 days if there is concern over a possibility of the patient acquiring a CLABSI (CDC, 2017b).

Maintaining Fluid Balance

The ubiquitous use of infusion pumps ensures that an accurate rate of parenteral nutrition administration can be achieved. A designated rate is set in milliliters per hour (i.e., mL/h), and the rate is routinely verified per institution policy, generally at least every 4 hours. The infusion rate should not be increased or decreased to compensate for fluids that have infused too quickly or too slowly. If the solution runs out, 10% dextrose and water is infused at the same rate to prevent hypoglycemia until the next parenteral nutrition solution is available for administration.

TABLE 41-7 Potential Complications of Parental Nutrition

Complications	Causes	Select Nursing Interventions	
		Therapeutic	Preventive
Pneumothorax	Improper catheter placement and inadvertent puncture of the pleura	Place patient in Fowler position. Offer reassurance. Monitor vital signs. Prepare for thoracentesis or chest tube insertion.	Assist patient to remain still in Trendelenburg position during catheter insertion.
Air embolism	Disconnected tubing Cap missing from port Blocked segment of vascular system	Replace tubing immediately and notify primary provider. Replace cap and notify primary provider. Turn patient on left side and place in the head-low position. Notify primary provider.	Examine all tubing connection sites for their security.
Clotted catheter line	Inadequate/infrequent saline/heparin flushes Disruption of infusion	At direction of primary provider, flush with thrombolytic medication as prescribed.	Flush lines per established protocols. Monitor infusion rate hourly and inspect integrity of the line.
Catheter displacement and contamination	Excessive movement, possibly with a nonsecured catheter Separation of tubing and contamination	Stop the infusion, and notify the primary provider.	Examine all tubing connection sites. Avoid interrupting the main line or piggybacking other lines.
Sepsis	Separation of dressings Contaminated solution Infection at insertion site of catheter	Reinforce or change dressing quickly using aseptic technique. Discard. Notify pharmacist. Notify primary provider. Monitor vital signs.	Maintain sterile technique when changing tubing, dressing, or parenteral nutrition bag. Scrub the hub for 15 s prior to accessing line for any reason; air-dry prior to use.
Hyperglycemia	Glucose intolerance	Notify primary provider; addition of insulin to parenteral nutrition solution may be prescribed.	Monitor glucose levels (blood and urine). Monitor urine output. Observe for stupor, confusion, or lethargy.
Fluid overload	Fluid infusing rapidly	Decrease infusion rate. Monitor vital signs. Notify primary provider.	Use infusion pump. Verify correct infusion rate ordered.

		Treat respiratory distress by sitting patient upright and administering oxygen as needed, if prescribed.	
Rebound hypoglycemia	Feedings stopped too abruptly	Monitor for symptoms (weakness, tremors, diaphoresis, headache, hunger, and apprehension); notify primary provider.	Gradually wean patient from parenteral nutrition.

Adapted from McClave, S. A., Taylor, B. E., Martindale, R. G., et al. (2016). Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (ASPEN). *Journal of Parenteral and Enteral Nutrition*, *40*(2), 159–211.

If the rate is too rapid, hyperosmolar diuresis can occur. Excess glucose is excreted by the renal tubules, pulling large volumes of water into the tubules via osmosis, resulting in higher-than-normal urine output and intravascular fluid volume deficit. If the flow rate is too slow, the patient does not receive the maximal benefit of calories and nitrogen. Intake and output is recorded on an ongoing basis so that fluid imbalance can be readily detected.

ENCOURAGING ACTIVITY

Activities and ambulation are encouraged when the patient is physically able. With a central catheter, the patient is free to move the extremities, and normal activity should be encouraged to maintain good muscle tone. If applicable, the education and exercise program initiated by occupational and physical therapists is reinforced.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Educating Patients About Self-Care. Successful home parenteral nutrition requires educating the patient and family in specialized skills using an intensive training program and follow-up supervision in the home. This is best accomplished through a team effort. Initiation of a home program facilitates the patient's discharge from the hospital.

Ideal candidates for home parenteral nutrition are patients who have a reasonable life expectancy after return home, have a limited number of illnesses other than the one that has resulted in the need for parenteral nutrition, and are highly motivated and fairly self-sufficient. Ethical dilemmas occur when the patient and family, as well as the caregiver, do not thoroughly understand what is involved in home parenteral nutrition. In addition, the ability to learn, availability of family interest and support, adequate finances, and physical plan of the home are factors that must be assessed when the decision about home parenteral nutrition is made (Worthington et al., 2017) (see Chart 41-6).

Chart 41-6  **ASSESSMENT**

Assessing for Home Nutrition Support

Be alert to the following assessment findings:

- *Water:* Water is necessary for hand hygiene and cleaning of work areas.
- *Electricity:* A reliable power source is needed to provide proper lighting and charging of pumps.
- *Refrigeration:* Refrigeration must be adequate for accommodation of several bags of parenteral nutrition solution.
- *Telephone:* A telephone is necessary for contacting home health personnel, arranging for prompt delivery of supplies, and for emergency purposes.
- *Environment:*
  - Should be free of rodents and insects
  - Should have storage that is not accessible to pets and small children
  - Should be assessed for stairs, carpets, and inaccessible areas, which can limit mobility with infusion pumps if the patient has a disability

Adapted from Worthington, P., Balint, J., Bechtold, M., et al. (2017). When is parenteral nutrition appropriate? Journal of Parenteral and Enteral Nutrition, 41(3), 324–377.

Many home health care agencies have developed education brochures and videos for home parenteral nutrition treatment. Topics include catheter and dressing care, the use of an infusion pump, administration of lipid emulsions, and catheter maintenance. Education begins in the hospital and continues in the home or ambulatory infusion center.

Continuing and Transitional Care. The home, community-based, or transitional care nurse should be aware that the typical patient needs several instruction sessions for assessment of learning and reinforcement. More information about home patient education is presented in Chart 41-7.

Evaluation

Expected patient outcomes may include:

1. Attains or maintains nutritional balance
2. Is free of catheter-related infection
   a. Is afebrile
   b. Has no purulent drainage from the catheter insertion site
3. Is hydrated, as evidenced by good skin turgor
4. Achieves an optimal level of activity, within limitations
5. Demonstrates skill in managing parenteral nutrition regimen
6. Prevents complications
   a. Maintains proper catheter and equipment function
   b. Maintains metabolic balance within normal limits

MANAGEMENT OF THE PATIENT REQUIRING AN OSTOMY

Approximately 100,000 patients have surgery to create fecal diversions in the United States annually (Taneja, Netsch, Ralstad, et al., 2017). Common indications for these

procedures include not only IBD and diverticulitis, but also advanced colorectal cancer (see later discussion) (Hendren, Hammond, Glasgow, et al., 2015). Fecal diversions may be either ileostomies or colostomies, both of which may be permanent or temporary. While an ileostomy surgically creates an opening into the small intestine, a **colostomy** surgically creates an opening into the colon; both divert fecal drainage to the abdominal wall by means of a stoma. The Plan of Nursing Care summarizes care for the patient requiring an ostomy (see Chart 41-8).

Chart 41-7  HOME CARE CHECKLIST

The Patient Receiving Parenteral Nutrition

At the completion of education, the patient and/or caregiver will be able to:

- State the goal and purpose of parenteral nutrition therapy and any impact on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State what types of changes are needed (if any) to support home parenteral nutrition therapy and maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, and parental nutrition supply vendor.
  - List emergency phone numbers
- State how to obtain medical supplies and carry out catheter and dressing care, and other prescribed regimens.
- Demonstrate how to perform catheter and dressing care.
- Discuss basic components of parenteral nutrition solution and intravenous fat emulsions.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate accurate and safe administration of medications.
- Demonstrate how to handle solutions and medications correctly.
- Demonstrate correct administration of parenteral nutrition
  - Operate infusion pump
  - Prime tubing and filter
  - Connect and disconnect parenteral nutrition infusion
  - Flush central line
  - Clean and maintain pump
  - Change tubing and filters as directed
- Discuss pump warning signals and how to address these signals.
- Identify possible parenteral nutrition complications and interventions.
- Identify a plan for refrigeration of parenteral nutrition solutions and operation of parental nutrition pump during a power outage or other emergency.
- State time and date of follow-up appointments and testing.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Chart 41-8 PLAN OF NURSING CARE

The Patient Undergoing Ostomy Surgery

NURSING DIAGNOSIS: Lack of knowledge about the surgical procedure and preoperative preparation

GOAL: Understands the surgical process and the necessary preoperative preparations

Nursing Interventions	Rationale	Expected Outcomes
Preoperative Care 1. Ascertain whether the patient has had a previous surgical experience, and ask for recollections of positive and negative impressions. 2. Determine what information the surgeon gave the patient and family and whether it was understood. Clarify and elaborate as necessary. Determine whether the stoma is permanent or temporary. Be aware of the patient's prognosis if carcinoma exists. 3. Use pictures, drawings, or websites to illustrate the location and appearance of the surgical wounds (abdominal, perineal) and the stoma if the patient is receptive. 4. Explain that oral/parenteral antimicrobial agents will be given to cleanse the bowel preoperatively. Mechanical cleansing may also be required. 5. Assist the patient during nasogastric/nasoenteric intubation, if indicated. Measure drainage from the tube.	1. Fear of a repeated negative experience increases anxiety. Talking about the experience with a nurse helps clarify misconceptions and helps the patient ventilate any repressed emotions. Positive experiences are reinforced. 2. Clarification prevents misunderstandings and alleviates anxiety. 3. Knowledge, for some, alleviates anxiety because fear of the unknown is decreased. Others choose not to know because it makes them more anxious. 4. Antimicrobial agents and mechanical cleansing (e.g., laxatives, enemas) reduce intestinal bacterial flora. 5. Nasoenteral intubation is used for decompression and drainage of GI contents before surgery.	• Expresses anxieties and fears about the surgical process • Projects a positive attitude toward the surgical procedure • Repeats in own words information given by the surgeon • Identifies normal anatomy and physiology of gastrointestinal (GI) tract and how it will be altered; can point to expected location of abdominal wound and stoma; describes stoma appearance and size • Adheres to "bowel prep" regimen of antimicrobial agents or mechanical cleansing • Tolerates the presence of nasogastric/nasoenteric tube, if present

NURSING DIAGNOSIS: Disturbed body image

GOAL: Attainment of a positive self-concept

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage the patient to verbalize feelings about the stoma. Offer to be present when the stoma is first viewed and touched. 2. Suggest that the spouse or significant other view the stoma. 3. Offer counseling, if desired. 4. Arrange for a visit, phone call, or online chat with another patient with a stoma.	1. Free expression of feelings allows the patient the opportunity to verbalize and identify concerns. Expressed concerns can be therapeutically addressed by health care team members. 2. Helps patient to overcome fears about the response of significant other. 3. Provides opportunity for additional support. 4. People with stomas can offer support and share mutual feelings and experiences.	• Freely expresses concerns and fears • Accepts support • Seeks help as needed • States is willing to talk with another patient with a stoma or participate in support groups or blog sites

NURSING DIAGNOSIS: Anxiety associated with the loss of bowel control
GOAL: Reduction of anxiety

Nursing Interventions	Rationale	Expected Outcomes
Postoperative Care 1. Provide information about expected bowel function: a. Characteristics of effluent b. Frequency of discharge 2. Explain how to prepare the appliance for an adequate fit. a. Choose the drainage appliance that will provide a secure fit around the stoma. Measure the stoma size with a	1. Emotional adjustment is facilitated if adequate information is provided at the level of the learner. 2. Adequate fit is necessary for successful use of the appliance. a. The appliance opening should be larger than the stoma for	• Expresses interest in learning about altered bowel function • Handles equipment correctly • Changes the appliance unassisted • Irrigates colostomy successfully, if indicated • Progresses toward a regular schedule of elimination

measuring guide provided by the ostomy equipment manufacturer and compare with the opening on the pouch. The barrier opening should be sized to "hug" the stoma and cover the peristomal skin; wafer barriers can be pulled or molded to the size of the stoma.

b. Remove any plastic covering that protects the appliance adhesive. *Note:* The pouch is applied by pressing the adhesive for 30 seconds to the skin barrier.

3. Demonstrate how to change the appliance or empty the pouch before leakage occurs. Be aware that the older adult may have diminished vision and difficulty handling equipment.
4. If appropriate, demonstrate how to irrigate the colostomy (usually on the 4th or 5th day). Recommend that irrigation be performed at a consistent time, depending on the type of colostomy.

an adequate fit. Available brands come in different sizes to fit the stoma. Adjustments are made as necessary.

b. The appliance is ready to apply directly to the skin or skin protector.

3. Manipulation of the appliance is a learned motor skill that requires practice and positive reinforcement.
4. Colostomy irrigation is used to regulate the passage of fecal material; alternatively, the bowel can be allowed to evacuate naturally. Irrigation is not routinely indicated.

NURSING DIAGNOSIS: Risk for impaired skin integrity associated with irritation of the peristomal skin by the effluent
GOAL: Maintenance of skin integrity

Nursing Interventions	Rationale	Expected Outcomes
1. Provide information about signs and symptoms of irritated or	1. Peristomal skin should be slightly pink without	• Describes appearance of healthy skin

inflamed skin. Use pictures if possible. 2. Instruct patient how to cleanse the peristomal skin gently. 3. Demonstrate how to apply a skin barrier (e.g., wafer). 4. Demonstrate how to remove the pouch.	abrasions and similar to that of the entire abdomen. 2. Mild friction with warm water and a gentle soap cleanses the skin and minimizes irritation and possible abrasions. After rinsing the soap, patting the skin dry prevents tissue trauma. 3. Skin barriers protect the peristomal skin from enzymes and bacteria. 4. Gently separate adhesive from the skin to avoid irritation. Never pull!	• Correctly cleanses the skin • Successfully applies a skin barrier • Gently removes the drainage appliance without skin damage • Demonstrates intact skin around the stoma
NURSING DIAGNOSIS: Impaired nutritional intake associated with avoidance of foods that may cause GI discomfort GOAL: Achievement of an optimal nutritional intake		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Conduct a complete nutritional assessment to identify any foods that may increase peristalsis by irritating the bowel. 2. Advise the patient to avoid food products with a cellulose or hemicellulose base (nuts, seeds). 3. Recommend moderation in intake of certain irritating fruits such as prunes, grapes, and bananas.	1. Patients react differently to certain foods because of individual sensitivity. 2. Cellulose food products are the nondigestible residue of plant foods. They hold water, provide bulk, and stimulate elimination. 3. These fruits tend to increase the quantity of effluent.	• Modifies diet to avoid offensive foods yet maintains adequate nutritional intake • Avoids cellulose-based foods, such as peanuts • Modifies intake of certain fruits
NURSING DIAGNOSIS: Impaired sexual functioning associated with altered body image		

GOAL: Attainment of satisfactory sexual performance

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage the patient to verbalize concerns and fears. The sexual partner is welcomed to participate in the discussion. 2. Recommend alternative sexual positions. 3. Seek assistance from a sexual therapist or wound-ostomy-continence nurse.	1. Expressed needs help to develop a plan of care. 2. Avoids patient embarrassment with the visual appearance of the stoma. Avoids peristomal skin irritation or stomal trauma secondary to friction. 3. Some patients may benefit from professional sexual counseling.	• Expresses fears and concerns • Discusses alternative sexual positions • Accepts services of a professional counselor

NURSING DIAGNOSIS: Risk for hypovolaemia associated with anorexia and vomiting and increased loss of fluids and electrolytes from GI tract

GOAL: Attainment of fluid balance

Nursing Interventions	Rationale	Expected Outcomes
1. Estimate fluid intake and output: a. Record intake and output b. Daily weights 2. Assess serum and urinary values of sodium and potassium. 3. Observe and record skin turgor and the appearance of the tongue.	1. Provides indication of fluid balance a. An early indicator of fluid imbalance is a daily, significant difference between intake and output. The average person ingests (food, fluids) and loses (from urine, feces, lungs) about 2 L of fluid every 24 hours. b. A gain/loss of 1 L of fluid is reflected in a body weight change of 1 kg (2.2 lb). 2. Sodium is the major electrolyte regulating water	• Maintains fluid balance • Maintains normal serum and urinary values for sodium and potassium • Normal skin turgor • Surface of tongue is pink, with a moist mucous membrane

balance. Vomiting results in decreased urinary and serum sodium levels. Urinary sodium values, in contrast to serum values, reflect early, sensitive changes in sodium balance. Sodium works in conjunction with potassium, which is also decreased with vomiting. A significant deficiency in potassium is associated with a decrease in intracellular potassium bicarbonate, which leads to acidosis and compensatory hyperventilation.

3. Adequate hydration is reflected by the skin's ability to return to its normal shape after being grasped between the fingers. *Note:* In the older person, it is normal for the return to be delayed. Changes in the mucous membrane covering the tongue are accurate and early indicators of hydration status.

Preoperative Nursing Management

A period of preparation with replacement of fluid, blood, and protein is necessary prior to surgery. Antibiotics may be prescribed. If the patient has been taking corticosteroids (e.g., to treat IBD), they will be continued during the surgical phase to prevent steroid-induced adrenal insufficiency. Usually, the patient is given a low-residue diet, provided in frequent, small feedings. All other preoperative measures are similar to those for general abdominal surgery. The abdomen is marked for the proper placement of the stoma by the surgeon or the WOC nurse. Care is taken to ensure that the stoma is conveniently placed—for instance, ileostomy stomas are usually placed in the right lower quadrant about 5 cm (2 inches) below the waist, in an area away from previous scars, bony prominences, skin folds, or fistulas. The stoma site must be visible to the patient.

The patient must have a thorough understanding of the surgery to be performed and what to expect after surgery. Preoperative education ideally should be delivered by a WOC nurse and include information about the ostomy by means of written materials, models, websites, and discussion. Preoperative education should also include management of drainage from the stoma; the nature of drainage; an introduction to use of common stoma appliances; and the need for NG intubation, parenteral fluids, and possibly perineal packing (Francone, 2020).

Postoperative Nursing Management

General abdominal surgery care is required. As with other patients undergoing abdominal surgery, the nurse encourages those with an ostomy to engage in early ambulation. It is important to administer prescribed pain medications as required. The nurse observes the stoma for color and size. It should be pink to bright red and shiny. Typically, a temporary clear or transparent plastic bag (i.e., appliance or pouch) with an adhesive facing is placed over the ostomy in the operating room and firmly pressed onto the surrounding skin. The nurse monitors the ostomy for fecal drainage, which should begin about 24 to 48 hours after surgery for an ileostomy and within 3 to 6 days after surgery for a colostomy.

The drainage from an ileostomy is a continuous liquid from the small intestine because the stoma does not have a controlling sphincter. The contents drain into the pouch and are thus kept from coming into contact with the skin. They are collected, measured, and discarded when the pouch becomes full. If a continent ileal reservoir was created, as described for the Kock pouch, continuous drainage is provided by an indwelling reservoir catheter for 2 to 3 weeks after surgery. This allows the suture lines to heal. Stool drainage from

transverse colostomies may be soft and unformed; whereas, stool from descending and sigmoid colostomies is more solid (see Fig. 41-8).

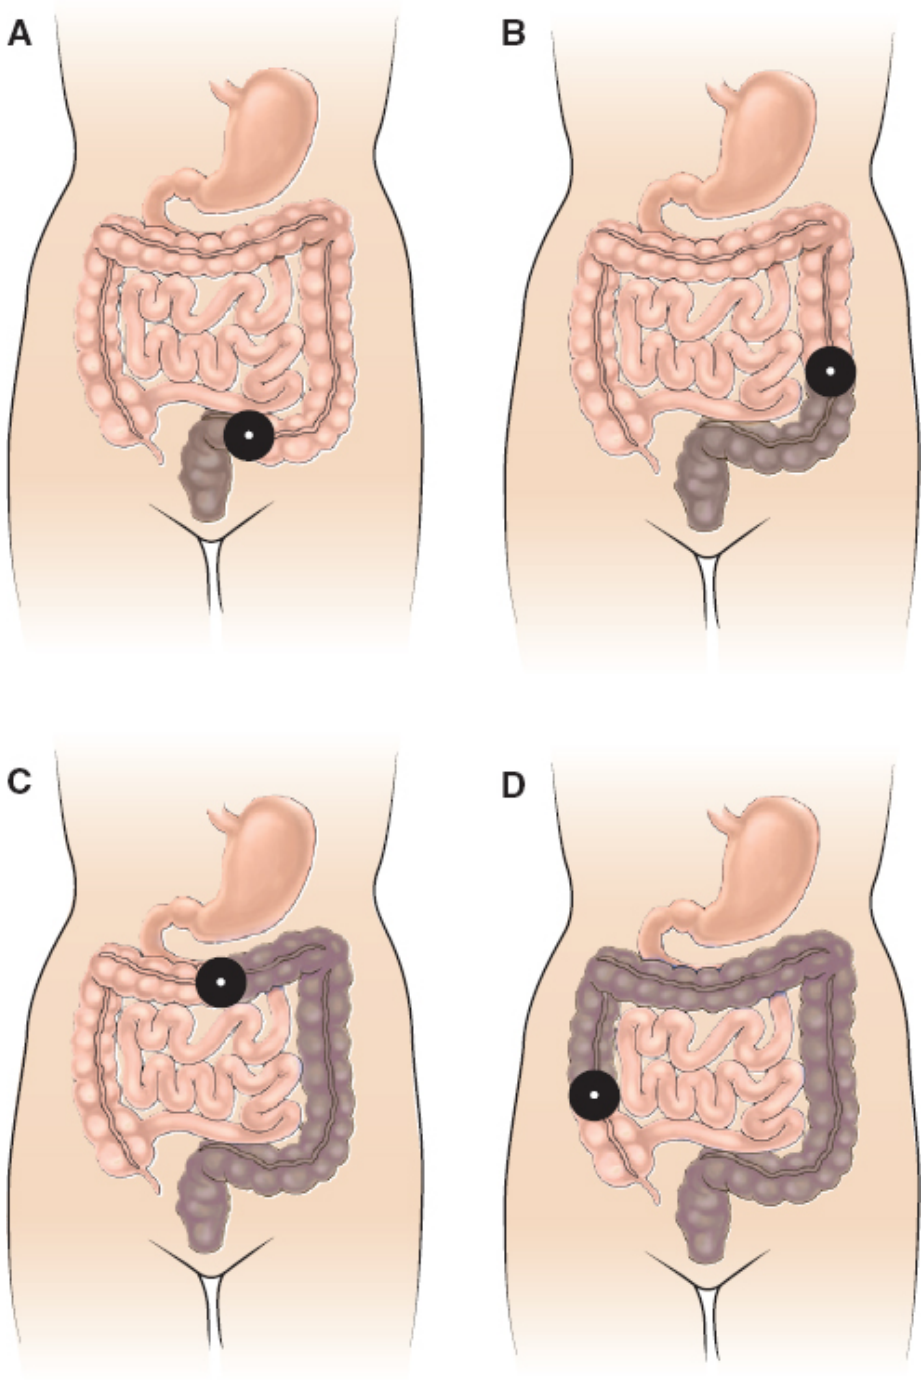

Figure 41-8 • Placement of permanent colostomies. The nature of the discharge varies with the site. *Shaded areas* show sections of bowel removed. **A.** With a sigmoid colostomy, the feces are formed. **B.** With a descending colostomy, the feces are semiformed. **C.** With a transverse colostomy, the feces are unformed. **D.** With an ascending colostomy, the feces are fluid.

Because patients lose large fluid volumes in the early postoperative period, an accurate record of fluid intake and output, including fecal discharge, is necessary to help gauge each patient's fluid needs. Between 600 and 1200 mL of daily output from an ileostomy and between 200 and 600 mL of daily output from a colostomy can be expected (Bridges, Nasser, & Parrish, 2019). With these losses, sodium and potassium are depleted. The nurse monitors laboratory values and administers electrolyte replacements as prescribed. Fluids may be given IV for 4 to 5 days to replace lost fluids.

NG suction may be a part of the immediate postoperative care, with the tube requiring frequent irrigation, as prescribed. The purpose of NG suction is to prevent a buildup of gastric contents while the intestines are not functioning. After the tube is removed, the nurse offers sips of clear liquids and gradually progresses the diet. Nausea and abdominal distention, which may indicate intestinal obstruction, must be reported immediately.

If rectal packing has been used, it is removed by the end of the first week. Because this procedure may be uncomfortable, the nurse may administer an analgesic agent an hour before the removal. After the packing is removed, the perineum is irrigated two or three times daily until full healing takes place.

Providing Emotional Support

The patient may think that everyone is aware of the ostomy and may view the stoma as a mutilation compared with other abdominal incisions that heal and are hidden. Because there is loss of a body part and a major change in anatomy and function, the patient often goes through the phases of grief—denial, anger, bargaining, depression, and acceptance. Nursing support through these phases is important, and understanding of the patient's emotional state should determine the approach taken. For example, education may be ineffective until the patient is ready to learn. Concern about body image may lead to questions related to family relationships, sexual function, and, for women of childbearing years, the ability to become pregnant and deliver a baby vaginally. Patients need to know that the nurse understands and cares about them; a calm, nonjudgmental attitude aids in gaining the patient's confidence. It is important to recognize that treatment of a possibly terminal illness (e.g., cancer) makes patients irritable, anxious, and unhappy. The nurse can coordinate patient care through meetings attended by consultants such as the primary provider, psychologist, psychiatrist, social worker, WOC nurse, and dietitian.

Conversely, a surgical procedure to create an ileostomy can produce dramatic positive changes in patients who have suffered from IBD for several years. After the discomfort of the disease has decreased and the patient learns how to take care of the ileostomy, they often develop a more positive outlook. Until the patient progresses to this phase, an empathetic and tolerant approach by the nurse plays an important part in recovery. The sooner the patient

masters the physical care of the ostomy, the sooner they will psychologically accept it.

Support from other people with ostomies is also helpful. The United Ostomy Associations of America (UOAA) is dedicated to the rehabilitation of people with ostomies. This organization gives patients useful information about living with an ostomy through an educational program of literature, lectures, and exhibits (see Resources section at the end of this chapter). Local associations offer consultations by qualified members who provide hope and rehabilitation services to patients with new ostomies. Hospitals and other health care agencies may have a WOC nurse on staff who can serve as a valuable resource person for the patient with an ileostomy.

Managing Skin and Stoma Care

The patient with an ileostomy cannot establish regular bowel habits because the contents of the ileum are fluid and are discharged continuously. The patient must wear a pouch at all times. Stomal size and pouch size vary initially; the stoma should be rechecked 3 weeks after surgery, when the edema has subsided. The final size and type of appliance is selected in 3 months, after the patient's weight has stabilized and the stoma shrinks to a stable shape.

The incidence of complications related to a colostomy is usually less than that of an ileostomy. Postoperatively, the stoma is examined for swelling (slight edema from surgical manipulation is normal), color (a healthy stoma is pink or red), discharge (a small amount of oozing is normal), and bleeding (an abnormal sign if bright red or more than trace amounts).

Skin excoriation around the stoma can be a persistent problem, particularly for ileostomies. Peristomal skin integrity may be compromised by several factors, such as an allergic reaction to the ostomy appliance, skin barrier, or paste; chemical irritation from the effluent; mechanical injury from the removal of the appliance; and infection. If irritation and yeast growth occur, antifungal spray, water-based cream, or powder can be applied on the peristomal skin and a pouch with skin barrier is applied over the affected area (Stelton, 2019).

Changing an Appliance 

A regular schedule for changing the appliance before leakage occurs must be established for those with an ostomy. The patient should be educated to change the pouch.

For the procedural guidelines for changing an ostomy appliance, go to thepoint.lww.com/Brunner15e.

The amount of time a person can keep the appliance sealed to the body surface depends on the location of the stoma and on body structure. The usual wearing time, which also depends on the type of skin barrier, is 5 to 10 days. The appliance is emptied every 4 to 6 hours, or at the same time the patient empties the bladder. An emptying spout at the bottom of the appliance is closed with a special clip or Velcro closure made for this purpose. If the patient wishes to bathe or shower before putting on a clean appliance, micropore tape applied to the sides of the pouch keeps it secure during bathing.

Most pouches are disposable and odor proof. Foods such as spinach and parsley act as deodorizers in the intestinal tract; foods that cause odors include asparagus, cabbage, onions, and fish. Bismuth subcarbonate tablets, which may be prescribed and taken orally three or four times each day, are effective in reducing odor. Oral diphenoxylate with atropine can be prescribed to diminish intestinal motility, thereby thickening the stool and assisting in odor control. Foods such as rice, mashed potatoes, and applesauce may also thicken stool.

Irrigating a Colostomy

The purpose of irrigating a colostomy is to empty the colon of gas, mucus, and feces so that the patient can go about social and business activities without fear of fecal drainage. A stoma does not have voluntary muscular control and may empty at irregular intervals. Regulating the passage of fecal material is achieved by irrigating the colostomy or allowing the bowel to evacuate naturally without irrigations. This choice depends on the person and the type of the colostomy (i.e., descending or sigmoid colostomies). By irrigating the stoma at a regular time, there is less gas and retention of the irrigant. The time for irrigating the colostomy should be consistent with the schedule that the person will follow after leaving the hospital.

Colostomy irrigation is not recommended for people with extensive pelvic irradiation because it carries a risk of perforation. Likewise, it is contraindicated in patients currently receiving chemotherapy, those with IBS, Crohn's disease, diverticulitis, and peristomal hernias (Bauer, Arnold-Long, & Kent, 2016).

As soon as the patient with a descending or sigmoid colostomy has established a routine for evacuation with irrigations, pouches may be dispensed with, and a closed ostomy appliance or a stoma cap is used to cover

the stoma. Except for gas and a slight amount of mucus, nothing escapes from the colostomy opening between irrigations. New assistive devices and ostomy care algorithms are available to help nurses learn ostomy assessment and ostomy product selection (see Resources section at the end of this chapter).

Irrigating a Continent Ileostomy

In the first several days postoperatively after a continent ileostomy (i.e., Kock pouch) is created, a catheter extends from the stoma and is attached to a closed drainage suction system. To ensure patency of the catheter, the nurse instills 10 to 20 mL of normal saline gently into the pouch usually every 3 hours; return flow is not aspirated but is allowed to drain by gravity.

After approximately 2 weeks, when the healing process has progressed to the point at which the catheter is removed from the stoma, the patient is educated how to drain the pouch. A catheter is inserted into the reservoir to drain the fluid. The length of time between drainage periods is gradually increased until the reservoir needs to be drained only every 4 to 6 hours and irrigated once each day. A pouch is not necessary; instead, most patients wear a small dressing over the opening.

When the fecal discharge is thick, water can be injected through the catheter to loosen and soften it. The consistency of the effluent is affected by food intake. At first, drainage is only 60 to 80 mL, but as time goes on, the amount increases significantly. The internal Kock pouch stretches, eventually accommodating between 500 and 1000 mL. The patient learns to use the sensation of pressure in the pouch as a gauge to determine how often the pouch should be drained.

Managing Dietary and Fluid Needs

A low-residue diet is followed for the first 6 to 8 weeks. Strained fruits and vegetables are ingested. These foods are important sources of vitamins A and C. Later, there are few dietary restrictions, except for avoiding foods that are high in fiber or hard-to-digest kernels, such as celery, popcorn, corn, poppy seeds, caraway seeds, and coconut, which may result in a stomal obstruction (food blockage) for the person with an ileostomy. Foods are reintroduced one at a time.

Getting enough fluids during the summer may be a challenge, when fluid lost through perspiration adds to the fluid loss through the ileostomy. Fluids such as sports drinks (Gatorade) are helpful in maintaining electrolyte balance. If the fecal discharge is too watery, fibrous foods (e.g., whole-grain cereals, fresh fruit skins, beans, corn, nuts) are restricted. If the effluent is excessively dry, salt intake is increased. Increased intake of water or fluid does not increase the effluent, because excess water is excreted in the urine.

Gerontologic Considerations

Some older adults may require an ostomy but have difficulty managing care due to decreased vision, impaired hearing, and difficulty with fine motor coordination. Skin care is a major concern in older patients with an ostomy because of the skin changes that occur with aging—the epithelial and subcutaneous fatty layers become thin, and the skin is irritated easily (Eliopoulos, 2018). To prevent skin breakdown, special attention is paid to skin cleansing and the proper fit of an appliance. Stoma skin barriers should be molded into shape around the stoma (e.g., ConvaTec; see Fig. 41-9). Arteriosclerosis may also be an issue; it causes decreased blood flow to the wound and stoma site, which may lead to delayed nutrient transport and prolonged healing time. Some patients have delayed elimination after irrigation because of decreased peristalsis and mucus production. Most patients require 6 months before they feel comfortable with their ostomy care.

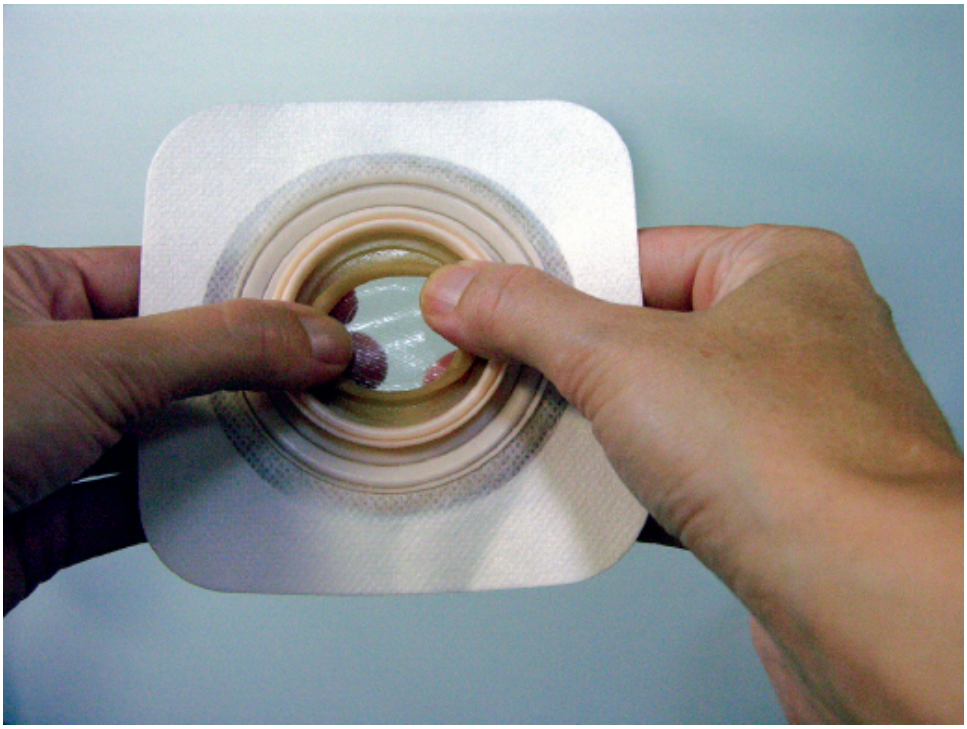

Figure 41-9 • Moldable stomal skin barrier. Reprinted with permission of ConvaTec, Inc.

Preventing Complications

Monitoring for complications is an ongoing activity for the patient with an ostomy. Peristomal skin irritation, which results from leakage of effluent, is the most common complication of an ileostomy. A drainable pouching system that does not fit well is often the cause. Components of the drainable pouching system include the pouch, a solid skin barrier, and adhesive. The WOC nurse

typically recommends the appropriate drainable pouching system. The solid skin barrier is the component of this system that is most important in ensuring healthy peristomal skin. Solid skin barriers are typically shaped as rectangular or elliptical wafers and are composed of polymers and hydrocolloids. They protect the skin around the stoma from effluent from the stoma and provide a stable interface between the stoma and the pouch. It is critical that the barrier be sized appropriately to "hug" the stoma (up to the stoma but not touching) and not expose peristomal skin.

Other common complications include diarrhea, stomal stenosis, urinary calculi, and cholelithiasis. Even in the presence of a properly fitted drainable pouching system, diarrhea can be problematic. Diarrhea, manifested by very irritating effluent that rapidly fills the pouch (every hour or sooner), can quickly lead to dehydration and electrolyte losses. Supplemental water, sodium, and potassium are given to prevent hypovolemia and hypokalemia. Antidiarrheal agents are given. Stenosis is caused by circular scar tissue that forms at the stoma site. The scar tissue must be surgically released. Urinary calculi may occur in patients with ileostomies and are at least partly attributed to dehydration from decreased fluid intake. Crohn's disease is a risk factor for cholelithiasis (i.e., gallstones) due to altered absorption of bile acids (see Chapter 44).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Wound and ostomy care has been identified by family caregivers as one of the most challenging care responsibilities (Kirkland-Kyhn, Martin, Zaratkiewicz, et al., 2018). Ostomy care can be complex and may be viewed as unpleasant by caregivers, and some patients may have body image issues (Kirkland-Kyhn et al., 2018). Nurses can provide the patient and family with information and resources prior to discharge, so they are prepared when the patient arrives home. The family should be familiar with adjustments that will be necessary; for example, they need to know why it is necessary for the patient to occupy the bathroom for 10 minutes or more at certain times of the day and why certain equipment is needed. Their understanding is necessary to reduce tension; a relaxed patient tends to have fewer problems. Visits from a home health, WOC, or transitional care nurse may be arranged to ensure that the patient is progressing as expected and to provide additional guidance and education as needed.

Continuing and Transitional Care

The patient needs to know the commercial name of the drainable pouching system to be used so that they can obtain a ready supply; the patient should also know how to obtain other supplies. The names and contact information of a local WOC nurse and local self-help groups are often helpful. Any restrictions on driving or working also need to be reviewed. The nurse educates the patient about common postoperative complications and how to recognize and report them (see Chart 41-9).

COLORECTAL NEOPLASMS

The term *neoplasm* means new growth. Colorectal neoplasms encompass both cancerous and benign growths, including colorectal cancer and cancerous and benign colorectal polyps.

Colorectal Cancer

Tumors of the colon and rectum are relatively common; the colorectal area (the colon and rectum combined) is the third most common site of new cancer cases in the United States. In the United States, approximately 104,600 new cases and 53,200 deaths from colorectal cancer occur annually; these deaths include 3640 people under age 50 years (American Cancer Society [ACS], 2020). Colorectal cancer is the third leading cause of cancer death in men or women and the second leading cause of cancer death among all adults in the United States (ACS, 2020). The WHO estimates there were 1.8 million new cases and nearly 861,000 deaths worldwide in 2018 (Macrae & Bendell, 2020).

Chart 41-9  **HOME CARE CHECKLIST**

Managing Ostomy Care

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
  - Describe the frequency and character of effluent.
- Identify sources for obtaining ostomy care/appliance supplies.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate ostomy care, including wound cleansing, irrigation, and appliance changing.
- Describe the importance of assessing and maintaining peristomal skin integrity.
- Identify dietary restrictions (foods that can cause diarrhea and constipation), process for reintroduction of foods, as well as foods that may be encouraged.
- Identify measures to be used to promote fluid and electrolyte balance.
- Describe potential complications and necessary actions to be taken if complications occur.
- Relate how to reach primary provider with questions or complications.
  - Identify how to contact wound-ostomy-continence or home health nurse.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, ostomy support, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

The most significant risk factor for colorectal cancer is older age. The median age at diagnosis is now 66 years of age compared to the median age 20 years ago of 72 years of age (ACS, 2020). The median age at diagnosis is younger for rectal cancer (62 years for men and 63 years for women) (ACS, 2020). The incidence of colorectal cancer in adults over 50 years of age has been declining by approximately 2% annually (Macrae & Bendell, 2020). This corresponds with an approximate 19% increase in colonoscopies being performed (Simonson, 2018). However, recent trends in epidemiologic data from the Surveillance, Epidemiology, and End Results registry (SEER) of the National Cancer Institute (NCI) revealed that nearly one in seven new

diagnoses of colorectal cancer were among adults younger than 50 years of age; furthermore, these patients were more likely to have more advanced disease at the time of diagnosis. These cancers are largely left-sided cancers (i.e., more distal); rectal cancer is particularly prevalent among younger adults with colorectal cancer (Macrae & Bendell, 2020). Research findings suggest that sedentary behavior in adults younger than 50 years of age might be linked to colorectal cancer (Nguyen, Liu, Zheng, et al., 2018).

Approximately 30% of patients with colorectal cancer have a family history of the disease (ACS, 2020). The exact cause of colon and rectal cancer is still unknown, but risk factors have been identified (see Chart 41-10). A specific form of hereditary colorectal cancer is *Lynch syndrome,* or hereditary non-polyposis colorectal cancer (HNPCC). HNPCC-defining cancers include those of the colorectum, uterus, stomach, ovaries, urinary epithelium, and small bowel. HNPCC is characterized by early age of onset. Another disorder with high risk of colorectal cancer is familial adenomatous polyposis (FAP), in which patients develop hundreds of colonic polyps that can become malignant.

The stage at presentation affects the prognosis in colon cancer. If the disease is localized and treated before it spreads, the 5-year survival rate is 89%; with distant metastases, the survival rate drops to 15% (ACS, 2020). SEER estimates the overall 5-year survival rate for all stages at 67% (ACS, 2020). Many people are asymptomatic for long periods and seek health care only when they notice a change in bowel habits or rectal bleeding (ACS, 2020). Education, prevention, and early screening are key to detection and reduction of mortality rates.

Pathophysiology

Cancer of the colon and rectum is predominantly (95%) adenocarcinoma (i.e., arising from the epithelial lining of the intestine) (Dragovich, 2020). It may start as a mutation of the adenomatous polyposis gene (*APC*), leading to malignancy. The genetic mutations are associated with the transformation of a benign polyp to invasive adenocarcinoma, which can invade and destroy normal tissues and extend into surrounding structures. Cancer cells may migrate away from the primary tumor and spread to other parts of the body, most often to the liver, peritoneum, and lungs.

Chart 41-10  **RISK FACTORS**

Colorectal Cancer

- Cigarette smoking
- Family history of colon cancer (especially if history of Lynch syndrome) or polyps (especially if history of familial adenomatous polyposis)
- High consumption of alcohol (i.e., >2 drinks daily in men, >1 drink daily in women)
- High-fat, high-protein (with high intake of beef), low-fiber diet
- History of genital cancer (e.g., endometrial cancer, ovarian cancer) or breast cancer (in women)
- History of inflammatory bowel disease
- History of radiation to the pelvis
- History of type 2 diabetes
- Increasing age
- Male gender
- Overweight or obesity
- Previous colon cancer or adenomatous polyps
- Racial/ethnic background: African American or Ashkenazi Jewish

Adapted from American Cancer Society (ACS). (2020). Colorectal cancer facts & figures 2020–2022, American Cancer Society, Inc., Surveillance Research; Colorectal (Colon) Cancer: What Are the Risk Factors for Colorectal Cancer? CDC. Retrieved on 3/09/2020 at: https://www.cdc.gov/cancer/colorectal/basic_info/risk_factors.htm

Clinical Manifestations

The symptoms are determined by the location of the tumor, the stage of the disease, and the function of the affected intestinal segment. The most common presenting symptom is a change in bowel habits. The passage of blood in or on the stools is the second most common symptom. Symptoms may also include unexplained anemia, anorexia, weight loss, and fatigue (ACS, 2020). Patients younger than 50 years of age may report abdominal pain rather than the usual "alarm" symptoms associated with colorectal cancer, which include rectal bleeding, a change in bowel habits, the presence of an abdominal mass, or anemia (Dragovich, 2020).

The symptoms most commonly associated with right-sided lesions (i.e., more proximal tumors) are dull abdominal pain and melena (i.e., black, tarry stools). Patients with right-sided tumors tend to have poorer outcomes than those with left-sided tumors. The symptoms most commonly associated with left-sided lesions are a change in bowel habits or those associated with obstruction (i.e., abdominal pain and cramping, narrowing stools, constipation, distention), as well as hematochezia (i.e., bright red blood in the stool). Symptoms associated with rectal lesions are tenesmus, rectal pain, the feeling

of incomplete evacuation after a bowel movement, alternating constipation and diarrhea, and bloody stool (Dragovich, 2020).

Assessment and Diagnostic Findings

Screening is an effective method to identify and prevent colorectal cancer. Screening colonoscopies can reduce mortality by decreasing the incidence of and increasing the survival rates for patients with colorectal cancer (ACS, 2020). Colorectal cancer develops slowly from polyps in the colon or rectum and if identified early, can be removed before undergoing malignant transformation (Simonson, 2018). Screening recommendations differ based on the organization publishing the guidelines; differences include the frequency and method of screening and age to begin and discontinue screening. The U.S. Preventive Services Task Force (USPSTF) recommends that all adults should begin periodic screening for colorectal cancer at the age of 50 years. Due to the increased incidence of colorectal cancer in people under age 50, the 2018 ACS guideline recommends screening begin at age 45 for people of average risk (ACS, 2020). Screening for high-risk people should begin earlier, based on their individual risk profile. The ACS offers information and guidelines for high-risk screening (see Resources). Whether or not to continue screening adults after the age of 75 years should be made based upon each patient's preference and overall health status. Adults older than 85 years of age should not continue to be screened (see Chapter 12, Table 12-3, for summary of colorectal cancer screening guidelines). Because colonoscopy is the only screening test that can also simultaneously remove precancerous polyps, thus preventing colorectal cancer, other experts recommend colonoscopies every 5 to 10 years beginning at the age of 50 years as the major screening test for colorectal cancer, including the American College of Gastroenterology and the National Comprehensive Cancer Network (see Chapter 38 for discussion of colonoscopies) (Cabebe, 2020).

A patient who has a tumor found on screening colonoscopy should have the tumor biopsied and tattooed during the colonoscopy to facilitate further workup. For the patient whose tumor was found on a diagnostic test other than a colonoscopy (e.g., flexible sigmoidoscopy, FIT), a colonoscopy is indicated to biopsy and tattoo the tumor (Rex, 2018).

The patient is referred to a colorectal surgeon. The preoperative workup consists of a focused history, to determine if there are any symptoms suggestive of colorectal cancer (see previous discussion in Clinical Manifestations). A family history is done to screen for a genetic predisposition (e.g., Lynch syndrome, FAP). Laboratory studies are done, including a CBC (may or may not reveal anemia), chemistry panel (to determine baseline status), and liver function tests (to screen for possible liver metastasis). A baseline carcinoembryonic antigen (CEA) level is also obtained. CEA is a

tumor marker that is recommended for assessing the presence of colorectal cancer, as well as its progression or recurrence, although it does yield both false positives and false negatives. However, at present there is no other readily available tumor marker test. Therefore, CEA is not used as the sole predictor of tumor status, including progression or recurrence. Other tests indicated include contrast CT scans of the abdomen, pelvis, and chest, to screen for extent of the tumor and any metastases (Macrae & Bendell, 2020).

Complications

Tumor growth may cause partial or complete bowel obstruction or perforation. Extension of the tumor and ulceration into the surrounding blood vessels can result in hemorrhage. Each of these complications can be treated surgically. Obstruction may be resected without anastomosis (e.g., Hartmann procedure) (see Fig. 41-4) or with anastomosis (e.g., colectomy or partial colectomy). Perforation typically carries a grim prognosis; it is typically treated with an ostomy. Acute hemorrhage is a rare complication; when it occurs, it is most effectively treated with surgical resection.

Gerontologic Considerations

Carcinomas of the colon and rectum are common malignancies in advanced age. In men, only the incidence of prostate cancer and lung cancer exceeds that of colorectal cancer. In women, only the incidence of breast cancer and lung cancer exceeds that of colorectal cancer (ACS, 2020). Symptoms are often insidious. Patients with colorectal cancer may report fatigue, which can be caused by iron deficiency anemia. In early stages, minor changes in bowel patterns and occasional bleeding may occur. The later symptoms most commonly reported by the older adult are abdominal pain, obstruction, tenesmus, and rectal bleeding.

Colon cancer in the older adult has been closely associated with dietary carcinogens. Lack of fiber is a major causative factor because the passage of feces through the intestinal tract is prolonged, which extends exposure to possible carcinogens. Excess dietary fat, high alcohol consumption, and smoking all increase the incidence of colorectal tumors. Physical activity and NSAIDs and aspirin have protective effects (ACS, 2020).

Prevention

Several primary prevention strategies might thwart the onset of colorectal cancer. Use of tobacco products is implicated in one third of all cancers, including colorectal cancer (see Chapter 23 for discussion of smoking cessation programs). Physical activity, dietary modification, and weight

reduction strategies mirror those for other cancers (see previous discussion of Life Style Factors in Chapter 12) (ACS, 2020). In addition to these strategies, the USPSTF recommends that adults between the ages of 50 and 59 who are also at risk for developing cardiovascular disease, and who have no contraindication to aspirin, take daily or alternate-day aspirin (dosage ≥75 mg) for 5 to 10 years, as an effective primary prevention strategy for both cardiovascular disease and colorectal cancer (Chubak, Kamineni, Buist, et al., 2015). To date, there is no expert consensus guideline that advocates routine prescription of aspirin postcolorectal cancer diagnosis.

Medical Management

Treatment for colorectal cancer depends on the stage of the disease (see Table 41-8) and consists of surgery to remove the tumor, supportive therapy, and adjuvant therapy. Definitive staging can only be done after surgical excision.

Surgical Management

Surgery is the mainstay of initial treatment for colorectal cancer. The goal is removal of the primary tumor with clean margins, including lymph nodes (Dragovich, 2020). It may be curative or palliative. Advances in surgical techniques can enable the patient with rectal cancer to have sphincter-sparing devices that restore continuity of the GI tract. The type of surgery recommended depends on the location and size of the tumor (Dragovich, 2020).

Patients who have Stage 0 tumors typically have endoscopic or laparoscopic excision of their tumors. Laparoscopic surgery for stage I, II, and III colorectal tumors achieves equivalent oncologic outcomes to surgery done by traditional open laparotomy (Dragovich, 2020). In addition, laparoscopic surgery is associated with shorter hospital lengths of stay, fewer postoperative complications, improved pain control, and earlier progression to a normal diet. Possible surgical procedures include the following (note that only segmental resections with anastomoses may be done by laparoscope):

- Segmental resection with anastomosis (i.e., removal of the tumor and portions of the bowel on either side of the growth, as well as the blood vessels and lymphatic nodes) (see Fig. 41-10)
- Abdominoperineal resection with permanent sigmoid colostomy (i.e., removal of the tumor and a portion of the sigmoid and all of the rectum and anal sphincter, also called *Miles resection*) (see Fig. 41-11)
- Temporary colostomy followed by segmental resection and anastomosis and subsequent reanastomosis of the colostomy,

allowing initial bowel decompression and bowel preparation before resection

- Permanent colostomy or ileostomy for palliation of unresectable obstructing lesions
- Construction of a coloanal reservoir called a *colonic J-pouch,* which is performed in two steps. A temporary loop ileostomy is constructed to divert intestinal flow, and the newly constructed J-pouch (made from 6 to 10 cm of colon) is reattached to the anal stump. About 3 months after the initial stage, the ileostomy is reversed and intestinal continuity is restored. The anal sphincter and therefore continence are preserved

TABLE 41-8 Staging of Colorectal Cancer: American Joint Committee on Cancer (AJCC) Stage Groupings

Stage	TNM	Description
Stage 0	Tis, N0, M0	Tis: carcinoma *in situ*; intraepithelial or invasion of lamina propria N0: no regional lymph node spread M0: no distant metastasis
Stage I	T1–2, N0, M0	T1: Tumor invades submucosa T2: Tumor invades muscularis propria
Stage IIA	T3, N0, M0	T3: Tumor invades through the muscularis propria into pericolorectal tissues arriving at colorectal fat tissue
Stage IIB	T4, T4a, N0, M0	T4: Tumor directly invades other organs T4a: Tumor directly penetrates visceral peritoneum
Stage IIC	T4b, N0, M0 Nx	T4b: Tumor directly invades or is adherent to other organs or structures Nx: Regional lymph nodes cannot be assessed
Stage IIIA	T1–T2, N1–N1c, M0 T1, N2a, M0	N1: Metastases in 1–3 regional lymph nodes N1a: Spread to 1 regional lymph node N1b: Spread to 2–3 regional lymph nodes N1c: Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis N2: Spread to ≥4 regional lymph nodes N2a: Spread to 4–6 regional lymph nodes
Stage IIIB	T3–T4a, N1–N1c, M0 T2–T3, N2a, M0 T1–T2, N2b, M0	N2b: Spread to ≥7 regional lymph nodes
Stage IIIC	T4a, N2a, M0 T3–T4a, N2b, M0 T4b, N1–N2, M0	
Stage IVA	Any T, Any N, M1a	M1a: Metastasis confined to 1 organ or site (e.g., liver, lung, ovary, nonregional node)
Stage IVB	Any T, Any N, M1b	M1b: Metastasis in >1 organ/site or the peritoneum
Stage	Any T,	M1c: Metastases to peritoneum with or without metastases to other

IVC	Any N, M1c	organs

Note: This is based upon AJCC 8th Edition and National Cancer Institute (NCI) recommendations that at least 12 regional lymph nodes are examined in patients with colorectal cancer to confirm staging.

T, primary tumor; N, regional lymph nodes; M, distant metastasis. Not listed on table: Tx: tumor cannot be assessed, T0: No evidence of primary tumor

Adapted from Tong, G. J., Zhang, G. Y., Lui, J., et al. (2018). Comparison of the eighth version of the American Joint Committee on Cancer manual to the seventh version for colorectal cancer: A retrospective review of our data. *World Journal of Clinical Oncology*, *9*(7), 148–161.

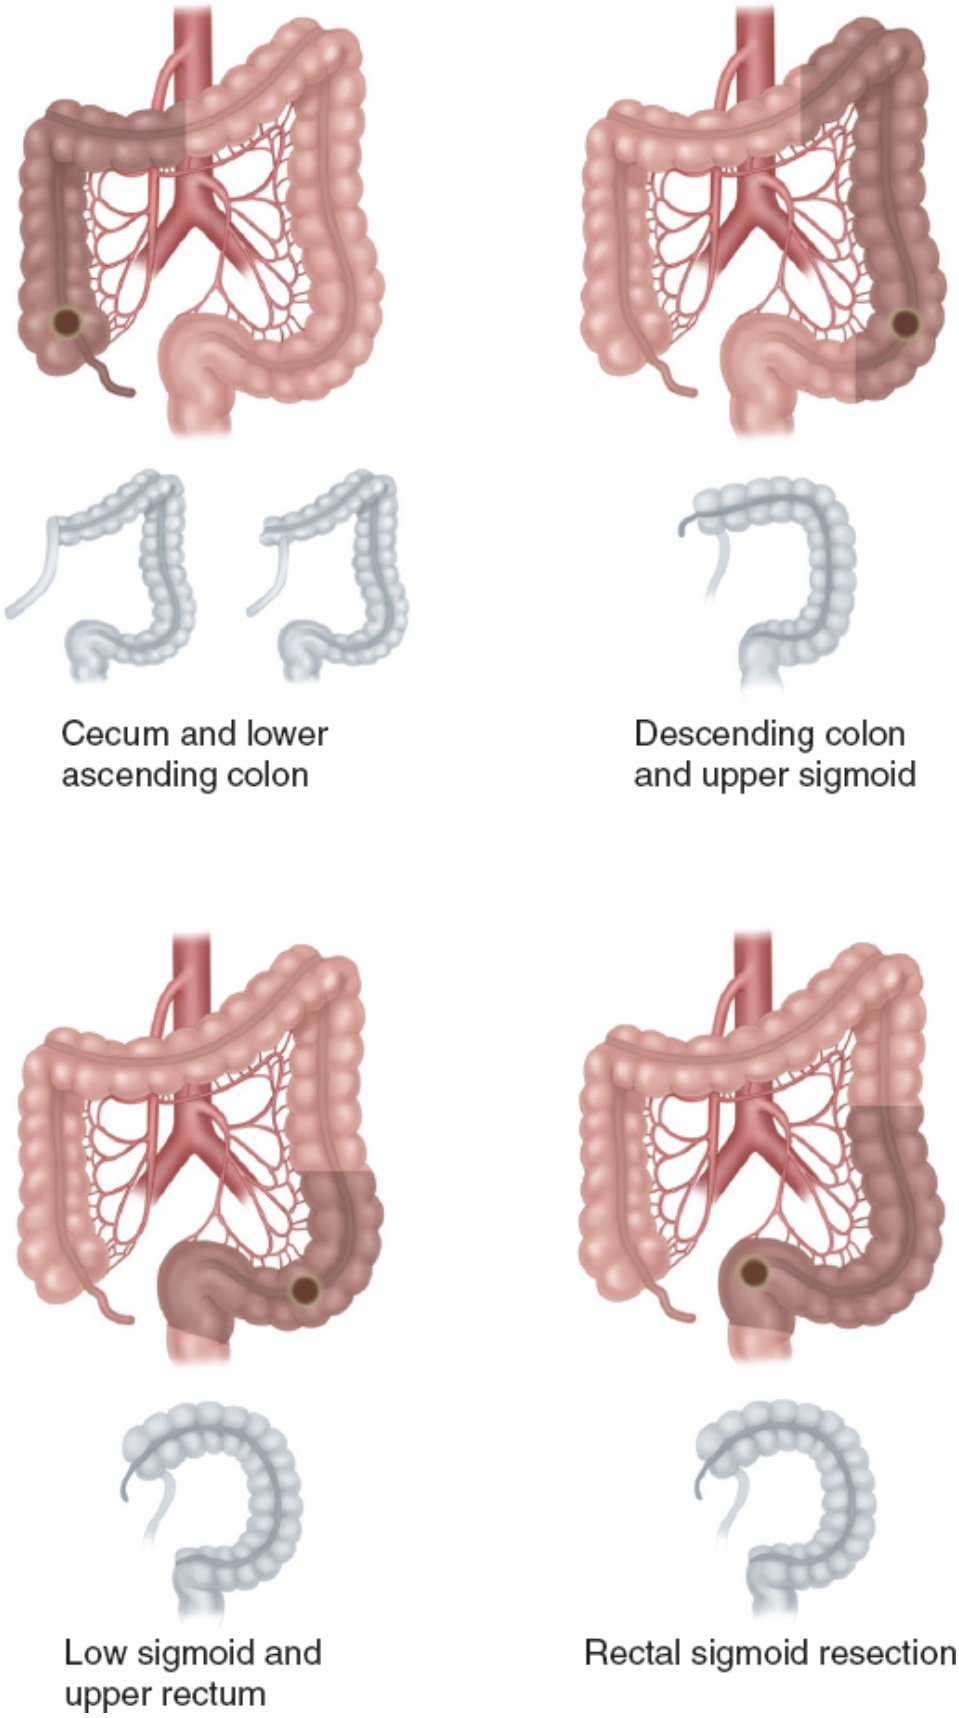

Figure 41-10 • Examples of areas where cancer can occur, the area that is removed, and how the anastomosis is performed (*small diagrams*).

The colostomy can be created as a temporary or permanent fecal diversion. It allows the drainage or evacuation of colon contents to the outside of the body. The consistency of the drainage is related to the placement of the colostomy, which is dictated by the location of the tumor and the extent of invasion into surrounding tissues (see Fig. 41-8).

Adjuvant Therapy and Ongoing Management

Patients diagnosed with colorectal cancer are referred to a medical oncologist for further management after they are discharged from the hospital after surgery. Patients at the lowest risk for recurrence (i.e., those with Stage 0 or I disease) do not require chemotherapy or radiation therapy. Those with Stage 0 disease do not require specific follow-up. Patients with stage I colorectal cancer should have follow-up colonoscopies 1-year postoperatively, then again in another 3 years, and then every 5 years.

Most patients with stage II disease do not require any adjuvant chemotherapy. However, some patients with stage II tumors have mutations in their DNA mismatch repair genes (MMR) that are classified as proficient (MMR-P). Patients in this subset have improved survival and less disease recurrence if they take the antimetabolite chemotherapeutic drug capecitabine for 6 months. In order to screen for the MMR-P gene, the tumor should be analyzed by a multigene assay (i.e., genetic test). Patients with stage II disease who may also benefit from capecitabine are those who had inadequately sampled lymph nodes, with T4-sized tumors, or with poorly differentiated tumors. Capecitabine is equivalent to the dual chemotherapeutic drugs 5-fluorouracil and leucovorin. It may be given either orally or intravenously. The most common adverse effects of capecitabine include anemia, neutropenia, fatigue, diarrhea, and palmar-plantar erythrodysesthesia (i.e., hand-foot syndrome), which manifests by reddening, pain, and swelling of the palms of the hands and soles of the feet (NCI, 2020).

Patients with stage III tumors are typically prescribed the combination chemotherapeutic drug of 5-fluorouracil, leucovorin, and oxaplatin. This combination chemotherapeutic drug is usually given over 6 months, but there is some debate whether 3 months of treatment is as effective (Lee & Chu, 2018; Sougklakos, Boukovinas, Xynogalos, et al., 2019). The 3-month treatment regimen is associated with less neurotoxicity (Dragovich, 2020). The adverse effects mirror those of capecitabine, plus patients frequently experience cold sensitivity and paresthesias of their hands and feet, which typically cease after the chemotherapy is completed. An alternative treatment is now available, and consists of a combination drug of capecitabine and oxaliplatin for 3 or 6 months of therapy (Dragovich, 2020).

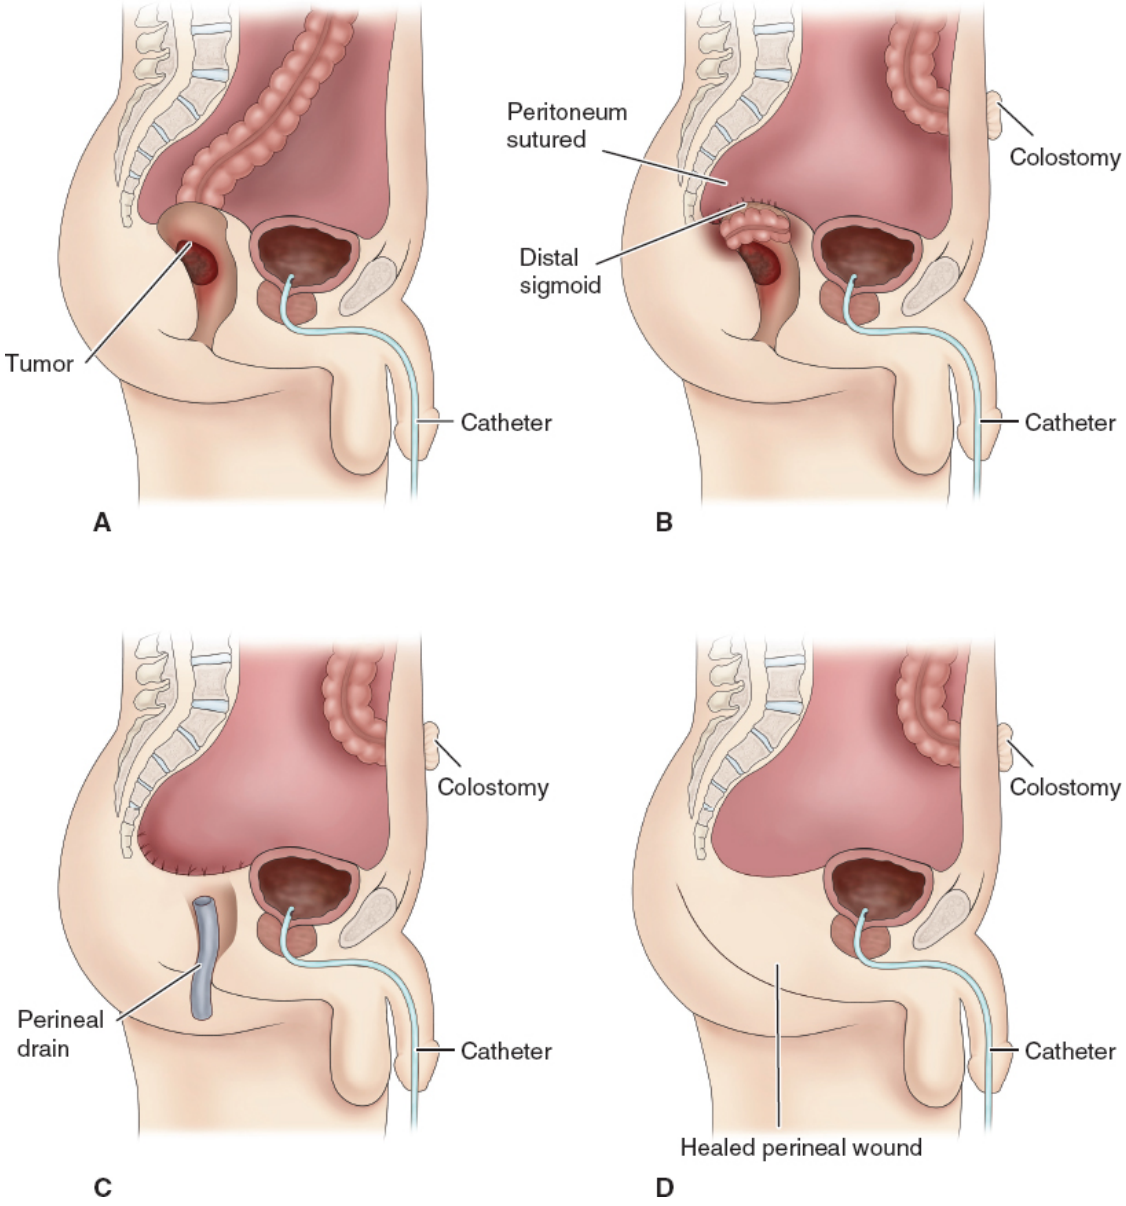

Figure 41-11 • Abdominoperineal resection for carcinoma of the rectum. **A.** Prior to surgery. Note tumor in rectum. **B.** During surgery, the sigmoid is removed and the colostomy is established. The distal bowel is dissected free to a point below the pelvic peritoneum, which is sutured over the closed end of the distal sigmoid and rectum. **C.** Perineal resection includes removal of the rectum and free portion of the sigmoid from below. A perineal drain is inserted. **D.** The final result after healing. Note the healed perineal wound and the permanent colostomy.

Patients with stage II or stage III tumors should have routine follow-ups and CEA testing every 3 to 6 months for 5 years. CT scans of the abdomen and chest should be done each year for 3 years. Colonoscopy should also be done 1-year postoperatively, and then every 5 years (NCI, 2020).

Patients with stage IV or recurrent colorectal tumors have metastases to distant organs. The treatment is highly variable and individualized, based upon the extent of the tumor mass(es), and the health status and wishes of the patient. Treatment might consist of targeted therapy aimed at possible cure, or palliative care (see Chapter 13). Chemotherapeutic drugs that might be tried include those previously described for treating stage II or stage III disease, as well as other categories of agents, including monoclonal antibodies (e.g., cetuximab, panitumumab), and anti-vascular endothelial growth factor (anti-VEGF) agents (e.g., bevacizumab, aflibercept), to name a few. When metastasis occurs, the liver is implicated half the time. Therapy targeted to treat metastases to the liver can include surgical resection, radiofrequency ablation, and intra-arterial chemotherapy (Dragovich, 2020). Maintaining quality of life is an important goal for many patients with cancer, particularly those receiving palliative care (Rohde, Kersten, Vistad, et al., 2017) (see Chart 41-11: Nursing Research Profile).

Chart 41-11  **NURSING RESEARCH PROFILE**

Spiritual Well-Being Among Patients with Metastatic Colorectal Cancer

Rohde, G., Kersten, C., Vistad, I., et al. (2017). Spiritual well-being in patients with metastatic colorectal cancer receiving noncurative chemotherapy: A qualitative study. *Cancer Nursing*, *40*(3), 209–216.

Purpose

Enhancing quality of life (QOL) for patients with noncurative cancer is an important treatment goal. The purpose of this study was to explore spiritual well-being, an important component of QOL, in patients with metastatic colorectal cancer receiving palliative chemotherapy.

Design

Twenty patients ages 34 to 75 with metastatic colorectal cancer receiving palliative chemotherapy were enrolled in this qualitative study in Norway. Researchers conducted semi-structured, in-depth interviews over a 1-year period with hermeneutic editing for analyses. The European Organisation for Research and Treatment of Cancer (EORTC) QOL group's subthemes of spiritual well-being were used as a framework. Inclusion criteria were patients 18 years or older with metastatic colorectal cancer referred for first- or second-line noncurative chemotherapy with an expected life expectancy that exceeded 6 months. Patients unable to read or understand Norwegian, or those with significant comorbidities or being treated with an investigational drug were excluded from the study. Participants varied in terms of sociodemographic data such as age, marital status, education level, and religious beliefs. Some examples of the interview questions included "How do you experience your life after you became ill?" "How is your relationship with your nearest family and friends?" Nineteen participant interviews were done in the hospital and 1 in the participant's home.

Findings

Low spiritual well-being is associated with low QOL in patients with cancer. Positive spiritual coping strategies may contribute to improved adjustment to illness, although evidence is mixed. Using the EORTC's model, the researchers identified subthemes of spiritual well-being, including *relationship with others* (strategies for inner harmony, sharing feelings with significant others), *existential issues* (coping with end-of-life thoughts) and *religious and/or spiritual beliefs and practices* (seeking faith as inner support). Participants identified and focused on short-term, positive, and achievable goals. Many reported an ability to live a good life, despite the prognosis. Some felt the ability to speak openly about their illness was a positive change and made relationships better. However, those who did not have good relationships before their illness did not see an improvement in relationships after their diagnosis. Some participants withheld information about their diagnosis and prognosis from their families by choice in an attempt to spare their feelings. When discussing end-of-life issues, trust

between the provider and patient was very important. Some participants would have welcomed a provider initiating a discussion on existential issues, while others thought it would be intrusive.

Nursing Implications

Patients with metastatic colorectal cancer use cognitive, affective, and behavioral strategies to adjust to health-related changes in their QOL and spiritual well-being. In the process of seeking inner harmony, most participants in this study underwent a response shift when learning of their diagnosis and shift in what was important in their lives. They tried to find a balance between sadness and grief and positive feelings; others were less able to adjust to their illness and focused more on negative feelings and sadness. The participants in this study did not expect health care providers to initiate a conversation about spiritual well-being or other existential issues, although many would have appreciated the provider listening without being intrusive. Understanding QOL and spiritual well-being issues that patients with colorectal cancer face may allow the nurse to identify patients in need of developing positive coping strategies or to act as facilitator for communication between the patient and family.

NURSING PROCESS

The Patient Having Surgery for Colorectal Cancer

Assessment

The nurse obtains a health history about the presence of fatigue, abdominal or rectal pain (e.g., location, frequency, duration, association with eating or defecation), past and present elimination patterns, and characteristics of stool (e.g., color, odor, consistency, presence of blood or mucus). Additional information includes a history of IBD or colorectal polyps, a family history of colorectal disease, Lynch syndrome, or FAP, and current medication therapy. The nurse assesses dietary patterns, including fat and fiber intake, as well as amounts of alcohol consumed and history of smoking. The nurse describes and documents a history of weight loss and feelings of weakness and fatigue.

Assessment includes auscultation of the abdomen for bowel sounds and palpation of the abdomen for areas of tenderness, distention, and solid masses. Stool specimens are inspected for character and presence of blood.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired nutritional intake associated with nausea and anorexia
- Risk for infection associated with surgery on bowel and disruption of colonic bacteria
- Risk for hypovolaemia associated with vomiting and dehydration
- Lack of knowledge concerning the diagnosis, the surgical procedure, and self-care after discharge
- Anxiety associated with impending surgery and the diagnosis of cancer
- Impaired skin integrity associated with the surgical incisions (abdominal or perianal)

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Intraperitoneal infection
- Complete large bowel obstruction
- GI bleeding
- Bowel perforation
- Peritonitis, abscess, and sepsis

Planning and Goals

The major goals for the patient may include attainment of optimal level of nutrition; prevention of infection; maintenance of fluid balance; knowledge about the diagnosis, surgical procedure, and self-care after discharge; reduction of anxiety; maintenance of optimal tissue healing; and avoidance of complications.

Nursing Interventions

The patient awaiting surgery for colorectal cancer has many concerns, needs, and fears. They may be physically debilitated and emotionally distraught with concerns about lifestyle changes after surgery, prognosis, ability to perform in established roles, and finances. Priorities for nursing care include preparing the patient physically for surgery; providing information about postoperative care; and supporting the patient and family emotionally. An Enhanced Recovery After Surgery (ERAS) Society pathway, first developed in 2005 and last revised in 2018, provides a care path developed for patients undergoing elective colorectal surgery (i.e., colorectal surgery that is planned in advance, rather than done emergently) to reduce perioperative stress, reduce length of stay, and optimize patient outcomes (Gustafsson, Scott, Hubner, et al., 2018). Multidisciplinary strategies included in the pathway are evidence-based and are associated with a reduction in morbidity, comparable or reduced 30-day hospital readmission rates, faster recovery, earlier discharge, and decreased costs (Riccardi, MacKay, & Joshi, 2019). Despite advanced age, patients over 70 years managed with the ERAS pathway experienced similar benefits in terms of length of stay and postoperative outcomes as did younger patients who underwent colorectal surgery (Joris, Hans, Coimbra, et al., 2019). (See Chapter 15 for further discussion of ERAS pathways.)

Providing Preoperative Care

Maintaining Optimal Nutrition. Physical preparation for surgery involves building the patient's stamina in the days preceding surgery. If the patient's condition permits, the nurse recommends a diet high in calories, protein, and carbohydrates and low in residue for several days before surgery to provide adequate nutrition and minimize cramping by decreasing excessive peristalsis. If the patient is hospitalized in the days preceding surgery, parenteral nutrition may be required to replace depleted nutrients, vitamins, and minerals. In some instances, parenteral nutrition is given at home before surgery (Gustafsson et al., 2018).

Preventing Infection. Postoperative infection is a major cause of morbidity and mortality following colorectal surgery (Rollins, Javanmard-Emamghissi, & Lobo, 2018). Preoperative mechanical bowel preparations (e.g., enemas, oral laxatives) traditionally have been prescribed to reduce fecal bulk and colonic bacteria. It had been posited that these measures

would prevent postoperative complications of infection. However, findings from a meta-analysis suggest that these interventions do not reduce the rates of postoperative infectious complications among patients having colorectal surgery (Rollins et al., 2018). Nonetheless, there is a lack of consensus regarding best practices that might reduce the rates of infections. The American Society of Colon and Rectal Surgeons supports the use of mechanical bowel preparations for elective colorectal surgery only when accompanied by preoperative oral antibiotics (Migaly, Bafford, Francone, et al., 2019). Antibiotics typically prescribed may include kanamycin, ciprofloxacin, neomycin, metronidazole, and cephalexin to be administered orally the day before surgery. IV antibiotics such as cefazolin and metronidazole are usually given within 60 minutes of the surgical incision (Gustaffsson et al., 2018).

Maintaining Fluid Volume Balance. For the patient who is very ill and hospitalized, the nurse measures and records intake and output, including vomitus, to provide an accurate record of fluid balance. The patient's intake of oral food and fluids may be restricted to prevent vomiting. The nurse administers antiemetic agents as prescribed. Full or clear liquids may be tolerated, or the patient may be NPO. An NG tube may be inserted to drain accumulated fluids and prevent abdominal distention. The nurse monitors the abdomen for increasing distention, loss of bowel sounds, and pain or rigidity, which may indicate obstruction or perforation. It also is important to monitor IV fluids and electrolytes. Monitoring serum electrolyte levels can detect the hypokalemia and hyponatremia that occur with GI fluid loss. The nurse observes for signs of hypovolemia (e.g., tachycardia, hypotension, decreased pulse volume); assesses hydration status; and reports decreased skin turgor, dry mucous membranes, and concentrated urine.

Providing Preoperative Education. The nurse assesses the patient's knowledge about the diagnosis, prognosis, surgical procedure, and expected level of functioning after surgery. Education is provided about the preparations for surgery, the expected appearance and care of the wound, dietary restrictions, pain control, and medication management. All procedures are explained in language the patient understands. If the patient is going to have a colostomy, the nurse manages the plan of care as described previously (see Nursing Management of the Patient Requiring an Ostomy).

Providing Emotional Support. Patients anticipating bowel surgery for colorectal cancer may be very anxious. They may grieve about the diagnosis and the impending surgery. The nurse's role is to assess the patient's anxiety level and coping mechanisms and suggest methods for reducing anxiety, such as deep-breathing exercises and visualizing a successful recovery from surgery and cancer. The nurse can arrange a

meeting with a spiritual advisor if the patient desires or with the primary provider if the patient wishes to discuss the treatment or prognosis. To promote patient comfort, the nurse projects a relaxed, professional, and empathetic attitude.

Providing Postoperative Care

Postoperative nursing care for patients undergoing colon resection is similar to nursing care for any abdominal surgery patient (see Chapter 16), including pain management during the immediate postoperative period. The nurse also monitors the patient for complications. The nurse assesses the abdomen for returning peristalsis and assesses the initial stool characteristics. It is important to help patients out of bed on the first postoperative day to prevent atelectasis, VTE, and accelerate the return of peristalsis (Chan, LeRoux, Stutzman, et al., 2019; Kaff, Wehner, & Litkouhi, 2018).

Maintaining Optimal Nutrition. The nurse educates the patient having surgery for colorectal cancer about the health benefits to be derived from consuming a healthy diet. The diet is individualized as long as it is nutritionally sound and does not cause diarrhea or constipation. The return to normal diet is rapid.

Providing Wound Care. The nurse frequently examines the abdominal dressing during the first 24 hours after surgery to detect signs of hemorrhage or infection. It is important to help the patient splint the abdominal incision during coughing and deep breathing to lessen tension on the edges of the incision. The nurse monitors temperature, pulse, and respiratory rate for elevations that may indicate an infectious process.

If the malignancy has been removed using the perineal route, the perineal wound is observed for signs of hemorrhage. This wound may contain a drain or packing that is removed gradually. Bits of tissue may slough off for a week. This process is hastened by mechanical irrigation of the wound or with sitz baths performed two or three times each day initially. The condition of the perineal wound and any bleeding, infection, or necrosis is documented.

Monitoring and Managing Potential Complications. The patient is observed for signs and symptoms of complications. The nurse monitors vital signs for increased temperature, pulse, and respirations and for decreased blood pressure that may indicate an intra-abdominal infectious process. It is important to frequently assess the abdomen, including bowel sounds and abdominal girth, to detect bowel obstruction. Rectal bleeding must be reported immediately because it indicates hemorrhage. The nurse monitors hemoglobin and hematocrit levels and administers blood component therapy as prescribed. Any abrupt change in abdominal pain is reported promptly. Elevated white blood cell counts and temperature or symptoms of shock are reported because they may indicate sepsis. The

nurse administers antibiotics as prescribed. Table 41-9 lists additional potential postoperative complications.

TABLE 41-9 Potential Complications and Nursing Interventions After Colorectal Surgery

Complication	Nursing Interventions
General Complications	
Paralytic ileus	Initiate or continue nasogastric intubation if prescribed (typically only indicated with vomiting or abdominal distention). Prepare patient for x-ray study or CT scan of abdomen. Ensure adequate fluid and electrolyte replacement; monitor serum electrolytes for abnormalities (e.g., hypokalemia, hyponatremia, hypomagnesemia). Prepare to institute or discontinue prescribed drugs or therapies that can increase motility (e.g., chewing gum increases motility, opioid analgesics can decrease motility).
Mechanical obstruction	Assess patient for intermittent colicky pain, nausea, and vomiting. Initiate or continue nasogastric intubation if prescribed. Prepare patient for x-ray study or CT scan of abdomen. Prepare patient for surgery.
Intra-abdominal Septic and Ischemic Conditions	
Peritonitis	Evaluate patient for nausea, hiccups, chills, spiking fever, tachycardia, rigid, boardlike abdomen. Administer antibiotics as prescribed. Prepare patient for drainage procedure. Administer parenteral fluid and electrolyte therapy as prescribed. Prepare patient for surgery if condition deteriorates.
Abscess formation	Administer antibiotics as prescribed. Apply warm compresses as prescribed. Prepare patient for surgical or percutaneous drainage.
Acute mesenteric ischemia	Assess patient for sudden onset of severe, colicky pain, abdominal distention, and sepsis. Prepare patient for x-ray study or CT scan of abdomen. Administer antibiotics as prescribed. Prepare patient for surgery.
Surgical Wound Complications	
Infection	Monitor temperature; report temperature elevation. Observe for redness, tenderness, induration (hardening), and pain around the surgical wound. Assist in establishing local drainage. Obtain specimen of drainage material for culture and sensitivity studies.
Wound dehiscence	Observe for sudden drainage of profuse serous fluid from wound. Cover wound area with sterile moist dressings.
Wound evisceration	Observe for wound dehiscence with protrusion of abdominal organs (e.g., intestines) through wound. Prepare patient immediately for surgery.
Abdominal wound	Monitor for evidence of constant or generalized abdominal pain, rapid pulse, and elevation of temperature.

infection	Prepare for tube decompression of bowel. Administer fluids and electrolytes by IV route as prescribed. Administer antibiotics as prescribed.
Anastomotic Complications	
Dehiscence of anastomosis	Prepare patient for surgery.
Fistulas	Prepare for tube decompression of bowel. Administer parenteral fluids as prescribed to correct fluid and electrolyte deficits.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patient education and discharge planning require the combined efforts of the primary provider, nurse, social worker, and dietitian. Patients are given specific information about wound care and signs and symptoms of potential complications that is individualized to their needs. Dietary instructions are essential to help patients identify and eliminate irritating foods that can cause diarrhea or constipation. It is important to educate patients about their prescribed medications (i.e., action, purpose, and possible side and toxic effects).

Some patients who are older with multiple comorbid conditions may need referral to a home care agency and the telephone number of the local chapter of the ACS. The home health nurse provides further care and education and assesses the patient's and family's adjustment. The home environment is assessed for adequacy of resources that allow the patient to manage self-care activities. A family member may assume responsibility for purchasing the equipment and supplies needed at home.

Patients need very specific directions about when to call their primary provider. They need to know which complications require prompt attention (i.e., bleeding, abdominal distention and rigidity, diarrhea, fever, wound drainage, and disruption of suture line). If chemotherapy is planned, the possible side effects (e.g., diarrhea, fatigue, palmar-plantar erythrodysesthesia, neuropathies) are reviewed.

Continuing and Transitional Care. Ongoing care of the patient with cancer extends well beyond the initial hospital stay. Transitional care nurses who work in cancer care infusion centers manage follow-up care and coordinate adjuvant therapy and surveillance follow-ups. Some patients are interested in and can benefit from involvement in colorectal cancer support groups (see Resources section at the end of this chapter).

Evaluation

Expected patient outcomes may include:

1. Consumes a healthy diet
    a. Avoids foods and fluids that cause diarrhea, constipation, and obstruction
    b. Substitutes nonirritating foods and fluids for those that are restricted
2. Does not exhibit any signs or symptoms of infection
    a. Is afebrile
3. Maintains fluid balance
    a. Experiences no vomiting or diarrhea
    b. Experiences no signs or symptoms of dehydration
4. Acquires information about diagnosis, surgical procedure, preoperative preparation, and self-care after discharge
    a. Discusses the diagnosis, surgical procedure, and postoperative self-care
    b. Demonstrates techniques of ostomy care
5. Feels less anxious
    a. Expresses concerns and fears freely
    b. Uses coping measures to manage stress
6. Maintains clean wound(s)
7. Recovers without complications
    a. Regains normal bowel activity
    b. Exhibits no signs and symptoms of perforation or bleeding
    c. Identifies signs and symptoms that should be reported to the health care provider

Polyps of the Colon and Rectum

A polyp is a mass of tissue that protrudes into the lumen of the bowel. Polyps can occur anywhere in the intestinal tract and rectum. They can be classified as neoplastic (i.e., typically adenocarcinomas) or non-neoplastic (i.e., mucosal and hyperplastic). Non-neoplastic polyps, which are benign epithelial growths, are common in the Western world. They occur more commonly in the large intestine than in the small intestine. Because polyps might develop into malignant neoplasms, they should be removed when they are identified, typically during screening colonoscopy (Enders, 2020). Adenomatous polyps are more common in men. The proportion of these polyps arising in the proximal part of the colon increases with age. The prevalence among adults over 60 years of age is estimated to be 10% (Enders, 2020).

Clinical manifestations depend on the size of the polyp and the amount of pressure it exerts on intestinal tissue. Most commonly, there are no symptoms. When there are clinical manifestations, the most common is rectal bleeding. Lower abdominal pain may also occur. If the polyp is large enough, symptoms of obstruction occur. The diagnosis is based on history and digital rectal examination, double-contrast barium enema studies, sigmoidoscopy, or colonoscopy (NIDDK, 2017a).

After a polyp is identified, it should be removed. Several methods are used: colonoscopy with the use of special equipment (i.e., biopsy forceps and snares), laparoscopy, or colonoscopic excision with laparoscopic visualization. The latter technique enables immediate detection of potential problems and allows laparoscopic resection and repair of the major complications of perforation and bleeding that may occur with polypectomy. Microscopic examination of the polyp then identifies the type of polyp and indicates what further surgery is required, if any (NIDDK, 2017a).

DISORDERS OF THE ANORECTUM

Anorectal disorders are common. Patients with anorectal disorders seek medical care primarily because of pain, rectal bleeding, or change in bowel habits. Other common complaints are protrusion of hemorrhoids, anal discharge, perianal itching, swelling, anal tenderness, stenosis, and ulceration. Constipation results from delaying defecation because of anorectal pain.

Proctitis

Proctitis refers to inflammation of the mucosa of the rectum, which may be secondary to infection, IBD, celiac disease, rectal instrumentation, antibiotic treatment, or radiation. Infectious diseases are the most frequent cause of proctitis; these etiologies may be either from enteric organism (e.g., *Shigella, Salmonella*) or from sexually transmitted infections (STIs; also called *sexually transmitted diseases,* or STDs).

Proctitis secondary to an STI may occur in any gender but is more prevalent among gay men who practice anorectal intercourse. It is commonly associated with recent anal-receptive intercourse with an infected partner. Symptoms include mucopurulent discharge or bleeding, rectal pain, and diarrhea. The pathogens most frequently involved are *Neisseria gonorrhoeae, Chlamydia trachomatis,* syphilis, herpes simplex virus, and *Clostridium difficile.* These infections may progress into proctocolitis and enteritis. Proctocolitis involves the rectum and lowest portion of the descending colon. Symptoms are similar to proctitis but may also include watery or bloody diarrhea, cramps, pain, and bloating. Enteritis involves more of the descending colon, and symptoms

include watery, bloody diarrhea; abdominal pain; and weight loss. The most common pathogens causing enteritis are *E. histolytica, Giardia lamblia, and Shigella,* and *Campylobacter* species (Irizarry, 2018).

Sigmoidoscopy is performed to identify portions of the anorectum involved. Samples are taken with rectal swabs, and cultures are obtained to identify the pathogens involved. Antibiotics (e.g., ceftriaxone, doxycycline) are the treatment of choice for gonorrheal proctitis. Acyclovir is given to patients with viral infections. Antiamebic therapy (i.e., metronidazole) is appropriate for infections with *E. histolytica* and *G. lamblia.* Metronidazole or oral vancomycin is recommended for patients with proctitis due to *C. difficile* infection (Irizarry, 2018).

Anorectal Abscess

An anorectal abscess is caused by obstruction of an anal gland with dried debris, resulting in retrograde infection. People with Crohn's disease or immunosuppressive conditions such as AIDS are particularly susceptible to these infections. Many of these abscesses result in fistulas (Hebra, 2018).

An abscess may occur in a variety of spaces in and around the rectum, usually in the path of least resistance, where anatomic structures are in close proximity without hard or thick structures to separate them. Most patients with anorectal abscesses will complain of dull perianal discomfort and itching, and increased pain with defecation. Approximately half will present with perianal edema; only one quarter will report any abnormal fecal discharge, such as pus, mucous, or blood. Only 21% report fever or chills (Hebra, 2018).

Prompt surgical treatment to incise and drain the abscess is the treatment of choice, to prevent complications such as fistula formation, fecal incontinence, and sepsis. This may be done in the emergency department or in an outpatient clinic office setting. The wound may be packed with an absorptive dressing (e.g., calcium alginate or hydrofiber) and allowed to heal by granulation (Hebra, 2018).

Anal Fistula

An anal fistula is a tiny, tubular, fibrous tract that extends into the anal canal from an opening located beside the anus in the perianal skin (see Fig. 41-12A). Fistulas usually result from an abscess. They may also develop from trauma, fissures, or Crohn's disease. Purulent drainage or stool may leak constantly from the cutaneous opening. Other symptoms may be the passage of flatus or feces from the vagina or bladder, depending on the location of the fistula tract.

Untreated fistulas may cause systemic infection with related symptoms (Hebra, 2018).

Surgery is recommended because few fistulas heal spontaneously. A fistulectomy (i.e., excision of the fistulous tract) is the recommended surgical procedure. The lower bowel is evacuated thoroughly with several prescribed enemas. The fistula is dissected or laid open by an incision from its rectal opening to its outlet. The wound is packed with gauze. Postoperative medications include analgesics and antibiotics. Fistulas recur in up to half of patients (Hebra, 2018).

Anal Fissure

An anal fissure is a longitudinal tear or ulceration in the lining of the anal canal usually just distal to the dentate line (see Fig. 41-12B). Fissures are usually caused by the trauma of passing a large, firm stool or from persistent tightening of the anal canal because of stress and anxiety (leading to constipation). Other causes include childbirth, trauma, and or anal intercourse.

Painful defecation, burning, and bleeding characterize fissures. Bright red blood may be seen on the toilet tissue after a bowel movement. Most of these fissures heal if treated by conservative measures that include dietary modification with addition of fiber supplements, stool softeners and bulk agents, an increase in water intake, and sitz baths (Poritz, 2018). Anal dilation under anesthesia may be required. Therapies such as perianal or intra-anal application of nitroglycerin ointment, calcium channel blockers, minoxidil, or botulinum toxin injections have increased the rate of healing and lowered pain levels in chronic anal fissures; these therapies should be tried before surgery. These agents work by increasing blood supply to the region and relaxing the anal sphincter (Poritz, 2018).

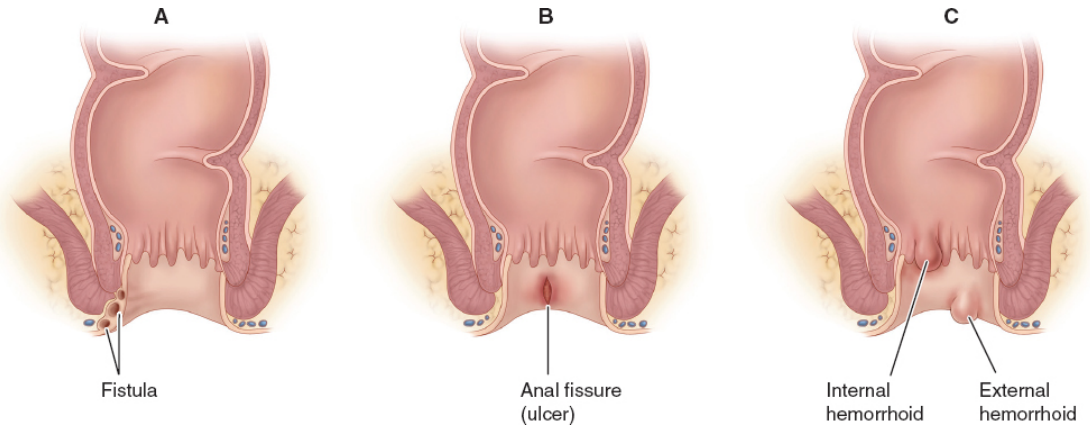

Figure 41-12 • Various types of anal lesions. **A.** Fistula. **B.** Fissure. **C.** External and internal hemorrhoids.

If fissures do not respond to conservative treatment, surgery is indicated. The procedure of choice is the lateral internal sphincterotomy with excision of the fissure.

Hemorrhoids

Hemorrhoids are dilated portions of veins in the anal canal. In the United States, approximately 10 million people have hemorrhoids; of these, nearly one third seek medical treatment for hemorrhoids annually (Perry, 2019). Shearing of the mucosa during defecation results in the sliding of the structures in the wall of the anal canal, including the hemorrhoidal and vascular tissues. Increased pressure in the hemorrhoidal tissue due to pregnancy may initiate hemorrhoids or aggravate existing ones. Hemorrhoids are classified into two types: those above the internal sphincter are called *internal hemorrhoids,* and those appearing outside the external sphincter are called *external hemorrhoids* (Perry, 2019) (see Fig. 41-12C). Internal hemorrhoids are classified by their degree of prolapse (Soweld, 2018):

- First degree—do not prolapse and protrude into anal canal
- Second degree—prolapse outside the anal canal during defecation but reduce spontaneously
- Third degree—prolapsed to the extent that they require manual reduction
- Fourth degree—prolapsed to the extent that they may not be reduced and are at risk for strangulation and thrombosis

Hemorrhoids cause itching and pain and are the most common cause of bright red bleeding with defecation. External hemorrhoids are associated with severe pain from the inflammation and edema caused by thrombosis (i.e., clotting of blood within the hemorrhoid). This may lead to ischemia of the area and eventual necrosis. Internal hemorrhoids are not usually painful until they bleed or prolapse when they become enlarged.

Hemorrhoid symptoms and discomfort can be relieved by good personal hygiene and by avoiding excessive straining during defecation. A high-residue diet that contains fruit and bran along with an increased fluid intake may be all the treatment that is necessary to promote the passage of soft, bulky stools to prevent straining. If this treatment is not successful, the addition of hydrophilic bulk-forming agents such as psyllium may help. Warm compresses, sitz baths, analgesic ointments and suppositories, and astringents (e.g., witch hazel) reduce engorgement (Perry, 2019).

There are several types of nonsurgical treatments for hemorrhoids. Infrared photocoagulation, bipolar diathermy, and laser therapy are used to affix the mucosa to the underlying muscle. Injection of sclerosing agents is also effective for small, bleeding hemorrhoids. Sclerotherapy involves injecting a

sclerosing agent (5% phenol in saline) into the base of the hemorrhoid to cause blood vessel thrombosis. These procedures help prevent prolapse (Perry, 2019).

A conservative surgical treatment of internal hemorrhoids is the rubber band ligation procedure. The hemorrhoid is visualized through the anoscope, and its proximal portion above the mucocutaneous lines is grasped with an instrument. A small rubber band is then slipped over the hemorrhoid. Tissue distal to the rubber band becomes necrotic after several days and sloughs off. Fibrosis occurs; the result is that the lower anal mucosa is drawn up and adheres to the underlying muscle. Although this treatment has been satisfactory for some patients, it has proven painful for others and may cause secondary hemorrhage. It has also been known to cause perianal infection (Soweld, 2018).

Stapled hemorrhoidopexy uses surgical staples to treat prolapsing hemorrhoids and is associated with less postoperative pain and fewer complications. If it is not successful, hemorrhoidectomy, or surgical excision, may be performed to remove all of the redundant tissue involved in the process. During surgery, the rectal sphincter is usually dilated digitally, and the hemorrhoids are removed with a clamp and cautery or are ligated and then excised. After the surgical procedures are completed, a small tube may be inserted through the sphincter to permit the escape of flatus and blood; pieces of absorbable gelatin sponge (Gelfoam) or oxidized cellulose (Oxycel) gauze may be placed over the anal wounds (Perry, 2019).

Pilonidal Sinus or Cyst

A pilonidal sinus or cyst is found in the intergluteal cleft on the posterior surface of the lower sacrum (see Fig. 41-13). Current theories suggest that it results from local trauma, causing penetration of hairs into the epithelium and subcutaneous tissue. It may also be formed congenitally by an infolding of epithelial tissue beneath the skin, which may communicate with the skin surface through one or several small sinus openings. Hair frequently is seen protruding from these openings, and this gives the cyst its name, *pilonidal* (i.e., a nest of hair). The cysts rarely cause symptoms until adolescence or early adult life, when infection produces an irritating drainage or an abscess. Perspiration and friction easily irritate this area (Koyfman, 2019).

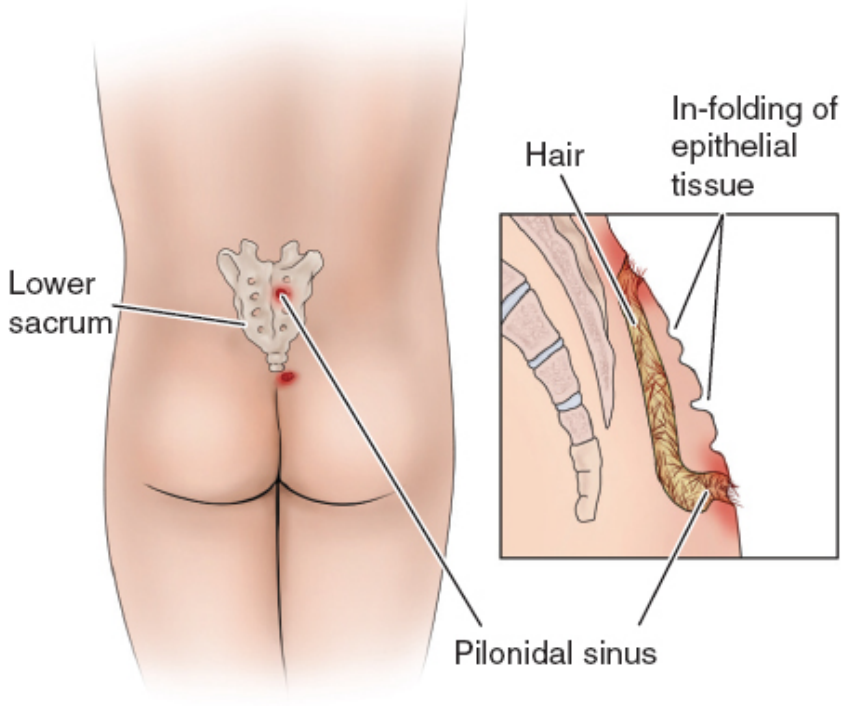

Figure 41-13 • (**Left**) Pilonidal sinus on lower sacrum about 5 cm (2 inches) above the anus in the intergluteal cleft. (**Right**) Hair particles emerge from the sinus tract, and localized indentations (pits) can appear on the skin near the sinus openings.

The abscess is incised and drained under local anesthesia. After the acute process resolves, further surgery might be indicated to excise the cyst and any secondary sinus tracts. The wound is allowed to heal by granulation. Absorptive dressings are placed in the wound to keep its edges separated while healing occurs (Koyfman, 2019).

Nursing Management of Patients with Anorectal Disorders

Most patients with anorectal disorders are not hospitalized. Those who undergo surgical procedures to correct the condition often are discharged directly from the outpatient surgical center. If they are hospitalized, it is for a short time, usually only 24 hours.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education is essential to facilitate recovery at home.

The nurse instructs the patient to keep the perianal area as clean as possible by gently cleansing with warm water and then drying with absorbent cotton wipes. The patient should avoid rubbing the area with toilet tissue. Instructions are provided about how to take a sitz bath and how to test the temperature of the water.

During the first 24 hours after rectal surgery, painful spasms of the sphincter and perineal muscles may occur. The nurse instructs the patient that ice and analgesic ointments may decrease the pain. Warm compresses may promote circulation and soothe irritated tissues. Sitz baths taken three to four times each day can relieve soreness and pain by relaxing sphincter spasm. Twenty-four hours after surgery, topical anesthetic agents may be beneficial in relieving local irritation and soreness. Medications may include topical anesthetics (i.e., suppositories), astringents, antiseptics, tranquilizers, and antiemetic agents. Patients are more adherent and less apprehensive if they are free of pain.

Wet dressings saturated with equal parts of cold water and witch hazel help relieve edema. When wet compresses are being used continuously, petrolatum is applied around the anal area to prevent skin maceration. The patient is instructed to assume a prone position at intervals because this position reduces edema of the tissue.

Continuing and Transitional Care

Sitz baths may be given in the bathtub or plastic sitz bath unit three to four times each day. Sitz baths should follow each bowel movement for 1 to 2 weeks after surgery. The nurse encourages intake of at least 2 L of water daily to provide adequate hydration and recommends high-fiber foods to promote bulk in the stool and to make it easier to pass fecal matter through the rectum. Bulk laxatives such as psyllium may be recommended, and stool softeners (e.g., docusate) may be prescribed. The patient is advised to set aside a time for bowel movements and to heed the urge to defecate as promptly as possible, in order to prevent constipation. The diet is modified to increase fluids and fiber. Moderate exercise is encouraged, and the patient is taught about the prescribed diet, the significance of proper eating habits and exercise, and the laxatives that can be taken safely.

CRITICAL THINKING EXERCISES

1 ipc You are a home health nurse making a first post-discharge visit for a 42-year-old female discharged home following a proctocolectomy with ileostomy. The patient has a 20-year history of Crohn's disease with multiple exacerbations, as well as a history of depression, anemia, malnutrition, and arthritis primarily affecting the metacarpal phalangeal (MCP) and proximal interphalangeal (PIP) joints of both hands. She is married and lives with her husband; an adult daughter lives out of state. The patient is a self-employed attorney. What interdisciplinary and community resources would you consider mobilizing that can facilitate the patient's recovery from surgery, help her to manage her ileostomy over the long-term, and improve her quality of life?

2 pq As a staff nurse on a hospital surgical unit, you are caring for a 68-year male admitted from the postanesthesia care unit (PACU) following emergent laparotomy for repair of an anastomotic leak of a segmental bowel resection done 10 days ago for stage II colon cancer. In addition to his history of colon cancer, the patient also has a history of hypertension, obstructive sleep apnea, and obesity (with a body mass index [BMI] of 36/m^2). The patient is drowsy, oriented to person, place, and time; he reports an abdominal pain score of "6" on a 0 to 10 numeric pain intensity scale. The patient's vital signs include: temperature 36.6°C (97.8°F), heart rate 82 bpm, respiratory rate 12/min, blood pressure 138/78, and SpO_2 of 99% on 2 L/min of O_2 by nasal cannula. The patient has a midline abdominal wound with staples with a small amount of serosanguinous drainage on the dressing and a Jackson-Pratt drain to bulb suction with scant bloody drainage, a Foley catheter to gravity drainage, and sequential compression devices in place bilaterally to his lower extremities. A peripheral IV line in his left forearm is infusing normal saline at 100 mL/h. What are your assessment priorities? Discuss the patient's risk for postoperative complications, and identify appropriate preventive interventions.

2 ebp You work in an outpatient gastroenterology clinic. The clinic manager asks you to develop an educational program for patients with inflammatory bowel disease. Describe your learning objectives for this program. What evidence-based health promotion strategies would you include? How might you monitor the effectiveness of your program?

UNIT 10

Metabolic and Endocrine Function

Case Study

APPLYING PATIENT-CENTERED CARE FOR THE PATIENT WITH DIABETES

You are a certified diabetes care and education specialist in a community hospital. Today you are making a home visit to a 53-year-old Black man to follow up on the results of a 13% $HgbA_{1c}$ that was drawn a few weeks ago. He is 5′5′, weighs 180 lb, his finger stick glucose today is 310 mg/dL, and he lives with his adult daughter. While discussing the associations between an $HgbA_{1c}$

and poor blood glucose control, you review the pharmacologic and nonpharmacologic treatments. During the visit the patient and his daughter state they want to try cinnamon tea and other alternative and complementary therapies to help control his blood glucose naturally. You intend to collaborate with the family's preferences and educate them on the various ways he can maintain glucose control through diet, exercise, and medications.

QSEN Competency Focus: Patient-Centered Care

The complexities inherent in today's health care system challenge nurses to demonstrate integration of specific interdisciplinary core competencies. These competencies are aimed at ensuring the delivery of safe, quality patient care (Institute of Medicine, 2003). The Quality and Safety Education for Nurses project (Cronenwett, Sherwood, Barnsteiner, et al., 2007; QSEN, 2020) provides a framework for the knowledge, skills, and attitudes (KSAs) required for nurses to demonstrate competency in these key areas, which include ***patient-centered care***, ***interdisciplinary teamwork and collaboration***, ***evidence-based practice***, ***quality improvement***, ***safety***, and ***informatics.***

Patient-Centered Care Definition: Recognize the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for patient's preferences, values, and needs.

SELECT PRE-LICENSURE KSAs	APPLICATION AND REFLECTION
Knowledge	
Integrate understanding of multiple dimensions of patient centered care: • patient/family/community preferences, values • coordination and integration of care • information, communication, and education • physical comfort and emotional support • involvement of family and friends • transition and continuity	Based on this patient's preferences, how can you provide education to this patient and his family regarding the management of his blood glucose? Identify how you can incorporate the patient's preferences for alternative and complementary therapies with diet and exercise management.
Describe how diverse cultural, ethnic and social backgrounds function as sources of patient, family, and community values	
Skills	
Communicate patient values, preferences and expressed needs to other members of health care team	During the visit, you discuss with the patient and family ways they can adhere to a diet, exercise, and medication regimen. How can you communicate support of their choice to incorporate alternative and complementary therapies in managing the patient's blood glucose so that healthy glycemic control is achieved?
Attitudes	
Value seeing health care situations "through patients' eyes" Respect and encourage individual expression of	Reflect on the complex interrelationships between the patient's desire to manage his blood glucose with alternative therapies. Think about your own desire for this patient to adhere to a diet, exercise, and medications regimen.

patient values, preferences, and expressed needs	How might you demonstrate that you value the patient's preferences to utilize alternative and complementary therapies?

42 Assessment and Management of Patients with Obesity

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Describe the causes, risks, and pathophysiology associated with obesity.
2. Discriminate between normal and abnormal assessment findings identified in the patient with obesity.
3. Identify strategies aimed at preventing and treating obesity, including lifestyle modification, pharmacologic therapy, and nonsurgical interventions.
4. Explain nursing management considerations for the patient with obesity using nonsurgical interventions.
5. Compare and contrast surgical modalities indicated to treat patients with obesity in terms of preoperative, postoperative, and long-term management and complications.
6. Use the nursing process as a framework for care of the patient who undergoes bariatric surgery.

NURSING CONCEPTS

Assessment
Metabolism

GLOSSARY

adiposopathy: dysfunction of adipose tissue that causes chronic inflammation and disease
bariatric: relating to obesity; term derives from two Greek words meaning "weight" and "treatment"
body mass index (BMI): a weight-to-height ratio, calculated by dividing weight in kilograms by height in meters squared; the most common measure used to classify and diagnose obesity
dumping syndrome: physiologic response to rapid emptying of gastric contents into the jejunum, manifested by nausea, weakness, sweating, palpitations, syncope, and possibly diarrhea (*synonym:* vagotomy syndrome)
dysphagia: difficulty swallowing
genome: the total complement of individual genes in an organism
microbiome: the collective genome of all microbes in a microbiota
microbiota: the complement of microbes in a given environment
obesity: a disease characterized by an abnormal or excessive accumulation of body fat that impairs health
obesogenic: a factor that promotes weight gain and obesity
orexigenic: a factor that stimulates appetite
satiety: feeling of having eaten sufficient quantities of food

Obesity in the United States and globally has reached pandemic proportions. Given the high prevalence of obesity, nurses will encounter adults with obesity in every inpatient and outpatient clinical setting. This chapter describes the etiology, risks, assessment, clinical manifestations, management, and related nursing care of the patient with obesity. The management of patients with obesity using both nonsurgical and surgical treatments is discussed.

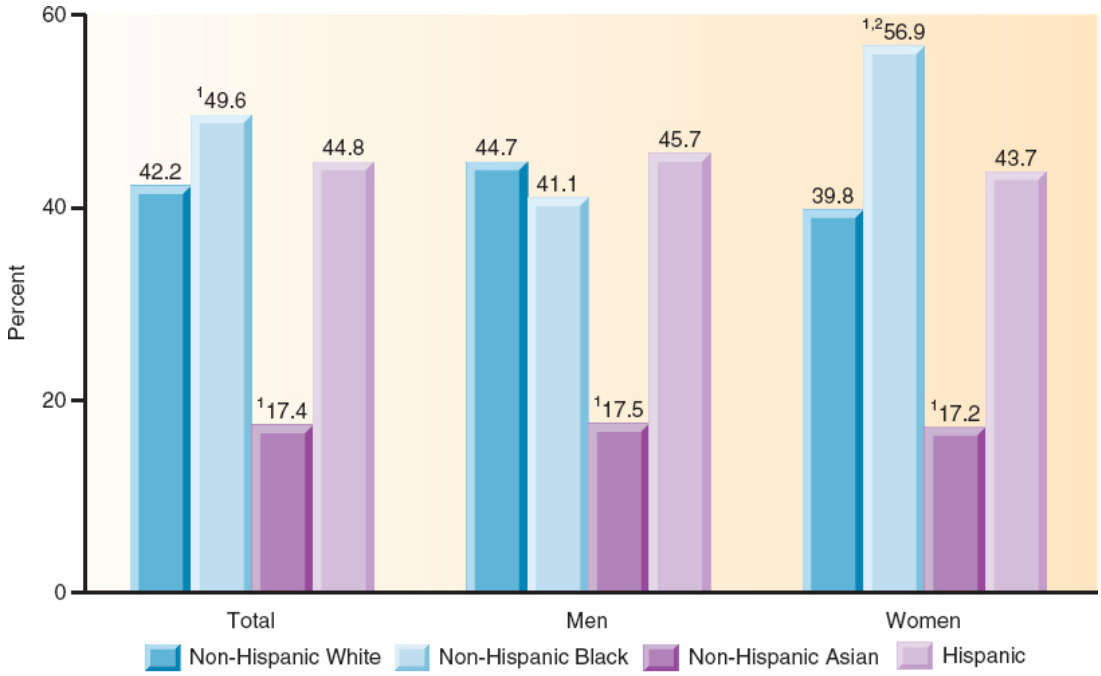
Obesity

Obesity is defined by the World Health Organization (WHO) as an "abnormal or excessive fat accumulation that may impair health" (WHO, 2018, p. 1). As a response to endorsements by multiple health care organizations and societies, including the American College of Cardiology, the Endocrine Society, and the

American College of Surgeons, to name a few, the American Medical Association (AMA) House of Delegates in 2013 officially resolved that obesity should be diagnosed and treated as a disease (AMA, 2013). This resolution was based on the scientific observation that obesity followed criteria commonly used for defining a disease; namely, it can be said that obesity impairs normal bodily function, possesses characteristic signs and symptoms, and causes morbidity (AMA, 2013).

Epidemiology of Obesity

Worldwide, over 650 million adults have obesity, and another 1.9 billion are overweight (WHO, 2018). Since 1975, the prevalence of obesity has more than tripled for men, and more than doubled for women. In particular, 3% of the world's men and 6% of the world's women had obesity in 1975, whereas 11% of the world's men and 15% of the world's women had obesity in 2016 (WHO, 2018). The burden of obesity is significant in both developed and developing nations. The WHO (2018) notes that many developing nations are now facing a "double-burden" effect from disorders linked to nutrition and metabolism; that is, these nations must simultaneously deal with the public health threats of both undernutrition and obesity. In developing nations, obesity has become particularly prevalent in urban settings (WHO, 2018).



Since 1980, the number of adults with obesity in the United States has continued to rise (Henry, 2018; Trust for America's Health [TFAH] & Robert Wood Johnson Foundation [RWJF], 2018). The prevalence of obesity in the United States is now the 12th highest among nations in the world, with Nauru, an island nation in Micronesia, being first, with an obesity prevalence of 61% (Hales, Carroll, Fryar, et al., 2020; Hales, Fryar, Carroll, et al., 2018). Among American adults, an estimated 42.4% have obesity (Hales et al., 2020); an estimated 70.9% have obesity or are overweight (Hales et al., 2018). The overall prevalence of overweight and obesity is slightly higher among American women than American men, and among African Americans and Hispanics than among Whites or Asian Americans (see Fig. 42-1). In general, those who are less educated and earn less income are more likely to have obesity, reflecting socioeconomic disparities in the disease burden of obesity (Hales et al., 2018; TFAH & RWJF, 2018). Being overweight or having obesity is the primary reason why young American adults are excluded from military service (Warren, Beck, & Rayburn, 2018) (see later discussion in Veterans Considerations section).

The economic burden of obesity to American society extends beyond limiting young adults with obesity from pursuing military service commitments. It is estimated that annual health care costs tied to obesity are approximately $190 billion (Warren et al., 2018), and that average annual health care expenditures for Americans with obesity are $3429 higher per person than for those Americans without obesity (Biener, Cawley, & Meyerhoefer, 2017).

Obesity Risks

The causes of obesity are complex and multifactorial, and include behavioral, environmental, physiologic, and genetic factors. While there are certain demographic groups who seem to be at risk for obesity (see Fig. 42-1) and while there are notable familial patterns of obesity, identification of risk factors that specify odds of being diagnosed with obesity is not as clearly elucidated as those for other diseases (Centers for Disease Control and Prevention [CDC], 2020), such as coronary artery disease (see Chapter 23) and cerebrovascular disease (see Chapter 62).

What is abundantly clear, however, is that obesity incurs a greater overall risk of mortality. Obesity alone does not decrease a person's lifespan (Kuk, Rotondi, Sui, et al., 2018). However, obesity is associated with a 2- to 6-year decrease in overall life expectancy when coupled with metabolic disease or another chronic illness (Khan, Ning, & Wilkins, 2018). Furthermore, obesity is associated with morbidity and mortality from numerous other diseases (see Fig. 42-2 and Chart 42-1). For instance, as body mass index (BMI) increases, so does the overall risk of cancer and risk for death from cancer; obesity is responsible for up to 90,000 deaths from cancer annually. Having obesity increases the likelihood of having type 2 diabetes by 10-fold and the likelihood of having either asthma or hypertension by nearly fourfold (American Society for Metabolic and Bariatric Surgery [ASMBS], 2019b). Adults with obesity are twice as likely to eventually be diagnosed with Alzheimer's disease than those adults who maintain a normal weight (Biener et al., 2017).

[1]Significantly different from all other race and Hispanic-origin groups.
[2]Significantly different from men for same race and Hispanic-origin group.
NOTES: Estimates were age adjusted by the direct method to the 2000 U.S. Census population using the age groups 20–39, 40–59, and 60 and over. Access data table for this figure at: https://www.cdc.gov/nchs/data/databriefs/db360_tables-508.pdf#2.

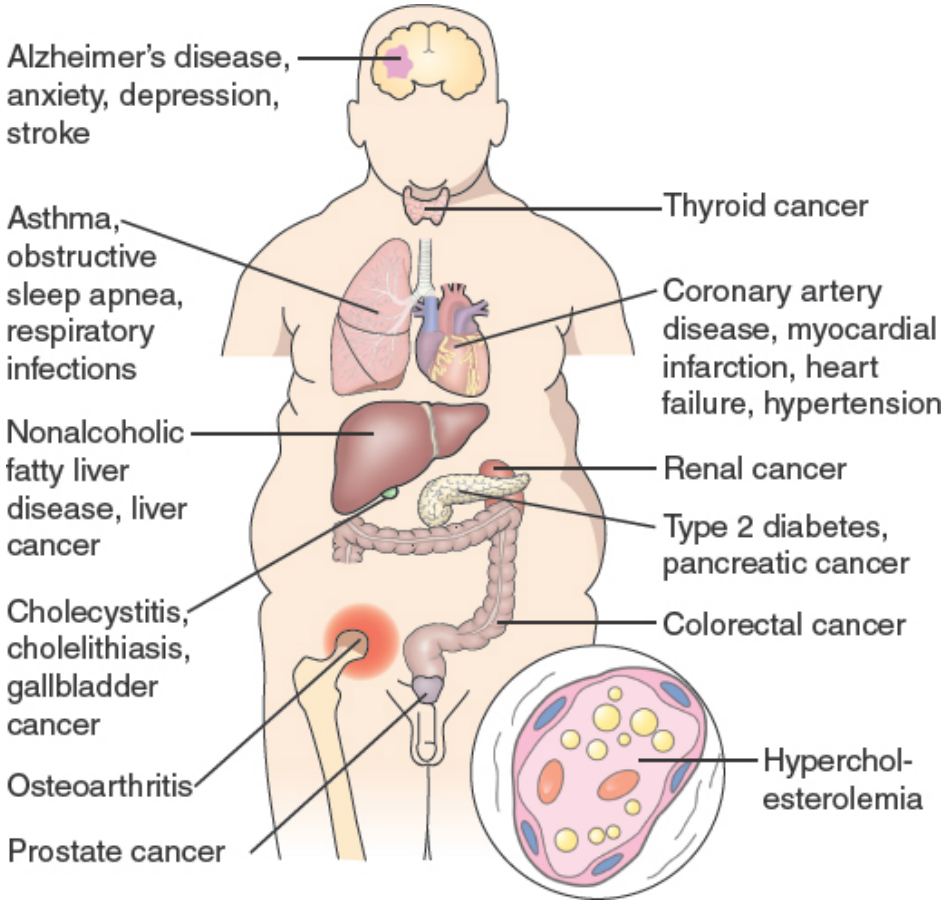

Figure 42-2 • Morbid diseases and disorders associated with obesity.

Chart 42-1

Diseases and Disorders Associated with Obesity

Alzheimer's disease
Anxiety and depression
Asthma
Cancers (breast, cervical, colorectal, endometrial, esophageal, gallbladder, liver, ovarian, non-Hodgkin lymphoma, pancreatic, prostate, kidney, thyroid)
Chronic low back pain
Coronary artery disease (angina, acute coronary syndrome, myocardial infarction)
Diabetes (type 2)
Gallbladder disease (cholecystitis, cholelithiasis)
Gastroesophageal reflux disease (GERD)
Gout
Heart failure
Hypercholesterolemia
Hypertension
Nonalcoholic fatty liver disease
Obstructive sleep apnea
Osteoarthritis
Respiratory infections
Stroke

Pathophysiology

Obesity is a chronic, relapsing disease characterized by an excessive accumulation of body fat and weight gain (ASMBS, 2019a). These increases in body fat cause **adiposopathy**, a dysfunction of adipose tissue, which promotes the development of metabolic, biomechanical, and psychosocial diseases and disorders (Fruh, 2017; Wu & Berry, 2018). Dysfunctional adipose tissue cells release biochemical mediators that cause chronic inflammatory changes, which can lead to a multitude of diseases, including heart disease, hypertension, and type 2 diabetes (ASMBS, 2018a).

At the most fundamental level, obesity results from a metabolic imbalance, characterized by an excess of caloric consumption relative to caloric expenditures. That is, too many foods are consumed and too little physical activity is conducted over the long term, resulting in weight gain (Norris, 2019). According to the "thrifty gene" hypothesis, the human **genome** (i.e., the total complement of genes in humans) was sequenced during times when finding and storing food sources expended more energy than during contemporary times.

Hunting for scarce food sources during prehistoric times consumed a lot of energy, and food sources were not abundant. Storing fat to provide energy sources during times of food scarcity was a physiologic adaptive response to these environmental challenges (van Meijel, Blaak, & Goossens, 2018).

The "thrifty gene" hypothesis has come under scrutiny in recent years, however, as human genome sequencing research findings suggest that a far more complex genetic explanation may be responsible for the recent global obesity pandemic. Research has identified 79 syndromes and 31 genes that cause obesity through monogenic (single gene) mutations and polygenic (multiple gene) mutations as well as gene–environment interactions (Rohde, Keller, la Cour Poulsen, et al., 2019). Although to date only 19 syndromes have been genetically characterized, it has been recognized that having at least one different genetic mutation can strongly predispose people who have ready access to food sources to having obesity (Rohde et al., 2019). For instance, the presence of a variant mutation of the *FTO* gene is associated with more daily meals, snacks, and fat and sweet intake (Rohde et al., 2019). However, these types of single genetic mutations are relatively rare occurrences, and therefore cannot account for the high prevalence of obesity. Most people who are predisposed to obesity are thought to have a collection of several genetic mutations from more than 700 possible mutated genes that each can contribute to several pounds of additional body fat (Yengo, Sidorenko, Kemper, et al., 2018).

The types and quantities of foods consumed affect complex digestive and metabolic pathways. Certain processed and high caloric foods that contain fructose corn syrup, simple sugars, or trans fats, are hypothesized to be **obesogenic** (i.e., promote weight gain) because they are associated with food cravings consonant with other type of addictive cravings (Campana, Brasiel, de Aguiar, et al., 2019). Additionally, the portions of both entrees and desserts served in fast food restaurants have increased over the past 30 years, subtly affecting consumers' feelings of **satiety** (i.e., feeling of having eaten sufficient amounts of food) (McCrory, Harbaugh, Appeadu, et al., 2019). Furthermore, there is a greater variety of entrees and desserts that may be selected on the menus of most fast food restaurants, providing the illusion of healthier meal options although there are actually less healthy food alternatives available for selection than 30 years ago (McCrory et al., 2019).

Multiple hormones that control food cravings and feelings of fullness could be affected by individual genes. In response to periods of fasting, the hormone ghrelin is secreted by the stomach and the hormone neuropeptide Y (NPY) is secreted by the small intestines. These hormones are **orexigenic**, meaning that they stimulate appetite through central nervous system (CNS) pathways that lead to the hypothalamus, signaling higher neural pathways that lead to eating behaviors. Once eating occurs, multiple hormones are released throughout the gastrointestinal (GI) tract that promote satiety, including somatostatin, cholecystokinin (CCK), and insulin, to name a few. CCK also slows gastric motility and emptying, stimulates gallbladder contraction and release of bile into

the duodenum, and stimulates the release of pancreatic digestive enzymes, all of which serve to enhance the digestive process. Somatostatin also slows gastric emptying but has other effects that are in opposition to CCK, such as decreasing the secretion of bile, depending on foods consumed and metabolic needs (Gimeno, Briere, & Seeley, 2020).

Increases in fat stores, or adipose tissue, result in increases in the hormone leptin, which is secreted by fat cells. Leptin also has the effect of signaling satiety in the hypothalamus. Patients with obesity who lose weight are thought to also have drops in leptin levels that persist for the long term, creating persistent feelings of hunger, which may partially explain why many patients with obesity who lose weight tend to regain it (Campana et al., 2019).

By adulthood, the GI tract **microbiota**, which is the complement of microbes within the gut, has been found to contain up to 100 trillion microbes, or 10 times the cells present in the human body (McElroy, Chung, & Regan, 2017). The collective genome of the microbiota, or the gut **microbiome**, has more than 100 times more genes than in the human genome. It has long been known that gut microbes perform numerous digestive, metabolic, and immunologic functions. The composition and diversity of these microbes may very well be tied in with obesity (McElroy et al., 2017). For instance, patients with obesity tend to have less diverse microbiota than patients who are of normal weight. In turn, patients with obesity who have less diverse microbiota typically also have dyslipidemia, impaired glucose metabolism, and low-grade generalized inflammatory disorders. "Western-style diets," which are high in processed foods, fat, and sugars and low in fiber, are thought to not only negatively affect the diversity of the gut microbiota, but also to negatively affect the complement of *Bacteroidetes* species microbes, which are associated with a leaner type of microbiome (McElroy et al., 2017). Whether or not it is possible to regulate the composition of the gut microbiota and prevent or treat obesity is the focus of ongoing research.

Assessment of Obesity

Assessment of the patient with obesity includes a health history and physical examination that evaluates the effects of obesity on the health of the patient.

Health History

Nurses need to approach patients with obesity with the same respectful, courteous, and empathetic behavior that they extend to patients without obesity. Confronting their own attitudes and beliefs about patients with obesity may help to mitigate biases. For instance, using patient-first language for all patients with diagnosed diseases, including the disease of obesity, can be an effective way to dispel bias. By referencing *the patient with obesity,* the nurse is effectively noting that the patient, not the disease, is the central point of concern and that the disease is amenable to treatment. On the other hand, referencing *the obese*

patient tends to define the person by having obesity, which can lead to subliminal impressions that the patient is somehow responsible for having obesity. Research studies report that many health care providers, including nurses, hold negative attitudes toward patients with obesity and believe that they are indulgent, lazy, and lack willpower (Robstad, Westergren, Siebler, et al., 2019; Smigelski-Theiss, Gampong, & Kurasaki, 2017).

Patients with obesity should be assessed to see if there have been any recent increases or decreases in body weight. If the patient has recently lost or gained weight, determining if that is intentional weight loss or gain may give clues to whether or not changes in weight might be secondary to another disease process. Other useful health history information to gather includes how long the patient has had obesity (e.g., since childhood, since a pregnancy) and whether or not there is a family history of obesity. Any patterns of weight loss over time, and prior successful or unsuccessful weight loss strategies should be analyzed. A history of exercise patterns and dietary patterns (see Chapter 4 for discussion of nutritional assessment) is also assessed. Some patients with obesity report sleep pattern disturbances (e.g., difficulty falling asleep, difficulty staying asleep); therefore, typical sleeping habits are evaluated. Some patients who quit smoking report significant weight gain after smoking cessation is achieved; consequently, the patient's smoking status is also determined (Perreault, 2020).

Some patients with obesity may develop secondary diseases or disorders (see Chart 42-1) and may be prescribed medications aimed at treating those secondary diseases or disorders that can exacerbate weight gain (see Chart 42-2). Other patients may not have had a previous history of obesity, but may gain weight after being prescribed specific medications associated with weight gain. A history of weight gain that parallels the time frame of commencing treatment with specific prescriptive medications may suggest that the medication has a key role in promoting weight gain. In some instances, prescription medication dosages may be adjusted or another medication may be prescribed. For instance, patients with type 2 diabetes and obesity may reap the dual benefits of achieving better glycemic control and weight loss by taking the prescription drug metformin (Apovian, Aronne, Bessesen, et al., 2015).

Physical Assessment

Patient's height and weight are measured to determine the **body mass index (BMI)**. The BMI is the definitive measure used to determine whether or not a patient has obesity; this is based on a ratio of body weight in kilograms and height in meters (see Chapter 4, Table 4-1). Patients identified as overweight or pre-obese have a BMI of 25 to 29.9 kg/m^2 and those with obesity have a BMI that exceeds 30 kg/m^2. Those with a BMI exceeding 40 kg/m^2 are considered to have severe or extreme obesity (Nguyen, Brethauer, Morton, et al., 2020; WHO, 2017) (see Fig. 42-3 and Table 42-1).

Chart 42-2  PHARMACOLOGY

Select Medications That Affect Body Weight

Many medications prescribed to treat a variety of chronic diseases and disorders have the untoward side effect of weight gain, whereas others are associated with weight loss. The following list contains some examples of each of these.

Medications Associated with Weight Gain

Anticonvulsant Medications:

- Carbamazepine
- Gabapentin
- Pregabalin
- Valproate
- Vigabatrin

Antidepressant Medications:

- Selective Serotonin Reuptake Inhibitors (SSRIs) (Note—these tend to be associated with early weight loss followed by gain within 6 months in some patients):
  - Citalopram
  - Escitalopram
  - Fluvoxamine
  - Paroxetine
  - Sertraline
- Tricyclic Antidepressants:
  - Amitriptyline
  - Clomipramine
  - Doxepin
  - Imipramine
  - Mirtazapine
  - Nortriptyline
  - Protriptyline
  - Trimipramine

Antihistamines:

- Azelastine
- Cetirizine
- Cyproheptadine
- Diphenhydramine
- Fexofenadine

Antihypertensive Medications:

- Alpha-Blocker:
  - Terazosin
- Beta-Blockers:

    - Atenolol
    - Metoprolol
    - Propranolol
- Dihydropyridine Calcium Channel Blockers:
    - Amlodipine
    - Felodipine
    - Nifedipine

Antipsychotic Medications:

- Asenapine
- Chlorpromazine
- Clozapine
- Haloperidol
- Iloperidone
- Olanzapine
- Paliperidone
- Quetiapine
- Risperidone

Diabetes Medications:

- Insulins:
    - Insulin aspart
    - Insulin glulisine
    - Insulin lispro
- Meglitinides:
    - Nateglinide
    - Repaglinide
- Sulfonylureas:
    - Chlorpropamide
    - Glimepiride
    - Glipizide
    - Glyburide
    - Tolbutamide
- Thiazolidinedione:
    - Pioglitazone

Hormones:

- Corticosteroids:
    - Prednisone
    - Budesonide
    - Methylprednisolone
- Hormonal Contraceptive:
    - Medroxyprogesterone

Mood Stabilizers:

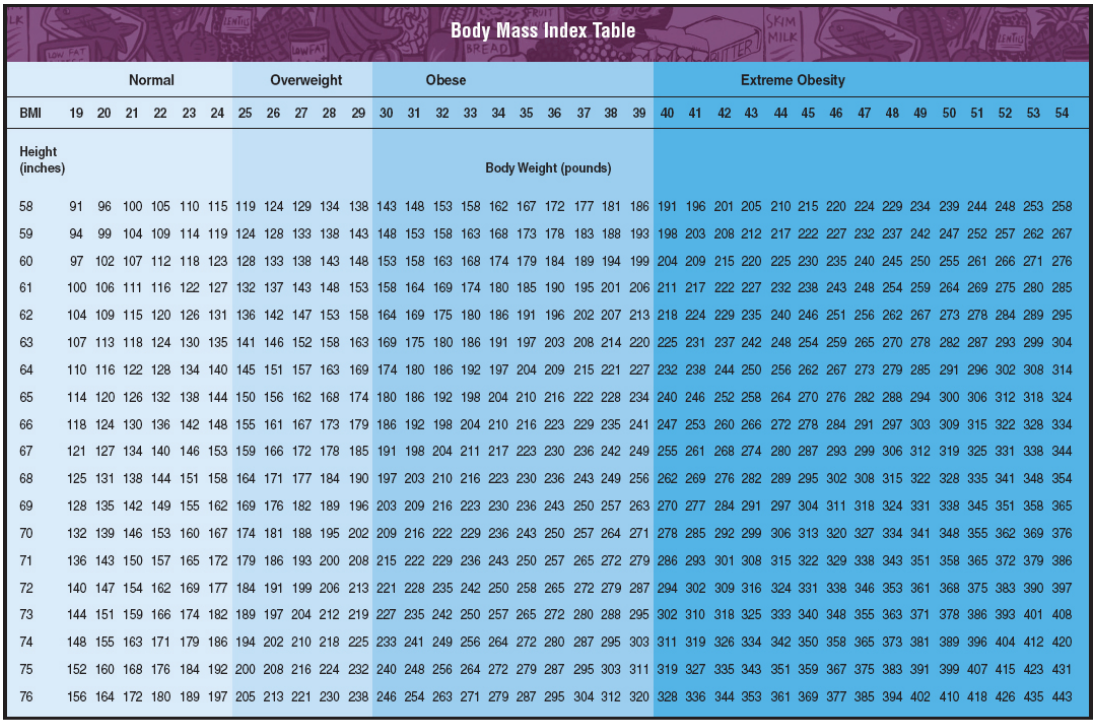
- Lithium

Medications Associated with Weight Loss

Anticonvulsant Medications:

- Lamotrigine
- Topiramate
- Zonisamide

Antidepressant Medication:



- Bupropion
- Desvenlafaxine
- Venlafaxine

Diabetes Medication:

- Dulaglutide
- Exenatide
- Liraglutide
- Lixisenatide
- Metformin
- Semaglutide

Medications that may increase weight. Retrieved on 5/1/2020 at: www.obesitymedicine.org/medications-that-cause-weight-gain

Patients with obesity may also have their waist circumferences assessed. Women with waist circumferences more than 35 inches and men with waist circumferences more than 40 inches have greater risks for obesity-related morbidity (see Chart 42-1) than those with smaller waistlines (Meigs, 2019). The hip may also be measured and the waist-to-hip ratio assessed. Women with waist-to-hip ratios greater than 0.80 and men with waist-to-hip ratios greater than 0.90 are presumed to have proportionally more visceral (i.e., abdominal) fat stores. This morphologic appearance is called android obesity, and is sometimes referenced as an "apple-shaped" appearance. Patients with android obesity have greater risk for developing hypertension, coronary artery disease, stroke, and type 2 diabetes, than patients who have gynoid obesity, also called the "pear-shaped" body (Weber & Kelley, 2018) (see Fig. 42-4).

Body Mass Index Table

	Normal						Overweight					Obese										Extreme Obesity																
BMI	19	20	21	22	23	24	25	26	27	28	29	30	31	32	33	34	35	36	37	38	39	40	41	42	43	44	45	46	47	48	49	50	51	52	53	54

Diagnostic Evaluation

Patients with obesity may have other diagnostic laboratory studies done to screen for cardiovascular diseases, such as cholesterol and triglycerides (see Chapter 23), for type 2 diabetes, such as fasting blood glucose and glycosylated hemoglobin (hemoglobin A1c) (see Chapter 46), or for nonalcoholic fatty liver disease, such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT) (Orringer, Harrison, Nichani, et al., 2020) (see Chapter 43). Obesity is the most important risk factor for obstructive sleep apnea (OSA), particularly among older men (Kline, 2020); therefore, the older male patient with obesity and sleep disturbances may undergo diagnostic sleep studies (see Chapter 18).

TABLE 42-1 Body Mass Index (BMI) Classification for Overweight and Obesity

Classification	BMI Range (kg/m^2)
Overweight/pre-obese	25–29.9
Class I obesity	30–34.9
Class II obesity	35–39.9
Class III (also called "extreme" or "severe") obesity	≥40

Adapted from Centers for Disease Control and Prevention (CDC). (2017). Defining adult overweight and obesity. Retrieved on 8/3/2019 at: www.cdc.gov/obesity/adult/defining.html

In some instances, obesity may be secondary to other diseases or disorders, such as hypothyroidism or Cushing's syndrome (see Chapter 45). In those particular cases, the diagnostic workup follows that prescribed for the primary disease or disorder, and, when the therapeutic regimen is implemented, the patient may lose weight and the obesity may even resolve (Orringer et al., 2020).

Medical Management

Treatment of obesity generally includes lifestyle modification, pharmacologic management, and nonsurgical or surgical interventions.

Lifestyle Modification

The first approach used to treat obesity consists of lifestyle modification aimed at weight loss and then weight maintenance. The U.S. Preventive Services Task Force (USPSTF) recommends that all adults with BMIs in excess of 30 kg/m^2 be advised to engage in multicomponent behavioral interventions that include (Curry, Krist, Owens, et al., 2018; LeBlanc, Patnode, Webber, et al., 2018):

- Setting weight loss goals,
- Improving lifestyle behaviors (e.g., diet habits, physical activity),
- Addressing barriers to change,
- Considering use of adjunctive pharmacotherapy agents, and
- Self-monitoring and strategizing ongoing lifestyle changes aimed at a healthy weight.

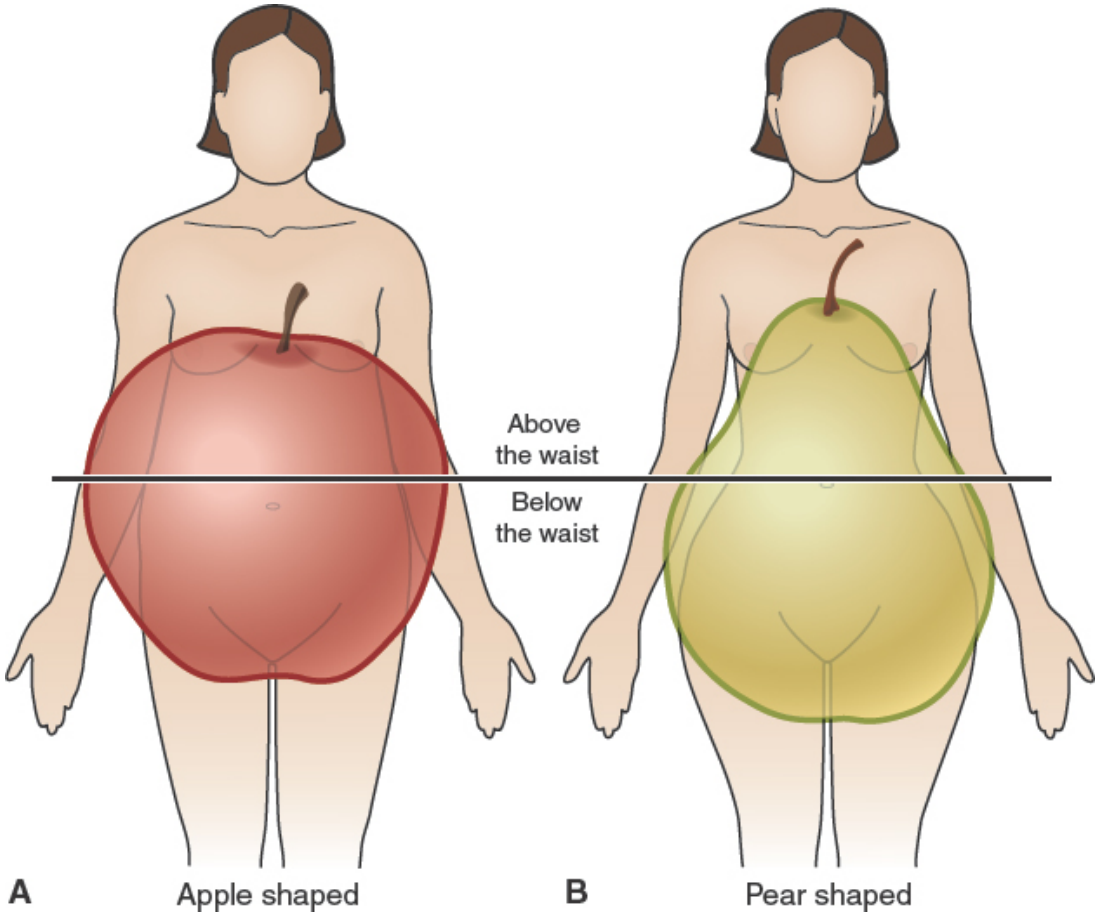

Figure 42-4 • **A.** Android obesity, with greater visceral/abdominal fat stores. **B.** Gynoid obesity. Reprinted with permission from Weber, J. R., & Kelley, J. H. (2018). *Health assessment in nursing* (6th ed.). Philadelphia, PA: Wolters Kluwer.

The most effective behavioral interventions are those considered high intensity; consisting of 12 to 24 sessions annually, which may include individual counseling sessions between the primary provider and patient, group nutrition education sessions, and physical activity sessions, to name a few (LeBlanc et al., 2018; Wadden, Tsai, & Tronieri, 2019). These interventions are called intensive behavioral therapy. The USPSTF notes that modest weight loss of 5% total body weight can be associated with significant clinical improvements and benefits to patients with obesity (LeBlanc et al., 2018).

A patient with obesity should be counseled to plan a caloric deficit of between 500 and 1000 calories daily from baseline, in order to achieve a 5% to 10% reduction in weight within about 6 months. This can be achieved through increasing physical activity and decreasing caloric dietary intake (Orringer et al., 2020).

Increasing physical activity through promotion of an exercise regimen is a key recommendation that can burn calories and result in weight loss. Physical activity recommendations for all adults (those with and without obesity) include at least 150 minutes of moderate-intensity aerobic exercise weekly or 75 minutes

of vigorous-intensity aerobic exercise weekly. In addition, muscle-strengthening exercises that engage all major muscle groups should be done at least twice weekly (Orringer et al., 2020). Patients with obesity who were previously sedentary and deconditioned may not be able to achieve this at the start; however, encouragement to move more and sit less along with 10 to 20 minutes of daily physical activity can result in weight loss and improved exercise tolerance (Campbell & Rutherford, 2018; DiPietro & Stachenfeld, 2017; Orringer et al., 2020).

Patients with obesity should be counseled that reducing dietary caloric intake is a necessary component of weight loss therapy. This must also include a change in dietary habits in order for weight loss to be sustained over the long term. It is important to identify current dietary patterns and typical daily caloric intake in order to recommend an appropriate diet plan. Assessing food records or 24-hour recalls or conducting dietary interviews are all effective methods to gather baseline dietary information from patients (see Chapter 4: Dietary Data). There are a plethora of commercial diets that patients may select (see Chart 42-3). Regardless of the diet plan chosen, successful weight loss occurs when patients consistently make healthier dietary choices (Thorn & Lean, 2017). To date, there have not been sufficiently rigorous longitudinal studies to determine which diet plans are superior to others in terms of achieving long-term weight loss, however (Yeh, Glick-Bauer, & Katz, 2017).

Patients need not purchase commercial diet plans in order to achieve weight loss and embrace healthy diet habits. Most nutritionists advocate that healthy diets include few processed foods, sugars, and trans fats, and are heavy in plant-based foods (Yeh et al., 2017). The Dietary Approaches to Stop Hypertension (DASH) diet is an example of a superior healthy noncommercial diet. Although initially promoted to manage hypertension, the DASH diet also provides a solid foundation for achieving and maintaining weight loss due to its focus on low intake of fat and carbohydrates (Goldstein, Mayer, Graybill, et al., 2020; Thorn & Lean, 2017) (see Chapter 27, Table 27-3: The DASH Diet). Another healthy diet plan that may form a basis for weight loss, though not specifically designed for this purpose, is the Mediterranean Diet (see Chapter 23). Patient education tips for managing ongoing healthy eating strategies are noted in Chart 42-4.

Chart 42-4 PATIENT EDUCATION

Healthy Eating Strategies

The nurse instructs the patient about the healthy eating strategies outlined below.
Limit or eliminate the following:

- Processed foods with limited nutritional value (e.g., packaged cakes, cookies, chips)
- High caloric beverages (sugar-sweetened, juices, cream-enhanced)
- Fast foods
- Vending machine foods
- Foods high in sugars (e.g., candies) and saturated fats (e.g., fried foods, hot dogs)

Track the following:

- Daily food intake (food journals, diaries, smartphone, and tablet applications)
- Nutritional value and caloric content on food labels

Encourage the following:

- Reduce portions; use smaller plates and measure foods
- Schedule and plan meals and snacks in advance for each day; prepack lunches and snacks when you are out of the home (e.g., for work)
- Eat at home more often than you would eat outside the home; when eating out or ordering take-out food, avoid fried foods and choose lean meats and vegetables and salads with condiments on the side
- Eat with your family members so that together you create a healthy eating environment
- Avoid screen time when eating
- Limit exposure to food and beverage marketing
- Eat breakfast
- Limit snacks
- Eat a variety of nutritious foods; monitoring quality of foods consumed is as important as the quantity of foods consumed
- Drink plenty of water
- Stay within your daily caloric intake plan; do not become discouraged if one day you do not adhere to your plan

Adapted from Orringer, K. A., Harrison, A. V., Nichani, S. S., et al. (2020). University of Michigan Health System Clinical Alignment and Performance Excellence Guideline: Obesity prevention and management. Retrieved on 5/1/2020 at: www.med.umich.edu/1info/FHP/practiceguides/obesity/obesity.pdf

In addition to promoting healthy exercise and diet habits, ensuring healthy sleep habits is an additional lifestyle strategy that is associated with weight loss

and maintenance of a healthy weight. It is posited that sleep deprivation can cause changes in cortisol levels that promote weight gain (Orringer et al., 2020). Advising patients with sleep disturbances to plan to be in bed with lights out at least 7 hours prior to wake-up time, to create a dark, relaxing bedroom environment, to avoid activities that can cause arousal around bedtime (e.g., text messaging), and to avoid beverages with caffeine after lunchtime can all be helpful strategies aimed at ensuring a restful night's sleep that is consonant with weight reduction (Orringer et al., 2020).

Pharmacologic Therapy

Patients who are not successful at meeting weight loss goals from lifestyle modification alone may be prescribed antiobesity medications. Some patients may exhibit initial success with lifestyle modifications, but be stymied with attempts to maintain a lower BMI over the long term. These patients may also benefit from antiobesity medications. Patients who are prescribed antiobesity medications should be counseled that these prescriptions are meant to supplement, not supplant diet modification and exercise (Coulter, Rebello, & Greenway, 2018; Saunders, Umashanker, Igel, et al., 2018). Indications for antiobesity medications include a BMI greater than 30 kg/m^2 or a BMI greater than 27 kg/m^2 with concomitant morbidity that is related to being overweight (e.g., type 2 diabetes, hypertension) (Saunders et al., 2018).

Antiobesity medications work by either inhibiting GI absorption of fats, or by altering central brain receptors to enhance satiety or reduce cravings (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2016b). Each of these medications has distinct side effects and contraindications; therefore, selection of these agents is individualized (see Table 42-2). The patient is monitored while taking the selected medication; if the patient does not lose at least 5% body weight after 12 weeks, the prescription may need to be changed, or the patient may be referred for other weight-reduction therapy (e.g., bariatric surgery) (NIDDK, 2016b).

Quality and Safety Nursing Alert

Antiobesity medications are believed to be teratogenic. Women with obesity who are of childbearing years should be screened carefully and advised to avoid pregnancy if they seek a prescription for an antiobesity medication.

The class of antiobesity medications known as the sympathomimetic amines are only supposed to be prescribed for short-term use (i.e., no longer than 12 weeks). They have many side effects (see Table 42-2), and patients do tend to regain weight once they are no longer taking these medications (NIDDK, 2016b).

Nonsurgical Interventions

Adult patients with obesity that does not respond to lifestyle interventions or antiobesity medications and who have either Class III/severe/extreme obesity (i.e., BMI in excess of 40 kg/m^2) or Class II obesity (BMI 35 to 39.9 kg/m^2) with obesity-related diseases or disorders (e.g., OSA, type 2 diabetes) may be candidates for bariatric surgical interventions (see later discussion). As an alternative, some patients may elect to pursue minimally invasive interventions, which may include vagal blocking therapy, intragastric balloon therapy, or bariatric embolization.

Vagal blocking therapy, also known as gastric stimulation, involves placement of a pacemakerlike device (vBloc™) into the subcutaneous tissue in the lateral thoracic cavity with two leads that are laparoscopically implanted at the point where the vagus nerve truncates, at the gastroesophageal junction. A pre-programmed, pulsating signal is delivered for 12 hours daily. This signal causes intermittent "blocking" of the vagus nerve. Vagal blocking results in diminished gastric contraction and emptying, limited ghrelin secretion, and diminished pancreatic enzyme secretion; these cause increased satiety, decreased cravings, and diminished absorption of calories, all of which lead to weight loss (Papasavas, El Chaar, Kothari, et al., 2016). Results from a randomized controlled trial found greater initial and 2-year sustained weight loss with participants with obesity who received vagal blocking versus control sham device implantation (Vairavamurthy, Cheskin, Kraitchman, et al., 2017). There are few adverse effects noted with use of this device, which include GI symptoms (e.g., heartburn, belching). Patients must be educated to recharge the device twice weekly for about an hour with an external coil device.

TABLE 42-2  Medications Prescribed to Treat Obesity

Medication	Adverse Effects	Nursing Considerations[a]
Gastrointestinal Lipase Inhibitor Mechanism of Action: Diminishes intestinal absorption and metabolism of fats, particularly triglycerides		
Orlistat *Note: Also available in lower dosages over-the-counter*	Diarrhea Flatus Oily stools Fecal incontinence	Patients may have associated problems with malabsorption of nutrients; advise them to take a concomitant daily multivitamin. Caution in patients with known history of renal insufficiency, liver disease, or gallbladder disease as concomitant use is associated with renal calculi, liver failure, and cholelithiasis. Do not administer with cyclosporine.
Selective Serotonin Receptor Agonist Mechanism of Action: Stimulates serotonin 5-HT2C receptors, causing excretion of the alpha-melanocortin–stimulating hormone (alpha-MSH) and elicits appetite suppression		
Lorcaserin	Fatigue Dizziness Nausea Headaches Cough Dry mouth Constipation	Encourage patient to stay well hydrated. Can be associated with deficits in attention or memory; administer with caution in patients who drive or work with hazardous equipment when first prescribed until effects are realized. Can cause hypoglycemia in patients with diabetes. Contraindicated for patients taking antidepressants or migraine medications due to synergistic effects. Discontinue in patients who express suicidal ideation. Rarely, serotonin syndrome may develop—be alert for high fevers, brisk reflexes, agitation, and diarrhea; notify primary provider immediately and hold medication if these occur.
GLP-1 Receptor Agonists Mechanism of Action: Mimics the effects of incretins, resulting in delayed gastric emptying, thus curbing appetite		

Liraglutide *Note: Also available in lower dosages to treat type 2 diabetes*	Nausea Diarrhea or constipation Headache Tachycardia	Must be given subcutaneously on a daily basis in the abdomen, thigh, or upper arm. Dosage increases weekly until week 5. Discontinue in patients who express suicide ideation. May be associated with pancreatitis; also associated with thyroid tumors in animal models.
Sympathomimetic Amines Mechanism of Action: Stimulate central noradrenergic receptors, causing appetite suppression		
Phentermine Benzphetamine Diethylpropion Phendimetrazine	Palpitations and tachycardia Tremors Hypertension Dizziness Insomnia Diarrhea or constipation Mouth dryness Restlessness Alterations in taste	These are only FDA approved for short-term use (i.e., no more than 12 weeks). Contraindications include heart disease, uncontrolled hypertension, hyperthyroidism, and glaucoma. Caution patients to not drink alcohol while taking one of these medications.
Dual Agents Mechanism of Action: Each of these medications combines two medications with known antiobesity effects; when taken together, the effects are synergistic		
Phentermine/topiramate-ER Mechanism of Action: combines the effectiveness of phentermine (see above) and topiramate, an anticonvulsant, which stimulates central GABA receptors and inhibits central glutamate receptors, suppressing appetite	Paresthesias Dizziness Insomnia Mouth dryness Alterations in taste Insomnia Constipation Tachycardia	Same contraindications apply as for phentermine (see above). May need to monitor electrolytes, as hypokalemia and metabolic acidosis are possible. Monitor creatinine and watch for manifestations of renal calculi.
Naltrexone/bupropion Mechanism of action: inhibits central opioid receptors and inhibits reuptake of dopamine and norepinephrine selectively, resulting in diminished appetite and cravings	Constipation or diarrhea Nausea Vomiting Insomnia Dizziness Mouth dryness Hypertension Tachycardia	Contraindications include uncontrolled hypertension, epilepsy, history of eating disorder such as anorexia nervosa or bulimia, and history of alcohol abuse or history of substance use disorder. Discontinue in patients who express suicidal ideation.

[a]All antiobesity medications may be teratogenic; pregnancy is a contraindication to all of these agents.

Prescription medications to treat overweight and obesity. Retrieved on 2/18/2020 at: www.niddk.nih.gov/health-information/weight-management/prescription-medications-treat-overweight-obesity

Intragastric balloon therapy involves endoscopic placement of a gas-filled balloon (ORBERA™) or a saline-filled dual balloon (ReShape™) into the stomach. The mechanism by which these devices result in weight loss is poorly understood, but thought to be related to increased feelings of satiety and decreased gastric emptying (Kurian, Kroh, Chand, et al., 2018). Post insertion, the intragastric balloon(s) remain in place for 3 to 6 months, and are then deflated and removed. Studies suggest greater weight loss with these than with sham therapy or with lifestyle interventions alone (Ali, Moustarah, Kim, et al., 2015; Kurian et al., 2018). Early adverse effects include complaints of nausea and vomiting, which are generally transient and do not require balloon removal. Pancreatitis and gastric or esophageal perforation may also occur although these are rare adverse events (Moore & Rosenthal, 2018). Balloon rupture can occur over the long term, however, which may lead to intestinal obstruction. In order to monitor for this serious complication, it is recommended that the balloon be impregnated with methylene blue pre-insertion so that patients with silent ruptures can report the presence of green urine to their primary providers and receive timely interventions to remove the deflated balloons before they cause obstruction. Patients who seem unlikely to return for follow-up appointments should not be candidates for intragastric balloons. Balloons should be removed within 6 months of placement; longer placement periods are associated with increased likelihood of rupture and intestinal obstruction (Ali et al., 2015).

Endovascular bariatric embolization is in the process of undergoing clinical trials to validate its safety and effectiveness. During this procedure, the gastric fundus is embolized with microspheres (beads) via the left gastric artery. The gastric fundus secretes approximately 90% of the orexigenic hormone ghrelin that is secreted in the body; therefore, it is posited that embolizing the fundus should effectively result in diminished secretion of ghrelin (Hafezi-Nejad, Bailey, Gunn, et al., 2019; Kurian et al., 2018). Preliminary results from clinical trials report an estimated weight loss ranging from 8% to 18% that is sustained for at least 1 year, without reported adverse events (Vairavamurthy et al., 2017).

Gerontologic Considerations

According to findings from the 2017–2018 United States National Health and Nutrition Examination Survey (NHANES), the prevalence of obesity for adults

60 years of age and older is 42.8%, slightly higher than the prevalence of obesity among all adults (Hales et al., 2020). Climbing rates of obesity among older adults mirrors the rate increases among all adults over the past few decades.

As adults age, lean skeletal mass decreases and adipose tissue increases. Adipose tissue does not burn calories as efficiently as lean skeletal mass; furthermore, basal metabolism drops by 2% for each additional decade of adult life. Therefore, older adults are more likely to gain weight unless they either increase activity levels or decrease their caloric intake (Eliopoulos, 2018).

Research suggests that older adults with obesity are at risk for complications that may negatively affect their quality of life. In particular, older adults with obesity may be at greater risk of falls and mobility impairments (Batsis & Zagaria, 2018; Messier, Resnik, Beavers, et al., 2018). Another study found that older adults with higher BMIs had more evidence of cognitive dysfunction compared to their normal weight counterparts (Rambod, Ghodsbin, & Moradi, 2020). More older adults with obesity are admitted to nursing homes than normal weight older adults (Zhou, Kozikowski, Pekmezaris, et al., 2017).

There is some evidence that older adults with an overweight body mass (i.e., between 25 and 29.9 kg/m^2) have reasonably good health outcomes; therefore, older adults who are overweight are not necessarily counseled to lose weight (Orringer et al., 2020). However, older adults with obesity (i.e., with BMIs in excess of 30 kg/m^2) should be encouraged to engage in lifestyle modifications, including diet and exercise, similar to younger adults (Orringer et al., 2020). Along with decreasing dietary caloric intake, older adult patients should be counseled that the quality of calories consumed should be the focus of the daily diet (see Chapter 8, Fig. 8-2). Fats should be limited to less than 30% of total calories, while proteins should comprise 10% to 20% of the daily diet. Intake of soluble fibers (e.g., oats, pectin) is particularly important since these can lower cholesterol levels and prevent cardiovascular diseases and cancers. Fewer than one third of older adults consume the recommended five servings of fruits and vegetables daily (Eliopoulos, 2018). Identifying barriers to consumption of these important sources of nutrients may help the older adult patient with obesity lose weight and adopt healthier eating habits. For instance, the older adult who has difficulty chewing raw fruits may enjoy fruit smoothies.

Whether or not older adult patients with obesity should be candidates for bariatric surgery (see later discussion) has been a point of ongoing debate. Research findings confirm that many older adults with obesity benefit from bariatric surgery, having outcomes and complications at rates comparable to their younger adult counterparts (Chouillard, Alsabah, Chahine, et al., 2018; Giordano & Victorzon, 2015). At present, there are no guidelines that identify the profile of which older adult patients with obesity can most benefit from bariatric surgery.

Veterans Considerations

Recruits into any branch of the U.S. military must meet prescribed height and weight requirements. Although these requirements vary slightly between branches of service, their general aim is to restrict recruitment to only applicants of normal weight. Despite having to meet height and weight standards during the recruitment process and then demonstrate the ability to meet standards of physical fitness on at least an annual basis, the rates of service members who have obesity or are overweight has reportedly tripled in the past 20 years (McCarthy, Elshaw, Szekeley, et al., 2017). The U.S. Department of Defense (DoD, 2019) reported that the overall prevalence of obesity (i.e., BMI greater than or equal to 30 kg/m^2) among men and women of all ages who serve in the Army, Navy, Marine Corps, and Air Force was 17.4% in 2019, reflecting a steady annual increase since 2014. Obesity in service members can hamper their ability to functionally meet their job requirements; as such, obesity in large sectors of the military population may adversely affect overall military readiness (McCarthy et al., 2017; Shiozawa, Madsen, Banaag, et al., 2019). Furthermore, service members with obesity utilize more health service resources than those who are of normal weight and risk nonvoluntary separation from military service because they cannot meet physical fitness requirements (Shiozawa et al., 2019).

The prevalence of obesity and overweight among the nearly 21 million military veterans in the United States is estimated to be higher than that in the general civilian population, suggesting that weight gain is widespread after separation or retirement from military service (Tarlov, Zenk, Matthews, et al., 2017). Tarlov and colleagues (2017) found that 89% of all veterans (approximately 19 million veterans) lived in areas of the country where access to supermarkets, grocery stores, fitness facilities, and parks was limited, which could partially explain weight gain in veterans. Other researchers have noted that cessation of having to meet physical fitness standards, changes in daily routines, and stresses incurred during military service can also partially explain why veterans may be at greater risk of obesity (Bookwalter, Porter, Jacobson, et al., 2019). Bookwalter and colleagues (2019) prospectively studied over 28,000 veterans who separated or retired from military service and found that approximately 36% of normal weight veterans became overweight and 26% of overweight veterans had obesity within 6 years post separation. Factors that mitigated weight gains in these veterans included engaging in at least 150 minutes of moderate activity weekly, not engaging in more than 7 hours of sedentary lifestyle behaviors daily, eating fast foods less than once per week, sleeping between 7 and 9 hours nightly, not currently smoking, and drinking at least one but no more than 14 alcoholic beverages weekly for men and no more than seven alcoholic beverages weekly for women (Bookwalter et al., 2019). These findings are consonant with the tenets of the United States Veterans Administration (VA) MOVE program, whose aim is to improve the health status of veterans with obesity by encouraging physical activity, good dietary choices, and weight reduction strategies (McCarthy et al., 2017; Tarlov et al., 2017).

COVID-19 Considerations

Several risks for both severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and pathogenesis to coronavirus disease 2019 (COVID-19) have been posed (see Chapter 66). Early epidemiologic data from China did not identify obesity as a risk for becoming infected with SARS-CoV-2. However, with the spread of the pandemic to both Europe and North America, the two continents with the highest prevalence of obesity in the world, that risk became apparent (Moriconi, Masi, Rebelos, et al., 2020). In particular, obesity seems to be a significant risk factor for younger adults requiring hospitalization to manage COVID-19 (Kass, Duggal, & Cingolani, 2020). Obesity is also associated with prolonged hospitalization, admission to critical-care units, and overall poorer outcomes in patients with COVID-19 (Kalligeros, Shehadeh, Mylona, et al., 2020; Moriconi et al., 2020; Tamara & Tahapary, 2020).

Nursing Management

Patients with obesity report feeling socially marginalized, judged, and unsupported by society at large. Many times, patients with obesity report that they suffer stigmatization by their health care providers, including nurses (Eisenberg, Noria, Grover, et al., 2019). The bias that nurses may have against patients with obesity may not directly affect their nursing care; however, indirectly, the consequences of this stigmatization can lead to poor health outcomes. Patients with obesity who feel stigmatized by their health care providers report increased depression, low self-esteem, and avoidance of health care appointments and health maintenance activities (e.g., diet and exercise) (Smigelski-Theiss et al., 2017).

The patient with obesity who requires medical-surgical nursing care, whether it is because the patient is admitted to the hospital, needs home health care, or is admitted to a transitional care setting, merits special considerations. Obesity can adversely affect the mechanics of ventilation and circulation, pharmacokinetics and pharmacodynamics, skin integrity, and body mechanics and mobility. These adverse effects are more common with higher BMIs; thus, the patient with Class III obesity (BMI in excess of 40 kg/m^2) is particularly vulnerable.

Obesity can result in anatomic remodeling, including compression of the oropharynx and increased neck circumference and chest diameter. These changes can predispose the patient with obesity to OSA (see Chapter 18), respiratory failure, and obesity hypoventilation syndrome. Obesity hypoventilation syndrome is characterized by daytime hypoventilation with hypercapnea (i.e., $PaCO_2$ greater than 45 mm Hg) and hypoxemia (i.e., PaO_2 less than 80 mm Hg), and sleep-disordered breathing. Potential adverse effects of obesity hypoventilation syndrome can be mitigated by maintaining the patient in the low Fowler position, which maximizes diaphragmatic chest expansion. Continuous

pulse oximetry monitoring may be advisable, as well as supplemental oxygen therapy (see Chapter 19) and frequent respiratory assessments (at least every shift). For the patient with a known diagnosis of OSA, ensuring that the patient utilizes prescribed therapy (e.g., oral appliance, continuous positive airway pressure [CPAP]) if newly hospitalized or in a different transitional care environment is important in order to ensure breathing effectiveness and avoid respiratory failure (Haesler, 2018; Holsworth & Gallagher, 2017; Petcu, 2017).

The patient with obesity may have central and peripheral circulatory compromise. Heart failure is more commonplace among patients with obesity (see Chapter 25). Hypertension is also more prevalent; the nurse must use appropriately sized blood pressure cuffs to obtain valid blood pressure readings (see Chapter 27). Peripheral blood flow can be compromised for the patient with obesity, resulting in stasis of blood flow, one of three components of the Virchow triad, which is the broad category of risk for venous thromboembolism (VTE) (see Chapter 26, Chart 26-8). Peripheral circulatory compromise not only can increase the risk for VTE formation (e.g., pulmonary embolism [PE] and deep vein thrombosis [DVT]), but it can also make finding venous access difficult when the patient with obesity requires intravenous (IV) therapy. Finding appropriate venous access can be exacerbated by the presence of increased adipose tissue in the extremities. Ultrasound guidance may be required in order to successfully gain IV access and place an IV cannula in the patient with obesity (Oliver, Oliver, Ohanyan, et al., 2019).

The patient with obesity may have differences in both pharmacokinetics (i.e., the movement of drug metabolites within the body) and pharmacodynamics (i.e., how drugs are metabolized and the effects of drugs) that can affect drug dosages, drug effectiveness, and patient safety. The effectiveness of many drugs is affected by the ratio of lean skeletal muscle mass to adipose tissue. The active metabolites of many drugs are protein bound in the plasma. In patients with greater adipose tissue, more of these active metabolites can be unbound in plasma, or free, and exert greater effects. Some drugs readily bind to adipose tissue, which may either inactivate them or prolong their effects. In addition, increased adiposity can have indirect effects on metabolic pathways within the liver, resulting in changes in drug metabolic pathways, which can result in either increased or decreased drug metabolism, depending on the drug and the affected metabolic pathway. In other words, some drugs have enhanced effects while others have diminished effects with patients with obesity compared to patients of normal weight. For instance, research studies have found that patients with obesity who are critically ill with sepsis require proportionally lower dosages of IV drip norepinephrine, which is typically given based on weight-based calculations, than patients with normal weight (Droege & Ernst, 2017; Radosevich, Patanwala, & Erstad, 2016). On the other hand, patients with obesity who require opioid agents to treat pain frequently require higher dosages of opioid agents to achieve pain relief, but are more likely to have serious adverse effects of sedation and respiratory depression (Meisenberg, Ness, Rao, et

al., 2017). The nurse should be cognizant that weight-based calculations of drug dosages for patients with obesity may need to be altered, depending on the patient and the drug, and should consult with clinical pharmacologists and the patient's primary provider as needed to ensure optimal drug effectiveness and patient safety.

Patients with obesity are particularly vulnerable to developing pressure injuries (see Chart 42-5). Increased adipose tissue can diminish the supply of blood, oxygen, and nutrients to peripheral tissue. The presence of more folds in the skin is associated with more skin moisture and increased skin friction, which are pressure injury risks. Moreover, skin folds may be present in uncommon areas, including under the breasts, under the lower abdomen, within gluteal folds, and at the nape of the neck (Haesler, 2018; Williamson, 2020). In addition, patients with obesity frequently have more limitations in mobility than patients of normal weight. Immobility is another risk for pressure injury development (Williamson, 2020). Consultation with a wound-ostomy-continence (WOC) nurse may be advisable to ensure that pressure injury risks for the patient with obesity are minimized.

Chart 42-5  **ETHICAL DILEMMA**

When Is Prescribed Care Beneficent and When Is It Paternalistic?

Case Scenario

T.N. is a 40-year-old woman admitted to the hospital 2 days ago for treatment of nonhealing and infected stage III pressure injuries. T.N. is 64 inches tall and weighs 275 pounds; thus, her BMI is 47.2 kg/m^2, consistent with Class III/severe obesity. T.N. has had obesity since childhood and reportedly has not been willing to listen to her family practice primary provider's repeated cautions to increased physical activity and decreased caloric dietary intake. The admitting primary provider has prescribed wound débridement, intravenous antibiotics, and a diet restricted to 1000 calories daily during her hospitalization. You are a staff nurse on the unit where T.N. has been admitted and are assigned to care for her. During oncoming shift report, you hear that staff members suspect T.N. is somehow having additional food brought into her room. During your initial assessment of T.N. she says to you "This hospital food is terrible. It tastes bad and I am not getting nearly enough to eat." The charge nurse suggests that T.N.'s visitors could be screened to discourage them from bringing T.N. outside food and to assist T.N. to adhere to the therapeutic regime to help facilitate healing.

Discussion

Patients with severe obesity are at risk for pressure injuries. Therefore, it seems reasonable to assume that T.N.'s overall health status will improve with weight reduction. Furthermore, it is common practice that patients are placed on dietary restrictions while hospitalized. For instance, patients with hypertension are typically prescribed low sodium diets. There are some bioethicists and clinicians who argue that patients should consent to such restrictions, and that placing patients on dietary restriction smacks of paternalism (i.e., "father knows best"). Others would argue that dietary restrictions are part of the holistic health care plan that benefits patients who are hospitalized.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 1, Chart 1-7). Does T.N. have the autonomous right to not adhere to her prescribed diet? Is it reasonable to enforce a caloric restriction on her while she is being hospitalized? Should her visitors be subjected to requests that they not bring her food, or does that breach the confidentiality of her treatment plan?
- Does placing T.N. on a calorie restricted diet during her hospitalization benefit her? If she does lose weight while she is hospitalized, might that accelerate the healing of her pressure injuries? Or might she become malnourished? Do a risk analysis. Are there more potential risks or more potential benefits entailed with this prescribed diet?
- T.N. has reportedly been resistant to changing her habits. It is not known whether or not her motivation to lose weight has ever been assessed;

yet, patients with severe obesity must be motivated to make changes in order to successfully manage their disease. Assume that her motivation is assessed and that she is motivated and ready to lose weight. What are the next steps? Admonishing her that she should adhere to the prescribed diet? Or are there other resources that might be mobilized to assist her to successfully manage her disease?

Resources

See Chapter 1, Chart 1-10 for Steps of an Ethical Analysis and Ethics Resources.

The nurse must ensure that appropriate specialty equipment is utilized as needed so that the patient with obesity who is immobilized is turned and mobilized as indicated to prevent pressure injuries. For many years, the traditional nursing protocol was that the patient who is immobilized and bedfast should be turned every 2 hours to prevent pressure injuries; that is now updated so that more frequent patient movements are encouraged, particularly in the patient with obesity (Haesler, 2018). Nurses should be familiar with and comfortable using specialized durable medical bariatric equipment (e.g., lifts, transport equipment, commodes) so that the patient with obesity receives necessary care. It is also important to enforce and implement safe patient handling protocols so that the nurse does not incur musculoskeletal injury.

The Patient Undergoing Bariatric Surgery

The term **bariatric** is derived from two Greek words meaning "weight" and "treatment." Thus, bariatric surgery is surgery indicated to treat obesity. Surgery is typically performed after other nonsurgical attempts at weight control have failed. Insurance coverage for bariatric surgery varies widely, but most insurance companies will consider surgery as a treatment if the patient has Class III obesity or Class II obesity with a related medical condition (e.g., type 2 diabetes, OSA) (see Table 42-1) (Obesity Action Coalition [OAC], 2019a).

According to estimates by the ASMBS (2018b), the number of bariatric surgeries performed in the United States grew by nearly 30% between 2011 and 2017. Bariatric surgical procedures work by restricting a patient's ability to eat

(restrictive procedure), interfering with ingested nutrient absorption (malabsorptive procedures), or both. The different types of bariatric surgical procedures require unique lifestyle modifications. In order to optimize their success, patients should be well informed about the specific lifestyle changes, eating habits, and bowel habits that may result from each type of procedure.

Bariatric surgery typically results in a weight loss of 10% to 35% of total body weight within 2 years postoperatively, with the majority of weight loss occurring within the first year (OAC, 2019b; Shanti & Patel, 2019). Comorbid conditions such as type 2 diabetes, hypertension, and OSA may resolve; and dyslipidemia improves (Nguyen et al., 2020; Shanti & Patel, 2019). Bariatric surgery has been extended to carefully selected adolescents with severe obesity and comorbidity because of the positive results it has achieved in adults (Ruiz-Cota, Bacardí-Gascón, & Jiménez-Cruz, 2019). However, the long-term benefits for patients who undergo bariatric surgery during adolescence are debatable, as weight regain and risk reduction of comorbidities tend to resume within 5 years postoperatively (Ruiz-Cota et al., 2019).

Patient selection is critical, and the preliminary process may necessitate months of counseling, education, and evaluation by a multidisciplinary team, including social workers, dietitians, a nurse counselor, a psychologist or psychiatrist, and a bariatric surgeon. The selection criteria for patients has changed considerably since the advent of bariatric surgery, with patients with BMIs as low as 30 kg/m^2 now considered candidates for surgical intervention if they have comorbid conditions that may demonstrably improve post weight loss (e.g., type 2 diabetes) (Nguyen et al., 2020; NIDDK, 2016a) (see Chart 42-6).

Because bariatric surgery involves a drastic change in the functioning of the digestive system, patients need counseling before and after the surgery. Guidelines have been developed to assist in the care of patients having bariatric surgery (Mechanick, Apovian, Brethauer, et al., 2019).

Chart 42-6

Selection Criteria for Bariatric Surgery

Patients with the Following BMIs and Associated Factors

- BMI ≥40 kg/m^2 without excessive surgical risk
- BMI ≥35 kg/m^2 and one or more severe obesity-associated comorbid conditions (e.g., hyperlipidemia, obstructive sleep apnea, obesity hypoventilation syndrome, nonalcoholic fatty liver disease, hypertension, asthma, debilitating arthritis, or considerably impaired quality of life)
- BMI ≥30 kg/m^2 with type 2 diabetes with poor glycemic control despite optimal medical treatments and lifestyle changes

Inclusion Criteria

- Ability to perform activities of daily living and self-care
- Presence of a support network of family and friends
- Failure of previous nonsurgical attempts at weight loss, including nonprofessional programs
- Expectation that patient will adhere to postoperative care, follow-up visits, and recommended medical management, including the use of dietary supplements

Exclusion Criteria

Reversible endocrine or other disorders that can cause obesity
Current substance use disorder (SUD: e.g., drug or alcohol abuse)
Uncontrolled, severe psychiatric illness
Lack of comprehension of risks, benefits, expected outcomes, alternatives, and lifestyle changes required with bariatric surgery

Adapted from Mechanick, J. I., Apovian, C., Brethauer, S., et al. (2019). Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient—2019 update: Cosponsored by the American Association of Clinical Endocrinologists, The Obesity Society, and American Society for Metabolic & Bariatric Surgery. *Endocrine Practice*, *25*(12), 1–75.

Surgical Procedures

Sleeve gastrectomy, Roux-en-Y gastric bypass (RYGB), biliopancreatic diversion with duodenal switch, and gastric banding are the current bariatric procedures that might be performed. These procedures may be performed by laparoscopy or by an open surgical technique. Currently, the sleeve gastrectomy is the most commonly performed procedure, followed by the RYGB; postoperative outcomes are equally favorable between sleeve gastrectomy and RYGB, and generally better than outcomes with gastric banding (ASMBS, 2018b; Kizy, Jahansouz, Downey, et al., 2017; Mechanick et al., 2019). Gastric banding tends to be done less commonly, as there have been reports of problems

with band failures and a need for more frequent patient postoperative monitoring (Tsai, Zehetner, Beel, et al., 2019). Biliopancreatic diversion with duodenal switch tends to result in the most postoperative weight loss, and is therefore more commonly indicated for patients with very high BMIs (Nguyen et al., 2020).

The RYGB is a combined restrictive and malabsorptive procedure. The gastric banding and sleeve gastrectomy are restrictive procedures, and the biliopancreatic diversion with duodenal switch combines gastric restriction with intestinal malabsorption. Figure 42-5A–D provides additional details about these procedures.

NURSING PROCESS

The Patient Undergoing Bariatric Surgery

Assessment

Preoperatively, the nurse assesses for contraindications to major abdominal surgery. Previous attempts at losing weight are also assessed, including strategies such as nutritional counseling, dieting, or exercise programs. The nurse ensures the patient has received education and counseling regarding the possible risks and benefits of bariatric surgery including the complications, postsurgical outcomes, dietary changes, and the need for lifelong follow-up. The nurse also confirms that the patient has been screened for behavioral disorders that may interfere with postsurgical outcomes. Dietary counseling is initiated preoperatively to prepare for postoperative dietary changes (Mechanick et al., 2019; OAC, 2019b).

The nurse ensures that preoperative screening tests are obtained and scrutinizes the results. Typical laboratory tests include a complete blood cell count (CBC), electrolytes, blood urea nitrogen (BUN), and creatinine. See Appendix A on thePoint for normal values for these laboratory tests. Patients with obesity may have OSA, gastroesophageal reflux disease (GERD), heart disease, nonalcoholic fatty liver disease, diabetes (or prediabetes), and vitamin and mineral deficiencies; thus, other screening tests that may be obtained include a sleep study, upper endoscopy, electrocardiogram (ECG), lipid panel, AST, ALT, glucose, and hemoglobin A1c, as well as iron, vitamin B_{12}, thiamine, folate, vitamin D, and calcium levels.

Postoperatively, the nurse assesses the patient to ensure that goals for recovery are met and that the patient exhibits absence of complications secondary to the surgical intervention. See Chapter 16 for general assessment of the postoperative patient.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Lack of knowledge about the nature of the surgical procedure, dietary limitations, and activities
- Anxiety associated with impending surgery
- Acute pain associated with surgical procedure
- Risk for hypovolaemia associated with nausea, gastric irritation, and pain
- Risk for infection associated with anastomotic leak
- Impaired nutritional status associated with dietary restrictions

- Disturbed body image associated with body changes from bariatric surgery

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Change in bowel habits, including diarrhea and/or constipation
- Hemorrhage
- Venous thromboembolism (VTE)
- Bile reflux
- Dumping syndrome
- Dysphagia
- Bowel or gastric outlet obstruction

Planning and Goals

Preoperative goals include that the patient will become knowledgeable about the preoperative and postoperative dietary routine/restrictions and will have decreased anxiety about the surgery. Postoperative goals include relief of pain, maintenance of homeostatic fluid balance, prevention of infection, adherence to detailed diet instructions to include progression of food intake as well as fluid intake (to prevent dehydration), knowledge about vitamin supplements and the need for lifelong follow-up, achievement of a positive body image, and maintenance of normal bowel habits (ASMBS, 2013; Mechanick et al., 2019).

Nursing Interventions

Fostering Patient Knowledge

Although care of patients with obesity who are undergoing surgery is best achieved with a multidisciplinary care team, nurses have the opportunity to lead patient education initiatives. A systematic review noted that weight management centers within and outside of the United States have not extensively tested education practices for their effectiveness (Groller, 2017). Furthermore, patient education was not comparable across centers with much variance between educational content and delivery practices specific to teaching style and educator role (Groller, 2017).

Education for patients undergoing bariatric surgery should include information on the surgical procedure, nutrition requirements, activity, and psychosocial behaviors (Groller, 2017). Providing this education to patients in small group and individualized teaching sessions will enable patients to ask questions and have the nurse evaluate patient understanding to promote adherence to the treatment plan.

The nurse counsels the patient anticipating bariatric surgery to ingest nothing but clear liquids for a specified period of time preoperatively

(typically about 24 to 48 hours before). Nutritional support for patients scheduled for bariatric surgery is tailored to meet each patient's individual need to ensure optimal consumption of micronutrients. Bariatric diets usually follow a slow progression from clear liquids only continuing for up to 48 hours postoperatively, to full liquids with sugar-free or low sugar options, to pureed diet, to soft solids and, eventually by approximately the 8-week postoperative time frame, to solid foods (Mechanick et al., 2019; Petcu, 2017). This slow progression is necessary to maximize weight loss, and to prevent complications such as nausea, vomiting, bile reflux, and diarrhea.

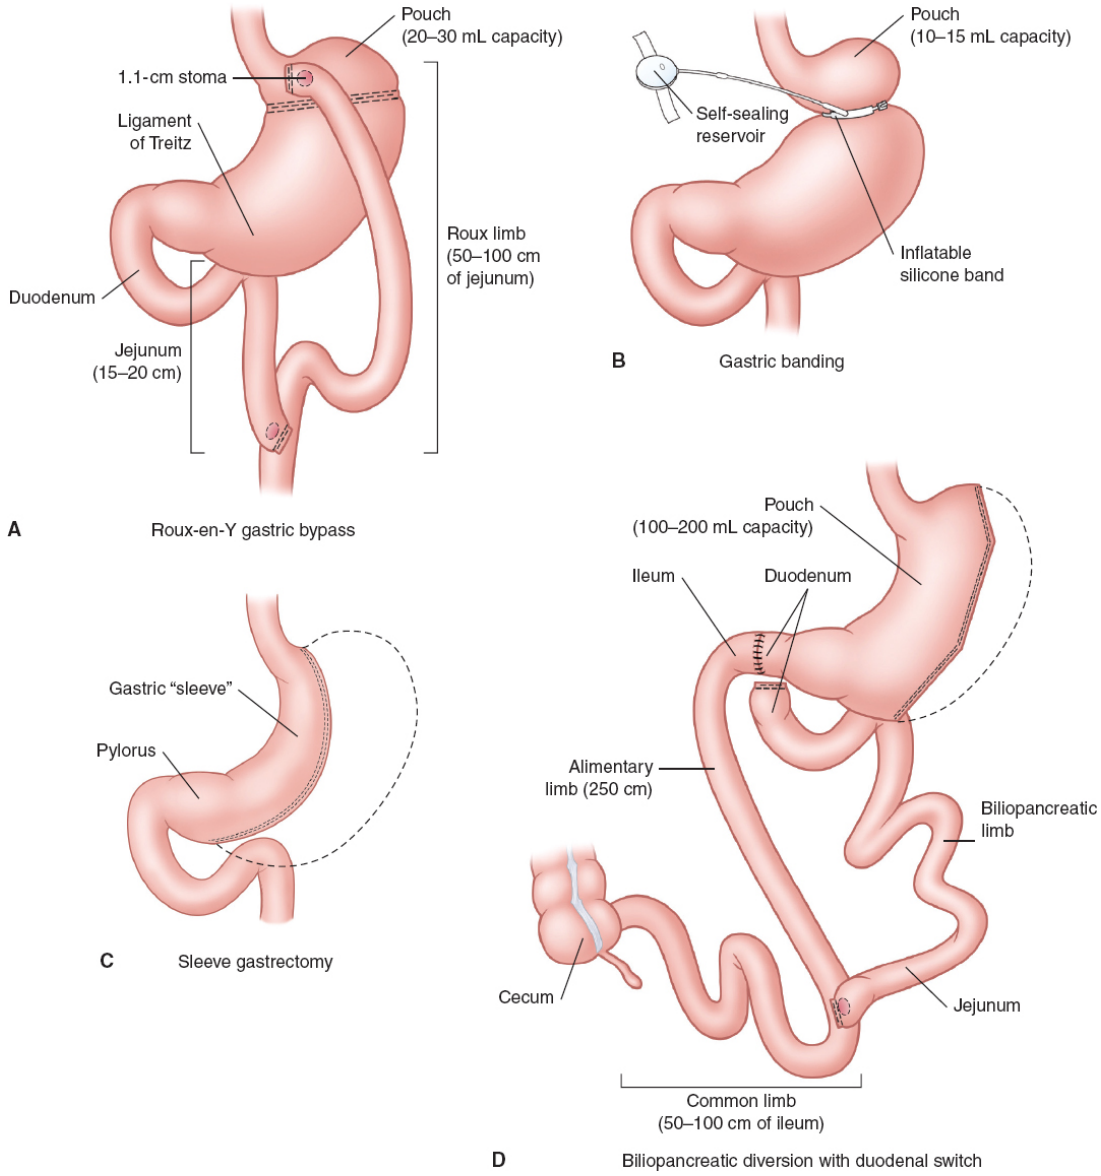

Figure 42-5 • Bariatric surgical procedures. **A.** Roux-en-Y gastric bypass. A horizontal row of staples across the fundus of the stomach creates a pouch with a capacity of 20 to 30 mL. The jejunum is divided distal to the ligament of Treitz, and the distal end is anastomosed to the new pouch. The proximal segment is anastomosed to the jejunum. **B.** Gastric banding. A prosthetic device is used to restrict oral intake by creating a small pouch of 10 to 15 mL that empties through the narrow outlet into the remainder of the stomach. **C.** Sleeve gastrectomy. The stomach is incised vertically and up to 85% of the stomach is surgically removed, leaving a "sleeve"-shaped tube that retains intact nervous innervation and does not obstruct or decrease the size of the gastric outlet. **D.** Biliopancreatic diversion with duodenal switch (also called *sleeve gastrectomy with duodenal switch*). Half of the stomach is removed, leaving a small area that holds about 60 mL. The entire jejunum is excluded from the rest of the gastrointestinal tract. The duodenum is disconnected and sealed off. The ileum is

divided above the ileocecal junction, and the distal end of the jejunum is anastomosed to the first portion of the duodenum. The distal end of the biliopancreatic limb is anastomosed to the ileum.

The patient's diet likely will be limited upon discharge from the hospital; because of this, patients scheduled for bariatric surgery are given guidelines prior to surgery on which foods and liquids they may consume postoperatively so that they may stock up on these items at home before they are admitted to the hospital. These typically include sugar-free drinks, gelatins and puddings, flavored electrolyte drinks, fat-free milk, protein drinks, sugar-free applesauce, and low-fat soups (Mechanick et al., 2019; Petcu, 2017).

REDUCING ANXIETY

The nurse provides the patient preparing for bariatric surgery anticipatory guidance as to what to expect during the surgery and postoperatively. In addition, the nurse may encourage the patient to join a bariatric surgery support group preoperatively, with the intent that the patient will continue to participate in this group postoperatively. Most bariatric surgery centers sponsor patient support groups that meet in person or online. These support groups provide a forum where patients contemplating bariatric surgery may talk with patients who have had the surgery and may provide them with guidance and tips that can help to lessen their anxiety (Mechanick et al., 2019).

RELIEVING PAIN

After surgery, analgesic agents may be given as prescribed to relieve pain and discomfort. In the past, patient-controlled analgesic pumps were used postoperatively; however, this is no longer recommended practice (Nguyen et al., 2020). The opioid crisis has stimulated research to question opioid prescription and use practices in this population (Heinberg, Pudalov, Alameddin, et al., 2019). New recommendations favor nonopioid agents and restriction to no more than 15 doses of oral opioids during any postoperative recovery (Friedman, Ghiassi, Hubbard, et al., 2019; Nguyen et al., 2020). Patients are usually prescribed oral immediate-release opioids (e.g., oxycodone) and other nonopioid agents, such as acetaminophen. The nurse should educate the patient about these medications and monitor their effectiveness. It is especially important to provide adequate pain relief so that the patient can perform pulmonary care activities (deep breathing and coughing) and leg exercises, turn from side to side, and ambulate. The nurse assesses the effectiveness of analgesic intervention and consults with other members of the health care team if pain is not adequately controlled (see Chapter 9). Positioning the patient in a low or high Fowler position promotes comfort and emptying of the stomach after any type of gastric surgery, including bariatric procedures.

ENSURING FLUID VOLUME BALANCE

Patients who have had bariatric surgery usually receive IV fluids for the first several hours postoperatively. Once they are awake and alert on the surgical unit, they are encouraged to begin intake of sugar-free oral fluids. Introducing small volumes of these liquids is believed to stimulate GI peristalsis and perfusion and thwart gastric reflux. Sugar-free fluids are preferred because they are not implicated in causing dumping syndrome (see later discussion). With a typical regimen, patients are encouraged to slowly sip 30 mL of these fluids every 15 minutes (Fencl, Walsh, & Vocke, 2015). Patients should stop ingesting fluids, however, if they feel nauseated or full. Antiemetic agents may be prescribed to relieve nausea and prevent vomiting, which could cause strain on the surgical site and cause either a hemorrhage or anastomotic leak (Mechanick et al., 2019).

PREVENTING INFECTION/ANASTOMOTIC LEAK

Disruption at the site of anastomosis (i.e., surgically resected site) may cause leakage of gastric contents into the peritoneal cavity, causing infection and possible sepsis. Patients at risk for this particular complication tend to be older, male, and with greater body mass. In addition, anastomotic leak is more commonly associated with open rather than laparoscopic procedures. Patients with anastomotic leaks typically exhibit nonspecific signs and symptoms that include fever, abdominal pain, tachycardia, and leukocytosis. This may progress to sepsis and possibly septic shock if not recognized and treated early (see Chapter 11). The nurse must be astute in recognizing these manifestations and alerting the patient's primary provider should they occur (Petcu, 2017).

A patient suspected of having an anastomotic leak may have an upper GI series that includes follow-up computed tomography (CT) scan with contrast dye, which may find leaking contrast dye, thus confirming the diagnosis. Treatment varies depending on the timing (early or late postoperatively) and severity of the leak. CT-guided drainage of the area may be appropriate for a less severe leak in the later postoperative phase of recovery, but an early or severe leak requires immediate open surgical intervention to repair the leak (Petcu, 2017).

ENSURING ADEQUATE NUTRITIONAL STATUS

After bowel sounds have returned and oral intake is resumed, six small feedings consisting of a total of 600 to 800 calories per day are provided, and consumption of fluids between meals is encouraged to prevent dehydration. The nurse instructs the patient to eat slowly and stop when feeling full. Eating too much or too fast or eating high-calorie liquids and soft foods can result in vomiting or painful esophageal distention. Gastric retention may be evidenced by abdominal distention, nausea, and vomiting. A nutritionist is typically consulted to assist with diet restrictions and diet progression (Mechanick et al., 2019; Nguyen et al., 2020) (see Chart 42-7).

Common dietary deficiencies in patients who have had bariatric surgery include malabsorption of organic iron, which may require supplementation with oral or parenteral iron, and a low serum level of vitamin B_{12}; the patient may be prescribed monthly vitamin B_{12} intramuscular injections to prevent pernicious anemia (Holsworth & Gallagher, 2017; Mechanick et al., 2019) (see Chapter 29 for further discussion of pernicious anemia).

SUPPORTING BODY IMAGE CHANGES

After bariatric surgery most patients report greatly improved perceptions of their body image, as well as improved quality of life. In particular, patients identified satisfaction with bariatric surgery when they achieved personal weight goals, adhered to postoperative care rules, and saw physical health improvements (Groller, Teel, Stegenga, et al., 2018). However, some patients report lingering dissatisfaction with their body images. In particular, some patients may report dissatisfaction related to loose skin folds and may eventually seek elective body-contouring surgical options (e.g., breast reductions, breast lifts, abdominoplasty) (Groller et al., 2018). The nurse provides support to the patient who reports dissatisfaction with body image post weight loss by acknowledging the patient's feelings as real, sharing that these perceptions are not unusual, and providing links to live or online supports groups or counselors, as necessary (see the Nursing Research Profile in Chart 42-8).

Chart 42-7  **PATIENT EDUCATION**

Dietary Guidelines for the Patient Who Has Had Bariatric Surgery

The nurse instructs the patient to:

- Eat smaller but more frequent meals that contain protein and fiber; each meal size should not exceed 1 cup.
- Eat only foods high in nutrients (e.g., peanut butter, cheese, chicken, fish, beans).
- Consume fat as tolerated.
- Ensure a low carbohydrate intake; in particular, avoid concentrated sources of carbohydrates (e.g., candy).
- Eat two protein snacks daily; animal protein may be poorly tolerated after Roux-en-Y gastric bypass, however.
- Eat slowly and chew thoroughly or may feel food "sticking" in throat.
- Assume a low Fowler position during mealtime and then remain in that position for 20 to 30 minutes after mealtime—this delays stomach emptying and decreases the likelihood of dumping syndrome.
- Know that antispasmodic agents, as prescribed, also may aid in delaying the emptying of the stomach.
- Avoid drinking fluid with meals; instead, consume fluids up to 30 minutes before a meal and 60 minutes after mealtime.
- Do drink plenty of water; refrain from drinking liquid calories (e.g., alcoholic beverages, fruit drinks, nondiet sodas).
- Take prescribed dietary supplements of vitamins and medium-chain triglycerides.
- Follow up with primary provider for monthly injections of vitamin B_{12} and iron as prescribed.
- Walk for at least 30 minutes daily.

Patient perspectives about bariatric surgery unveil experiences, education, satisfaction, and recommendations for improvement. *Surgery for Obesity and Related Diseases*, *14*(6), 785–796; Mechanick, J. I., Apovian, C., Brethauer S., et al. (2019). Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient—2019 update: Cosponsored by the American Association of Clinical Endocrinologists, The Obesity Society, and American Society for Metabolic & Bariatric Surgery. *Endocrine Practice*, *25*(12), 1–75.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

After surgery, the nurse assesses the patient for complications from the bariatric surgery, such as changes in bowel habits, hemorrhage, venous thromboembolism (VTE), bile reflux, dumping syndrome, dysphagia, and bowel or gastric outlet obstruction.

Change in Bowel Habits. Patients may complain of either diarrhea or constipation postoperatively. Diarrhea is more common an occurrence after

bariatric surgery, particularly after malabsorptive procedures (Mechanick et al., 2019). Both may be prevented if the patient consumes a nutritious diet that is high in fiber. Steatorrhea also may occur as a result of rapid gastric emptying, which prevents adequate mixing with pancreatic and biliary secretions (Mechanick et al., 2019). In mild cases, reducing the intake of fat and administering an antimotility medication (e.g., loperamide) may control symptoms. Persistent diarrhea or steatorrhea may warrant further diagnostic testing, such as an upper endoscopy or colonoscopy with biopsies to rule out the presence of additional pathology, such as celiac disease or *Clostridium difficile* infection (Mechanick et al., 2019) (see Chapter 41).

Hemorrhage. Postoperative hemorrhage may be a complication following bariatric surgery. Intra-abdominal hemorrhage may be evident by frank, bright red oral or rectal bleeding, tarry melena, bloody output from the wound or drains, if present, as well as typical clinical manifestations of severe bleeding and hemorrhagic shock (e.g., tachycardia, hypotension, syncope) (see Chapter 11). Bleeding within the first 72 hours postoperatively is most likely caused by disruption in a staple or suture. Bleeding 72 hours to 30 days postoperatively is most likely from formation of a gastric or duodenal ulcer (Nguyen et al., 2020; Petcu, 2017) (see Chapter 40).

Venous Thromboembolism. Patients who have bariatric surgery are at moderate to high risk of VTE, including both PE and DVT. Patients who are older, have higher BMIs, and have a prior history of a VTE or coagulation defect are at higher risk (Holsworth & Gallagher, 2017; Nguyen et al., 2020). ASMBS guidelines for VTE prevention specify that in the immediate postoperative period, patients who have had bariatric surgery should be prescribed mechanical compression (e.g., intermittent pneumatic compression devices) and prophylactic anticoagulation with subcutaneous low-molecular-weight heparin (LMWH) agents (e.g., dalteparin, enoxaparin). The duration of time that mechanical compression and anticoagulation should continue postoperatively is not described, however, and is left to the discretion of the patient and primary provider. In addition to implementing this prescribed therapy, nurses caring for patients post bariatric surgery should encourage them to begin early ambulation to further deter the advent of VTE (Holsworth & Gallagher, 2017; Nguyen et al., 2020) (see Chapter 26).

Bile Reflux. Bile reflux may occur with procedures that manipulate or remove the pylorus, which acts as a barrier to the reflux of duodenal contents. Reflux of bile can cause gastritis or esophagitis (inflammation of the stomach or esophagus, respectively). Burning epigastric pain and vomiting of bilious material manifest this condition. Eating or vomiting does not relieve the symptoms. Bile reflux may be managed with proton pump inhibitors (e.g., omeprazole) (Nguyen et al., 2020).

Dumping Syndrome. **Dumping syndrome** is an unpleasant set of vasomotor and GI symptoms that commonly occur in patients who have had bariatric surgery. For many years, it had been theorized that the hypertonic

gastric food boluses that quickly transit into the intestines drew extracellular fluid from the circulating blood volume into the small intestines to dilute the high concentration of electrolytes and sugars, resulting in symptoms. Now, it is thought that this rapid transit of the food bolus from the stomach into the small intestines instead causes a rapid and exuberant release of metabolic peptides that are responsible for the symptoms of dumping syndrome (Mattar & Rogers, 2020).

Chart 42-8  **NURSING RESEARCH PROFILE**

Patient Experiences with Education and Satisfaction in Weight Loss Surgery

Groller, K. D., Teel, C., Stegenga, K. H., et al. (2018). Patient perspectives about bariatric surgery unveil experiences, education, satisfaction, and recommendations for improvement. *Surgery for Obesity and Related Diseases*, *14*(6), 785–796.

Purpose

Accreditation standards require weight management centers to provide programs before and after weight loss surgery (WLS) to educate and support patients throughout lifestyle transitions. The educational programs offered at weight management centers vary by curriculum, timing, and delivery approach and may not be evidence based or patient centered. Despite these educational efforts, up to 35% of patients who undergo WLS will experience some type of weight recidivism (gain) within the first 2 postoperative years. Patient risk of regaining 5% or more from maximum weight lost continues to increase each year postoperatively. First-line treatment for patients who regain previously lost weight after WLS is to enroll and participate in additional educational programs that reinforce previously learned concepts about lifestyle demands post surgery. This study sought to obtain patient perspectives about their WLS journey with emphasis on their experiences with education, satisfaction, and recommendations to enhance the experience for future patients.

Design

This qualitative descriptive study used a purposive sampling method to recruit adult patients from an accredited weight management center. Fifty percent of all WLS cases completed within the previous 6 months were randomly selected and were mailed an invitation letter to participate in the research study. English-speaking adult patients who responded to the invitation letter were interviewed. All 11 participants, 36% male, participated in an audio-recorded interview with one researcher using a semistructured interview guide. Interview recordings were transcribed verbatim and evaluated using Colaizzi's method for inductive content analysis. Interview responses were categorized and grouped into codes, subthemes, and main themes once data saturation was achieved. Member-checking occurred to confirm final themes and subthemes that emerged from the interview data.

Findings

The study sample was fairly homogenous and oversampled males to obtain perspectives from both genders. The concept of A New Me-Version 2.0 included three main themes that emerged from participant interviews. Programming and Tools (Theme 1) provided insight on how individuals undergoing WLS obtained support from the weight management center program. Updates and Upgrades (Theme 2) explained lifestyle challenges and routines before and after WLS and quality-of-life concerns. The last theme, Lessons Learned and Future Considerations (Theme 3), described

satisfaction level through the lived experience and provided suggestions for improving the experience for future patients.

Nursing Implications

Results from this study provide insight into the lived WLS patient experience. Through emerged themes, WLS success was associated with meeting weight goals, adhering to new lifestyle routines, and seeing improved health. Participants emphasized education efforts should focus on explaining program objectives, incorporating technology to support monitoring of holistic transformations, and fostering a network of community members. This study also identified the need for future research to develop WLS education best practices and study the impact WLS education has on clinical outcomes.

Symptoms of dumping syndrome typically occur within a few minutes to 2 hours after eating and include tachycardia, dizziness, sweating, nausea, vomiting, bloating, abdominal cramping, and diarrhea (Mattar & Rogers, 2020). These symptoms typically resolve once the intestine has been evacuated (i.e., with defecation). Later, blood glucose rises rapidly, followed by increased insulin secretion. This results in a reactive hypoglycemia, which also is unpleasant for the patient. Vasomotor symptoms that occur 10 to 90 minutes after eating include pallor, perspiration, palpitations, headache, and feelings of warmth, dizziness, and even drowsiness. Anorexia may also result from dumping syndrome, because the patient may be reluctant to eat (Mattar & Rogers, 2020).

Dysphagia. **Dysphagia,** or difficulty swallowing, may occur in patients who have had any type of restrictive bariatric procedure. If it occurs, it tends to be most severe 4 to 6 weeks postoperatively and may persist for up to 6 months after surgery. Dysphagia may be prevented by educating patients to eat slowly, to chew food thoroughly, and to avoid eating tough foods such as steak or dry chicken or doughy bread. Patients with severe dysphagia who have had gastric banding may benefit from having their bands adjusted. Patients who have had other restrictive procedures may experience relief of symptoms after having stomal strictures relieved endoscopically (Mechanick et al., 2019).

Bowel and Gastric Outlet Obstruction. Bowel or gastric outlet obstruction may occur as a complication of bariatric surgery. The typical manifestations and treatments of gastric outlet obstruction are described in Chapter 40; however, there is a key difference in the treatment of a patient who has undergone bariatric surgery with a gastric outlet obstruction. It is contraindicated to insert a nasogastric (NG) tube in patients that have had bariatric surgery, even if they have a gastric outlet obstruction. Alternative treatment options may include endoscopic procedures aimed at relieving the obstruction, such as balloon dilation, or surgical revisions (King & Herron, 2020).

Quality and Safety Nursing Alert

Insertion of NG tubes is contraindicated in the patient post bariatric surgery. This procedure may disrupt the surgical suture line and cause anastomotic leak or hemorrhage.

PROMOTING HOME, COMMUNITY-BASED, AND TRANSITIONAL CARE

Patients are usually discharged from the hospital within 4 days postoperatively (this may be within 24 to 72 hours for patients who have had laparoscopic procedures) with detailed dietary instructions (see Chart 42-7) as well as instructions about how to either begin or resume an appropriate exercise regimen. Instructions on making follow-up appointments with the bariatric surgeon for routine postoperative visits or for complications are shared with the patient (Mechanick et al., 2019).

Educating Patients About Self-Care. The nurse provides education with the patient about nutrition, nutritional supplements, pain management, the importance of physical activity, and the symptoms of dumping syndrome and measures to prevent or minimize these symptoms. Patients who undergo laparoscopic or open RYGB procedures may have one or more Jackson–Pratt drains, which may remain in place after discharge. The nurse educates the patient or caregiver about how to empty, measure, and record the amount of drainage. Patients should be instructed to avoid taking nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen) post discharge, as they have been implicated in development of stomach ulcers (Mechanick et al., 2019; Peterson & Kempenich, 2020). The nurse must emphasize the continued need for follow-up (even after weight loss goals are met) and continued support group participation.

Continuing and Transitional Care. After bariatric surgery, all patients require lifelong monitoring of weight, comorbidities, metabolic and nutritional status, and dietary and activity behaviors because they are at risk for developing malnutrition or weight gain. Women of childbearing age who have bariatric surgery are advised to use contraceptives for at least 18 months after surgery to avoid pregnancy until their weight stabilizes. After weight loss, the patient may elect additional surgical interventions for body contouring. These may include breast reductions, lipoplasty to remove fat deposits, or a panniculectomy or abdominoplasty to remove excess abdominal skin folds (Mechanick et al., 2019; OAC, 2019b).

Evaluation

Expected patient outcomes may include the following:

1. Improved knowledge
   a. Reports appropriate expectations for surgical procedure
   b. Verbalizes understanding of diet and fluid restrictions post surgery

2. Diminished anxiety
    a. Exhibits calm demeanor
    b. Identifies support resources
3. Relief of pain
    a. Reports relief of pain
    b. Engages in early mobilization activities as prescribed
4. Maintenance of fluid balance
    a. Able to tolerate progressive fluid intake without complaints of nausea or gastric reflux
    b. Voids at least 400 mL in 24 hours and 0.5 mL/kg/h for any 6-hour time frame postoperatively
5. Maintenance of asepsis
    a. No evidence of infection (e.g., no fever, no leukocytosis, no complaints of abdominal pain)
6. Achievement of nutritional balance
    a. Able to consume small, frequent meals as prescribed
    b. Adheres to prescribed intake of vitamins and supplements
    c. Achieves and maintains weight reduction goals
7. Promotion of positive body image
    a. Verbalizes continued satisfaction with weight reduction plan and its effect on body image
8. Has no complications (e.g., no diarrhea, constipation, bleeding, VTE, bile reflux, dumping syndrome, dysphagia, or bowel or gastric outlet obstruction)

CRITICAL THINKING EXERCISES

1 ebp You work as a staff nurse in a women's health clinic. A 50-year-old female patient presents for her annual physical examination. You measure her height as 65 inches and weight as 196 pounds. As you record these into her electronic health record, you note that last year she weighed 180 pounds. What is her BMI? As you reconcile her medications and allergies, she discloses how unhappy she is with regard to her increase in body weight despite her daily physical activity regimen of brisk walking or strength training. She reports symptoms of menopause. She asks, "Can you recommend a diet that will help me lose the 16 pounds of weight I gained over this year? I just want to get back to the normal me." What other information will you need to elicit from this patient in order to provide her with guidance about a healthier lifestyle? What diet may you recommend for her? Describe the strength of the evidence you use to offer her the healthiest weight loss outcomes.

2 pq A 47-year-old male patient is 6 weeks postoperative from a sleeve gastrectomy procedure. He presents to the emergency department with vomiting and dehydration. His temperature is 99.9°F (37.7°C), BP is 130/76 mm Hg, heart rate is 118 bpm, and respiratory rate is 22 breaths/min with an SpO_2 of 97%. During triage, his wife shares that he has been unable to eat for the past 3 days as he vomits soon afterward. He has not been able "keep liquids down" for the past 12 hours. Explain what nursing assessments you will conduct. What nursing interventions would you implement and why?

3 ipc You are a nurse who works at a weight management center. A 25-year-old female patient is referred by her primary care provider to visit the weight management center for treatment as she has had repeated attempts of unsuccessful weight loss for the past 18 months. She is 5 feet tall with a current weight of 192 pounds. She reports being newly married with a history of polycystic ovary syndrome (PCOS). She wishes to become pregnant. Although her last menstrual period was 3 months ago, she is not currently pregnant. What members of the interdisciplinary team could be consulted to help this woman achieve her goals of both weight loss and pregnancy?

43 Assessment and Management of Patients with Hepatic Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify the metabolic functions of the liver, the pathophysiologic alterations and clinical manifestations that occur with hepatic disorders, and the significance of liver function test findings.
2. Explain and demonstrate the proper techniques to perform a health history and physical assessment and discriminate between normal and abnormal findings identified in the patient with alterations of the liver.
3. Relate jaundice, portal hypertension, ascites, varices, nutritional deficiencies, and hepatic encephalopathy and coma to pathophysiologic alterations of the liver.
4. Describe the medical, surgical, and nursing management of patients with esophageal varices.
5. Compare the various types of hepatitis and their causes, prevention, clinical manifestations, management, prognosis, and home health care needs.
6. Use the nursing process as a framework for care of the patient with cirrhosis of the liver.
7. Specify nonsurgical management, surgical management, and nursing care of patients with cancer of the liver and of patients undergoing liver transplantation.

GLOSSARY

acute hepatic failure: sudden, severe onset of acute liver failure that occurs within 8 weeks after the first symptoms of jaundice (*formerly:* fulminant hepatic failure)

ascites: an albumin-rich fluid accumulation in the peritoneal cavity

asterixis: involuntary flapping movements of the hands

cirrhosis: a chronic liver disease characterized by fibrotic changes, the formation of dense connective tissue within the liver, subsequent degenerative changes, and loss of functioning cells

constructional apraxia: inability to draw figures in two or three dimensions

endoscopic variceal ligation (EVL): procedure that uses a modified endoscope loaded with an elastic rubber band passed through an overtube directly onto the varix (or varices) to be banded to ligate the area and stop bleeding (*synonym:* variceal banding)

fetor hepaticus: sweet, slightly fecal odor to the breath, presumed to be of intestinal origin

hepatic encephalopathy: central nervous system dysfunction frequently associated with elevated ammonia levels that produce changes in mental status, altered level of consciousness, and coma

jaundice: condition where the body tissues, including the sclerae and the skin, become tinged yellow or greenish-yellow, due to high bilirubin levels

orthotopic liver transplantation (OLT): grafting of a donor liver into the normal anatomic location, with removal of the diseased native liver

portal hypertension: elevated pressure in the portal circulation resulting from obstruction of venous flow into and through the liver

sclerotherapy: the injection of substances into or around esophagogastric varices to cause constriction, thickening, and hardening of the vessel and stop bleeding

Liver function is complex, and hepatic dysfunction affects all body systems. For this reason, the nurse must understand how the liver functions and must have expert clinical assessment and management skills to care for patients undergoing diagnostic and treatment procedures. The nurse also must have an understanding of technologic advances in the management of hepatic disorders. Liver disorders are common and may result from a virus, obesity, insulin resistance, or exposure to toxic substances, such as alcohol, or tumors (Norris, 2019).

ASSESSMENT OF THE LIVER

Anatomic and Physiologic Overview

The liver, the largest gland of the body and a major organ, can be considered a chemical factory that manufactures, stores, alters, and excretes a large number of substances involved in metabolism (Hammer & McPhee, 2019; Sanyal, Boyer, Terrault, et al., 2018). The location of the liver is essential because it receives nutrient-rich blood directly from the gastrointestinal (GI) tract and then either stores or transforms these nutrients into chemicals that are used elsewhere in the body for metabolic needs. The liver is especially important in the regulation of glucose and protein metabolism. The liver manufactures and secretes bile, which has a major role in the digestion and absorption of fats in the GI tract. The liver removes waste products from the bloodstream and secretes them into the bile. The bile produced by the liver is stored temporarily in the gallbladder until it is needed for digestion, at which time the gallbladder empties and bile enters the intestine (see Fig. 43-1).

Anatomy of the Liver

The liver is a large, highly vascular organ located behind the ribs in the upper right portion of the abdominal cavity. It weighs between 1200 and 1500 g in the average adult and is divided into four lobes. A thin layer of connective tissue surrounds each lobe, extending into the lobe itself and dividing the liver mass into small, functional units called *lobules* (Barrett, Barman, Brooks, et al., 2019; Hammer & McPhee, 2019).

The circulation of the blood into and out of the liver is of major importance to liver function. The blood that perfuses the liver comes from two sources. Approximately 80% of the blood supply comes from the portal vein, which drains the GI tract and is rich in nutrients but lacks oxygen. The remainder of the blood supply enters by way of the hepatic artery and is rich in oxygen. Terminal branches of these two blood vessels join to form common capillary beds, which constitute the sinusoids of the liver (see Fig. 43-2). Thus, a mixture of venous and arterial blood bathes the hepatocytes (liver cells). The sinusoids empty into venules that occupy the center of each liver lobule and are called the *central veins*. The central veins join to form the hepatic vein, which constitutes the venous drainage from the liver and empties into the inferior vena cava, close to the diaphragm (Barrett et al., 2019; Hammer & McPhee, 2019; Sanyal et al., 2018).

In addition to hepatocytes, phagocytic cells belonging to the reticuloendothelial system are present in the liver. Other organs that contain reticuloendothelial cells are the spleen, bone marrow, lymph nodes, and lungs. In the liver, these cells are called *Kupffer cells* (Barrett et al., 2019; Hammer & McPhee, 2019). As the most common phagocyte in the human body, their main function is to engulf particulate matter (e.g., bacteria) that enters the liver through the portal blood.

The smallest bile ducts, called *canaliculi,* are located between the lobules of the liver. The canaliculi receive secretions from the hepatocytes and carry them to larger bile ducts, which eventually form the hepatic duct. The hepatic duct from the liver and the cystic duct from the gallbladder join to form the common bile duct, which empties into the small intestine. The sphincter of Oddi, located at the junction where the common bile duct enters the duodenum, controls the flow of bile into the intestine.

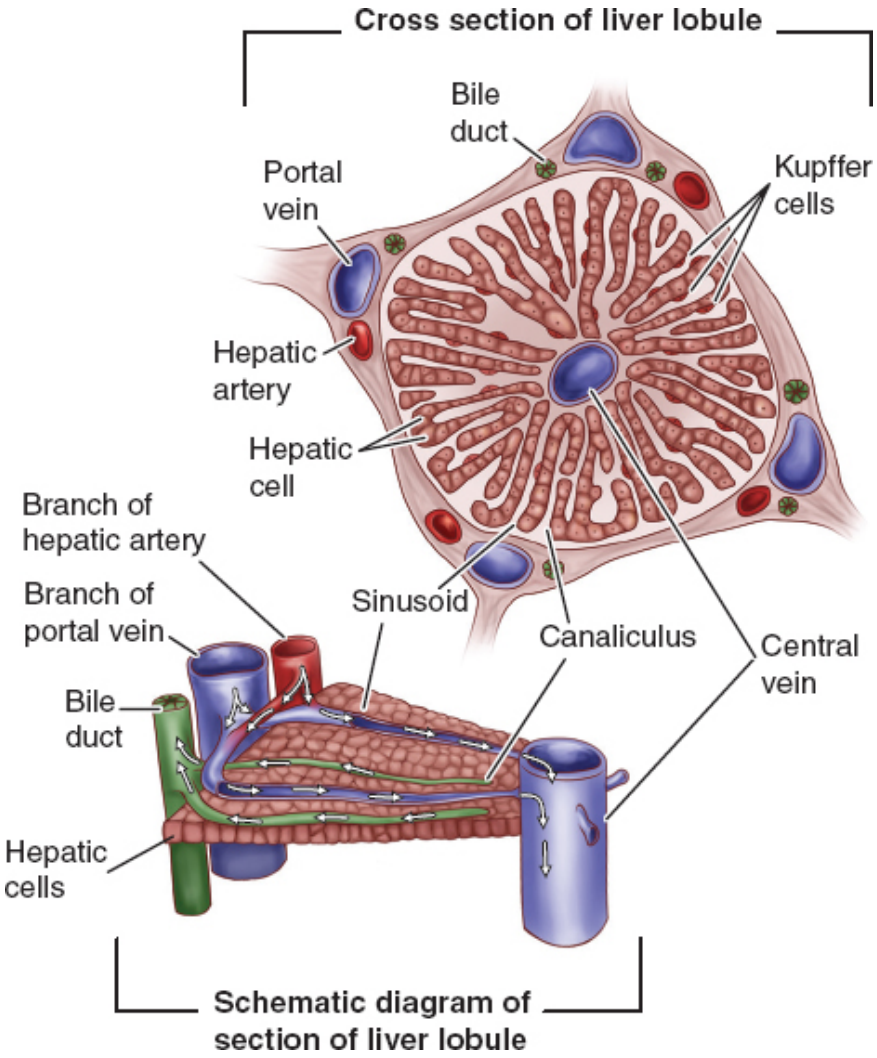

Figure 43-2 • A section of liver lobule showing the location of hepatic veins, hepatic cells, liver sinusoids, and branches of the portal vein and hepatic artery.

Functions of the Liver

Glucose Metabolism

The liver plays a major role in the metabolism of glucose and the regulation of blood glucose concentration. After a meal, glucose is taken up from the portal venous blood by the liver and converted into glycogen, which is stored in the hepatocytes. Subsequently, the glycogen is converted back to glucose through a process called glycogenolysis and is released as needed into the bloodstream to maintain normal levels of blood glucose. However, this process provides a limited amount of glucose. Additional glucose can be synthesized by the liver through a process called *gluconeogenesis*. For this process, the liver uses amino acids from protein breakdown or lactate produced by exercising

muscles. This process occurs in response to hypoglycemia (Barrett et al., 2019; Hammer & McPhee, 2019).

Ammonia Conversion

The use of amino acids from protein for gluconeogenesis results in the formation of ammonia as a by-product. The liver converts this metabolically generated ammonia into urea. Ammonia produced by bacteria in the intestines is also removed from portal blood for urea synthesis. In this way, the liver converts ammonia, a potential toxin, into urea, a compound that is excreted in the urine (Barrett et al., 2019; Hammer & McPhee, 2019).

Protein Metabolism

The liver also plays an important role in protein metabolism. It synthesizes almost all of the plasma proteins (except gamma-globulin), including albumin, alpha-globulins and beta-globulins, blood clotting factors, specific transport proteins, and most of the plasma lipoproteins. Vitamin K is required by the liver for synthesis of prothrombin and some of the other clotting factors. Amino acids are used by the liver for protein synthesis (Barrett et al., 2019; Hammer & McPhee, 2019).

Fat Metabolism

The liver is also active in fat metabolism. Fatty acids can be broken down for the production of energy and ketone bodies (acetoacetic acid, beta-hydroxybutyric acid, and acetone). Ketone bodies are small compounds that can enter the bloodstream and provide a source of energy for muscles and other tissues. Breakdown of fatty acids into ketone bodies occurs primarily when the availability of glucose for metabolism is limited, as in starvation or in uncontrolled diabetes. Fatty acids and their metabolic products are also used for the synthesis of cholesterol, lecithin, lipoproteins, and other complex lipids (Hammer & McPhee, 2019; Sanyal et al., 2018).

Vitamin and Iron Storage

Vitamins A, B, and D and several of the B-complex vitamins are stored in large amounts in the liver. Certain substances, such as iron and copper, are also stored in the liver.

Bile Formation

Bile is continuously formed by the hepatocytes and collected in the canaliculi and bile ducts. It is composed mainly of water and electrolytes such as sodium, potassium, calcium, chloride, and bicarbonate, and it also contains significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. Bile is collected and stored in the gallbladder and is emptied into the intestine as

needed for digestion. The functions of bile are excretory, as in the excretion of bilirubin; bile also serves as an aid to digestion through the emulsification of fats by bile salts.

Bile salts are synthesized by the hepatocytes from cholesterol. After conjugation or binding with amino acids (taurine and glycine), bile salts are excreted into the bile. The bile salts, together with cholesterol and lecithin, are required for emulsification of fats in the intestine, which is necessary for efficient digestion and absorption. Bile salts are then reabsorbed, primarily in the distal ileum, into portal blood for return to the liver and are again excreted into the bile. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the *enterohepatic circulation.* Because of the enterohepatic circulation, only a small fraction of the bile salts that enter the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells (Hammer & McPhee, 2019).

Bilirubin Excretion

Bilirubin is a pigment derived from the breakdown of hemoglobin by cells of the reticuloendothelial system, including the Kupffer cells of the liver. Hepatocytes remove bilirubin from the blood and chemically modify it through conjugation to glucuronic acid, which makes the bilirubin more soluble in aqueous solutions. The conjugated bilirubin is secreted by the hepatocytes into the adjacent bile canaliculi and is eventually carried in the bile into the duodenum.

In the small intestine, bilirubin is converted into urobilinogen, which is partially excreted in the feces and partially absorbed through the intestinal mucosa into the portal blood. Much of this reabsorbed urobilinogen is removed by the hepatocytes and secreted into the bile once again (enterohepatic circulation). Some of the urobilinogen enters the systemic circulation and is excreted by the kidneys in the urine. Elimination of bilirubin in the bile represents the major route of its excretion.

Drug Metabolism

The liver metabolizes many medications, such as barbiturates, opioids, sedatives, anesthetics, and amphetamines (Goldman & Schafer, 2019; Hammer & McPhee, 2019; Sanyal et al., 2018). Metabolism generally results in drug inactivation, although activation may also occur. One of the important pathways for medication metabolism involves conjugation (binding) of the medication with a variety of compounds, such as glucuronic acid or acetic acid, to form more soluble substances. These substances may be excreted in the feces or urine, similar to bilirubin excretion. Bioavailability is the fraction of the given medication that actually reaches the systemic circulation. The bioavailability of an oral medication (absorbed from the GI tract) can be

decreased if the medication is metabolized to a great extent by the liver before it reaches the systemic circulation; this is known as first-pass effect. Some medications have such a large first-pass effect that their use is essentially limited to the parenteral route, or oral doses must be substantially larger than parenteral doses to achieve the same effect.

Gerontologic Considerations

Chart 43-1 summarizes age-related changes in the liver. In the older adult, the most common change in the liver is a decrease in size and weight, accompanied by a decrease in total hepatic blood flow. However, in general, these decreases are proportional to the decreases in body size and weight seen in normal aging. Results of liver function tests do not normally change with age; abnormal results in older patients indicate abnormal liver function and are not a result of the aging process itself.

Chart 43-1

Age-Related Changes of the Hepatobiliary System

- Atypical clinical presentation of biliary disease
- Decreases in the following:
  - Clearance of hepatitis B surface antigen
  - Drug metabolism and clearance capabilities
  - Intestinal and portal vein blood flow
  - Gallbladder contraction after a meal
  - Rate of replacement and or repair of liver cells after injury
  - Size and weight of the liver, particularly in women
- Increased prevalence of gallstones due to the increase in cholesterol secretion in bile
- More rapid progression of hepatitis C infection and lower response rate to therapy
- More severe complications of biliary tract disease

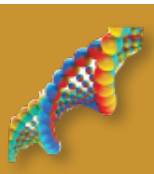
Adapted from Townsend, C. M., Beauchamp, R. D., Evers, B. M., et al. (2016). *Sabiston's textbook of surgery: The biological basis of modern surgical practice*. Philadelphia, PA: Elsevier.

Metabolism of medications by the liver decreases in the older adult, but such changes are usually accompanied by changes in intestinal absorption, renal excretion, and altered body distribution of some medications secondary to changes in fat deposition. These alterations necessitate careful medication

administration and monitoring; if appropriate, reduced dosages may be needed to prevent medication toxicity.

Assessment

Health History



If liver function test results are abnormal, the patient is evaluated for liver disease. In such cases, the health history focuses on previous exposure of the patient to hepatotoxic substances or infectious agents. The patient's occupational, recreational, and travel history may assist in identifying exposure to hepatotoxins (e.g., industrial chemicals, other toxins). The patient's history of alcohol and drug use, including but not limited to the use of intravenous (IV) or injection drugs, provides additional information about exposure to toxins and infectious agents. Many medications (including acetaminophen, ketoconazole, and valproic acid) are responsible for hepatic dysfunction and disease (Friedman & Martin, 2018). A thorough medication history should address all current and past prescription medications, over-the-counter (OTC) medications, herbal remedies, illicit drugs, and dietary supplements.

Lifestyle behaviors that increase the risk of exposure to infectious agents are identified. IV or injection drug use, sexual practices, and foreign travel are all potential risk factors for liver disease. The amount and type of alcohol consumed are identified using screening tools (questionnaires) that have been developed for this purpose (see Chapter 4). The amount of alcohol required to produce chronic liver disease varies widely, but men who consume 60 to 80 g/day of alcohol (approximately four glasses of beer, wine, or mixed drinks) and women whose alcohol intake is 40 to 60 g/day are considered at high risk for cirrhosis. **Cirrhosis** is a chronic liver disorder characterized by fibrotic changes, the formation of dense connective tissue within the liver, subsequent degenerative changes, and loss of functional liver tissue (Barrett et al., 2019; Sanyal et al., 2018).

The history also includes an evaluation of the patient's past medical history to identify risk factors for the development of liver disease. Current and past medical conditions, including those of a psychological or psychiatric nature, are identified. The family history includes questions about familial liver disorders that may have their origin in alcohol abuse or gallstone disease, as well as other familial or genetic disorders (see Chart 43-2).

The history also addresses symptoms that suggest liver disease. Symptoms that may have their origin in liver disease but are not specific to hepatic dysfunction include jaundice, malaise, weakness, fatigue, pruritus, abdominal pain, fever, anorexia, weight gain, edema, increasing abdominal girth, hematemesis, melena, hematochezia (passage of bloody stools), easy bruising,

changes in mental acuity, personality changes, sleep disturbances, and decreased libido in men and secondary amenorrhea in women.

Chart 43-2  GENETICS IN NURSING PRACTICE

Hepatic Disorders

A number of hepatic disorders have an underlying genetic cause. However, other genetic disorders associated with metabolic, gastrointestinal, or bleeding disorders will also impact the function of the liver. Some examples of hepatic disorders caused by genetic abnormalities include:
Autosomal Dominant:

- Alagille syndrome
- Hereditary coproporphyria
- Polycystic liver disease

Autosomal Recessive:

- Crigler–Najjar syndrome
- Dublin–Johnson syndrome
- Hemochromatosis
- Progressive familial intrahepatic cholestasis
- Thalassemia
- Wilson disease

Inheritance Pattern is not distinct; however, there is a genetic predisposition for the disorder:

- Biliary atresia
- Gilbert syndrome

Other genetic disorders that impact the hepatic system:

- Alpha-1 antitrypsin deficiency
- Cystic fibrosis
- Glycogen storage disease
- Lysosomal storage disease
- Polycystic kidney disease
- Zellweger syndrome

Nursing Assessments

Refer to Chapter 4, Chart 4-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Related to Hepatic Disorders

- Collect family history for three generations of maternal and paternal relatives in the patient's family
- Assess family history for relatives with early-onset hepatic disease

Patient Assessment Related to Genetic Hepatic Disorders

- Assess for physical signs or history of the following:

- Abdominal bloating, and constipation
- Changes to skin color or yellow hue to sclera
- Enlarged liver, spleen, or abdomen
- Episodes of nausea and vomiting
- Hemorrhoids, esophageal varices, or gallstones
- Intolerance to fatty foods or alcohol
- Pale-colored stools
- Presence and frequency of indigestion or reflux
- Unexplained weight loss

- Assess for associated nervous system disorders such as depression and mood changes especially anger and irritability (Wilson disease).
- Assess for associated blood sugar problems such as hypoglycemia
- Inquire about and assess for abnormal bleeding or bruising
- Obtain and review laboratory values: Liver function tests, ammonia, bilirubin, fat soluble vitamins (e.g., vitamins A, D, E, K)

Genetics Resources

American Liver Foundation, www.liverfoundation.org
See Chapter 6, Chart 6-7 for components of genetic counseling.

Physical Assessment

The nurse assesses the patient for physical signs that may occur with liver dysfunction, including the pallor often seen with chronic illness and jaundice. The skin, mucosa, and sclerae are inspected for jaundice, and the extremities are assessed for muscle atrophy, edema, and skin excoriation secondary to scratching. The nurse observes the skin for petechiae or ecchymotic areas (bruises), spider angiomas (see Fig. 43-3), and palmar erythema. The male patient is assessed for unilateral or bilateral gynecomastia and testicular atrophy due to hormonal changes. The patient's cognitive status (recall, memory, abstract thinking) and neurologic status are assessed. The nurse observes for general tremor, **asterixis** (involuntary flapping movements of the hands), weakness, and slurred speech. These symptoms are discussed later.

In some conditions, lipids may accumulate in the hepatocytes, resulting in the abnormal condition called *fatty liver disease.* If unrelated to alcohol, this disease is referred to as nonalcoholic fatty liver disease (NAFLD). A condition known as nonalcoholic steatohepatitis (NASH) represents a more serious condition within the broad spectrum of NAFLDs and may result in damage, fibrotic changes in the liver, and cirrhosis (Hammer & McPhee, 2019).

NAFLD and NASH are two diseases within the spectrum of fatty liver disease to fibrosis and cirrhosis that are strongly associated with obesity (Barrett et al., 2019). Some studies suggest that being overweight and drinking

too much alcohol can cause severe harm to the liver. People who are overweight and people with obesity who are heavy drinkers have a significantly increased risk of developing and dying of chronic liver disease (Bellentani, 2017; Friedman & Martin, 2018; Schiff, Maddrey, & Reddy, 2018). Studies have also identified that there is an increased risk of liver cancer in people with alcoholic cirrhosis who also have fatty liver disease, type 2 diabetes, and are overweight or have obesity (Bellentani, 2017; Schiff et al., 2018). In patients who are overweight, have obesity, or have high alcohol intake, the nurse observes for signs of associated liver dysfunction.

Figure 43-3 • Spider angioma. This vascular (arterial) spider appears on the skin. Beneath the elevated center and radiating branches, the blood vessels are looped and tortuous.

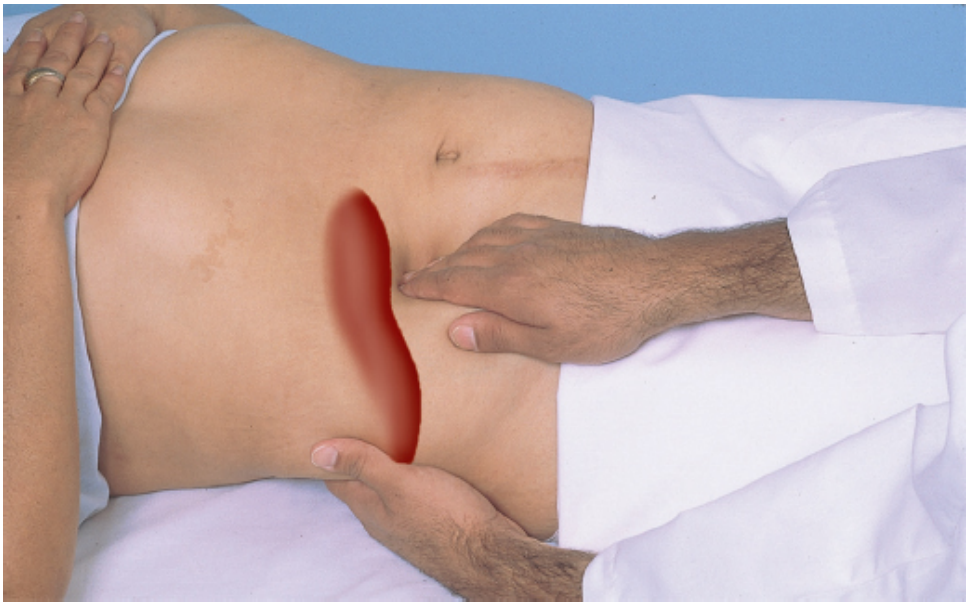


Figure 43-4 • Technique for palpating the liver. The examiner places one hand under the right lower rib cage and presses downward during inspiration with light pressure with the other hand. Reprinted with permission from Bickley, L. S. (2017). *Bates' guide to physical examination and history taking* (12th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

The nurse assesses for the presence of an abdominal fluid wave (discussed later). The abdomen is palpated to assess liver size and to detect any tenderness over the liver. The liver may be palpable in the right upper quadrant. A palpable liver presents as a firm, sharp ridge with a smooth surface (see Fig. 43-4). The nurse estimates the size of the liver by percussing its upper and lower borders. If the liver is not palpable but tenderness is suspected, tapping the lower right thorax briskly may elicit tenderness. For comparison, the nurse then performs a similar maneuver on the left lower thorax.

If the liver is palpable, the nurse notes and records its size, its consistency, any tenderness, and whether its outline is regular or irregular. If the liver is enlarged, the degree to which it descends below the right costal margin is recorded to provide some indication of its size. The nurse determines whether the liver's edge is sharp and smooth or blunt and whether the enlarged liver is nodular or smooth. The liver of a patient with cirrhosis is small and hard in late-stage cirrhosis, whereas the liver of a patient with acute hepatitis is soft and the hand easily moves the edge.

Tenderness of the liver indicates recent acute enlargement with consequent stretching of the liver capsule. The absence of tenderness may imply that the enlargement is of long-standing duration. The liver of a patient with viral hepatitis is tender, whereas that of a patient with alcoholic hepatitis is not.

Enlargement of the liver is an abnormal finding that requires evaluation (Hammer & McPhee, 2019).

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with hepatic disorders. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should note trends in results because they provide information about disease progression as well as the patient's response to therapy.

Liver Function Tests

More than 70% of the parenchyma of the liver may be damaged before liver function test results become abnormal. Function is generally measured in terms of serum enzyme activity (i.e., serum aminotransferases, alkaline phosphatase, lactic dehydrogenase) and serum concentrations of proteins (albumin and globulins), bilirubin, ammonia, clotting factors, and lipids (Hammer & McPhee, 2019; Mansour & McPherson, 2018; Sanyal et al., 2018; Wendon, Cordoba, Dhawan, et al., 2017). Several of these tests may be helpful for assessing patients with liver disease. However, the nature and extent of hepatic dysfunction cannot be determined by these tests alone, because other disorders can affect test results.

Serum aminotransferases are sensitive indicators of injury to the liver cells and are useful in detecting acute liver disease such as hepatitis. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transferase (GGT) (also called gamma-glutamyl transpeptidase [GGTP]) are the most frequently used tests of liver damage (Friedman & Martin, 2018; Maher & Schreibman, 2018; Schiff et al., 2018). ALT levels increase primarily in liver disorders and may be used to monitor the course of hepatitis or cirrhosis or the effects of treatments that may be toxic to the liver. AST is present in tissues that have high metabolic activity; therefore, the level may be increased if there is damage to or death of tissues of organs such as the heart, liver, skeletal muscle, and kidney. Although not specific to liver disease, levels of AST may be increased in cirrhosis, hepatitis, and liver cancer. Increased GGT levels are associated with cholestasis but can also be due to alcoholic liver disease. Although the kidney has the highest level of the enzyme, the liver is considered the source of normal serum activity. The test determines liver cell dysfunction and is a sensitive indicator of cholestasis. Its main value in liver disease is confirming the hepatic origin of an elevated alkaline phosphatase level. Common liver function tests are summarized in

Table 43-1, additional laboratory values can be found in Appendix A on thePoint.

Liver Biopsy

Liver biopsy is the removal of a small amount of liver tissue, usually through needle aspiration. It permits examination of liver cells. The most common indication is to evaluate diffuse disorders of the parenchyma and to diagnose space-occupying lesions. Liver biopsy is especially useful when clinical findings and laboratory tests are not diagnostic. Though rare due to the radiologic guidance now available, peritonitis caused by blood or bile after liver biopsy is the most common complication; therefore, coagulation studies are obtained, their values are noted, and abnormal results are treated before liver biopsy is performed (Schiff et al., 2018). Other techniques for liver biopsy are preferred if **ascites** (an accumulation of albumin-rich fluid in the peritoneal cavity) or coagulation abnormalities exist. A liver biopsy can be performed percutaneously with ultrasound guidance or transvenously through the right internal jugular vein to right hepatic vein under fluoroscopic control. Liver biopsy can also be performed laparoscopically.

For the procedural guidelines for assisting with percutaneous liver biopsy, go to thepoint.lww.com/Brunner15e.

TABLE 43-1 Common Laboratory Tests to Assess Liver Function

Test	Normal	Clinical Functions
Pigment Studies		
Serum bilirubin, direct Serum bilirubin, total Urine bilirubin Urine urobilinogen Fecal urobilinogen (infrequently used)	0.1–0.4 mg/dL (1.7–3.7 mcmol/L) 0.3–1 mg/dL (5–17 mcmol/L) <0.25 mg/24 h (<0.42 mcmol/24 h) (Urine urobilinogen) 0.05–2.5 mg/24 h (0.5–4 Ehrlich U/24 h) (Fecal urobilinogen) 50–300 mg/24 h (100–400 Ehrlich U/100 g)	These studies measure the ability of the liver to conjugate and excrete bilirubin. Results are abnormal in liver and biliary tract disease and are associated with jaundice clinically.
Protein Studies		
Total serum protein Serum albumin Serum globulin Serum protein electrophoresis Albumin α_1-Globulin α_2-Globulin β-Globulin γ-Globulin A/G ratio	7–7.5 g/dL (70–75 g/L) 3.5–5.2 g/dL (35–52 g/L) 2.3–3.5 g/dL (23–35 g/L) 3.5–5.2 g/dL (35–52 g/L) 0.1–0.3 g/dL (1–3 g/L) 0.6–1 g/dL (6–10 g/L) 0.5–1 g/dL (5–10 g/L) 0.6–1.3 g/dL (6–13 g/L) A > G or 1.5:1–2.5:1	Proteins are manufactured by the liver. Their levels may be affected in a variety of liver impairments: albumin is affected in cirrhosis, chronic hepatitis, edema; and ascites; globulins are affected in cirrhosis, liver disease, chronic obstructive jaundice, and viral hepatitis. A/G ratio is reversed in chronic liver disease (decreased albumin and increased globulin).
Prothrombin Time/International Normalized Ratio (PT/INR)	100% or 11–13 s/the INR is a calculation based on results of the PT. INR levels	Prothrombin time and INR may be prolonged in liver disease. It is an indicator of synthetic hepatic function. It will not return to normal with vitamin K in severe liver cell damage.

	<1.1 are considered normal	
Serum Alkaline Phosphatase	Varies with method: *Adults:* 52–142 U/L	Serum alkaline phosphatase is manufactured in bones, liver, kidneys, and intestine and excreted through biliary tract. In the absence of bone disease, it is a sensitive measure of biliary tract obstruction. Results may vary because this test is temperature and lab method dependent.
Serum Aminotransferase Studies		
AST ALT	10–40 U/mL (0.34–0.68 U/L) 8–40 U/mL (0.14–0.68 U/L)	The studies are based on release of enzymes from damaged liver cells. These enzymes are elevated in liver cell damage. Normal values may differ in men and women.
GGT, GGTP	0–30 U/L IU/L	Values are elevated in alcohol abuse and markers for biliary cholestasis.
LDH	100–200 units (100–225 U/L)	
Ammonia (plasma)	15–45 mcg/dL (11–32 mcmol/L)	Liver converts ammonia to urea. Ammonia level rises in liver failure.
Cholesterol		
Ester HDL LDL	60–70% of total cholesterol, fraction of total cholesterol 0.60–0.70 *Male:* 35–70 mg/dL; *Female:* 35–85 mg/dL <130 mcg/dL	Cholesterol levels are elevated in biliary obstruction and decreased in parenchymal liver disease.

A/G, albumin/globulin; ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, gamma-glutamyl transferase; GGTP, gamma-glutamyl transpeptidase; HDL, high-density lipoprotein; LDH, lactate dehydrogenase; LDL, low-density lipoprotein.

Other Diagnostic Tests

Ultrasonography, computed tomography (CT) scans, and magnetic resonance imaging (MRI) are used to identify normal structures and abnormalities of the liver and biliary tree. A radioisotope liver scan may be performed to assess liver size, blood flow, and obstruction. Noninvasive liver stiffness measurements or elastography uses ultrasound-based vibration and scanning to identify liver fibrosis and determine its extent. Magnetic resonance elastography uses mechanical shear waves to identify stiff tissue (Schiff et al., 2018). Liver fibrosis and other liver diseases can be identified, evaluated and monitored with a variety of other noninvasive studies. These studies may reduce the need for liver biopsy (Friedman & Martin, 2018; Schiff et al., 2018).

Laparoscopy (insertion of a fiberoptic endoscope through a small abdominal incision) is used to examine the liver and other pelvic structures. It is also used to perform guided liver biopsy, to determine the cause of ascites, and to diagnose and stage tumors of the liver and other abdominal organs.

MANIFESTATIONS OF HEPATIC DYSFUNCTION

Hepatic dysfunction results from damage to the liver's parenchymal cells, directly from primary liver diseases, or indirectly from either obstruction of bile flow or derangements of hepatic circulation. Liver dysfunction may be acute or chronic; the latter is far more common.

Chronic liver disease, including cirrhosis, is the 12th leading cause of death in the United States among young and middle-aged adults (Schiff et al., 2018). At least 40% of those deaths are associated with alcohol use. The rate of chronic liver disease for men is twice that for women, and chronic liver disease is more common in Asian and African countries than it is in Europe and the United States. Compensated cirrhosis, in which the damaged liver is still able to perform normal functions, often goes undetected for extended periods, and as many as 1% of people may have subclinical or compensated cirrhosis (Bope & Kellerman, 2018; Schiff et al., 2018). Approximately 80% of patients diagnosed with cirrhosis compensate and remain asymptomatic for the next 10 years (Schiff et al., 2018).

Disease processes that lead to hepatocellular dysfunction may be caused by infectious agents such as bacteria and viruses and by anoxia, metabolic disorders, toxins and medications, nutritional deficiencies, and hypersensitivity states. The most common cause of parenchymal damage is malnutrition, especially that related to alcoholism (Moon, Singal, & Tapper, 2018). It is important to remember that even patients who are overweight or have obesity may suffer from not only malnutrition related to liver disease, but also from sarcopenia, the significant loss of muscle tissue. Sarcopenia is associated with

increased morbidity and mortality in patients with end-stage liver disease (ESLD) (Aby & Saab, 2019).

The parenchymal cells respond to most noxious agents by replacing glycogen with lipids, producing fatty infiltration with or without cell death or necrosis. This is commonly associated with inflammatory cell infiltration and growth of fibrous tissue. Cell regeneration can occur if the disease process is not too toxic to the cells. The result of chronic parenchymal disease is the shrunken, fibrotic liver seen in cirrhosis.

The consequences of liver disease are numerous and varied. Their ultimate effects are often incapacitating or life-threatening, and their presence is ominous. Among the most common and significant manifestations of liver disease are jaundice, portal hypertension, ascites and varices, nutritional deficiencies (resulting from the inability of damaged liver cells to metabolize certain vitamins), and **hepatic encephalopathy** or coma.

Jaundice

The bilirubin concentration in the blood may be increased in the presence of liver disease, if the flow of bile is impeded (e.g., by gallstones in the bile ducts), or if there is excessive destruction of red blood cells. With bile duct obstruction, bilirubin does not enter the intestine; as a consequence, urobilinogen is absent from the urine and decreased in the stool (Hammer & McPhee, 2019).

When the bilirubin concentration in the blood is abnormally elevated, all of the body tissues, including the sclerae and the skin, become tinged yellow or greenish-yellow, a condition known as **jaundice**. Jaundice becomes clinically evident when the serum bilirubin level exceeds 2.0 mg/dL (34 mmol/L) (Hammer & McPhee, 2019). Increased serum bilirubin levels and jaundice may result from impairment of hepatic uptake, conjugation of bilirubin, or excretion of bilirubin into the biliary system. There are several types of jaundice: hemolytic, hepatocellular, and obstructive jaundice, and jaundice due to hereditary hyperbilirubinemia. Hepatocellular and obstructive jaundice are the two types commonly associated with liver disease.

Hemolytic Jaundice

Hemolytic jaundice is the result of an increased destruction of the red blood cells; the effect is that the plasma is rapidly flooded with bilirubin so that the liver, although functioning normally, cannot excrete the bilirubin as quickly as it is formed. This type of jaundice is encountered in patients with hemolytic transfusion reactions and other hemolytic disorders. In these patients, the bilirubin in the blood is predominantly unconjugated or free. Fecal and urine

urobilinogen levels are increased, but the urine is free of bilirubin. Patients with this type of jaundice, unless their hyperbilirubinemia is extreme, do not experience symptoms or complications as a result of the jaundice per se. However, prolonged jaundice, even if mild, predisposes to the formation of pigment stones in the gallbladder, and extremely severe jaundice (levels of free bilirubin exceeding 20 to 25 mg/dL) poses a risk for central nervous system effects (Goldman & Schafer, 2019).

Hepatocellular Jaundice

Hepatocellular jaundice is caused by the inability of damaged liver cells to clear normal amounts of bilirubin from the blood. The cellular damage may be caused by hepatitis viruses, other viruses that affect the liver (e.g., yellow fever virus, Epstein–Barr virus), chemical toxins (e.g., carbon tetrachloride, phosphorus, arsenicals, certain medications), or alcohol. Cirrhosis of the liver is a form of hepatocellular disease that may produce jaundice. It is usually associated with excessive alcohol intake, but it may also be a late result of liver cell necrosis caused by viral infection. In prolonged obstructive jaundice, cell damage eventually develops, and both types of jaundice (i.e., obstructive and hepatocellular jaundice) appear together.

Patients with hepatocellular jaundice may be mildly or severely ill, with lack of appetite, nausea, malaise, fatigue, weakness, and possible weight loss. In some cases of hepatocellular disease, jaundice may not be obvious. The serum bilirubin concentration and the urine urobilinogen level may be elevated. In addition, AST and ALT levels may be increased, indicating cellular necrosis. The patient may report headache, chills, and fever if the cause is infectious. Depending on the cause and extent of the liver cell damage, hepatocellular jaundice may be completely reversible.

Obstructive Jaundice

Obstructive jaundice resulting from extrahepatic obstruction may be caused by occlusion of the bile duct from a gallstone, an inflammatory process, a tumor, or pressure from an enlarged organ (e.g., liver, gallbladder). The obstruction may also involve the small bile ducts within the liver (i.e., intrahepatic obstruction); this may be caused, for example, by pressure on these channels from inflammatory swelling of the liver or by an inflammatory exudate within the ducts themselves. Intrahepatic obstruction resulting from stasis and inspissation (thickening) of bile within the canaliculi may occur after the ingestion of certain medications, which are referred to as cholestatic agents. These include phenothiazines, antithyroid medications, sulfonylureas, tricyclic antidepressant agents, nitrofurantoin, androgens and estrogens, and some antibiotics.

Regardless of whether the obstruction is intra- or extrahepatic, and regardless of its cause, bile cannot flow normally into the intestine and becomes backed up into the liver. It is then reabsorbed into the blood and carried throughout the entire body, staining the skin, mucous membranes, and sclerae. It is excreted in the urine, which becomes deep orange and foamy. Because of the decreased amount of bile in the intestinal tract, the stools become light or clay colored. The skin may itch intensely, requiring repeated soothing baths. Dyspepsia and intolerance to fatty foods may develop because of impaired fat digestion in the absence of intestinal bile. In general, AST, ALT, and GGT levels rise only moderately, but bilirubin and alkaline phosphatase levels are elevated.

Hereditary Hyperbilirubinemia

Hyperbilirubinemia (increased serum bilirubin levels), resulting from any of several inherited disorders, can also produce jaundice. Gilbert syndrome is a familial disorder characterized by an increased level of unconjugated bilirubin that causes jaundice. Although serum bilirubin levels are increased, liver histology and liver function test results are normal, and there is no hemolysis. This syndrome affects 3% to 8% of the population, predominantly males (Bope & Kellerman, 2018).

Other conditions that are probably caused by inborn errors of biliary metabolism include Dubin–Johnson syndrome (chronic idiopathic jaundice, with pigment in the liver) and Rotor syndrome (chronic familial conjugated hyperbilirubinemia, without pigment in the liver); the "benign" cholestatic jaundice of pregnancy, with retention of conjugated bilirubin, probably secondary to unusual sensitivity to the hormones of pregnancy; and benign recurrent intrahepatic cholestasis.

Portal Hypertension

Portal hypertension is the increased pressure throughout the portal venous system that results from obstruction of blood flow into and through the damaged liver. Commonly associated with hepatic cirrhosis, it can also occur with noncirrhotic liver disease. Although splenomegaly (enlarged spleen) with possible hypersplenism is a common manifestation of portal hypertension, the two major consequences of portal hypertension are ascites and varices (Friedman & Martin, 2018).

Ascites

Pathophysiology

The mechanisms responsible for the development of ascites are not completely understood. Portal hypertension and the resulting increase in capillary pressure and obstruction of venous blood flow through the damaged liver are contributing factors. The vasodilation that occurs in the splanchnic circulation (the arterial supply and venous drainage of the GI system from the distal esophagus to the midrectum, including the liver and spleen) is also a suspected causative factor. The failure of the liver to metabolize aldosterone increases sodium and water retention by the kidney. Sodium and water retention, increased intravascular fluid volume, increased lymphatic flow, and decreased synthesis of albumin by the damaged liver all contribute to the movement of fluid from the vascular system into the peritoneal space. The process becomes self-perpetuating; loss of fluid into the peritoneal space causes further sodium and water retention by the kidney in an effort to maintain the vascular fluid volume.

As a result of liver damage, large amounts of albumin-rich fluid, 20 L or more, may accumulate in the peritoneal cavity as ascites (Hammer & McPhee, 2019; Mansour & McPherson, 2018). Ascites may also occur with disorders such as cancer, kidney disease, and heart failure. With the movement of albumin from the serum to the peritoneal cavity, the osmotic pressure of the serum decreases. This, combined with increased portal pressure, results in movement of fluid into the peritoneal cavity (see Fig. 43-5).

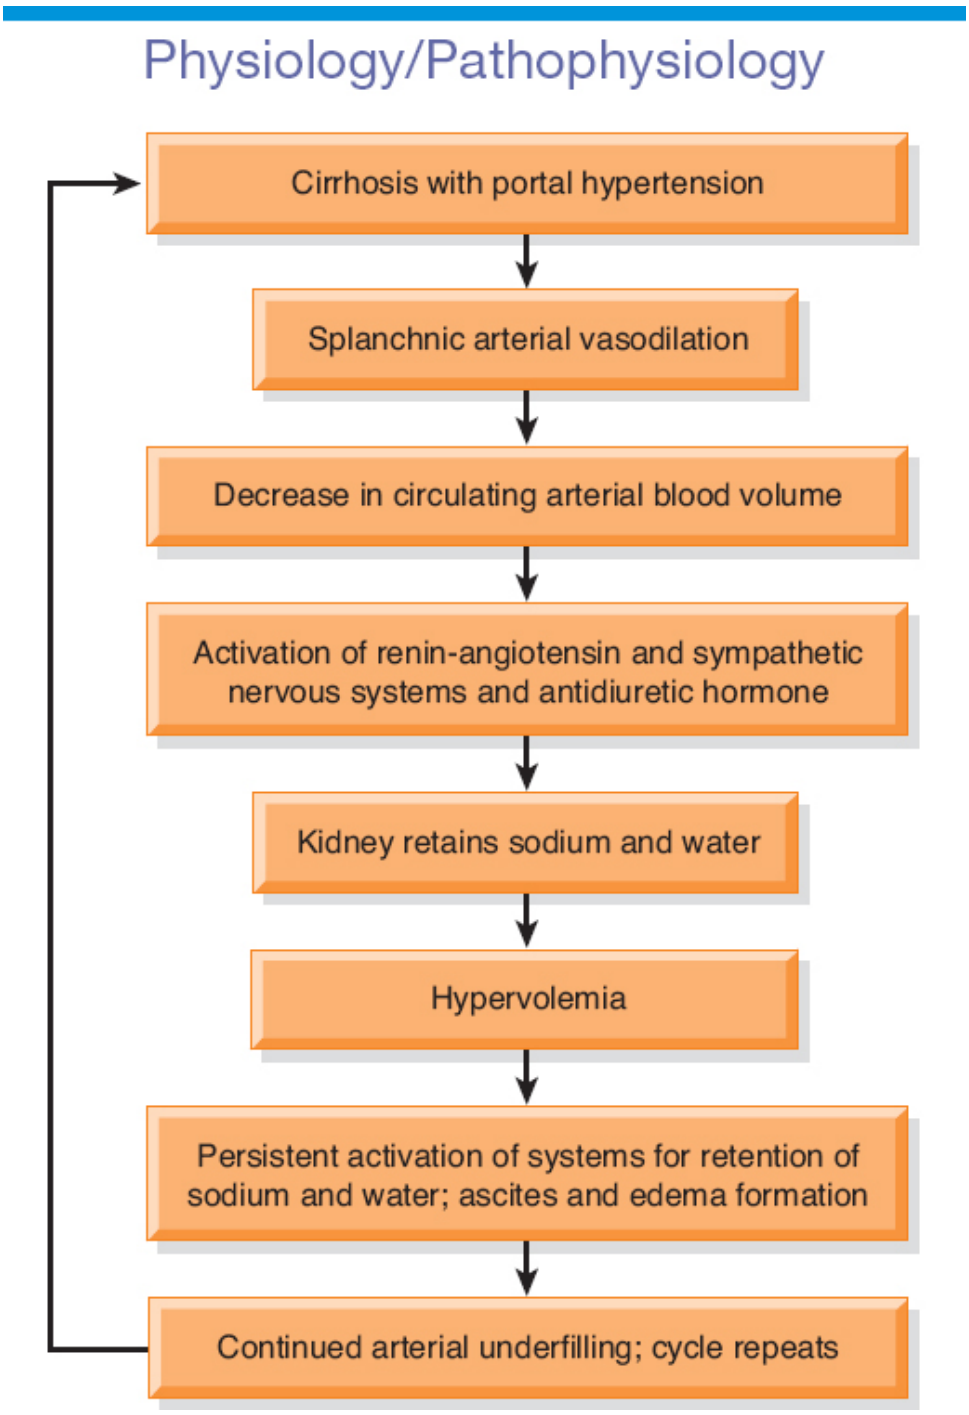

Figure 43-5 • Pathogenesis of ascites (arterial vasodilation theory).

Clinical Manifestations

Increased abdominal girth and rapid weight gain are common presenting symptoms of ascites. The patient may be short of breath and uncomfortable from the enlarged abdomen; striae and distended veins may be visible over the abdominal wall. Umbilical hernias also occur frequently in those patients with cirrhosis. Fluid and electrolyte imbalances are common.

Assessment and Diagnostic Findings

The presence and extent of ascites are assessed by percussion of the abdomen. When fluid has accumulated in the peritoneal cavity, the flanks bulge when the patient assumes a supine position. The presence of fluid can be confirmed by percussing for shifting dullness or by detecting a fluid wave (see Fig. 43-6) (Weber & Kelley, 2018). A fluid wave is likely to be found only if a large amount of fluid is present (Hammer & McPhee, 2019). Daily measurement and recording of abdominal girth and body weight are essential to assess the progression of ascites and its response to treatment.

Medical Management

The medical management of the patient with ascites includes dietary modifications, pharmacologic therapy, bed rest, paracentesis, the use of shunts, and other therapies.

Nutritional Therapy

The goal of treatment for the patient with ascites is a negative sodium balance to reduce fluid retention. Table salt, salty foods, salted butter and margarine, and all canned and frozen foods that are not specifically prepared for low-sodium (2-g sodium) diets should be avoided (Hammer & McPhee, 2019; Simonetto, Liu, & Kamath, 2019). It may take 2 to 3 months for the patient's taste buds to adjust to unsalted foods. In the meantime, the taste of unsalted foods can be improved by using salt substitutes such as lemon juice, oregano, and thyme. Commercial salt substitutes need to be approved by the patient's primary provider, because those that contain ammonia could precipitate hepatic encephalopathy and coma. Most salt substitutes contain potassium and should be avoided if the patient has impaired renal function. The patient should make liberal use of powdered, low-sodium milk and milk products. If fluid accumulation is not controlled with this regimen, the daily sodium allowance may be reduced further to 500 mg, and diuretic agents may be given. However, most patients will not accept such a severe sodium restriction as 500 mg, so clinicians often will not recommend it (Simonetto et al., 2019).

Figure 43-6 • Assessing for abdominal fluid wave. The examiner places the hands along the sides of the patient's flanks, then strikes one flank sharply, detecting any fluid wave with the other hand. An assistant's hand is placed (ulnar side down) along the patient's midline to prevent the fluid wave from being transmitted through the tissues of the abdominal wall.

Dietary control of ascites via strict sodium restriction is difficult to achieve at home. The likelihood that the patient will follow a 2-g sodium diet increases if the patient and the person preparing meals understand the rationale for the diet and receive periodic guidance about selecting and preparing appropriate foods. Approximately 10% of patients with ascites respond to these measures alone. Patients who do not respond and those who find sodium restriction difficult require diuretic therapy (Hammer & McPhee, 2019; Simonetto et al., 2019).

Pharmacologic Therapy

The use of diuretic agents along with sodium restriction is successful in 90% of patients with ascites (Hammer & McPhee, 2019; Mansour & McPherson, 2018). Spironolactone, an aldosterone-blocking agent, is most often the first-line therapy in patients with ascites from cirrhosis. When used with other

diuretic agents, spironolactone helps prevent potassium loss. Oral diuretic agents such as furosemide may be added but should be used cautiously, because long-term use may induce severe hyponatremia (sodium depletion). Ammonium chloride and acetazolamide are contraindicated because of the possibility of precipitating hepatic encephalopathy and coma. Daily weight loss should not exceed 1 kg (2.2 lb) in patients with ascites and peripheral edema or 0.5 to 0.75 kg (1.1 to 1.65 lb) in patients without edema (Bope & Kellerman, 2018; Hammer & McPhee, 2019; Simonetto et al., 2019). Fluid restriction is not attempted unless the serum sodium concentration is very low.

Possible complications of diuretic therapy include fluid and electrolyte disturbances (including hypovolemia, hypokalemia, hyponatremia, and hypochloremic alkalosis) (see Chapter 10) and encephalopathy. Encephalopathy may be precipitated by dehydration and hypovolemia. In addition, when potassium stores are depleted, the amount of ammonia in the systemic circulation increases, which may cause impaired cerebral functioning and encephalopathy.

Bed Rest

In patients with ascites, an upright posture is associated with activation of the renin–angiotensin–aldosterone system and sympathetic nervous system (Hammer & McPhee, 2019). This causes reduced renal glomerular filtration and sodium excretion and a decreased response to loop diuretics. Therefore, bed rest may be a useful therapy, especially for patients whose condition is refractory to diuretic agents.

Paracentesis

Paracentesis is the removal of fluid (ascites) from the peritoneal cavity through a puncture or a small surgical incision through the abdominal wall under sterile conditions (Hammer & McPhee, 2019; Simonetto et al., 2019). Ultrasound guidance may be indicated in some patients who are at high risk for bleeding because of an abnormal coagulation profile and in those who have had previous abdominal surgery and may have adhesions. Paracentesis was once considered a routine form of treatment for ascites. However, it is now performed primarily for diagnostic examination of ascitic fluid; in treatment for massive ascites that is resistant to nutritional and diuretic therapy and is causing severe problems to the patient; and as a prelude to diagnostic imaging studies, peritoneal dialysis, or surgery. A sample of the ascitic fluid may be sent to the laboratory for cell count, albumin and total protein levels, culture, and other tests.

Large-volume (5 to 6 L) paracentesis is a safe method for treating patients with severe ascites. The use of this therapeutic intervention should not be restricted to patients in whom diuretic therapy has failed but should be

considered the treatment of choice for all patients with large-volume ascites (Hammer & McPhee, 2019; Mansour & McPherson, 2018; Simonetto et al., 2019). This technique, in combination with the IV infusion of salt-poor albumin or other colloid, has become a standard management strategy yielding an immediate effect. Refractive, massive ascites is unresponsive to multiple diuretic agents and sodium restriction for 2 weeks or more and can result in severe sequelae such as respiratory distress, which requires rapid intervention. Albumin infusions help to correct decreases in effective arterial blood volume that lead to sodium retention. The use of this colloid reduces the incidence of postparacentesis circulatory dysfunction with renal dysfunction, hyponatremia, and rapid reaccumulation of ascites associated with decreased effective arterial volume (Hammer & McPhee, 2019; Mansour & McPherson, 2018; Simonetto et al., 2019). The beneficial effects of albumin administration on hemodynamic stability and renal functional status may be related to an improvement in cardiac function as well as a decrease in the degree of arterial vasodilation. Although the patient with cirrhosis has a greatly increased extracellular blood volume, the kidney incorrectly senses that the intravascular volume has decreased. The renin–angiotensin–aldosterone axis is stimulated, and sodium is reabsorbed (Hammer & McPhee, 2019). In addition, antidiuretic hormone secretion increases, which leads to increased retention of free water and sometimes to the development of dilutional hyponatremia. Therapeutic paracentesis provides only temporary removal of fluid; ascites rapidly recurs, necessitating repeated fluid removal.

For the procedural guidelines for assisting with a paracentesis, go to thepoint.lww.com/Brunner15e.

Transjugular Intrahepatic Portosystemic Shunt Assisting with Paracentesis

Transjugular intrahepatic portosystemic shunt (TIPS) is a method of treating ascites in which a cannula is threaded into the portal vein by the transjugular route (see Fig. 43-7). To reduce portal hypertension, an expandable stent is inserted to serve as an intrahepatic shunt between the portal circulation and the hepatic vein. This is extremely effective in decreasing sodium retention, improving the renal response to diuretic therapy, and preventing recurrence of fluid accumulation (Hammer & McPhee, 2019; Simonetto et al., 2019). TIPS is an effective management strategy for refractive ascites. However, due to a higher risk of encephalopathy and higher cost of TIPS compared with large-volume paracentesis plus albumin, many consider TIPS a second-line therapy

for refractive ascites that continues to occur despite medical management (Hammer & McPhee, 2019; Hung & Lee, 2019; Simonetto et al., 2019).

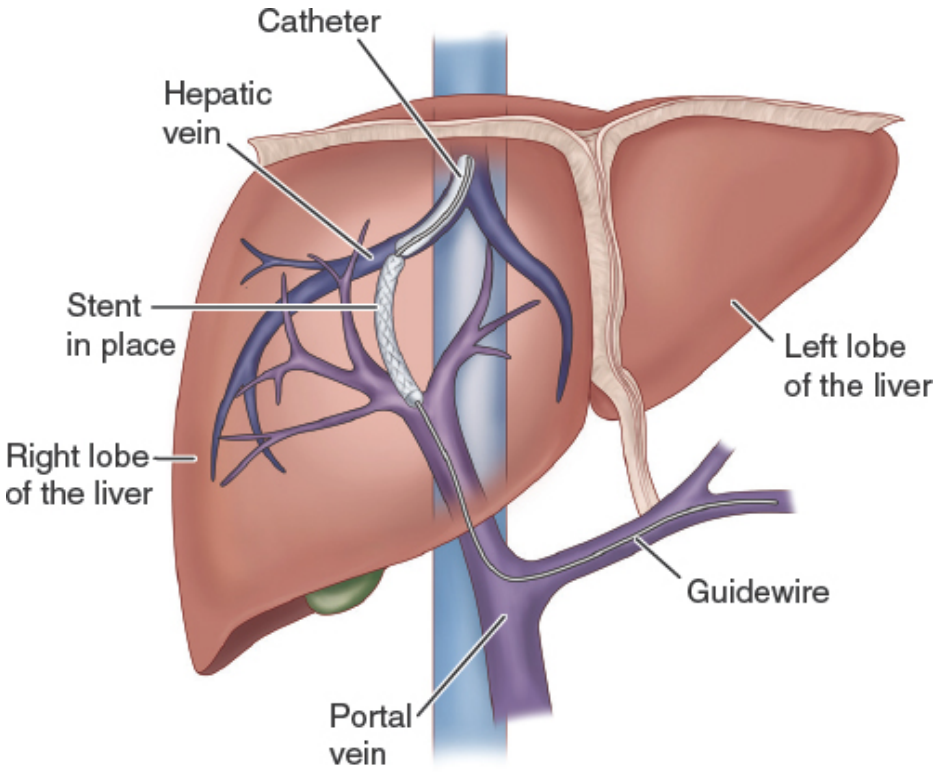

Figure 43-7 • Transjugular intrahepatic portosystemic shunt. A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension.

Because the development of ascites in patients with cirrhosis is associated with a 50% mortality rate, patients considered candidates for liver transplantation may be referred for TIPS if paracentesis is contraindicated.

Other Methods of Treatment

Ascites can also be treated by the insertion of a peritoneovenous shunt to redirect ascitic fluid from the peritoneal cavity into the systemic circulation via an abdominal and a thoracic catheter that drain into the superior vena cava through a one-way valve (Hammer & McPhee, 2019; Simonetto et al., 2019). However, this procedure is rarely used due to the availability of newer, more effective therapies such as TIPS. In patients with ESLD, some with refractory ascites may be candidates for peritoneal catheters for palliation (Macken, Hashim, Mason, et al., 2019).

Nursing Management

If a patient with ascites from liver dysfunction is hospitalized, nursing measures include assessment and documentation of intake and output (I&O), abdominal girth, and daily weight to assess fluid status. The nurse also closely monitors the respiratory status because large volumes of ascites can compress the thoracic cavity and inhibit adequate lung expansion. The nurse monitors serum ammonia, creatinine, and electrolyte levels to assess electrolyte balance, response to therapy, and indications of hepatic encephalopathy.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The patient treated for ascites is likely to be discharged with some ascites still present. Before hospital discharge, the nurse educates the patient and family about the treatment plan, including the need to avoid all alcohol intake, adhere to a low-sodium diet, take medications as prescribed, and check with the primary provider before taking any new medications, including OTC and herbal preparations. Additional home care education is summarized in Chart 43-3.

Continuing and Transitional Care

A referral for transitional, home, or community-based care may be warranted, especially if the patient lives alone or cannot provide self-care. The home visit enables the nurse to assess changes in the patient's condition and weight, abdominal girth, skin, and cognitive and emotional status. The nurse assesses the home environment and the availability of resources needed to adhere to the treatment plan (e.g., a scale to obtain daily weights, facilities to prepare and store appropriate foods, resources to purchase needed medications). The nurse also assesses the patient's adherence to the treatment plan and the ability to buy, prepare, and eat appropriate foods. The nurse reinforces previous education and emphasizes the need for regular follow-up and the importance of keeping scheduled health care appointments.

Esophageal Varices

Esophageal varices are present in 30% of patients with compensated cirrhosis and 60% of patients with decompensated cirrhosis at the time of diagnosis (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019) (see Clinical Manifestations in the Hepatic Cirrhosis section for further discussion). Varices are varicosities that develop from elevated pressure in the veins that drain into the portal system. They are prone to rupture and often are

the source of massive hemorrhages from the upper GI tract and the rectum. In addition, abnormalities in blood clotting, often seen in patients with severe liver disease, increase the likelihood of bleeding with significant blood loss.

Once esophageal varices form, they increase in size over time and may eventually bleed (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019). In cirrhosis, varices are the most significant source of bleeding. The first bleeding episode has a mortality rate of 10% to 30% depending on the severity of the liver disease and is one of the major causes of death in patients with cirrhosis. Overall mortality associated with acute variceal bleeding ranges from 10% to 40%. The mortality rate is related to failure to control a bleeding episode and the occurrence of early rebleeding (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019). Patients surviving the first episode of variceal bleeding are at very high risk for recurrent bleeding (approximately 70%) and death (30% to 50%) (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019).

Pathophysiology

Esophageal varices are dilated, tortuous veins that are usually found in the submucosa of the lower esophagus but may develop higher in the esophagus or extend into the stomach. This condition is almost always caused by portal hypertension, which results from obstruction of the portal venous circulation within the damaged liver.

Chart 43-3  **HOME CARE CHECKLIST**

Management of Ascites

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of ascites and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe effects, side effects, and monitoring parameters for diuretic therapy.
- Discuss importance of avoiding nonsteroidal anti-inflammatory agents, medications containing alcohol (e.g., cough mixtures), antibiotics, or antacids containing salt.
- Make appropriate dietary choices consistent with dietary prescription and recommendations.
  - Explain the use of salt substitutes must be approved by primary provider.
- State the importance of weighing self-daily and keeping a daily record of weight.
  - Maintain record of daily weight, and identify daily weight-loss goals.
  - List weight changes (loss or gain) that should be reported to the primary provider.
- Identify rationale for fluid restrictions (if needed), and for monitoring and keeping a daily record intake and output.
  - Maintain a record of daily intake and output.
  - Identify changes in output that should be reported to primary provider (e.g., decreasing urine output).
- Identify need to stop all alcohol intake as critical to well-being.
- Explain how to contact Alcoholics Anonymous or alcohol counselors in related organizations if indicated.
- Demonstrate how to inspect and care for skin, alleviate pressure over bony prominences by turning when in bed or chair, and decrease edema by position changes.
- Identify early signs and symptoms of complications (encephalopathy, spontaneous bacterial peritonitis, dehydration, electrolyte abnormalities, azotemia).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community).
- Identify the contact details for support services for patients and their caregivers/families.

- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

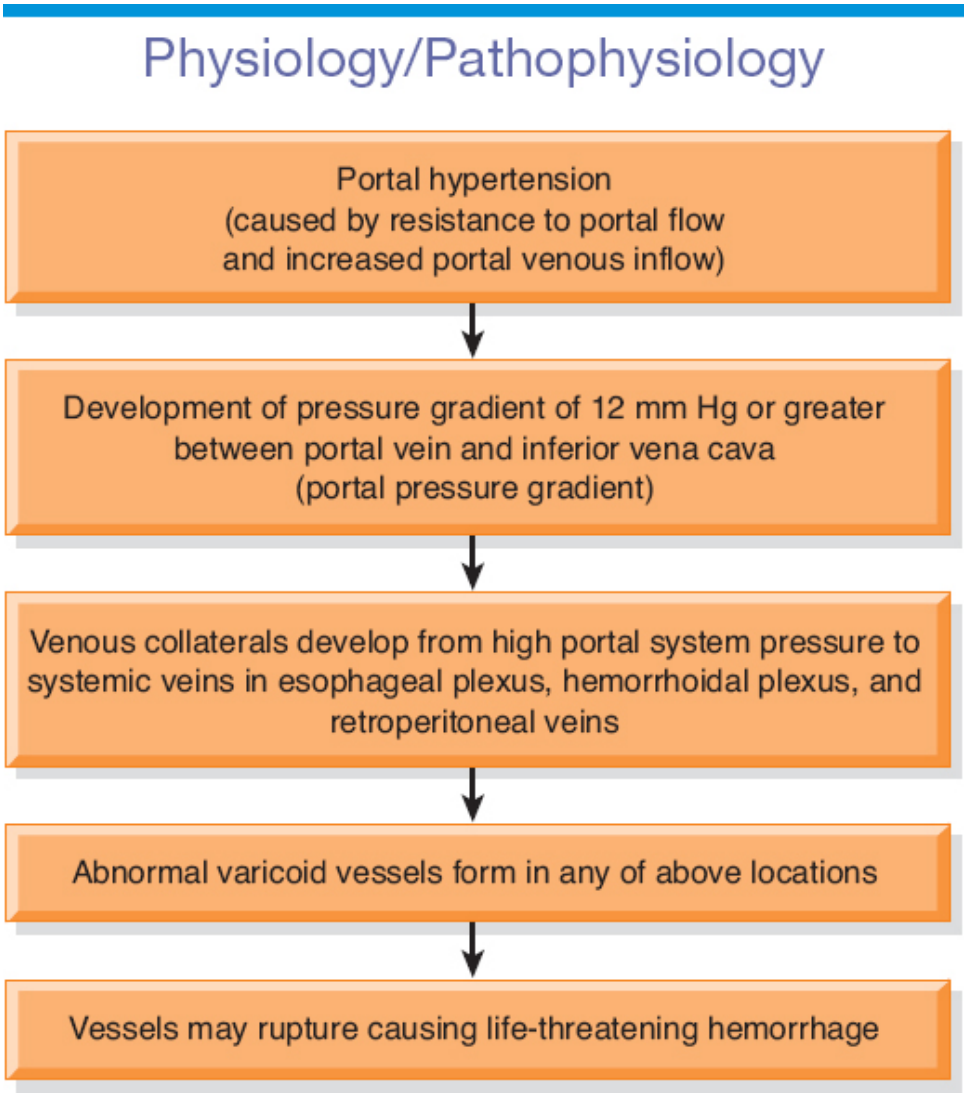

Figure 43-8 • Pathogenesis of bleeding esophageal varices.

Because of increased obstruction of the portal vein, venous blood from the intestinal tract and spleen seeks an outlet through collateral circulation (new pathways for return of blood to the right atrium). The effect is increased pressure, particularly in the vessels in the submucosal layer of the lower esophagus and upper part of the stomach. These collateral vessels are not very elastic; rather, they are tortuous and fragile, and they bleed easily (see Fig. 43-8). Less common causes of varices are abnormalities of the circulation in the splenic vein or superior vena cava and hepatic venothrombosis.

Bleeding esophageal varices are life-threatening and can result in hemorrhagic shock that produces decreased cerebral, hepatic, and renal

perfusion. In turn, there is an increased nitrogen load from bleeding into the GI tract and an increased serum ammonia level, increasing the risk of encephalopathy. Usually, the dilated veins cause no symptoms. However, if the portal pressure increases sharply and the mucosa or supporting structures become thin, massive hemorrhaging occurs.

Factors that contribute to hemorrhage are muscular exertion from lifting heavy objects; straining at stool; sneezing, coughing, or vomiting; esophagitis; irritation of vessels by poorly chewed foods or irritating fluids; and reflux of stomach contents (especially alcohol). Salicylates and any medication that erodes the esophageal mucosa or interferes with cell replication also may contribute to bleeding.

Clinical Manifestations

The patient with bleeding esophageal varices may present with hematemesis, melena, or general deterioration in mental or physical status and often has a history of alcohol abuse. Signs and symptoms of shock (cool clammy skin, hypotension, tachycardia) may be present (see Chapter 11).

Assessment and Diagnostic Findings

Endoscopy is used to identify the bleeding site, along with ultrasonography, CT scanning, and angiography. Another diagnostic tool, the endoscopic video capsule, can detect esophageal varices but does not substitute for endoscopy unless this test cannot be performed. Standard endoscopy is superior to video capsule for the diagnosis of esophageal varices (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019). Because varices are present in 50% of patients with cirrhosis, it is recommended that patients who have been diagnosed with cirrhosis undergo screening endoscopy. If no varices are detected on initial endoscopy, the test should be repeated in 2 to 3 years in an effort to identify and treat large varices, which are the ones most likely to bleed. If small varices are identified on initial endoscopy, the test should be repeated in 1 to 2 years (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019).

Endoscopy

Immediate endoscopy (see Chapter 38) is indicated to identify the cause and the site of bleeding; approximately 40% of patients with suspected bleeding from esophageal varices are actually bleeding from another source (gastritis, ulcer) (Hammer & McPhee, 2019; Kovacs & Jensen, 2019; Simonetto et al., 2019). Nursing support is essential during this often stressful experience. Careful monitoring can detect early signs of cardiac arrhythmias, perforation, and hemorrhage.

After the examination, fluids are not given until the patient's gag reflex returns. Lozenges and gargles may be used to relieve throat discomfort if the patient's physical condition and mental status permit. If the patient is actively bleeding, oral intake will not be permitted, and the patient will be prepared for further diagnostic and therapeutic procedures.

Portal Hypertension Measurements

Portal hypertension may be suspected if dilated abdominal veins and hemorrhoids are detected. Splenomegaly and ascites may also be present. Portal venous pressure can be measured directly or indirectly. Indirect measurement of the hepatic vein pressure gradient is the most common procedure. The measurement requires insertion of a catheter with a balloon into the antecubital or femoral vein. The catheter is advanced under fluoroscopy to a hepatic vein. Fluid is infused once the catheter is in position to inflate the balloon. A "wedged" pressure (similar to pulmonary artery wedge pressure) is obtained by occluding the blood flow in the blood vessel; pressure in the unoccluded vessel is also measured and the hepatic venous pressure gradient (HVPG) is obtained. An HVPG of over 10 mm Hg is indicative of clinically significant portal hypertension (Kovacs & Jensen, 2019). Although the values obtained may underestimate portal pressure, this measurement may be taken several times to evaluate the results of therapy (Kovacs & Jensen, 2019; Schiff et al., 2018).

Direct measurement of portal vein pressure can be obtained by several methods. One direct measurement requires insertion of a catheter into the portal vein or one of its branches (Kovacs & Jensen, 2019; Schiff et al., 2018). Endoscopic measurement of pressure within varices is used only in conjunction with endoscopic sclerotherapy (see later discussion).

Laboratory Tests

Laboratory studies may include various liver function tests, such as serum aminotransferases, bilirubin, alkaline phosphatase, and serum proteins. Splenoportography, which involves serial or segmental x-rays, is used to detect extensive collateral circulation in esophageal vessels, which would indicate varices. Other tests are hepatoportography and celiac angiography. These are usually performed in the operating room or x-ray department.

Medical Management

Bleeding from esophageal varices is an emergency that can quickly lead to hemorrhagic shock. The patient is critically ill, requiring aggressive medical care and expert nursing care, and is usually transferred to the intensive care unit (ICU) for close monitoring and management. See Chapter 11 for a

discussion of care of the patient in shock. The extent of bleeding is evaluated, and vital signs are monitored continuously if hematemesis and melena are present.

Because patients with bleeding esophageal varices have intravascular volume depletion and are subject to electrolyte imbalance, IV fluids, electrolytes, and volume expanders are provided to restore fluid volume and replace electrolytes. Transfusion of blood components also may be required.

Caution must be taken with volume resuscitation so that overhydration does not occur, because this would raise portal pressure and increase bleeding. An indwelling urinary catheter is usually inserted to permit frequent monitoring of urine output.

Although a variety of pharmacologic, endoscopic, and surgical approaches are used to treat bleeding esophageal varices, none is ideal, and most are associated with considerable risk to the patient. Nonsurgical treatment of bleeding esophageal varices is preferable because of the high mortality rate of emergency surgery to control bleeding esophageal varices and because of the poor physical condition that is typical of the patient with severe liver dysfunction.

Pharmacologic Therapy

In suspected variceal bleeding, vasoactive drugs such as octreotide or vasopressin need to be given as soon as possible and before endoscopy (Kovacs & Jensen, 2019; Simonetto et al., 2019). In a patient who is actively bleeding, medications are given initially because they can be obtained and given more quickly than other therapies. Octreotide, a synthetic analog of the hormone somatostatin, is effective in decreasing bleeding from esophageal varices, and lacks the vasoconstrictive effects of vasopressin. Because of this safety and efficacy profile, octreotide is considered the preferred treatment regimen for immediate control of variceal bleeding. These medications cause selective splanchnic vasoconstriction by inhibiting glucagon release and are used mainly in the management of active hemorrhage. Adverse effects are rare with octreotide but mild hypoglycemia and abdominal cramping can occur (Kovacs & Jensen, 2019; Simonetto et al., 2019).

Vasopressin may be the initial mode of therapy in urgent situations because it produces constriction of the splanchnic arterial bed and decreases portal pressure. As described previously, splanchnic circulation comprises the arterial blood supply and venous drainage of the entire GI tract from the distal esophagus to the midrectum, including the liver and spleen. Vasopressin constricts distal esophageal and proximal gastric veins, thus reducing the inflow into the portal system and therefore the portal pressure. Vital signs and the presence or absence of blood in the gastric aspirate indicate the effectiveness of vasopressin. Monitoring of I&O and electrolyte levels is

necessary because hyponatremia may develop, and vasopressin may have an antidiuretic effect.

Coronary artery disease is a contraindication to the use of vasopressin because coronary vasoconstriction is a side effect that may precipitate myocardial infarction. The combination of vasopressin with nitroglycerin (given by the IV, sublingual, or transdermal route) has been effective in reducing or preventing the side effects (constriction of coronary vessels and angina) caused by vasopressin alone. Side effects of vasopressin include myocardial and extremity ischemia as well as cardiac arrhythmias; therefore, vasopressin is used only in urgent situations or when other agents such as octreotide are not available. Vasopressin must be given with close monitoring (Kovacs & Jensen, 2019; Simonetto et al., 2019).

Beta-blocking agents such as propranolol, nadolol, or carvedilol that decrease portal pressure are the most common medications used both to prevent a first bleeding episode in patients with known varices and to prevent rebleeding (Bunchorntavakul & Reddy, 2019; Hammer & McPhee, 2019; Simonetto et al., 2019). Beta-blockers have been shown to effectively reduce the risk of variceal bleeding and its associated mortality. Beta-blockers should not be used in acute variceal hemorrhage, but they are effective prophylaxis against initial and recurrent bleeding episodes (Bunchorntavakul & Reddy, 2019; Hammer & McPhee, 2019; Simonetto et al., 2019). Nitrates such as isosorbide lower portal pressure by venodilation and decreased cardiac output and may be used in combination with beta-blockers to reduce the risk of recurrent variceal bleeding (Bunchorntavakul & Reddy, 2019; Kovacs & Jensen, 2019).

Balloon Tamponade

Although used infrequently today, balloon tamponade therapy may be used to temporarily control hemorrhage and to stabilize a patient with massive bleeding prior to other definitive management (Kovacs & Jensen, 2019; Simonetto et al., 2019). This procedure involves the insertion of a tube from the nose into the stomach. This tube has two inflatable balloons, one esophageal and one gastric. When inflated from a port external to the patient, these balloons compress bleeding varices in the stomach or esophagus to inhibit bleeding.

When indicated, balloon tamponade can be successful; however, there are risks. Displacement of the tube and the inflated balloon into the oropharynx can cause life-threatening obstruction of the airway and asphyxiation. This may occur if the patient pulls on the tube because of confusion or discomfort. It may also result from rupture of the gastric balloon, which causes the

esophageal balloon to move into the oropharynx. Sudden rupture of the balloon causes airway obstruction and aspiration of gastric contents into the lungs. Therefore, the tube must be tested before insertion to minimize this risk by ensuring that the balloons can attain and maintain inflation. Aspiration of blood and secretions into the lungs is frequently associated with balloon tamponade, especially in the stuporous or comatose patient. Endotracheal intubation before insertion of the tube protects the airway and minimizes the risk of aspiration. Ulceration and necrosis of the nose, the mucosa of the stomach, or the esophagus may occur if the tube is left in place too long, inflated too long, or inflated at too high a pressure. The therapy is used for as short a time as possible to control bleeding while emergency treatment is completed and definitive therapies are instituted (no longer than 12 hours, preferably less) (Kovacs & Jensen, 2019; Mansour & McPherson, 2018; Simonetto et al., 2019).

Quality and Safety Nursing Alert

The patient being treated with balloon tamponade must remain under close observation in the ICU and must be monitored continuously because of the risk of serious complications such as aspiration, esophageal ulcer formation, and perforation. Precautions must be taken to ensure that the patient does not pull on or inadvertently displace the tube.

Nursing measures include frequent mouth and nasal care. For secretions that accumulate in the mouth, tissues should be within easy reach of the patient. Oral suction may be necessary to remove secretions.

Although balloon tamponade stops the bleeding in 90% of patients, bleeding recurs in 60% to 70%, necessitating other treatment modalities, such as endoscopic therapies (see later discussion). Once the balloons are deflated or the tube is removed, the patient must be assessed frequently because of the high risk of recurrent bleeding (Kovacs & Jensen, 2019; Mansour & McPherson, 2018; Simonetto et al., 2019).

Endoscopic Sclerotherapy

In endoscopic **sclerotherapy** (see Fig. 43-9), also referred to as injection sclerotherapy, a sclerosing agent (i.e., sodium morrhuate, ethanolamine oleate, sodium tetradecyl sulfate, or ethanol) is injected through a fiberoptic endoscope into or adjacent to the bleeding esophageal varices to promote thrombosis and eventual sclerosis (Kovacs & Jensen, 2019; Mansour & McPherson, 2018). The process of sclerotherapy causes inflammation of the involved vein with eventual thrombosis and loss of the lumen of the vessel.

The procedure has been used successfully to treat acute GI hemorrhage but is not recommended for prevention of first and subsequent variceal bleeding episodes where **endoscopic variceal ligation (EVL)**, also known as esophageal banding therapy (discussed later), is the first-line treatment (Kovacs & Jensen, 2019; Mansour & McPherson, 2018).

After treatment for acute hemorrhage, the patient must be observed for bleeding, perforation of the esophagus, aspiration pneumonia, and esophageal stricture. Antacids, histamine-2 (H_2) antagonists such as cimetidine, or proton pump inhibitors such as pantoprazole may be given after the procedure to counteract the chemical effects of the sclerosing agent on the esophagus and the acid reflux associated with the therapy.

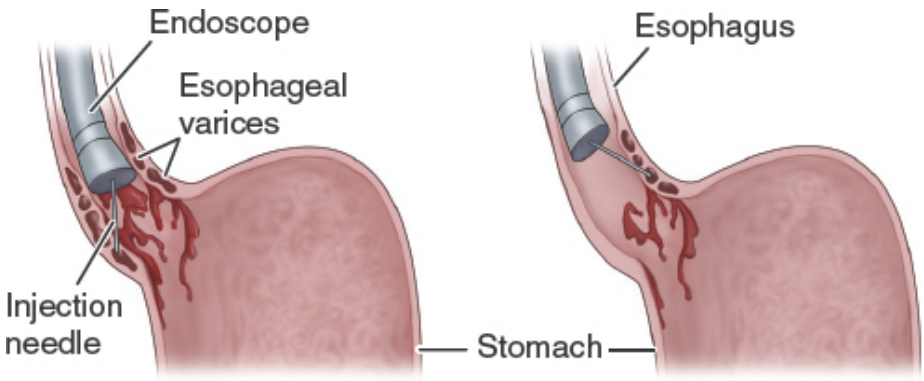

Figure 43-9 • Endoscopic or injection sclerotherapy. Injection of sclerosing agent into esophageal varices through an endoscope promotes thrombosis and eventual sclerosis, thereby obliterating the varices.

Endoscopic Variceal Ligation (Esophageal Banding Therapy)

In EVL (see Fig. 43-10), also referred to as variceal banding, a modified endoscope loaded with an elastic rubber band is passed through an overtube directly onto the varix (or varices) to be banded. After the bleeding varix is suctioned into the tip of the endoscope, the rubber band is slipped over the tissue, causing necrosis, ulceration, and eventual sloughing of the varix.

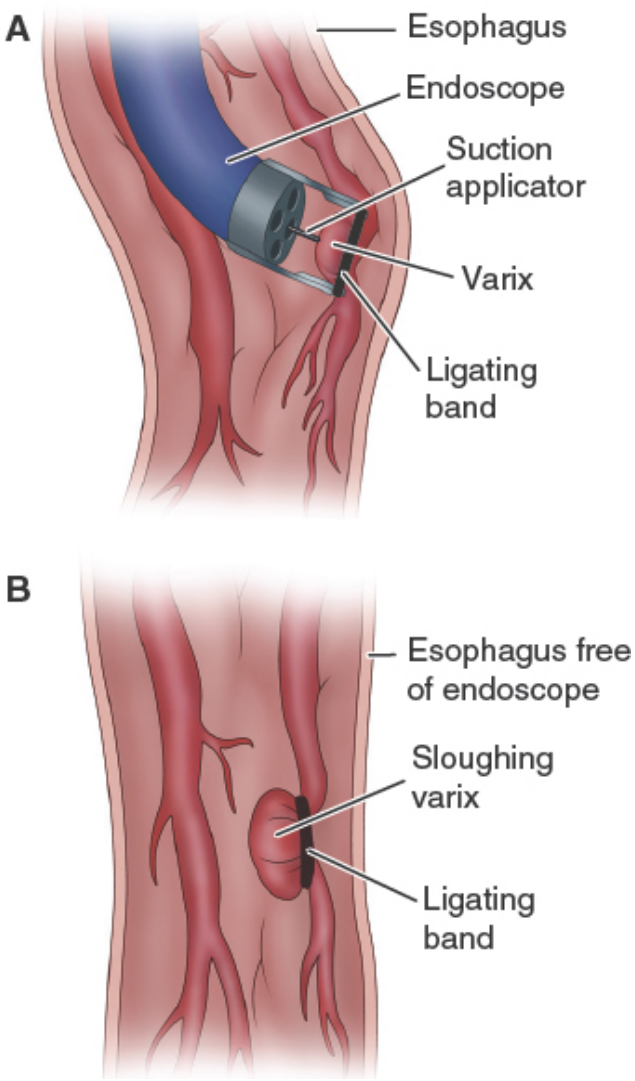

Figure 43-10 • Endoscopic variceal ligation. **A.** A rubber band–like ligature is slipped over an esophageal varix via an endoscope. **B.** Necrosis results, and the varix eventually sloughs off.

An EVL procedure is effective in controlling acute bleeding. Compared with sclerotherapy, EVL also significantly reduces the rebleeding rate, mortality, procedure-related complications, as well as number of sessions needed to eradicate varices and thus has replaced sclerotherapy as the treatment of choice in the management of esophageal varices (Kovacs & Jensen, 2019; Simonetto et al., 2019). Potential complications include superficial ulceration and dysphagia, transient chest discomfort, and, rarely, esophageal strictures. An EVL procedure in combination with pharmacologic therapy may be more effective than monotherapy (i.e., a single mode of therapy) in the treatment of acute hemorrhage. EVL is also recommended for patients who have experienced variceal bleeding while receiving beta-blocker therapy and for those who cannot tolerate beta-blocking agents (Kovacs & Jensen, 2019; Simonetto et al., 2019).

Transjugular Intrahepatic Portosystemic Shunt

A TIPS procedure (see Fig. 43-9) is indicated for the treatment of an acute episode of uncontrolled variceal bleeding refractory to pharmacologic or endoscopic therapy. In 10% to 20% of patients for whom urgent band ligation or sclerotherapy and medications are not successful in eradicating bleeding, a TIPS procedure can effectively control acute variceal hemorrhage by rapidly lowering portal pressure. Polytetrafluoroethylene-covered TIPS placement should be considered in high-risk patients with cirrhosis and active bleeding at the time of endoscopy (Kovacs & Jensen, 2019; Simonetto et al., 2019). Potential complications of TIPS include bleeding, sepsis, heart failure, organ perforation, shunt thrombosis, and progressive liver failure.

Additional Therapies

The use of endoscopically placed tissue adhesives and fibrin glue has been successful in the treatment of gastric and esophageal varices. Coated expandable stents (placed via endoscope) have also been used effectively for the same purpose (Kovacs & Jensen, 2019; Simonetto et al., 2019). Portosystemic shunting into lower resistance vessels (those vessels not affected by the high pressure in the portal system) and the end-organ collateral variceal formation that results in bleeding may also be treated by a variety of embolization procedures, including balloon-occluded retrograde transvenous obliteration (BRTO) (Brunicardi, 2019; Philips, Rajesh, Augustine, et al., 2019).

Surgical Management

Several surgical procedures have been developed to treat esophageal varices and to minimize rebleeding, but these procedures have significant risk. Procedures that may be used for esophageal varices are direct surgical ligation of varices; splenorenal, mesocaval, and portacaval venous shunts to relieve portal pressure; and esophageal transection with devascularization. These procedures are rarely used and remain controversial, as studies regarding their effectiveness and outcomes continue. What is known is that these procedures are very effective in controlling variceal bleeding. They may be considered as second-line management (rescue therapy) in those patients for whom all other treatments have failed, those who are not candidates for liver transplantation, and those who require a bridge to transplantation. There is a high incidence of encephalopathy after the surgical shunting procedures, and morbidity and mortality statistics remain high (Kovacs & Jensen, 2019; Philips et al., 2019). The TIPS procedure has largely replaced the use of surgical decompression shunts and ligation procedures but these interventions may still be used in some cases to manage esophageal varices.

Surgical Bypass Procedures

Surgical decompression (shunt surgery) of the portal circulation may be used with the advent of a variceal bleeding episode. Although effective in eradicating bleeding, survival statistics and encephalopathy are worse than other preventative measures such as a TIPS procedure when this method is employed for prophylaxis, and shunt surgery for this purpose has largely been abandoned worldwide (Brunicardi, 2019; Kovacs & Jensen, 2019). The current recommendation is that surgical shunts be considered only in patients who have Model for End-Stage Liver Disease (MELD) scores of <15, who are not candidates for hepatic transplantation, or who have limited access to TIPS therapy and needed follow-up. (See later discussion of MELD classification in Liver Transplantation section.)

An aim of a surgical shunt is to reduce portal venous pressure (Brunicardi, 2019). One surgical shunting procedure (see Fig. 43-11) is the distal splenorenal shunt, which is made between the splenic vein and the left renal vein after splenectomy. A mesocaval shunt is created by anastomosing the superior mesenteric vein to the proximal end of the vena cava or to the side of the vena cava using grafting material. The goal of distal splenorenal and mesocaval shunts is to decrease portal pressure by draining only a portion of venous blood from the portal bed; therefore, they are considered selective shunts. The liver continues to receive some portal flow, and the incidence of encephalopathy may be reduced. Portacaval shunts are considered nonselective shunts because they divert all portal flow to the vena cava via end-to-side or side-to-side approaches.

These procedures are extensive and are not always successful because of secondary thrombosis in the veins used for the shunt and because of complications (e.g., encephalopathy, accelerated liver failure). The effectiveness of these procedures has been studied extensively. All shunt procedures are equally effective in preventing recurrent variceal bleeding but may cause further impairment of liver function and encephalopathy. Partial portacaval shunts with interposition grafts are as effective as other shunts but are associated with a lower rate of encephalopathy (Cameron & Cameron, 2020; Schiff et al., 2018). The severity of the disease (by a classification such as the Child–Pugh system, discussed later) and the potential for future liver transplantation guide the treatment decision. If the cause of portal hypertension is the rare Budd–Chiari syndrome (which is manifested by noncirrhotic portal hypertension caused by hepatic vein thrombosis) or other venous obstructive disease, a portacaval or a mesoatrial shunt may be performed (see Fig. 43-11). The mesoatrial shunt is required when the infrahepatic vena cava is thrombosed and must be bypassed.

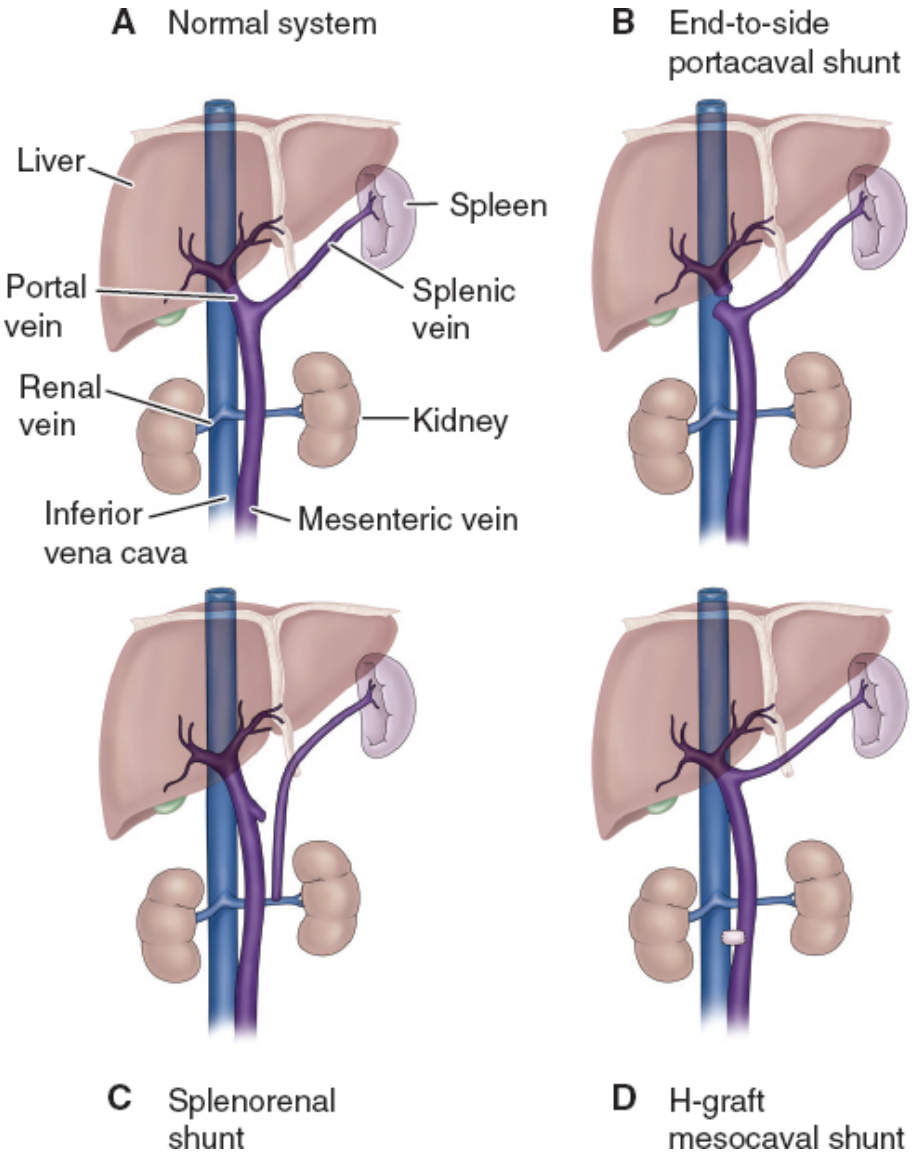

Figure 43-11 • Portosystemic shunts. **A.** Normal portal system. **B–D.** Examples of portal shunts to reduce portal pressure.

Devascularization and Transection

Devascularization and staple-gun transection procedures to separate the bleeding site from the high-pressure portal system have been used in the emergency management of variceal bleeding. The lower end of the esophagus is reached through a small gastrostomy incision; a staple gun permits anastomosis of the transected ends of the esophagus. Rebleeding is a risk, and the outcomes of these procedures vary among patient populations.

Quality and Safety Nursing Alert

The surgical procedures used to treat esophageal varices do not alter the course of the progressive liver disease, and bleeding may recur as new collateral vessels develop. The risk of complications (hypovolemic or hemorrhagic shock, hepatic encephalopathy, electrolyte imbalance, metabolic and respiratory alkalosis, alcohol withdrawal syndrome, and seizures) is high.

Nursing Management

Nursing assessment includes monitoring the patient's physical condition and evaluating emotional responses and cognitive status. The nurse monitors and records vital signs and assesses the patient's nutritional and neurologic status. This assessment assists in identifying hepatic encephalopathy (see later discussion).

If complete rest of the esophagus is indicated because of bleeding, parenteral nutrition is initiated. Gastric suction usually is initiated to keep the stomach as empty as possible and to prevent straining and vomiting. The patient often complains of severe thirst, which may be relieved by frequent oral hygiene and moist sponges to the lips. The nurse closely monitors the blood pressure. Vitamin K therapy and multiple blood transfusions often are indicated because of blood loss. A quiet environment and calm reassurance may help to relieve the patient's anxiety and reduce agitation.

Bleeding anywhere in the body is anxiety provoking, resulting in a crisis for the patient and family. If the patient has been a heavy user of alcohol, delirium secondary to alcohol withdrawal can complicate the situation. The nurse provides support and explanations about medical and nursing interventions to prepare both the patient and the family, because these procedures can be difficult to undergo and observe. Close monitoring of the patient helps in detecting and managing complications. Management modalities and nursing care of the patient with bleeding esophageal varices are summarized in Table 43-2.

TABLE 43-2 Select Modalities and Nursing Care for the Patient with Bleeding Esophageal Varices

Treatment Modality[a]	Nursing Interventions
Nonsurgical Modalities	
Pharmacologic agents	Observe response to therapy.
Propranolol Carvedilol Nadolol Vasopressin	Monitor for side effects: *propranolol, carvedilol, nadolol*—decreased pulse pressure, impaired cardiovascular response to hemorrhage; *vasopressin*—angina (nitroglycerin may be prescribed to prevent or treat angina).
Octreotide	Support patient during treatment.
Balloon tamponade	Explain procedure to patient briefly to obtain cooperation with insertion and maintenance of esophageal/gastric tamponade tube and reduce patient's fear of the procedure. Monitor closely to prevent inadvertent removal or displacement of tube, subsequent airway obstruction, and aspiration. Provide frequent oral hygiene.
Endoscopic sclerotherapy	Observe for aspiration, perforation of the esophagus, and recurrence of bleeding after treatment.
Endoscopic variceal ligation	Observe for recurrence of bleeding, esophageal perforation.
Transjugular intrahepatic portosystemic shunt (TIPS)	Observe for rebleeding and signs of infection.
Balloon-occluded retrograde transvenous obliteration (BRTO) procedure	Observe for rebleeding, signs of infection, or changes in mental status.
Surgical Modalities	
Portal-systemic shunt	Observe for development of portal-systemic encephalopathy (altered mental status, neurologic dysfunction), hepatic failure, and rebleeding. Requires intensive, expert nursing care for prolonged period.
Surgical ligation of varices	Observe for rebleeding.
Esophageal transection and devascularization	Observe for rebleeding. Provide postthoracotomy care.

[a]Several modalities may be used concurrently or in sequence.

Hepatic Encephalopathy and Coma

Hepatic encephalopathy, or portosystemic encephalopathy, is a life-threatening complication of liver disease that occurs with profound liver failure. Patients with this condition may have no overt signs of the illness but have abnormalities on neuropsychological testing (Hammer & McPhee, 2019; Simonetto et al., 2019; Yanny, Winters, Boutros, et al., 2019). Hepatic encephalopathy is the neuropsychiatric manifestation of hepatic failure associated with portal hypertension and the shunting of blood from the portal venous system into the systemic circulation (Mansour & McPherson, 2018; Yanny et al., 2019). This reversible metabolic form of encephalopathy can improve with recovery of liver function. The onset is often insidious and subtle, and initially the disease is termed *subclinical* or *minimal hepatic encephalopathy.*

Pathophysiology

Despite the frequency with which hepatic encephalopathy occurs, the precise pathophysiology is not fully understood (Yanny et al., 2019). Two major alterations underlie its development in acute and chronic liver disease. First, hepatic insufficiency may result in encephalopathy because of the inability of the liver to detoxify toxic by-products of metabolism. Second, portosystemic shunting, in which collateral vessels develop as a result of portal hypertension, allows elements of the portal blood (laden with potentially toxic substances usually extracted by the liver) to enter the systemic circulation (Yanny et al., 2019). Ammonia is considered the major etiologic factor in the development of encephalopathy. Ammonia enters the brain and excites peripheral benzodiazepine-type receptors on astrocyte cells, increasing neurosteroid synthesis, and stimulating gamma-aminobutyric acid (GABA) neurotransmission. GABA causes depression of the central nervous system that inhibits neurotransmission and synaptic regulation (Yanny et al., 2019), producing sleep and behavior patterns associated with hepatic encephalopathy.

Circumstances that increase serum ammonia levels tend to aggravate or precipitate hepatic encephalopathy. The largest source of ammonia is the enzymatic and bacterial digestion of dietary and blood proteins in the GI tract. Ammonia from these sources increases as a result of GI bleeding (i.e., bleeding esophageal varices, chronic GI bleeding), a high-protein diet, bacterial infection, or uremia. The ingestion of ammonium salts also increases the blood ammonia level. In the presence of alkalosis or hypokalemia, increased amounts of ammonia are absorbed from the GI tract and from the

renal tubular fluid. Conversely, serum ammonia is decreased by elimination of protein from the diet and by the administration of antibiotics, such as neomycin sulfate, which reduce the number of intestinal bacteria capable of converting urea to ammonia (Hammer & McPhee, 2019; Yanny et al., 2019).

Other factors unrelated to increased serum ammonia levels that can cause hepatic encephalopathy in susceptible patients include excessive diuresis, dehydration, infections, surgery, fever, and some medications (sedatives, tranquilizers, analgesics, and diuretics that cause potassium loss). Additional causes include elevated levels of serum manganese (Schiff et al., 2018), as well as changes in the types of circulating amino acids, mercaptans, and levels of dopamine and other neurotransmitters in the central nervous system (Schiff et al., 2018). Mercaptans are toxic metabolites of sulfur-containing compounds that are excreted by the liver under normal conditions. Mercaptans and these other so-called "false" neurotransmitters may be generated from an intestinal source or from metabolism of protein by the liver and, with defective hepatic clearance, may precipitate encephalopathy.

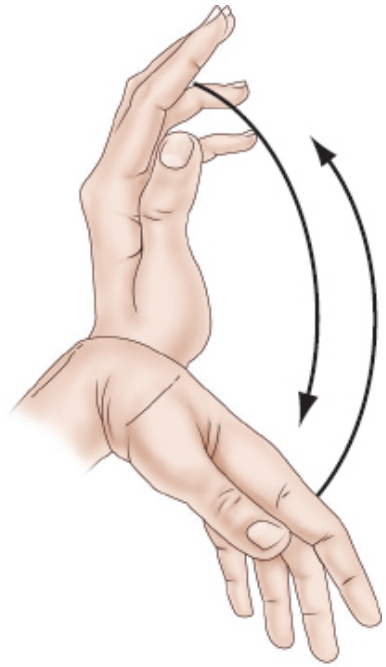

Figure 43-12 • Asterixis ("liver flap") may occur in hepatic encephalopathy. The patient is asked to hold the arm out with the handheld upward (dorsiflexed). Within a few seconds, the hand falls forward involuntarily and then quickly returns to the dorsiflexed position.

Clinical Manifestations

The earliest symptoms of hepatic encephalopathy include mental status changes and motor disturbances. The patient appears confused and unkempt

and has alterations in mood and sleep patterns. The patient tends to sleep during the day and has restlessness and insomnia at night. As hepatic encephalopathy progresses, the patient may become difficult to awaken and completely disoriented with respect to time and place. With further progression, the patient lapses into frank coma and may have seizures.

Asterixis, an involuntary flapping of the hands, may be seen in stage II encephalopathy (see Fig. 43-12). Simple tasks, such as handwriting, become difficult. A handwriting or drawing sample (e.g., star figure), taken daily, may provide graphic evidence of progression or reversal of hepatic encephalopathy. Inability to reproduce a simple figure in two or three dimensions (see Fig. 43-13) is referred to as **constructional apraxia**. In the early stages of hepatic encephalopathy, the deep tendon reflexes are hyperactive; with worsening of the encephalopathy, these reflexes disappear and the extremities may become flaccid.

Occasionally, **fetor hepaticus**, a sweet, slightly fecal odor to the breath that is presumed to be of intestinal origin, may be noticed. The odor has also been described as similar to that of freshly mowed grass, acetone, or old wine. Fetor hepaticus is prevalent with extensive collateral portal circulation in chronic liver disease.

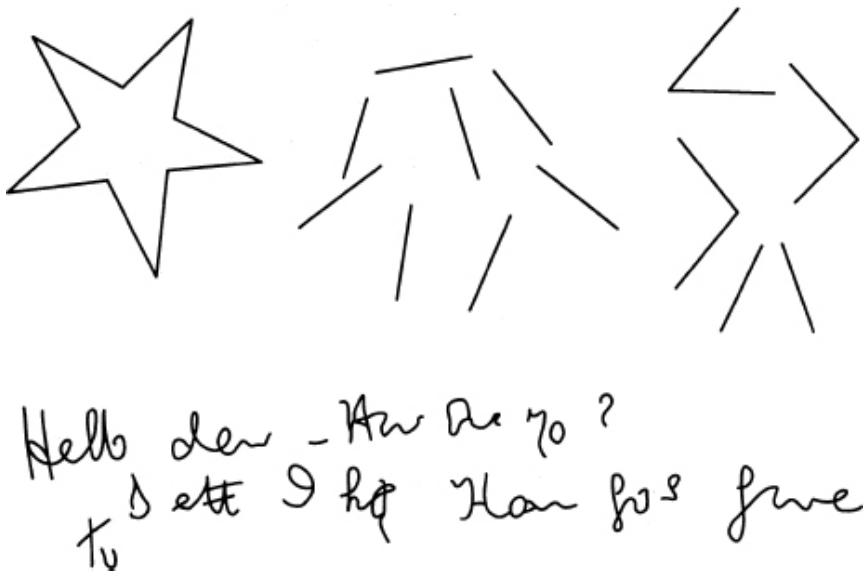

Figure 43-13 • Effects of constructional apraxia. Deterioration of handwriting and inability to draw a simple star figure occurs with progressive hepatic encephalopathy. Reprinted with permission from Morgan, M. (2018). Hepatic encephalopathy in patients with cirrhosis. In J. Dooley, A. S. Lok, G. Garcia-Tsao, & P. Massimo (Eds.). *Sherlock's diseases of the liver and biliary system* (13th ed.). Oxford, UK: John Wiley & Sons.

Assessment and Diagnostic Findings

Several diagnostic algorithms and a variety of psychometric tests are used in determining the presence and severity of hepatic encephalopathy. The electroencephalogram shows generalized slowing, an increase in the amplitude of brain waves, and characteristic triphasic waves. The survival rate after a first episode of overt hepatic encephalopathy in patients with cirrhosis is approximately 40% at 1 year. Eligible patients should be referred for liver transplantation after this initial episode (Mansour & McPherson, 2018; Yanny et al., 2019).

Medical Management

Medical management focuses on identifying and eliminating the precipitating cause, if possible, initiating ammonia-lowering therapy, minimizing potential medical complications of cirrhosis and depressed consciousness, and reversing the underlying liver disease, if possible. Correction of the possible reasons for the deterioration such as bleeding, electrolyte abnormalities, sedation, or azotemia is essential. Lactulose is given to reduce serum ammonia levels. It acts by trapping and expelling the ammonia in the feces (Hammer & McPhee, 2019; Mansour & McPherson, 2018; Yanny et al., 2019). Two or three soft stools per day are desirable; this indicates that lactulose is performing as intended.

Quality and Safety Nursing Alert

The patient receiving lactulose is monitored closely for the development of watery diarrhea stools, because they indicate a medication overdose. Serum ammonia levels are closely monitored as well.

Possible side effects of lactulose include intestinal bloating and cramps, which usually disappear within a week. To mask the sweet taste, which some patients dislike, it can be diluted with fruit juice. The patient is closely monitored for hypokalemia and dehydration. Other laxatives are not prescribed during lactulose administration because their effects disturb dosage regulation. Lactulose may be given by nasogastric tube or enema for patients who are comatose or for those in whom oral administration is contraindicated or not possible (Yanny et al., 2019).

Other management strategies include IV administration of glucose to minimize protein breakdown, administration of vitamins to correct deficiencies, and correction of electrolyte imbalances (especially potassium). Antibiotics may also be added to the treatment regimen. Neomycin, metronidazole, and rifaximin have been used to reduce levels of ammonia-

forming bacteria in the colon. However, no benefit has been shown for long-term treatment with these antibiotics (Mansour & McPherson, 2018; Yanny et al., 2019). Additional management strategies for hepatic encephalopathy include the following:

- Neurologic status is assessed frequently.
- Mental status is monitored by keeping a daily record of handwriting and arithmetic performance.
- I&O and body weight are recorded each day.
- Vital signs are measured and recorded every 4 hours.
- Potential sites of infection (peritoneum, lungs) are assessed frequently, and abnormal findings are reported promptly.
- Serum ammonia level is monitored daily.
- Dietary protein intake should not be restricted in hepatic encephalopathy as recommended in the past. Protein intake should be maintained at 1.2 to 1.5 g/kg/day (European Association for the Study of the Liver [EASL], 2019; Styskel, Natarajan, & Kanwal, 2019; Yanny et al., 2019; Yao, Fung, Chu, et al., 2018) (see Chart 43-4). The danger of protein malnutrition far outweighs the risk of worsening hepatic encephalopathy caused by increased protein intake (Styskel et al., 2019; Yanny et al., 2019; Yao et al., 2018).
- Enteral feeding is provided for patients whose encephalopathic state persists.
- Reduction in the absorption of ammonia from the GI tract is accomplished by the use of gastric suction, enemas, or oral antibiotics.
- Electrolyte status is monitored and corrected if abnormal.
- Sedatives, tranquilizers, and analgesic medications are discontinued.
- Benzodiazepine antagonists such as flumazenil may be administered IV to improve encephalopathy, whether or not the patient has previously taken benzodiazepines. This action may have short-term efficacy because patients with hepatic encephalopathy have an increased concentration of benzodiazepine receptors (Friedman & Martin, 2018).

Chart 43-4

Nutritional Management of Hepatic Encephalopathy

- Minimize the formation and absorption of toxins, principally ammonia, from the intestine.
- Keep daily protein intake between 1.2 and 1.5 g/kg body weight per day.
- Avoid protein restriction if possible, even in those with encephalopathy.
- For patients who are truly protein intolerant, provide additional nitrogen in the form of an amino acid supplement. The use of branched-chain amino acids should be a consideration in patients with cirrhosis. It has improved outcomes in varied populations with the disease.
- Provide small, frequent meals and 3 small snacks per day in addition to a late-night snack before bed.

Nursing Management

Table 43-3 presents the stages of hepatic encephalopathy, common signs and symptoms, and potential nursing diagnoses for each stage. The nurse is responsible for maintaining a safe environment to prevent injury, bleeding, and infection. The nurse administers the prescribed treatments and monitors the patient for the numerous potential complications. The potential for respiratory compromise is great given the patient's depressed neurologic status. The nurse encourages deep breathing and position changes to prevent the development of atelectasis, pneumonia, and other respiratory complications. Despite aggressive pulmonary care, patients may develop respiratory compromise. They may require intubation and mechanical ventilation to protect the airway, and they are frequently admitted to the ICU.

The nurse communicates with the patient's family to inform them about the patient's status and supports them by explaining the procedures and treatments that are part of the patient's care. If the patient recovers from hepatic encephalopathy and coma, rehabilitation is likely to be prolonged. Therefore, the patient and family will require assistance to understand the causes of this severe complication and to recognize that it may recur.

Promoting Home, Community-Based and Transitional Care

Educating Patients About Self-Care

If the patient has recovered from hepatic encephalopathy and is to be discharged home, the nurse educates the family about subtle signs of recurrent encephalopathy. The goals for caloric intake and protein intake should be 35 to 40 kcal/kg body weight per day and 1.2 to 1.5 g/kg body weight per day (see Chart 43-4) (Styskel et al., 2019; Yanny et al., 2019; Yao et al., 2018). Protein intake should not be limited too severely, because doing so worsens nutritional status and increases mortality (Styskel et al., 2019; Yanny et al., 2019; Yao et al., 2018). Continued use of lactulose after discharge is not uncommon, and the patient and family should closely monitor its efficacy and side effects. They should also be cautioned that constipation can precipitate encephalopathy and may be prevented through the prescribed use of lactulose.

Continuing and Transitional Care

Referral for transitional, home, or community-based care is warranted for the patient who returns home after recovery from hepatic encephalopathy. The nurse assesses the patient's physical and mental status and collaborates closely with the primary provider. The home visit provides an opportunity for the nurse to assess the home environment and the ability of the patient and family to monitor signs and symptoms and follow the treatment regimen. The nurse must evaluate the patient's fluid volume status and be alert for changes indicative of hypovolemia due to decreased intake and for decreased urine output associated with hepatorenal syndrome (see later discussion). Monitoring of laboratory values continues to be important, and the nurse must obtain prescriptions to correct abnormalities, especially electrolyte imbalances, which also can worsen encephalopathy.

The safety of the home environment is assessed closely to identify areas of risk for falls and other injuries. Home or transitional care visits are especially important if the patient lives alone because encephalopathy may affect the patient's ability to remember or follow the treatment regimen. The nurse reinforces previous education and reminds the patient and family about the importance of dietary restrictions, close monitoring, and follow-up. In addition, the nurse must observe the patient for subtle behavior changes of worsening hepatic encephalopathy. Patients with all types and stages of hepatic encephalopathy should have periodic neurologic evaluations to determine their cognitive function so that they do not engage in potentially harmful activities. Even subtle neuropsychiatric abnormalities may preclude patients from

driving, operating machinery, or participating in other activities that require psychomotor coordination.

Patients and families may need additional support during those times that the patient exhibits mood disturbances and sleep disorders. Patients should be as active as possible during the day and develop a normal sleep–wake pattern. Sedating medications should be avoided because they may precipitate encephalopathy. Patients and families may require assistance in developing plans to cope with changes in mood and mental status changes. This plan should identify support persons to attend to the patient in the home if needed. Social workers and case managers may make appropriate referrals for assistance with physical and psychosocial support and care. Referrals to psychologists, psychiatric liaison nurses, case managers, social workers, or therapists may assist family members with coping. Spiritual advisors may also provide another outlet for communication and guidance. If alcohol played a role in the development of the liver disease and encephalopathy, referral to Alcoholics Anonymous or Al-Anon may provide needed support and education.

TABLE 43-3 Stages of Hepatic Encephalopathy and Applicable Nursing Diagnoses

Stage	Clinical Symptoms	Clinical Signs and EEG Changes	Select Potential Nursing Diagnoses[a]
1	Normal level of consciousness with periods of lethargy and euphoria; reversal of day–night sleep patterns	Impaired writing and ability to draw line figures. Normal EEG.	Activity intolerance Impaired ability to manage regime Impaired sleep pattern
2	Increased drowsiness; disorientation; inappropriate behavior; mood swings; agitation	Asterixis; fetor hepaticus. Abnormal EEG with generalized slowing.	Impaired socialisation Impaired role performance Risk for injury Acute confusion
3	Stuporous; difficult to rouse; sleeps most of time; marked confusion; incoherent speech	Asterixis; increased deep tendon reflexes; rigidity of extremities. EEG markedly abnormal.	Impaired nutritional intake Impaired mobility Impaired verbal communication
4	Comatose; may not respond to painful stimuli	Absence of asterixis; absence of deep tendon reflexes; flaccidity of extremities. EEG markedly abnormal.	Risk for aspiration Impaired gas exchange Impaired tissue integrity

EEG, electroencephalogram.

[a]Nursing diagnoses are likely to progress; thus, most nursing diagnoses present at earlier stages will occur during later stages as well.

Adapted from information in Feldman, M., Friedman, L. S., & Brandt, L. J. (2016). *Sleisinger & Fordtran's gastrointestinal & liver disease* (10th ed.). Philadelphia, PA: Saunders Elsevier.

Other Manifestations of Hepatic Dysfunction

Edema and Bleeding

Many patients with liver dysfunction develop generalized edema caused by hypoalbuminemia due to decreased hepatic production of albumin. The production of blood clotting factors by the liver is also reduced, leading to an

increased incidence of bruising, epistaxis, bleeding from wounds, and, as described previously, GI bleeding. Abnormalities in the number and effectiveness of platelets also contribute to the bleeding in liver dysfunction. Congestion of the spleen secondary to portal hypertension causes hypersplenism (increased pooling of platelets in the organ). The resultant thrombocytopenia generally correlates with spleen size. In patients who abuse alcohol, suppression of bone marrow by the acute toxic effects of alcohol or folate deficiency may contribute to the thrombocytopenia (Goldman & Schafer, 2019). These factors predispose patients to easy bruising, petechiae formation, and bleeding from a variety of sources such as the GI or genitourinary tract (Goldman & Shafer, 2019).

Vitamin Deficiency

Decreased production of several clotting factors may be partially due to deficient absorption of vitamin K from the GI tract. This probably is caused by the inability of liver cells to use vitamin K to make prothrombin (Barrett et al., 2019; Hammer & McPhee, 2019). Absorption of the other fat-soluble vitamins (vitamins A, D, and E) as well as dietary fats may also be impaired because of decreased secretion of bile salts into the intestine.

Another group of problems common to patients with severe chronic liver dysfunction results from inadequate intake of sufficient vitamins. These include the following:

- Vitamin A deficiency, resulting in night blindness and eye and skin changes
- Thiamine deficiency, leading to beriberi, polyneuritis, and Wernicke–Korsakoff psychosis
- Riboflavin deficiency, resulting in characteristic skin and mucous membrane lesions
- Pyridoxine deficiency, resulting in skin and mucous membrane lesions and neurologic changes
- Vitamin C deficiency, resulting in the hemorrhagic lesions of scurvy
- Vitamin K deficiency, resulting in hypoprothrombinemia, characterized by spontaneous bleeding and ecchymoses
- Folic acid deficiency, resulting in macrocytic anemia

Because of these potential vitamin deficiencies, the diet of every patient with chronic liver disease (especially if alcohol related) is supplemented with vitamins A, B complex, C, K, and folic acid (EASL, 2019; Styskel et al., 2019; Yao et al., 2018).

Metabolic Abnormalities

Abnormalities of glucose metabolism also occur; the blood glucose level may be abnormally high shortly after a meal (similar to that when diabetes is present), but hypoglycemia may occur during fasting because of decreased hepatic glycogen reserves and decreased gluconeogenesis. Medications must be used cautiously and in reduced dosages because the ability to metabolize medications is decreased in the patient with liver failure.

Many endocrine abnormalities also occur with liver dysfunction because the liver cannot properly metabolize hormones, including androgens and sex hormones. Failure of the damaged liver to inactivate estrogens normally can cause gynecomastia, amenorrhea, testicular atrophy, loss of pubic hair in the male, menstrual irregularities in the female, and other disturbances of sexual function and sex characteristics.

Pruritus and Other Skin Changes

Patients with liver dysfunction resulting from biliary obstruction commonly develop severe pruritus due to retention of bile salts. Patients may develop vascular (or arterial) spider angiomas on the skin (see Fig. 43-3), usually above the waistline. These are numerous small vessels resembling a spider's legs. They are most often associated with cirrhosis, especially in alcoholic liver disease. Patients may also develop palmar erythema ("liver palms" or reddened palms).

VIRAL HEPATITIS

Viral hepatitis is a systemic, viral infection in which necrosis and inflammation of liver cells produce a characteristic cluster of clinical, biochemical, and cellular changes. To date, five definitive types of viral hepatitis that cause liver disease have been identified: hepatitis A, B, C, D, and E. Hepatitis A and E are similar in mode of transmission (fecal–oral route), whereas hepatitis B, C, and D share many other characteristics.

Hepatitis is easily transmitted and causes high morbidity and prolonged loss of time from school or employment. Acute viral hepatitis affects 0.5% to 1% of people in the United States each year. Hepatitis A virus (HAV) was responsible for 3366 cases in the United States in 2017. Incidence rates decreased more than 95% from 1995 to 2011, then increased by 140% from 2011 to 2017. In 2017, large person-to-person outbreaks began occurring, among persons who use drugs and persons experiencing homelessness (Centers for Disease Control and Prevention [CDC], 2017). During the same year, the hepatitis B virus (HBV) was the offending agent in a total of 3407 cases of acute viral hepatitis nationwide. The occurrence rate of viral hepatitis C (HCV) in 2017 was 3186 cases, with an incidence of 1.0 cases per 100,000 population, which represents an increase since 2013. Rates have been

influenced by the opioid crisis. An estimated 2.4 million people in the United States are living with HCV infection (CDC, 2017).

The number of reported acute hepatitis B cases has remained stable with a slight increase in 2017. The increase is most likely due to increasing injection drug use related to the opioid crisis, and improved surveillance (CDC, 2017). The overall decrease in HBV rates since 1990 is largely due to the use of hepatitis A and B vaccines, the introduction of universal precautions and blood supply safety measures as well as public health education regarding high-risk behaviors (Goldman & Schafer, 2019). Conversely, the incidence of HAV and HCV infections has been on the rise. It is estimated that 60% to 90% of viral hepatitis cases go unreported (CDC, 2017). The occurrence of subclinical cases, failure to recognize mild cases, and misdiagnosis are thought to contribute to the underreporting. Table 43-4 compares the major forms of viral hepatitis.

The clinical presentation of hepatitis varies with individual patients as well as with the specific causative virus. Four phases of infectious hepatitis describe the clinical presentation. Phase 1 is the viral replication phase in which patients are asymptomatic but laboratory studies will reveal markers of hepatitis. Phase 2 is the preicteric or prodromal phase when those affected may experience anorexia, nausea, vomiting, fatigue and pruritus. Phase 3 is the icteric phase which is characterized by jaundice and dark urine. Some patients experience abdominal pain from an enlarged liver. Phase 4 is the convalescent phase when signs and symptoms resolve and laboratory values return to normal. Not all patients will experience all phases, especially those with a mild form of the disease (Chi, Cleary, & Bocchini, 2018; Shin, 2018).

TABLE 43-4 Comparison of Major Forms of Viral Hepatitis

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Previous Names	Infectious Hepatitis	Serum Hepatitis	Non-A, non-B Hepatitis		
Epidemiology					
Cause	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)	Hepatitis D virus (HDV)	Hepatitis E virus (HEV)
Immunity	*Average:* 30 days Homologous	*Average:* 70–80 days Homologous	*Average:* 50 days Second attack may indicate weak immunity or infection with another agent.	*Average:* 35 days Homologous	*Average:* 31 days Unknown
Nature of Illness					
Signs and symptoms	May occur with or without symptoms; flu-like illness *Preicteric phase:* Headache, malaise, fatigue, anorexia, fever *Icteric phase:* Dark urine, jaundice of sclera and skin, tender liver	May occur without symptoms May develop arthralgias, rash	Similar to HBV; less severe and anicteric	Similar to HBV	Similar to HAV; very severe in pregnant women
Outcome	Usually mild with recovery. No carrier state or increased risk of chronic hepatitis, cirrhosis, or hepatic cancer.	May be severe. Carrier state possible. Increased risk of chronic hepatitis, cirrhosis, and hepatic cancer.	Frequent occurrence of chronic carrier state and chronic liver disease, but effective therapies that provide a sustained virologic response (SVR) are available. SVR is indicative of a cure of HCV infection. Increased risk of hepatic cancer if disease is not treated.	Similar to HBV but greater likelihood of carrier state, chronic active hepatitis, and cirrhosis	Similar to HAV except very severe in pregnant women

Hepatitis A Virus

The HAV accounts for 20% to 25% of cases of clinical hepatitis in the United States (CDC, 2017). Hepatitis A, formerly called *infectious hepatitis,* is caused by an RNA virus of the enterovirus family. In the United States, the disease is seen mainly in the adult population. HAV is transmitted primarily through the fecal–oral route, by the ingestion of food or liquids infected with the virus. It is more prevalent in countries with overcrowding and poor sanitation. The virus has been found in the stool of infected patients before the onset of symptoms and during the first few days of illness.

Typically, a child or a young adult acquires the infection at school through poor hygiene, hand-to-mouth contact, or other close contact. The virus is carried home, where haphazard sanitary habits spread it through the family. An infected food handler can spread the disease, and people can contract it by consuming water or shellfish from sewage-contaminated waters. Outbreaks have occurred in day care centers and institutions as a result of poor hygiene among people with developmental disability. Hepatitis A can be transmitted during sexual activity; this is more likely with oral–anal contact or anal intercourse and with multiple sex partners (Chi et al., 2018; Goldman & Schafer, 2019; Shin & Jeong, 2018). Hepatitis A is not transmitted by blood transfusions.

The incubation period is estimated to be between 2 and 6 weeks, with a mean of approximately 4 weeks (CDC, 2017; Chi et al., 2018; Shin & Jeong, 2018). The illness may be prolonged, lasting 4 to 8 weeks. It usually lasts longer and is more severe in those older than 40 years. Most patients recover from hepatitis A; it rarely progresses to acute liver necrosis or acute hepatic failure resulting in cirrhosis of the liver or death. The mortality rate of hepatitis A is approximately 0.5% for those younger than 40 years and 1% to 2% for older adults. In patients with underlying chronic liver disease, morbidity and mortality are increased in the presence of an acute hepatitis A infection. No carrier state exists, and no chronic hepatitis is associated with the HAV. The virus is present only briefly in the serum; by the time jaundice occurs, the patient is likely to be noninfectious. Although hepatitis A confers immunity against itself, the person may contract other forms of hepatitis.

Clinical Manifestations

Many patients are anicteric (without jaundice) and symptomless. When symptoms appear, they resemble those of a mild, flu-like upper respiratory tract infection, with low-grade fever. Anorexia, an early symptom, is often severe. It is thought to result from release of a toxin by the damaged liver or from failure of the damaged liver cells to detoxify an abnormal product. Later, jaundice and dark urine may become apparent. Indigestion is present in

varying degrees, marked by vague epigastric distress, nausea, heartburn, and flatulence. The patient may also develop a strong aversion to the taste of cigarettes or the presence of cigarette smoke and other strong odors (Papadakis & McPhee, 2020; Shin & Jeong, 2018). These symptoms tend to clear as soon as the jaundice reaches its peak, perhaps 10 days after its initial appearance. Symptoms may be mild in children; in adults, they may be more severe and the course of the disease prolonged.

Assessment and Diagnostic Findings

The liver and spleen are often moderately enlarged for a few days after onset; other than jaundice, there are few other physical signs. An HAV antigen may be found in the stool 7 to 10 days before illness and for 2 to 3 weeks after symptoms appear. HAV antibodies are detectable in the serum, although usually not until symptoms appear. Analysis of subclasses of immunoglobulins can help determine whether the antibody represents acute or past infection.

Prevention

A number of strategies exist to prevent transmission of HAV. Patients and their families are encouraged to follow general precautions that can prevent transmission of the virus. Scrupulous hand hygiene, safe water supplies, and proper control of sewage disposal are just a few of these prevention strategies.

Effective (95% to 100% after two to three doses) and safe HAV vaccines are available (Link-Gelles, Hofmeister, & Nelson, 2018). It is recommended that the two-dose vaccine be given to adults 18 years of age or older, with the second dose given 6 to 12 months after the first. Protection against HAV develops within several weeks after the first dose of the vaccine. Children and adolescents 1 to 18 years of age receive three doses; the second dose is given 1 month after the first, and the third dose is given 6 to 12 months later. HAV routine immunization of young children has proved to be effective in reducing disease incidence and maintaining very low incidence levels among vaccine recipients and across all age groups in many settings (Chi et al., 2018; Goldman & Schafer, 2019). As a result of its effectiveness in decreasing HAV, the hepatitis A vaccination recommendations have been expanded to include all children at 1 year of age. Hepatitis A vaccine is also recommended for people traveling to locations where sanitation and hygiene are unsatisfactory. Vaccination is also recommended for those from high-risk groups, such as men who have sex with men, people who use IV or injection drugs, staff of day care centers, health care personnel and those who work with the virus in research or animal care settings (Chi et al., 2018). The vaccine has also been used to interrupt community-wide outbreaks. A combined HAV and HBV vaccine is available for vaccination of people 18 years of age and older with indications

for both HAV and HBV vaccination. Vaccination consists of three doses, given on the same schedule as that used for single-antigen HBV vaccine.

For people who have not been previously vaccinated, HAV can be prevented by intramuscular administration of globulin during the incubation period, if given within 2 weeks of exposure. This bolsters the person's antibody production and provides 6 to 8 weeks of passive immunity. Immune globulin may suppress overt symptoms of the disease; the resulting subclinical case of HAV would produce immunity to subsequent episodes of the virus.

Immune globulin is also recommended for household members and sexual contacts of people with HAV. Susceptible people in the same household as the patient are usually also infected by the time the diagnosis is made and should receive immune globulin. Institutional contacts of patients with HAV should also receive post-exposure prophylaxis with immune globulin. Prophylaxis is not necessary for casual contacts of an infected person, such as classmates, coworkers, or hospital employees (Link-Gelles et al., 2018). Although rare, systemic reactions to immune globulin do occur. Caution is required when anyone who has previously had angioedema, hives, or other allergic reactions is treated with any human immune globulin. Epinephrine should be available in case of systemic, anaphylactic reaction.

Pre-exposure prophylaxis is recommended for those traveling to developing countries or settings with poor or uncertain sanitation conditions who do not have sufficient time to acquire protection by administration of hepatitis A vaccine (Chi et al., 2018). Prevention strategies for HAV are outlined in Chart 43-5.

Medical Management

Bed rest during the acute stage and a nutritious diet are important aspects of treatment. During the period of anorexia, the patient should receive frequent small feedings, supplemented if necessary by IV fluids with glucose. Because the patient often has an aversion to food, gentle persistence, and creativity may be required to stimulate appetite. Optimal food and fluid levels are necessary to counteract weight loss and to speed recovery. Even before the icteric phase, however, many patients recover their appetites (see Chart 43-6).

The patient's sense of well-being and laboratory test results are generally appropriate guides to bed rest and restriction of physical activity. Gradual but progressive ambulation hastens recovery.

Chart 43-5  **HEALTH PROMOTION**

Prevention of Hepatitis

Hepatitis A

- Educate patients regarding safe practices for preparing and dispensing food.
- Encourage conscientious individual hygiene.
- Encourage proper community and home sanitation.
- Facilitate mandatory reporting of viral hepatitis to local health departments.
- Promote community health education programs.
- Promote vaccination to interrupt community-wide outbreaks.
- Recommend pre-exposure vaccination for all children 12–23 months of age. Continue existing immunization programs for children 1–18 years of age.
- Recommend vaccination for travelers to developing countries, illegal drug users (injection and noninjection drug users), men who have sex with men, people with chronic liver disease, people who work with HAV-infected animals or work with HAV in research facilities and recipients (e.g., hemophiliacs) of pooled plasma products for clotting factor disorders.
- Support effective health supervision of schools, dormitories, extended care facilities, barracks, and camps.

Hepatitis B

- Advise avoidance of high-risk behaviors.
- Avoid multidose vials in patient care settings.
- Monitor cleaning, disinfection, and sterilization of reusable devices in patient care settings.
- Recommend vaccination for international travelers to regions with high or intermediate levels of endemic hepatitis B virus infection and for persons with chronic liver disease or with human immune deficiency virus infection.
- Recommend vaccination for persons at risk for infection by sexual exposure, by percutaneous or mucosal exposure to blood.
- Recommend vaccination of all infants in the United States regardless of the mother's hepatitis B.
- Use barrier precautions in situations of contact with blood or body fluids.
- Use needleless IV and injection systems in health care.
- Use standard precautions in clinical care.

Hepatitis C

- Advise avoidance of high-risk behaviors such as IV drug use.
- Avoid multidose vials in patient care settings.

- Monitor cleaning, disinfection, and sterilization of reusable devices in patient care settings.
- Use barrier precautions in situations of contact with blood or body fluids.
- Use needleless IV and injection systems in health care.
- Use standard precautions in clinical care.

Chart 43-6

Dietary Management of Hepatitis

- Advise patient to avoid substances (medications, herbs, illicit drugs, and toxins) that may affect liver function, such as St. John's wort in patients taking hepatitis C virus protease inhibitors.
- Be aware that enteral feedings may be necessary if anorexia, nausea, and vomiting persist.
- Carefully monitor fluid balance.
- Instruct patient to abstain from alcohol during acute illness and for at least 6 months after recovery.
- Provide intake of 25–30 kcal/kg/day.
- Provide protein intake of 1.2–1.5 g/kg/day.
- Recommend small, frequent meals; minimize periods without food intake.

EASL clinical practice guidelines on nutrition in chronic liver disease. *Journal of Hepatology*, *70*(1), 172–193; Styskel, B., Natarajan, Y., & Kanwal, F. (2019). Nutrition in alcoholic liver disease: An update. *Clinics in Liver Disease*, *23*(1), 99–114.

Nursing Management

Management usually occurs in the home unless symptoms are severe. Therefore, the nurse assists the patient and family in coping with the temporary disability and fatigue that are common with HAV and educates them to seek additional health care if the symptoms persist or worsen. The patient and family also need specific guidelines about diet, rest, follow-up blood work, and the importance of avoiding alcohol, as well as sanitation and hygiene measures (particularly hand hygiene) to prevent spread of the disease to other family members.

Specific education for patients and families about reducing the risk of contracting HAV includes good personal hygiene, stressing careful hand

hygiene (after bowel movements and before eating) and environmental sanitation (safe food and water supply, effective sewage disposal).

Hepatitis B Virus

Unlike HAV, the HBV is transmitted primarily through blood (percutaneous and permucosal routes). HBV can be found in blood, saliva, semen, and vaginal secretions and can be transmitted through mucous membranes and breaks in the skin. HBV is also transferred from carrier mothers to their infants, especially in areas with a high incidence (e.g., Southeast Asia). The infection usually is not transmitted via the umbilical vein but from the mother at the time of birth and during close contact afterward.

HBV has a long incubation period. It replicates in the liver and remains in the serum for relatively long periods, allowing transmission of the virus. Risk factors for HBV infection are summarized in Chart 43-7. Screening of blood donors has greatly reduced the occurrence of HBV after blood transfusion.

Chart 43-7 RISK FACTORS

Hepatitis B

- Close contact with carrier of hepatitis B virus
- Frequent exposure to blood, blood products, or other body fluids
- Health care workers: hemodialysis staff, oncology and chemotherapy nurses, personnel at risk for needlesticks, operating room staff, respiratory therapists, surgeons, dentists
- Hemodialysis
- IV/injection drug use
- Gay men and bisexual activity
- Mother-to-child transmission
- Multiple sexual partners
- Receipt of blood or blood products (e.g., clotting factor concentrate)
- Recent history of sexually transmitted infection
- Tattooing
- Travel to or residence in area with uncertain sanitary conditions

Adapted from Bope, E. T., & Kellerman, R. D. (Eds.). (2018). *Conn's current therapy*. Philadelphia, PA: Saunders.

Most people (more than 90%) who contract HBV infection develop antibodies and recover spontaneously in 6 months. The mortality rate from acute HBV has been reported to be as high as 1%. Another 10% of patients

who have HBV progress to a carrier state or develop chronic hepatitis with persistent HBV infection and hepatocellular injury and inflammation. It remains a major worldwide cause of cirrhosis and hepatocellular carcinoma (HCC) with higher mortality rates (Papadakis & McPhee, 2020; Sedhom, 2018; Schiff et al., 2018). In fact, approximately 15% of those who develop chronic hepatitis B during adulthood die of cirrhosis or liver cancer. Mortality rates are even higher (25%) for those whose chronic infection occurs during childhood (Chi et al., 2018). An estimated 730,000 adult residents of the United States are afflicted with chronic hepatitis B infection; however, there has been a small but significant decrease in the prevalence among U.S.-born adults who are 20 to 49 years of age (CDC, 2017; Sedhom, 2018).

Gerontologic Considerations

The immune system is altered in older adults. A less responsive immune system may be responsible for the increased incidence and severity of HBV among older adults and the increased incidence of liver abscesses secondary to decreased phagocytosis by the Kupffer cells. The older patient with HBV has a serious risk of severe liver cell necrosis or acute hepatic failure, particularly if other illnesses are present. With the advent of an HBV vaccine as the standard for prevention, the incidence of hepatic diseases may decrease in the future.

Clinical Manifestations

Clinically, HBV closely resembles HAV, but the incubation period is much longer (1 to 6 months). Signs and symptoms of HBV may be insidious and variable. Fever and respiratory symptoms are rare; some patients have arthralgias and rashes. The patient may have loss of appetite, dyspepsia, abdominal pain, generalized aching, malaise, and weakness. Jaundice may or may not be evident. If jaundice occurs, light-colored stools and dark urine accompany it. The liver may be tender and enlarged to 12 to 14 cm vertically. The spleen is enlarged and palpable in a few patients; the posterior cervical lymph nodes may also be enlarged. Subclinical episodes also occur frequently.

Assessment and Diagnostic Findings

HBV is a deoxyribonucleic acid (DNA) virus composed of the following antigenic particles:

- HBcAg—hepatitis B core antigen (antigenic material in an inner core)
- HBsAg—hepatitis B surface antigen (antigenic material on the viral surface, a marker of active replication and infection)

- HBeAg—an independent protein circulating in the blood
- HBxAg—gene product of X gene of HBV DNA

Each antigen elicits its specific antibody and is a marker for different stages of the disease process:

- anti-HBc—antibody to core antigen of HBV; persists during the acute phase of illness; may indicate continuing HBV in the liver
- anti-HBs—antibody to surface determinants on HBV; detected during late convalescence; usually indicates recovery and development of immunity
- anti-HBe—antibody to hepatitis B e-antigen; usually signifies reduced infectivity
- anti-HBxAg—antibody to the hepatitis B x-antigen; may indicate ongoing replication of HBV

HBsAg appears in the circulation in 80% to 90% of infected patients 1 to 10 weeks after exposure to HBV and 2 to 8 weeks before the onset of symptoms or an increase in transferase levels. Patients with HBsAg that persists for 6 months or longer after acute infection are considered to be HBsAg carriers (Chi et al., 2018; Sedhom, 2018). HBeAg is the next antigen of HBV to appear in the serum. It usually appears within 1 week of the appearance of HBsAg but before changes in aminotransferase levels; it disappears from the serum within 2 weeks. HBV DNA, detected by polymerase chain reaction testing, appears in the serum at about the same time as HBeAg. HBcAg is not always detected in the serum in HBV infection.

In the United States, the number of cases of chronic HBV is estimated to be 0.8 to 1.4 million persons. However, an accurate estimate is difficult to obtain because there is no national chronic-hepatitis surveillance program (CDC, 2017; Younossi, Stepanova, Younossi, et al., 2019). In 2013, males who died with HBV had a mortality rate that was nearly three times the mortality rate of females who died with HBV (0.8 deaths/100,000 population compared to 0.3 deaths/100,000 population). From 2009 to 2013, HBV-related mortality remained relatively stable for males and females (CDC, 2017). In 2015, hepatitis B resulted in an estimated 887,000 deaths worldwide, mostly from cirrhosis and HCC (World Health Organization [WHO], 2019).

Prevention

Prevention of hepatitis B transmission requires a multifaceted approach, including public health interventions and education as well as programs to foster immunization against this virulent virus in an effort to reduce the disease burden.

Preventing Transmission

Continued screening of blood donors for the presence of hepatitis B antigen (HBAg) further decreases the risk of transmission by blood transfusion. The use of disposable syringes, needles, and lancets and the introduction of needleless IV administration systems have reduced the risk of spreading this infection from one patient to another or to health care personnel during the collection of blood samples or the administration of parenteral therapy. In the clinical laboratory and the hemodialysis unit, work areas are disinfected daily. Gloves are worn when handling all blood and body fluids, as well as HBAg–positive specimens, or when there is potential exposure to blood (e.g., blood drawing) or to patients' secretions. Eating is prohibited in the laboratory and in other areas exposed to secretions, blood, or blood products. Patient education regarding the nature of the disease, its infectiousness, and prognosis is a critical factor in preventing transmission and protecting contacts (see Chart 43-5).

Active Immunization: HBV

Active immunization is recommended for people who are at high risk for HBV (e.g., health care personnel, patients undergoing hemodialysis). In addition, people with HCV and other chronic liver diseases should receive the vaccine. In 2018, the Advisory Committee on Immunization **Practices** (**ACIP**) recommended the use of a newly licensed hepatitis B vaccine, HEPLISAV-B, for people over the age of 18. This new vaccine is administered in two doses given 1 month apart. The decreased number of doses and abbreviated time period between doses may increase the rates of completion of the full vaccine series (Chi et al., 2018).

Prior to 2019, a yeast-recombinant hepatitis B vaccine was used to provide active immunity and has shown rates of protection greater than 90% in healthy people (Chan, Wong, Qin, et al., 2016; Terrault, Lok, McMahon, et al., 2018). Although antibody levels may become low or undetectable, immunologic memory may remain intact for at least 5 to 10 years. Measurable levels of antibodies may not be essential for protection. In general, in those with normal immune systems, booster doses are not required, and no data support the use of booster doses of hepatitis B vaccine among people who are immunocompetent and have responded to the vaccination series. However, booster doses are recommended for people who are immunocompromised (Chan et al., 2016; Terrault et al., 2018). A hepatitis B vaccine prepared from plasma of humans chronically infected with HBV is used only rarely in patients who are immunodeficient or allergic to recombinant yeast-derived vaccines.

Hepatitis B vaccines should be administered to adults in the deltoid muscle. Antibody response may be measured by anti-HBs levels 1 to 3 months after completion of the basic course of vaccine, but this testing is not routine and is not currently recommended. People who do not respond may benefit from additional doses (Terrault et al., 2018).

People at high risk, including nurses and other health care personnel exposed to blood or blood products, should receive active immunization. Health care workers who have had frequent contact with blood are screened for anti-HBs to determine whether immunity is already present from previous exposure. The vaccine produces active immunity to HBV in 90% to 95% of healthy people (Chi et al., 2018; Friedman & Martin, 2018; Terrault et al., 2018). It does not provide protection to those already exposed to HBV nor does it provide protection against other types of viral hepatitis.

Because HBV infection is frequently transmitted sexually, hepatitis B vaccination is recommended for all people who are unvaccinated and are being evaluated for a sexually transmitted infection (STI). It is also recommended for those with a history of an STI, people with multiple sex partners, people who have sex with people who use injection drugs, and men who are sexually active and have sex with other men (CDC, 2017; Chi et al., 2018; Terrault et al., 2018).

Universal childhood vaccination for hepatitis B prevention has been instituted in the United States, and universal vaccination of all infants is encouraged. Catch-up vaccination is recommended for all children and prepubertal adolescents up to the age of 19 years who have not been previously immunized (Feldman et al., 2016). Development of chronic carrier states has not been reported in adult responders to the vaccine.

Passive Immunity: Hepatitis B Immune Globulin

Hepatitis B immune globulin (HBIG) provides passive immunity to HBV and is indicated for people exposed to HBV who have never had hepatitis B and have never received hepatitis B vaccine. Specific indications for postexposure vaccine with HBIG include inadvertent exposure to HBAg-positive blood through percutaneous (needlestick) or transmucosal (splashes in contact with mucous membrane) routes, sexual contact with people positive for HBAg, and perinatal exposure (infants born to HBV-infected mothers should receive HBIG within 12 hours after delivery). HBIG is prepared from plasma selected for high titers of anti-HBs. Prompt immunization with HBIG (within hours to a few days after exposure to hepatitis B) increases the likelihood of protection. Both active and passive immunization are recommended for people who have been exposed to HBV through sexual contact or through the percutaneous or transmucosal routes. If HBIG and hepatitis B vaccines are given at the same time, separate sites and separate syringes should be used. HBIG is considered very safe, and there has been no evidence that infectious diseases have been transmitted due its administration (Chi et al., 2018; Terrault et al., 2018).

Medical Management

Goals are to minimize infectivity and liver inflammation and decrease symptoms. Of all the agents that have been used to treat chronic type B viral hepatitis, alpha-interferon is the single modality of therapy that offers the most promise. A regimen of 5 million U daily or 10 million U three times weekly for 16 to 24 weeks results in remission of disease in approximately one third of patients (Chan et al., 2016; Terrault et al., 2018). A prolonged course of treatment may also have additional benefits and is under study. Interferon must be given by injection and has significant side effects, including fever, chills, anorexia, nausea, myalgias, and fatigue. Delayed side effects are more serious and may necessitate dosage reduction or discontinuation. These include bone marrow suppression, thyroid dysfunction, alopecia, and bacterial infections. Several recombinant forms of alpha-interferon are also available, including the pegylated form (peginterferon alfa-2a), with once-weekly dosing. Pegylated interferon, also referred to as peginterferon, has largely replaced standard interferon due to its dosing schedule (Terrault et al., 2018). The American Association for the Study of Liver Diseases (AASLD) recommends pegylated interferon, entecavir or tenofovir, as preferred initial therapy for adults with chronic hepatitis B (AASLD, 2020; Terrault et al., 2018). These two antiviral agents, entecavir and tenofovir, are oral nucleoside analogs approved for use in chronic hepatitis B in the United States. They are the currently recommended agents for patients with HBV-related decompensated cirrhosis (AASLD, 2020; Terrault et al., 2018). Studies have revealed improved seroconversion rates and loss of detectable virus, improved liver function, and reduced progression to cirrhosis with entecavir and tenofovir. These agents can also be used for patients with decompensated cirrhosis who are awaiting liver transplantation (Chan et al., 2016; Terrault et al., 2018). Patients with decompensated cirrhosis have such severely damaged liver parenchyma that normal liver function severely deteriorates, resulting in life-threatening ascites, encephalopathy, or variceal hemorrhage (Chan et al., 2016; Schiff et al., 2018).

Bed rest may be recommended until the symptoms of hepatitis have subsided. Activities are restricted until the hepatic enlargement and levels of serum bilirubin and liver enzymes have decreased. Gradually, increased activity is then allowed.

Adequate nutrition should be maintained. Proteins are not restricted. Protein intake should be 1.2 to 1.5 g/kg/day (Schiff et al., 2018; Yao et al., 2018). Measures to control the dyspeptic symptoms and general malaise include the use of antacids and antiemetic agents, but all medications should be avoided if vomiting occurs. If vomiting persists, the patient may require hospitalization and fluid therapy. Because of the mode of transmission, the patient is evaluated for other bloodborne diseases (e.g., human immune deficiency virus infection).

Nursing Management

Convalescence may be prolonged, with complete symptomatic recovery sometimes requiring 3 to 4 months or longer (Papadakis & McPhee, 2020). During this stage, gradual resumption of physical activity is encouraged after the jaundice has resolved.

The nurse identifies psychosocial issues and concerns, particularly the effects of separation from family and friends if the patient is hospitalized during the acute and infective stages. Even if not hospitalized, the patient will be unable to work and must avoid sexual contact. Planning is required to minimize social isolation. Planning that includes the family helps to reduce their fears and anxieties about the spread of the disease.

Promoting Home, Community-Based and Transitional Care

Educating Patients About Self-Care

Because of the prolonged period of convalescence, the patient and family must be prepared for care in the home. Provision for adequate rest and nutrition must be ensured. The nurse educates family members and friends who have had intimate contact with the patient about the risks of contracting HBV and makes arrangements for them to receive hepatitis B vaccine or HBIG as prescribed. Those at risk must be made aware of the early signs of HBV and of ways to reduce risk by avoiding all modes of transmission. Patients with all forms of hepatitis should avoid drinking alcohol (Chan et al., 2016; Friedman & Martin, 2018; Schiff et al., 2018; Wang, Cheng, & Kao, 2020).

Continuing and Transitional Care

Follow-up visits by a transitional or home health nurse may be needed to assess the patient's progress and answer family members' questions about disease transmission. During a home visit, the nurse assesses the patient's physical and psychological status and confirms that the patient and family understand the importance of adequate rest and nutrition. The nurse also reinforces previous education. Because of the risk of transmission through sexual activity, strategies to prevent exchange of body fluids are recommended, such as abstinence or the use of condoms. The nurse emphasizes the importance of keeping follow-up appointments and participating in other health promotion activities and recommended health screenings.

Hepatitis C Virus

Blood transfusions and sexual contact once accounted for most cases of HCV in the United States, but other parenteral means, such as sharing of contaminated needles by those who use IV or injection drugs and unintentional needlesticks and other injuries in health care workers now account for a significant number of cases. In 2017, a total of 3186 cases of acute hepatitis C were reported to the CDC. After adjusting for under-ascertainment and under-reporting, an estimated 44,300 acute hepatitis C cases occurred in 2017. Approximately 2.5 million people in the United States are living with HCV, making it the most common chronic bloodborne infection nationally, though many of those infected are unaware of the disease (CDC, 2017). The highest prevalence of HCV is in adults 40 to 59 years of age; in this age group, its prevalence is highest among African Americans. In 2017, 17,253 U.S. death certificates had HCV recorded as an underlying or contributing cause of death but it has been suggested that deaths from this cause are underestimated (CDC, 2017; Houghton, 2019). HCV is the underlying cause of about one third of cases of HCC, and it is one of the most common reason for liver transplantation (CDC, 2017; Houghton, 2019).

People who are at particular risk for HCV include those who use IV or injection drugs, people who are sexually active with multiple partners, patients receiving frequent transfusions, those who require large volumes of blood, and health care personnel (see Chart 43-8). The incubation period is variable and may range from 15 to 160 days. The clinical course of acute HCV is similar to that of HBV; symptoms are usually mild or absent. However, a chronic carrier state occurs frequently, and there is an increased risk of chronic liver disease, including cirrhosis or liver cancer, after HCV. It is for this reason that those in high- and moderate-risk groups as well as those known to have high prevalence rates (e.g., those born in certain countries or regions) be screened for HCV as well as for HBV (CDC, 2017; Houghton, 2019; Schiff et al., 2018). Small amounts of alcohol taken regularly appear to cause progression of the disease. Therefore, alcohol and medications that may affect the liver should be avoided.

Chart 43-8  **RISK FACTORS**

Hepatitis C

- Children born to women infected with hepatitis C virus
- Health care and public safety workers after needlestick injuries or mucosal exposure to blood
- Multiple contacts with a person who is infected with hepatitis C virus
- Multiple sex partners, history of sexually transmitted infection, unprotected sex
- Past/current illicit IV/injection drug use
- Recipient of blood products or organ transplant before 1992 or clotting factor concentrates before 1987

Adapted from Kumar, V., Abbas, A. K., Fausto, N., et al. (2014). *Robbins and Cotran pathologic basis of disease* (9th ed.). Philadelphia, PA: Saunders Elsevier.

There is no benefit from rest, diet, or vitamin supplements. The treatment for HCV infection has evolved since the introduction of highly effective HCV protease inhibitor therapies in 2011. Currently available therapies can achieve sustained virologic response (SVR) defined as the absence of detectable virus 12 weeks after completion of treatment; an SVR is indicative of a cure of HCV infection. Over 90% of persons infected with HCV can be cured of HCV infection regardless of HCV genotype (there are over 67 identified subtypes but type 1 is most common), with 8 to 12 weeks of oral therapy (CDC, 2017). HCV direct-acting antivirals (DAA) including simeprevir plus sofosbuvir, ledipasvir-sofosbuvir, and ombitasvir-paritaprevir-ritonavir packaged with dasabuvir have fewer side effects, shorter treatment durations, and higher cure rates than previously recommended antiviral agents. A newer dual combination that includes another derivative of daclatasivir with sofosbuvir is equally effective against all HCV genotypes (Chan et al., 2016; Houghton, 2019). Prescribers must take into account the degree of cirrhosis in individual patients in order to determine the most appropriate protease inhibitor. The American Association for the Study of Liver Diseases (AASLD, 2020) recommends regimens of glecaprevir/pibrentasvir or sofusbuvir/velpatasvir for those patients who meet the criteria for simplified HCV treatment that includes treatment-naive adults without cirrhosis or those with compensated cirrhosis. The choice of medication is dependent on the genotype as well (AASLD, 2020).

There are HCV treatments in development that are expected to be more effective in curing the disease and better tolerated with fewer adverse effects and contraindications (Houghton, 2019). As a result of the rapidly changing landscape for treatment of viral infections, it is important to monitor related websites for the most up-to-date recommendations (CDC, 2017; Houghton,

2019). A key challenge remains how to deliver the currently expensive DAA drugs to all global carriers of HCV (Houghton, 2019).

Screening of blood has reduced the incidence of HCV associated with blood transfusion, and public health programs are helping to reduce the number of cases associated with shared needles in IV or injection drug use (see Chart 43-5).

Hepatitis D Virus

Hepatitis D virus (delta agent) infection occurs in some cases of hepatitis B. Because the virus requires HBsAg for its replication, only people with hepatitis B are at risk for hepatitis D. Anti-delta antibodies in the presence of HBAg on testing confirm the diagnosis. Hepatitis D is common among those who use IV or injection drugs, patients undergoing hemodialysis, and recipients of multiple blood transfusions. Sexual contact with those who have hepatitis B is considered to be an important mode of transmission of hepatitis B and D. The incubation period varies between 30 and 150 days (Schiff et al., 2018).

The symptoms of hepatitis D are similar to those of hepatitis B, except that patients are more likely to develop acute hepatic failure and to progress to chronic active hepatitis and cirrhosis. Treatment is similar to that of other forms of hepatitis. Currently, interferon alfa is the only licensed drug available in the treatment for HDV infection. The rate of recurrence is high, and the efficacy of interferon is related to the dose and duration of treatment. High-dose, long-duration therapy for at least a year is recommended (Friedman & Martin, 2018; Schiff et al., 2018; Sedhom, D'Souza, John, et al., 2018).

Hepatitis E Virus

It is believed that HEV is transmitted by the fecal–oral route, principally through contaminated water in areas with poor sanitation. The incubation period is variable, estimated to range between 15 and 65 days. In general, hepatitis E resembles hepatitis A. It has a self-limited course with an abrupt onset. Jaundice is almost always present. Chronic forms do not develop.

Avoiding contact with the virus through good hygiene, including handwashing, is the major method of prevention of hepatitis E. The effectiveness of immune globulin in protecting against HEV is uncertain.

Hepatitis G Virus and GB Virus-C

It has long been believed that there is another non-A–E agent causing hepatitis in humans. The incubation period for posttransfusion hepatitis is 14 to 145 days—too long for hepatitis B or C. In the United States, about 5% of chronic liver disease remains cryptogenic (i.e., does not appear to be autoimmune or viral in origin), and 50% of these patients have received blood transfusions before developing disease. Therefore, another form of hepatitis, referred to as hepatitis G virus (HGV) or GB virus-C (GBV-C), has been described; these are thought to be two different isolates of the same virus, which are percutaneously transmitted. Autoantibodies are absent.

The clinical significance of this virus remains uncertain. Risk factors are similar to those for hepatitis C. There is no clear relationship between HGV/GBV-C infection and progressive liver disease. Persistent infection does occur but does not affect the clinical course (Papadakis & McPhee, 2020; Sedhom et al., 2018).

NONVIRAL HEPATITIS

Certain chemicals have toxic effects on the liver and produce acute liver cell necrosis or toxic hepatitis when inhaled, injected parenterally, or taken by mouth. Some chemicals commonly implicated in this disease include carbon tetrachloride and phosphorus. These substances are true hepatotoxins. Many medications can induce hepatitis but are only sensitizing rather than toxic. Drug-induced hepatitis is similar to acute viral hepatitis, but parenchymal destruction tends to be more extensive. Medications that can lead to hepatitis include isoniazid, halothane, acetaminophen, methyldopa, and certain antibiotics, antimetabolites, and anesthetic agents.

Toxic Hepatitis

At the onset of disease, toxic hepatitis resembles viral hepatitis. Obtaining a history of exposure to hepatotoxic chemicals, medications, botanical agents, or other toxic agents assists in early treatment and removal of the causative agent. Anorexia, nausea, and vomiting are the usual symptoms; jaundice and hepatomegaly are noted on physical assessment. Symptoms are more intense for the more severely toxic patient.

Recovery from acute toxic hepatitis is rapid if the hepatotoxin is identified early and removed or if exposure to the agent has been limited. Recovery is unlikely if there is a prolonged period between exposure and onset of symptoms. There are no effective antidotes. The fever rises; the patient becomes toxic and prostrated. Vomiting may be persistent, with the emesis containing blood. Clotting abnormalities may be severe, and hemorrhages may appear under the skin. The severe GI symptoms may lead to vascular collapse. Delirium, coma, and seizures develop, and within a few days the patient may

die of acute hepatic failure (discussed later) unless they receive a liver transplant.

Short of liver transplantation, few treatment options are available. Therapy is directed toward restoring and maintaining fluid and electrolyte balance, blood replacement, and comfort and supportive measures. A few patients recover from acute toxic hepatitis only to develop chronic liver disease. If the liver heals, there may be scarring, followed by postnecrotic cirrhosis.

Drug-Induced Hepatitis

Drug-induced liver disease is the most common cause of acute liver failure, accounting for more than 50% of all cases in the United States (Schiff et al., 2018; Stravitz & Lee, 2019; Thomas & Lewis, 2018). Manifestations of sensitivity to a medication may occur on the first day of its use or not until several months later. Usually, the onset is abrupt, with chills, fever, rash, pruritus, arthralgia, anorexia, and nausea. Later, there may be jaundice, dark urine, and an enlarged and tender liver. After the offending medication is withdrawn, symptoms may gradually subside. However, reactions can be severe, or even fatal, even if the medication is stopped. If fever, rash, or pruritus occurs from any medication, its use should be stopped immediately.

Although any medication can affect liver function, the use of acetaminophen (found in many OTC medications used to treat fever and pain) has been identified as the leading cause of acute liver failure (Schiff et al., 2018; Stravitz & Lee, 2019). Other causes commonly associated with liver injury include many anesthetic agents, medications used to treat rheumatic and musculoskeletal disease, antidepressants, psychotropic medications, anticonvulsants, and antituberculosis agents (Schiff et al., 2018; Stravitz & Lee, 2019; Thomas & Lewis, 2018).

A short course of high-dose corticosteroids may be used in patients with severe hypersensitivity reactions, although its efficacy is uncertain. Liver transplantation is an option for drug-induced hepatitis, but outcomes may not be as successful as with other causes of liver failure.

Acute Liver Failure

Acute hepatic failure or **acute liver failure** (ALF) is the clinical syndrome of sudden and severely impaired liver function in a person who was previously healthy. The definition of ALF includes neurologic dysfunction, an elevated prothrombin time and international normalized ratio (PT/INR) ≥1.5, no prior evidence of liver disease, and a disease course of ≤26 weeks (Friedman & Martin, 2018; Maher & Schreibman, 2018; Montrief, Koyfman, & Long, 2019; Schiff et al., 2018). The time from the onset of symptoms such as jaundice to

the development of hepatic encephalopathy categorizes the different forms of acute liver failure: a very rapid injury (within hours) is referred to as hyperacute liver failure; and a slower, immune-based injury (days to weeks) is considered acute or subacute (Maher & Schreibman, 2018; Stravitz & Lee, 2019). In hyperacute liver failure, the duration of jaundice before the onset of encephalopathy is 0 to 7 days; in acute liver failure, it is 8 to 28 days; and in subacute liver failure, it is 28 to 72 days. The prognosis for acute hepatic failure is much worse than for chronic liver failure. However, in acute failure, the hepatic lesion is potentially reversible, and survival rates are approximately 20% to 50%, depending greatly on the cause. Those who do not survive die of massive hepatocellular injury and necrosis (Maher & Schreibman, 2018; Montrief et al., 2019; Stravitz & Lee, 2019).

Viral hepatitis is a common cause of ALF; other causes include toxic medications (e.g., acetaminophen) and chemicals (e.g., carbon tetrachloride), metabolic disturbances (e.g., Wilson disease, a hereditary syndrome with deposition of copper in the liver), and structural changes (e.g., Budd–Chiari syndrome, an obstruction to outflow in major hepatic veins) (Maher & Schreibman, 2018; Stravitz & Lee, 2019).

Jaundice and profound anorexia may be the initial reasons the patient seeks health care. ALF is often accompanied by coagulation defects, kidney disease and electrolyte disturbances, cardiovascular abnormalities, infection, hypoglycemia, encephalopathy, and cerebral edema (Maher & Schreibman, 2018; Montrief et al., 2019; Stravitz & Lee, 2019).

The key to optimized treatment is rapid recognition of ALF and intensive intervention. Supporting the patient in the ICU and assessing the indications for and feasibility of liver transplantation are hallmarks of management. The use of antidotes for certain conditions may be indicated, such as *N*-acetylcysteine for acetaminophen toxicity and penicillin for mushroom poisoning. Treatment modalities may include plasmapheresis to correct coagulopathy, to reduce serum ammonia levels, and to stabilize the patient awaiting liver transplantation, and prostaglandin therapy to enhance hepatic blood flow. Although these treatment modalities may be implemented, no evidence exists indicating any clinical improvement with their use (Maher & Schreibman, 2018; Montrief et al., 2019; Stravitz & Lee, 2019; Wendon et al., 2017). Hepatocytes within synthetic fiber columns have been tested as liver support systems (liver assist devices) to provide a bridge to transplantation.

Research into interventions for ALF has begun to focus on techniques that combine the efficacy of a whole liver with the convenience and biocompatibility of hemodialysis. The acronyms ELAD (*e*xtracorporeal *l*iver *a*ssist *d*evices) and BAL (*bio**a**rtificial *l*iver) have been used to describe these hybrid devices. These short-term devices, which remain experimental, may help patients survive until transplantation is possible (Villarreal & Sussman, 2019; Wendon et al., 2017). The BAL device exposes separated plasma to a

cartridge containing porcine liver cells after the plasma has flowed through a charcoal column that removes substances toxic to hepatocytes. The ELAD exposes whole blood to cartridges containing human hepatoblastoma cells, resulting in removal of toxic substances. These approaches appear promising and have had success in animal studies. In human clinical application, the use of various BAL systems has resulted in improved neurologic and biochemical parameters. Adding albumin to extracorporeal dialysis in a process known as molecular adsorbent recirculating system (MARS), and therapeutic plasma exchanges (TPE) have been used to remove protein-bound toxins and is potentially useful in unstable patients with ALF or acute or chronic liver disease (Bañares et al., 2019; Larsen, 2019; Wendon et al., 2017).

In patients who have ALF with stage 4 encephalopathy (see Table 43-3), there is a high risk of cerebral edema, a life-threatening complication. The cause is not fully understood, although disruption of the blood–brain barrier and plasma leakage into the cerebrospinal fluid may be one cause. An increase in the intracellular osmolarity within cerebral astrocyte cells, possibly related to increased sodium and glutamine in these cells, may be another (Montrief et al., 2019; Stravitz & Lee, 2019). These patients require intracranial pressure monitoring. Measures to promote adequate cerebral perfusion include careful fluid balance and hemodynamic assessments, a quiet environment, and diuresis with mannitol, an osmotic diuretic.

The use of pharmacologic neuromuscular blockade (NMB) and sedation is indicated to prevent surges in intracranial pressure related to agitation. Other support measures include monitoring for and treating hypoglycemia, coagulopathies, and infection. Despite these treatment modalities, the mortality rate remains high. Consequently, liver transplantation (discussed later) is the treatment of choice for ALF.

HEPATIC CIRRHOSIS

Cirrhosis is a chronic disease characterized by replacement of normal liver tissue with diffuse fibrosis that disrupts the structure and function of the liver. There are three types of cirrhosis or scarring of the liver:

- Alcoholic cirrhosis, in which the scar tissue characteristically surrounds the portal areas. This is most frequently caused by chronic alcoholism and is the most common type of cirrhosis.
- Postnecrotic cirrhosis, in which there are broad bands of scar tissue. This is a late result of a previous bout of acute viral hepatitis.
- Biliary cirrhosis, in which scarring occurs in the liver around the bile ducts. This type of cirrhosis usually results from chronic biliary obstruction and cholangitis (bile duct infection); it is much less common.

The portion of the liver chiefly involved in cirrhosis consists of the portal and the periportal spaces, where the bile canaliculi of each lobule communicate to form the liver bile ducts. These areas become the sites of inflammation, and the bile ducts become occluded with inspissated (thickened) bile and pus. The liver attempts to form new bile channels; hence, there is an overgrowth of tissue made up largely of disconnected, newly formed bile ducts and surrounded by scar tissue.

Pathophysiology

Several factors have been implicated in the etiology of cirrhosis. Nutritional deficiency with reduced protein intake contributes to liver destruction in cirrhosis, but excessive alcohol intake is the major causative factor in fatty liver and its consequences. However, cirrhosis can occur in people who do not consume alcohol and in those who consume a normal diet and have a high alcohol intake.

Some people appear to be more susceptible than others to this disease, whether or not they have alcoholism or are malnourished. Other factors may play a role, including exposure to certain chemicals (carbon tetrachloride, chlorinated naphthalene, arsenic, or phosphorus) or infectious schistosomiasis. Twice as many men as women are affected, although, for unknown reasons, women are at greater risk for development of alcohol-induced liver disease. Most patients are between 40 and 60 years of age. Alcohol-associated cirrhosis contributes to up to 50% of the overall cirrhosis burden in the United States and worldwide (Lucey, 2019). From 1999 to 2016 in the United States, annual deaths from cirrhosis increased by 65% to approximately 35,000 (Baki, 2019; Tapper, 2018).

Alcoholic cirrhosis is characterized by episodes of necrosis involving the liver cells, which sometimes occur repeatedly throughout the course of the disease. The destroyed liver cells are gradually replaced by scar tissue. Eventually, the amount of scar tissue exceeds that of the functioning liver tissue. Islands of residual normal tissue and regenerating liver tissue may project from the constricted areas, giving the cirrhotic liver its characteristic hobnail appearance. The disease usually has an insidious onset and a protracted course, occasionally proceeding over a period of 30 or more years.

The prognoses for different forms of cirrhosis caused by various liver diseases have been investigated in several studies. Of the many prognostic indicators, the Child–Pugh classification seems most useful in predicting the outcome of patients with liver disease (see Table 43-5). It is also used in choosing management approaches.

Clinical Manifestations

Signs and symptoms of cirrhosis increase in severity as the disease progresses, and severity is used to categorize the disorder as compensated or decompensated cirrhosis (see Chart 43-9). Compensated cirrhosis, with its less severe, often vague symptoms, may be discovered secondarily at a routine physical examination. The hallmarks of decompensated cirrhosis result from failure of the liver to synthesize proteins, clotting factors, and other substances and manifestations of portal hypertension (see earlier sections of this chapter for clinical manifestations and management of portal hypertension, ascites, varices, and hepatic encephalopathy).

TABLE 43-5 Modified Child–Pugh Classification of the Severity of Liver Disease

	Points Assigned		
Parameter	1	2	3
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	≤2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time (seconds over control)	1–3	4–6	>6
Encephalopathy	None	Grade 1–2	Grade 3–4

Total score of 5–6, grade A; 7–9, grade B; 10–15, grade C.

Adapted from Feldman, M., Friedman, L. S., & Brandt, L. J. (2016). *Sleisinger & Fordtran's gastrointestinal & liver disease* (10th ed.). Philadelphia, PA: Saunders Elsevier.

Chart 43-9  **ASSESSMENT**

Assessing for Cirrhosis

Be alert to the following signs and symptoms:

Compensated

- Abdominal pain
- Ankle edema
- Firm, enlarged liver
- Flatulent dyspepsia
- Intermittent mild fever
- Palmar erythema (reddened palms)
- Splenomegaly
- Unexplained epistaxis
- Vague morning indigestion
- Vascular spiders

Decompensated

- Ascites
- Clubbing of fingers
- Continuous mild fever
- Epistaxis
- Gonadal atrophy
- Hypotension
- Jaundice
- Muscle wasting
- Purpura (due to decreased platelet count)
- Sparse body hair
- Spontaneous bruising
- Weakness
- Weight loss
- White nails

Adapted from Lee, S. S., & Moreau, R. (2015). *Cirrhosis: A practical guide to management* (1st ed.). Hoboken, NJ: John Wiley & Sons, Ltd.

Liver Enlargement

Early in the course of cirrhosis, the liver tends to be large, and the cells are loaded with fat. The liver is firm and has a sharp edge that is noticeable on palpation. Abdominal pain may be present because of recent, rapid enlargement of the liver, which produces tension on Glisson capsule (the fibrous covering of the liver). Later in the disease, the liver decreases in size as scar tissue contracts the liver tissue. The liver edge, if palpable, is nodular.

Portal Obstruction and Ascites

Portal obstruction and ascites—late manifestations of cirrhosis—are caused partly by chronic failure of liver function and partly by obstruction of the portal circulation. Almost all of the blood from the digestive organs is collected in the portal veins and carried to the liver. Because a cirrhotic liver does not allow free blood passage, blood backs up into the spleen and the GI tract, and these organs become the seat of chronic passive congestion—that is, they are stagnant with blood and therefore cannot function properly. Indigestion and altered bowel function result. Fluid rich in protein may accumulate in the peritoneal cavity, producing ascites. This can be detected through percussion for shifting dullness or a fluid wave (see Fig. 43-6).

Infection and Peritonitis

Bacterial peritonitis may develop in patients with cirrhosis and ascites in the absence of an intra-abdominal source of infection or an abscess. This condition is referred to as spontaneous bacterial peritonitis (SBP). Bacteremia due to translocation of intestinal flora is believed to be the most likely route of infection. Clinical signs may be absent, necessitating paracentesis for diagnosis. Antibiotic therapy is effective in the treatment and prevention of recurrent episodes of SBP. The development of SBP is a precipitating factor to the onset of hepatorenal syndrome, a form of acute kidney injury unresponsive to administration of fluid or diuretic agents (Adebayo, Neong, & Wong, 2019; Schiff et al., 2018). This type of kidney disease is characterized by a lack of pathologic changes in the kidney; there is no evidence of dehydration or obstruction of the urinary tract or any other renal disorder.

Gastrointestinal Varices

The obstruction to blood flow through the liver caused by fibrotic changes also results in the formation of collateral blood vessels in the GI system and shunting of blood from the portal vessels into blood vessels with lower pressures. As a result, the patient with cirrhosis often has prominent, distended abdominal blood vessels, called *caput medusae,* which are visible on abdominal inspection and distended blood vessels throughout the GI tract. The esophagus, stomach, and lower rectum are common sites of collateral blood vessels. These distended blood vessels form varices or hemorrhoids, depending on their location.

Because these vessels were not intended to carry the high pressure and volume of blood imposed by cirrhosis, they may rupture and bleed. Therefore, assessment must include observation for occult and frank bleeding from the GI tract.

Edema

Another late symptom of cirrhosis is edema, which is attributed to chronic liver failure. A reduced plasma albumin concentration predisposes the patient to the formation of edema. Although edema is generalized, it often affects the lower extremities, the upper extremities, and the presacral area. Facial edema is not typical. Overproduction of aldosterone occurs, causing sodium and water retention and potassium excretion.

Vitamin Deficiency and Anemia

Because of inadequate formation, use, and storage of certain vitamins (notably vitamins A, C, and K), signs of deficiency are common, particularly hemorrhagic phenomena associated with vitamin K deficiency. Chronic gastritis and impaired GI function, together with inadequate dietary intake and impaired liver function, account for the anemia that is often associated with cirrhosis. The patient's anemia, poor nutritional status, and poor state of health result in severe fatigue, which interferes with the ability to carry out routine activities of daily living.

Mental Deterioration

Additional clinical manifestations include deterioration of mental and cognitive function with impending hepatic encephalopathy and hepatic coma, as described previously. Serial neurologic assessment is indicated, including assessment of the patient's general behavior, cognitive abilities, orientation to time and place, and speech patterns.

Assessment and Diagnostic Findings

The extent of liver disease and the type of treatment are determined after review of the laboratory findings. The functions of the liver are complex, and many diagnostic tests provide information about liver function (see Table 43-1). The patient needs to know why these tests are being performed and how to cooperate.

In severe parenchymal liver dysfunction, the serum albumin level tends to decrease, and the serum globulin level rises. Enzyme tests indicate liver cell damage: serum alkaline phosphatase, AST, ALT, and GGT levels increase, and the serum cholinesterase level may decrease. Bilirubin tests are performed to measure bile excretion or retention; increased levels of bilirubin can occur with cirrhosis and other liver disorders. Prothrombin time is prolonged. Normal values for laboratory data are listed in Appendix A on thePoint.

Ultrasound scanning is used to measure the difference in density of parenchymal cells and scar tissue. CT, MRI, radioisotope liver scans, and elastography studies give information about liver size, hepatic blood flow and obstruction and the presence of liver fibrosis. Diagnosis is confirmed by liver

biopsy. Arterial blood gas analysis may reveal a ventilation–perfusion imbalance and hypoxia.

Medical Management

Management of the patient with cirrhosis is usually based on the presenting symptoms. For example, antacids or H_2 antagonists are prescribed to decrease gastric distress and minimize the possibility of GI bleeding. Vitamins and nutritional supplements promote healing of damaged liver cells and improve the patient's general nutritional status. Potassium-sparing diuretic agents such as spironolactone or triamterene may be indicated to decrease ascites, if present; these diuretics are preferred because they minimize the fluid and electrolyte changes commonly seen with other agents. An adequate diet and avoidance of alcohol are essential. Although the fibrosis of the cirrhotic liver cannot be reversed, its progression may be halted or slowed by such measures.

Many medications possess antifibrotic activity for the treatment of cirrhosis. Some of these medications include colchicine, angiotensin system inhibitors, statins, diuretics including spironolactone, immunosuppressants, and glitazones such as pioglitazone or rosiglitazone. Angiotensin receptor blocker (ARB) medications also have antifibrogenic properties and may also be prescribed (Schiff et al., 2018).

Many advances have been made in the treatment of liver fibrosis. Understanding of the pathogenic mechanisms of liver disease and fibrogenesis has led to the recent increase in the number of clinical trials, particularly for patients with NASH. Fibrosis is a key predictor of liver mortality in NASH, and many studies have focused on evaluating the potential of drugs to reduce liver fibrogenesis. Drugs that target different pathways in NASH are, therefore, being evaluated in isolation or as combination therapy. Some of the antifibrotic medications currently under study can reduce injury and inflammation and include vitamin E and chemokine receptor (CCR2/CCR5) inhibitors. Peroxisome proliferator-activated receptor (PPAR) agonists have been shown to cause cell death of hepatic stellate cells that potentiate fibrosis. Farnesoid X receptor agonists, such as obeticholic acid, have been reported to prevent chronic inflammation and liver fibrosis (Manka Zeller, & Syn, 2019; Schiff et al., 2018).

Many patients who have ESLD with cirrhosis use the herb milk thistle (*Silybum marianum*) to treat jaundice and other symptoms. This herb has been used for centuries because of its healing and regenerative properties for liver disease. Silymarin from milk thistle has anti-inflammatory and antioxidant properties that may have beneficial effects, especially in hepatitis, alcohol-induced liver injury and HCC (Weiskirchen, Weiskirchen, & Tacke, 2018). The natural compound SAM-e (S-adenosylmethionine) may improve outcomes in liver disease by improving liver function, possibly through enhancing

antioxidant function. Primary biliary cirrhosis has been treated with ursodeoxycholic acid to improve liver function.

Nursing Management

Nursing management for the patient with cirrhosis of the liver is described in detail in Chart 43-10. Nursing interventions are directed toward promoting patient's rest, improving nutritional status, providing skin care, reducing risk of injury, and monitoring and managing potential complications.

Promoting Rest

The patient with cirrhosis requires rest and other supportive measures to permit the liver to reestablish its functional ability. If the patient is hospitalized, weight and I&O are measured and recorded daily. The nurse adjusts the patient's position in bed for maximal respiratory efficiency, which is especially important if ascites is marked, because it interferes with adequate thoracic excursion. Oxygen therapy may be required in liver failure to oxygenate the damaged cells and prevent further cell destruction.

Chart 43-10  **PLAN OF NURSING CARE**

The Patient with Impaired Liver Function

NURSING DIAGNOSIS: Activity intolerance associated with fatigue, lethargy, and malaise

GOAL: Patient reports decrease in fatigue and reports increased ability to participate in activities

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of activity tolerance and degree of fatigue, lethargy, and malaise when performing routine activities of daily living. 2. Assist with activities and hygiene when fatigued. 3. Encourage rest when fatigued or when abdominal pain or discomfort occurs. 4. Assist with selection and pacing of desired activities and exercise. 5. Provide diet high in carbohydrates with protein intake of 1.2 to 1.5 g/kg/day. 6. Administer supplemental vitamins (A, B complex, C, and K).	1. Provides baseline for further assessment and criteria for assessment of effectiveness of interventions. 2. Promotes exercise and hygiene within patient's level of tolerance. 3. Conserves energy and protects the liver. 4. Stimulates patient's interest in selected activities. 5. Provides calories for energy and protein for healing. 6. Provides additional nutrients.	• Exhibits increased interest in activities and events • Participates in activities and gradually increases exercise within physical limits • Reports increased strength and well-being • Reports absence of abdominal pain and discomfort • Plans activities to allow ample periods of rest • Takes vitamins as prescribed

NURSING DIAGNOSIS: Impaired nutritional intake associated with abdominal distention, discomfort, and anorexia

GOAL: Positive nitrogen balance, no further loss of muscle mass; meets nutritional requirements

Nursing Interventions	Rationale	Expected Outcomes
1. Assess dietary intake and nutritional status through diet history and diary, daily weight measurements, and laboratory data. 2. Provide diet high in carbohydrates with protein intake of 1.2 to 1.5 g/kg/day. 3. Assist patient in identifying low-sodium foods. 4. Elevate the head of the bed during meals. 5. Provide oral hygiene before meals and pleasant environment for meals at mealtime. 6. Offer smaller, more frequent meals (6/day). 7. Encourage patient to eat meals and supplementary feedings. 8. Provide attractive meals and an aesthetically pleasing setting at mealtime.	1. Identifies deficits in nutritional intake and adequacy of nutritional state. 2. Provides calories for energy and protein for healing. 3. Reduces edema and ascites formation. 4. Reduces discomfort from abdominal distention and decreases sense of fullness produced by pressure of abdominal contents and ascites on the stomach. 5. Promotes positive environment and increased appetite; reduces unpleasant taste. 6. Decreases feeling of fullness, bloating. 7. Encouragement is essential for the patient with anorexia and gastrointestinal discomfort. 8. Promotes appetite and sense of well-being. 9. Eliminates "empty calories" and further damage from alcohol. 10. Reduces gastrointestinal symptoms and	• Exhibits improved nutritional status by increased weight (without fluid retention) and improved laboratory data • States rationale for dietary modifications • Identifies foods high in carbohydrates and protein • Reports improved appetite • Participates in oral hygiene measures • Reports increased appetite; identifies rationale for smaller, frequent meals • Demonstrates intake of high-calorie diet; adheres to protein intake recommendations • Identifies foods and fluids that are nutritious and permitted on diet • Gains weight without increased edema or ascites formation

9. Eliminate alcohol. 10. Administer medications prescribed for nausea, vomiting, diarrhea, or constipation. 11. Encourage increased fluid intake and exercise if the patient reports constipation.	discomforts that decrease the appetite and interest in food. 11. Promotes normal bowel pattern and reduces abdominal discomfort and distention.	• Reports increased appetite and well-being • Excludes alcohol from diet • Takes medications for gastrointestinal disorders as prescribed • Reports normal gastrointestinal function with regular bowel function

NURSING DIAGNOSIS: Impaired skin integrity associated with pruritus from jaundice and edema

GOAL: Decrease potential for pressure injury development; breaks in skin integrity

Nursing Interventions	Rationale	Expected Outcomes
1. Assess degree of discomfort related to pruritus and edema. 2. Note and record degree of jaundice and extent of edema.	1. Assists in determining appropriate interventions. 2. Provides baseline for detecting changes and evaluating effectiveness of interventions.	• Exhibits intact skin without redness, excoriation, or breakdown • Reports relief from pruritus • Exhibits no skin excoriation from scratching
Nursing Interventions	**Rationale**	**Expected Outcomes**
3. Keep patient's fingernails short and smooth. 4. Provide frequent skin care; avoid the use of soaps	3. Prevents skin excoriation and infection from scratching. 4. Removes waste products from skin	• Uses nondrying soaps and lotions; states rationale for the use of nondrying soaps and lotions

and alcohol-based lotions. 5. Massage every 2 hours with emollients; turn every 2 hours. 6. Initiate use of alternating-pressure mattress or low air loss bed. 7. Recommend avoiding the use of harsh detergents. 8. Assess skin integrity every 4–8 hours. Instruct patient and family in this activity. 9. Restrict sodium as prescribed. 10. Perform range-of-motion exercises every 4 hours; elevate edematous extremities whenever possible.	while preventing dryness of skin. 5. Promotes mobilization of edema. 6. Minimizes prolonged pressure on bony prominences susceptible to breakdown. 7. May decrease skin irritation and need for scratching. 8. Edematous skin and tissue have compromised nutrient supply and are vulnerable to pressure and trauma. 9. Minimizes edema formation. 10. Promotes mobilization of edema.	Turns self • periodically; exhibits reduced edema of dependent parts of the body • Exhibits no areas of skin breakdown • Exhibits decreased edema; normal skin turgor

NURSING DIAGNOSIS: Risk for injury associated with altered clotting mechanisms and altered level of consciousness
GOAL: Reduced risk of injury

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of consciousness and cognitive level.	1. Assists in determining patient's ability to protect self and comply with required self-protective actions; may detect deterioration of hepatic function.	• Is oriented to time, place, and person • Exhibits no hallucinations and demonstrates no efforts to get up unassisted or to leave hospital
2. Provide safe environment (pad side rails, remove obstacles in room, prevent falls).	2. Minimizes falls and injury if falls occur.	
3. Provide frequent surveillance to orient patient, and avoid the use of restraints.	3. Protects patient from harm while stimulating and orienting patient; the use of restraints may disturb patient further.	• Exhibits no ecchymoses (bruises), cuts, or hematoma • Uses electric razor rather than sharp-edged razor
4. Replace sharp objects (razors) with safer items.	4. Avoids cuts and bleeding.	
5. Observe each stool for color, consistency, and amount.	5. Permits detection of bleeding in gastrointestinal tract.	• Exhibits absence of frank bleeding from gastrointestinal tract
6. Be alert to symptoms of anxiety, epigastric fullness, weakness, and restlessness.	6. May indicate early signs of bleeding and shock.	• Exhibits absence of restlessness, epigastric fullness, and other indicators of hemorrhage and shock
7. Test each stool and emesis for occult blood.	7. Detects early evidence of bleeding.	• Exhibits negative results of test
8. Observe for hemorrhagic manifestations: ecchymosis, epistaxis, petechiae, and bleeding gums.	8. Indicates altered clotting mechanisms.	
9. Record vital signs at frequent intervals, depending on patient		

acuity (every 1–4 hours). 10. Keep patient quiet, and limit activity. 11. Assist provider in passage of tube for esophageal balloon tamponade, if its insertion is indicated. 12. Observe during blood transfusions. 13. Measure and record nature, time, and amount of vomitus. 14. Maintain patient in fasting state, if indicated.	9. Provides baseline and evidence of hypovolemia and hemorrhagic shock. 10. Minimizes risk of bleeding and straining. 11. Promotes nontraumatic insertion of tube in a patient who is anxious and combative for immediate treatment of bleeding. 12. Permits detection of transfusion reactions (risk increased with multiple blood transfusions needed for active bleeding from esophageal varices). 13. Assists in evaluating extent of bleeding and blood loss. 14. Reduces risk of aspiration of gastric contents and minimizes risk of further trauma to esophagus and stomach by preventing vomiting.	for occult gastrointestinal bleeding • Is free of ecchymotic areas or hematoma formation • Exhibits normal vital signs • Maintains rest and remains quiet if active bleeding occurs • Identifies rationale for blood transfusions and measures to treat bleeding • Uses measures to prevent trauma (e.g., uses soft toothbrush, blows nose gently, avoids bumps, falls, straining during defecation) • Experiences no side effects of medications • Takes all medications as prescribed • Identifies rationale for precautions

		with the use of all medications • Adheres to prescribed treatment modalities
Nursing Interventions	**Rationale**	**Expected Outcomes**
15. Administer vitamin K as prescribed. 16. Remain with patient during episodes of bleeding. 17. Offer cold liquids by mouth when bleeding stops (if prescribed). 18. Institute measures to prevent trauma. a. Maintain safe environment. b. Encourage *gentle* blowing of nose. c. Provide soft toothbrush, and avoid the use of toothpicks. d. Encourage intake of foods with high content of vitamin C. e. Apply cold compresses where indicated. f. Record location of bleeding sites. g. Use small-gauge needles for injections.	15. Promotes clotting by providing fat-soluble vitamin necessary for clotting. 16. Reassures patient who is anxious and permits monitoring and detection of further needs of the patient. 17. Minimizes risk of further bleeding by promoting vasoconstriction of esophageal and gastric blood vessels. 18. Promotes safety of patient. a. Minimizes risk of trauma and bleeding by avoiding falls and cuts, etc. b. Reduces risk of epistaxis (nosebleed) secondary to trauma and decreased clotting. c. Prevents trauma to oral mucosa	

19. Administer medications carefully; monitor for side effects.	while promoting good oral hygiene. d. Promotes healing. e. Minimizes bleeding into tissues by promoting local vasoconstriction. f. Permits detection of new bleeding sites and monitoring of previous sites of bleeding. g. Minimizes oozing and blood loss from repeated injections. 19. Reduces risk of side effects secondary to damaged liver's inability to detoxify (metabolize) medications normally.	
Nursing Diagnosis: Disturbed body image associated with changes in appearance, sexual dysfunction, and role function **Goal:** Patient verbalizes feelings consistent with improvement of body image and self-esteem		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess changes in appearance and the meaning these changes have for patient and family. 2. Encourage patient to verbalize reactions	1. Provides information for assessing impact of changes in appearance, sexual function, and role on the patient and family.	• Verbalizes concerns related to changes in appearance, life, and lifestyle

and feelings about these changes. 3. Assess patient's and family's previous coping strategies. 4. Assist and encourage patient to maximize appearance (such as strategies to limit the appearance of jaundice and ascites through careful selection of colors and type of clothing) and explore alternatives to previous sexual and role functions. 5. Assist patient in identifying short-term goals. 6. Encourage and assist patient in decision making about care. 7. Identify with patient resources to provide additional support (counselor, spiritual advisor). 8. Assist patient in identifying previous practices that may have been harmful to self (substance use disorder). Involve patient in goal setting, and provide positive feedback for accomplishments.	2. Enables patient to identify and express concerns; encourages patient and significant others to share these concerns. 3. Permits encouragement of those coping strategies that are familiar to patient and have been effective in the past. 4. Encourages patient to continue safe roles and functions while encouraging exploration of alternatives. 5. Accomplishing these goals serves as positive reinforcement and increases self-esteem. 6. Promotes patient's control of life and improves sense of well-being and self-esteem. 7. Assists patient in identifying resources and accepting assistance from others when indicated. 8. Recognition and acknowledgment of the harmful effects of these practices are necessary for identifying a healthier lifestyle.	• Shares concerns with significant others • Identifies past coping strategies that have been effective • Uses past effective coping strategies to deal with changes in appearance, life, and lifestyle • Maintains good grooming and hygiene • Identifies short-term goals and strategies to achieve them • Takes an active role in decision making about self and care • Identifies resources that are not harmful • Verbalizes that some of previous lifestyle practices may have been harmful, if applicable • Uses healthy expressions of

		frustration, anger, anxiety
NURSING DIAGNOSIS: Comfortable with respect to enlarged tender liver and ascites **GOAL:** Increased level of comfort		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Maintain bed rest when patient experiences abdominal discomfort. 2. Administer antispasmodic and analgesic agents as prescribed. 3. Observe, record, and report presence and character of pain and discomfort. 4. Reduce sodium and fluid intake if prescribed. 5. Prepare patient and assist with procedures for management of ascites such as paracentesis or TIPS procedure, if indicated. 6. Encourage the use of distracting activities such as music, reading, or meditation.	1. Reduces metabolic demands and protects the liver. 2. Reduces irritability of the gastrointestinal tract and decreases abdominal pain and discomfort. 3. Provides baseline to detect further deterioration of status and to evaluate interventions. 4. Minimizes further formation of ascites. 5. Removal of ascites fluid may decrease abdominal discomfort. 6. Distraction may limit the perception of pain.	• Reports pain and discomfort if present • Maintains bed rest and decreases activity in presence of pain • Takes antispasmodic and analgesic agents as indicated and as prescribed • Reports decreased pain and abdominal discomfort • Reduces sodium and fluid intake to prescribed levels if indicated to treat ascites • Exhibits decreased abdominal girth and appropriate weight changes

	• Reports decreased discomfort after paracentesis or other procedure to manage ascites such as TIPS procedure

NURSING DIAGNOSIS: Hypervolemia associated with ascites and edema formation

GOAL: Restoration of normal fluid volume

Nursing Interventions	Rationale	Expected Outcomes
1. Restrict sodium and fluid intake if prescribed. 2. Administer diuretic agents, potassium, and protein supplements as prescribed. 3. Record intake and output every 1–8 hours depending on response to interventions and on patient acuity. 4. Measure and record abdominal girth and weight daily. 5. Explain rationale for sodium and fluid restriction. 6. Prepare patient and assist with paracentesis or TIPS procedure, if indicated.	1. Minimizes formation of ascites and edema. 2. Promotes excretion of fluid through the kidneys and maintenance of normal fluid and electrolyte balance. 3. Indicates effectiveness of treatment and adequacy of fluid intake. 4. Monitors changes in ascites formation and fluid accumulation. 5. Promotes patient's understanding of restriction and cooperation with it. 6. Paracentesis will temporarily decrease amount of ascites present and a TIPS procedure will lower portal pressure and thus limit the accumulation of ascitic fluid.	• Consumes diet low in sodium and within prescribed fluid restriction • Takes diuretic agents, potassium, and protein supplements as indicated without experiencing side effects • Exhibits increased urine output • Exhibits decreasing abdominal girth • Exhibits no rapid increase in weight • Identifies rationale for sodium and fluid restriction • Shows a decrease in ascites with decreased weight

NURSING DIAGNOSIS: Acute confusion associated with abnormal liver function and increased serum ammonia level

GOAL: Improved mental status; safety maintained; ability to cope with cognitive and behavioral changes

Nursing Interventions	Rationale	Expected Outcomes
1. Give frequent, small feedings of carbohydrates and protein. 2. Protect from infection. 3. Keep environment warm and draft free. 4. Pad the side rails of the bed. 5. Limit visitors.	1. Promotes consumption of adequate carbohydrates for energy requirements and protein for healing. 2. Minimizes risk of further increase in metabolic requirements. 3. Minimizes shivering, which would increase metabolic requirements. 4. Provides protection for the patient should hepatic coma and seizure activity occur. 5. Minimizes patient's activity and metabolic requirements.	• Demonstrates an interest in events and activities in environment • Demonstrates normal attention span • Follows and participates in conversation appropriately • Is oriented to person, place, and time • Remains in bed when indicated • Experiences no seizures • No neurologic or respiratory depression • Patient develops no cognitive impairments, but if they develop, they are quickly identified and treated, enhancing the potential of recovery
Nursing Interventions	**Rationale**	**Expected Outcomes**
6. Provide careful nursing surveillance to	6. Provides close monitoring of new symptoms and minimizes trauma to	• Patient and family describe adequate feelings of

ensure patient's safety. 7. Avoid opioids and barbiturates. 8. Awaken at intervals (every 2–4 hours during daytime hours for the patient who is stable) to assess cognitive status. 9. Identify subtle changes in behavior or sleep–wake pattern (consistent staff caring for the patient enhances this assessment as they become familiar with patient's baseline). 10. Assess handwriting or drawing skill daily as indication of cognitive ability. 11. Encourage patient and family to participate in therapeutic strategies to enhance coping with episodes of mental deterioration. 12. Encourage patient and family to discuss feeling of fear, powerlessness, or emotional distress related to patient's	the patient who is confused. 7. Prevents masking of symptoms of hepatic coma and prevents drug overdose secondary to reduced ability of the damaged liver to metabolize opioids and barbiturates; prevents respiratory depression. 8. Provides stimulation to the patient and opportunity for observing patient's level of consciousness. 9. These changes may herald worsening of encephalopathy, which requires rapid intervention, including medication. 10. These changes may herald worsening of encephalopathy, which requires rapid intervention, including medication. 11. Promoting activities such as listening to music, relaxation techniques, or preillness coping strategies can reduce anxiety. 12. Actively listening demonstrates caring and concern.	coping and lowered anxiety. They demonstrate ability to listen and to make decisions as able • Patient and family communicate their feelings and their needs in a secure and caring environment

mental deterioration.

NURSING DIAGNOSIS: Risk for impaired thermoregulation: failure to maintain normal body temperature due to inflammatory process of cirrhosis or hepatitis

GOAL: Maintenance of normal body temperature, free from infection

Nursing Interventions	Rationale	Expected Outcomes
1. Record temperature regularly (every 4 hours). 2. Encourage fluid intake. 3. Apply cool sponges or ice bag for elevated temperature. 4. Administer antibiotics as prescribed. 5. Avoid exposure to infections by use of appropriate hand hygiene and limiting use of central lines and urinary catheters to the shortest period of time, only when they are necessary. 6. Keep patient at rest while temperature is elevated. 7. Assess for abdominal pain, tenderness. 8. Use sterile technique for all invasive procedures.	1. Provides baseline to detect fever and to evaluate interventions. 2. Corrects fluid loss from perspiration and fever and increases patient's level of comfort. 3. Promotes reduction of fever and increases patient's comfort. 4. Ensures appropriate serum concentration of antibiotics to treat infection. 5. Minimizes risk of further infection and further increases in body temperature and metabolic rate. 6. Reduces metabolic rate. 7. May occur with bacterial peritonitis. 8. Many evidence-based practice guidelines (e.g., central venous catheter care) recommend the use of sterile technique to prevent health care-associated infections.	• Exhibits normal temperature and reports absence of chills or sweating • Demonstrates adequate intake of fluids • Exhibits no evidence of local or systemic infection • Develops no health care–associated infections related to invasive procedures/lines

NURSING DIAGNOSIS: Impaired breathing associated with restriction of thoracic excursion secondary to ascites, abdominal distention, and fluid in the thoracic cavity

GOAL: Improved respiratory status

Nursing Interventions	Rationale	Expected Outcomes
1. Elevate head of bed to at least 30 degrees. 2. Conserve patient's strength by providing rest periods and assisting with activities. 3. Change position every 2 hours. 4. Assist with paracentesis, TIPS or thoracentesis, if indicated. a. Explain procedure and its purpose to patient. b. Have patient void before paracentesis. c. Support and maintain position during procedure. d. Record both the amount and the character of fluid aspirated. e. Observe for evidence of coughing, increasing dyspnea, or pulse rate. 5. Provide education to patients who may be discharged with an indwelling peritoneal drainage catheter for	1. Reduces abdominal pressure on the diaphragm and permits fuller thoracic excursion and lung expansion. 2. Reduces metabolic and oxygen requirements. 3. Promotes expansion and oxygenation of all areas of the lungs. 4. Paracentesis, TIPS, and thoracentesis (performed to remove fluid from the abdominal and thoracic cavities, respectively) may be frightening to the patient. a. Helps obtain patient's cooperation with procedures. b. Prevents inadvertent bladder injury. c. Prevents inadvertent organ or tissue injury.	• Reports decreased shortness of breath • Reports increased strength and sense of well-being • Exhibits normal respiratory rate (12–18 breaths/min) with no adventitious sounds • Exhibits full thoracic excursion without shallow respirations • Exhibits normal arterial blood gases • Exhibits adequate oxygen saturation by pulse oximetry • Absence of confusion or cyanosis • Reports improved comfort level • Exhibits no complications

palliation of refractory ascites. a. Explain procedure and its purpose to patient. b. Explain care of the catheter and assessment of complications	d. Provides record of fluid removed and indication of severity of limitation of lung expansion by fluid. e. Indicates irritation of the pleural space and evidence of pneumothorax or hemothorax. 5. a. Explaining the purpose of the catheter demonstrates respect for the patient's self-determination b. Explanations promote patient adherence to the therapeutic regimen	related to the indwelling catheter, as appropriate
COLLABORATIVE PROBLEM: Gastrointestinal bleeding and hemorrhage **GOAL:** Absence of episodes of gastrointestinal bleeding and hemorrhage		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess patient for evidence of gastrointestinal bleeding or hemorrhage. If bleeding does occur: a. Monitor vital signs (blood pressure, pulse, respiratory rate) every 4 hours or more frequently, depending on acuity.	1. Allows early detection of signs and symptoms of bleeding and hemorrhage.	• Experiences no episodes of bleeding and hemorrhage • Vital signs are within acceptable range for patient • No evidence of bleeding from gastrointestinal tract

b. Assess skin temperature, level of consciousness every 4 hours or more frequently, depending on acuity. c. Monitor gastrointestinal secretions and output (emesis, stool for occult or obvious bleeding). Test emesis for blood once per shift and with any color change. Hematest each stool. d. Monitor hematocrit and hemoglobin for trends and changes.		• Hematocrit and hemoglobin levels within acceptable limits • Turns and moves without straining and increasing intra-abdominal pressure • No straining with bowel movements • No further bleeding episodes if aggressive treatment of bleeding and hemorrhage was needed • Patient and family state rationale for treatments
2. Avoid activities that increase intra-abdominal pressure (straining, turning). a. Avoid coughing/sneezing. b. Assist patient to turn. c. Keep all needed items within easy reach. d. Use measures to prevent constipation such as adequate fluid intake, stool softeners.	2. Minimizes increases in intra-abdominal pressure that could lead to rupture and bleeding of esophageal or gastric varices. 3. Equipment, medications, and supplies will be readily available if patient experiences bleeding from ruptured	• Patient and family identify supports available to them • Patient and family describe signs and symptoms of a recurrent bleeding episode and identify needed action

e. Ensure small meals.

3. Have equipment (balloon tamponade tube medications, IV fluids) available if indicated.
4. Assist with procedures and therapy needed to treat gastrointestinal bleeding and hemorrhage such as endoscopic variceal ligation (EVL) or sclerotherapy.
5. Monitor respiratory status every hour, and minimize risk of respiratory complications if balloon tamponade is needed.
6. Prepare patient physically and psychologically for other treatment modalities if needed.
7. Monitor patient for recurrence of bleeding and hemorrhage.
8. Keep family informed of patient's status.
9. Once recovered from bleeding episode, provide patient and family with information regarding signs and symptoms of gastrointestinal bleeding.

esophageal or gastric varices.

4. Gastrointestinal bleeding and hemorrhage require emergency measures (e.g., insertion of Sengstaken–Blakemore tube™, administration of fluids, medications).
5. The patient is at high risk for respiratory complications, including asphyxiation if gastric balloon of tamponade tube ruptures or migrates upward.
6. The patient who experiences hemorrhage is very anxious and fearful; minimizing anxiety assists in control of hemorrhage.
7. Risk of rebleeding is high with all treatment modalities used to halt gastrointestinal bleeding.
8. Family members are likely to be anxious about the patient's status; providing information will reduce their anxiety level and

	promote more effective coping. 9. Risk of rebleeding is high. Subtle signs may be more quickly identified.	
COLLABORATIVE PROBLEM: Hepatic encephalopathy **GOAL:** Absence of changes in cognitive status and of injury		
Nursing Interventions	**Rationale**	**Expected Outcomes**
1. Assess cognitive status every 4–8 hours. a. Assess patient's orientation to person, place, and time. b. Monitor patient's level of activity, restlessness, and agitation. Assess for presence of asterixis (flapping hand tremors) (see Fig. 43-12). c. Obtain and record daily sample of patient's handwriting or ability to construct a simple figure (e.g., star) (see Fig. 43-13). d. Assess neurologic signs (deep tendon reflexes, ability to follow instructions). 2. Monitor medications to prevent administration of those that may precipitate hepatic encephalopathy	1. Data will provide baseline of patient's cognitive status and enable detection of changes. 2. Medications are a common precipitating factor in development of hepatic encephalopathy in patients at risk. 3. Increases in serum ammonia level are associated with hepatic encephalopathy and coma.	• Remains awake, alert, and aware of surroundings • Is oriented to time, place, and person • Deep tendon reflexes remain within normal limits • Absence of asterixis • Exhibits no restlessness or agitation • Record of handwriting demonstrates no deterioration in cognitive function • States rationale for treatment used to prevent or treat hepatic encephalopathy • Demonstrates stable serum ammonia level within

(sedative, hypnotic, analgesic agents). 3. Monitor laboratory data, especially serum ammonia level.		acceptable limits • Takes medications as prescribed • Breath sounds normal without adventitious sounds • Skin and tissue intact without evidence of pressure or breaks in integrity • Verbalizes understanding of need for treatments and procedures to promote recovery
Nursing Interventions	**Rationale**	**Expected Outcomes**
4. Notify primary provider of even subtle changes in patient's neurologic assessment, cognitive function, sleep pattern, or mood. 5. Administer medications prescribed to reduce serum ammonia level (e.g., lactulose, antibiotics, glucose, benzodiazepine antagonist [flumazenil] if indicated). 6. Assess respiratory status, and initiate	4. Allows early initiation of treatment of hepatic encephalopathy and prevention of hepatic coma. 5. Reduces breakdown and conversion of protein to ammonia. Reduces serum ammonia level. 6. The patient who develops hepatic coma is at risk for respiratory complications (i.e.,	

measures to prevent complications. 7. Protect patient's skin and tissue from pressure and breakdown. 8. Provide support and active listening for patient and family as patient's mental status deteriorates.	pneumonia, atelectasis, infection). 7. The patient in coma is at risk for skin breakdown and pressure injury formation. 8. The patient with hepatic encephalopathy can experience episodes of mental deterioration due to liver failure. This can produce feelings of fear and anxiety.	

Rest reduces the demands on the liver and increases the liver's blood supply. Because the patient is susceptible to the hazards of immobility, efforts to prevent respiratory, circulatory, and vascular disturbances are initiated. These measures may help prevent such problems as atelectasis, pneumonia, venous thromboemboli formation, and pressure injuries. After nutritional status improves and strength increases, the nurse encourages the patient to increase activity gradually. Activity and mild exercise, as well as rest, are planned.

Improving Nutritional Status

The patient with cirrhosis without ascites, edema, or signs of impending hepatic coma should receive a nutritious, high-protein diet, if tolerated, supplemented by vitamins of the B complex, as well as A, C, and K. The nurse encourages the patient to eat. If ascites is present, small, frequent meals may be better tolerated than three large meals because of the abdominal pressure exerted by ascites.

The use of probiotics for the management of hepatic encephalopathy is currently the topic of ongoing research. Imbalance of the intestinal flora is not uncommon. Some research suggests that the oral ingestion of 1 cup of probiotic yogurt three times a day reduces intestinal flora imbalance by decreasing *Escherichia coli* counts and promoting the growth of non–urease-producing bacteria. This strategy is thought to then reduce ammonia levels and improve mental status (Acharya & Bajaj, 2018).

Patients with steatorrhea (fatty stools) should receive water-soluble forms of fat-soluble vitamins A, D, and E. Folic acid and iron are prescribed to prevent anemia. Sodium restriction is also indicated to prevent ascites. Patients with prolonged or severe anorexia and those who are vomiting or eating poorly for any reason may receive nutrients by the enteral or parenteral route (see Chapter 39 for further details on enteral nutrition and Chapter 41 for further details on parenteral nutrition).

Providing Skin Care

Providing careful skin care is important because of subcutaneous edema, the patient's immobility, jaundice, and increased susceptibility to skin breakdown and infection. Frequent changes in position are necessary to prevent pressure injuries. Irritating soaps and the use of adhesive tape are avoided to prevent trauma to the skin. Lotion may be soothing to irritated skin; the nurse takes measures to minimize scratching by the patient.

Reducing Risk of Injury

The nurse protects the patient with cirrhosis from falls and other injuries. The side rails should be in place and pads used in case the patient becomes agitated or restless. To minimize agitation, the nurse orients the patient to time and place and explains all procedures. The nurse instructs the patient to ask for assistance to get out of bed. The nurse carefully evaluates any injury because of the possibility of internal bleeding.

Because of the risk for bleeding from abnormal clotting, the patient should use an electric razor rather than a safety razor. A soft-bristled toothbrush helps minimize bleeding gums, and pressure applied to all venipuncture sites helps minimize bleeding.

Monitoring and Managing Potential Complications

A major role of the nurse is monitoring of the patient with cirrhosis for complications.

Bleeding and Hemorrhage

The patient is at increased risk for bleeding and hemorrhage because of decreased production of prothrombin and decreased ability of the diseased liver to synthesize the necessary substances for blood coagulation (see the Esophageal Varices section).

Hepatic Encephalopathy

Hepatic encephalopathy and coma, which are complications of cirrhosis, may manifest as deteriorating mental status (delirium) or as physical signs such as

abnormal voluntary and involuntary movements. Hepatic encephalopathy was discussed earlier in the chapter in detail.

Monitoring is essential to identify early deterioration in mental status. The nurse monitors the patient's mental status closely and reports changes so that treatment for encephalopathy can be initiated promptly. An extensive baseline and ongoing neurologic evaluation is key to identify progression through the four stages of encephalopathy (see Table 43-3).

Each advancing stage demands more intensive nursing interventions aimed at providing for patient safety and prevention and early identification of life-threatening complications such as respiratory failure and cerebral edema, which would necessitate interventions in an ICU. Because electrolyte disturbances can contribute to encephalopathy, serum electrolyte levels are carefully monitored and corrected if abnormal. Oxygen is given if oxygen desaturation occurs. The nurse monitors for fever or abdominal pain, which may signal the onset of bacterial peritonitis or other infection (see earlier discussion of hepatic encephalopathy).

Fluid Volume Excess

Patients with advanced chronic liver disease develop cardiovascular abnormalities. These occur due to an increased cardiac output and decreased peripheral vascular resistance, possibly resulting from the release of vasodilators. A hyperdynamic circulatory state develops in patients with cirrhosis, and plasma volume increases. This increase in circulating plasma volume is probably multifactorial, but some studies have implicated excess production of nitrous oxide, such as that seen in sepsis, as one causative factor (Friedman & Martin, 2018). The greater the degree of hepatic decompensation, the more severe the hyperdynamic state. Close assessment of cardiovascular and respiratory status is of key importance for the care of patients with this disorder. Pulmonary compromise is always a potential complication of ESLD because of plasma volume excess; consequently, the nurse has an important role in preventing pulmonary complications. Administering diuretic agents, implementing fluid restrictions, and enhancing patient positioning can optimize pulmonary function. Fluid retention may be noted in the development of ascites, lower extremity swelling, and dyspnea. Monitoring of I&O, daily weight changes, changes in abdominal girth, and edema formation is part of nursing assessment in the hospital or in the home setting. Patients are also monitored for nocturia and, later, for oliguria, because these states indicate increasing severity of liver dysfunction (Mansour & McPherson, 2018; Schiff et al., 2018).

Promoting Home, Community-Based and Transitional Care

Educating Patients About Self-Care

During the hospital stay, the nurse and other health care providers prepare the patient with cirrhosis for discharge, focusing on dietary education. Of greatest importance is the exclusion of alcohol from the diet. The patient may benefit from referral to Alcoholics Anonymous, psychiatric care, or counseling or support from a spiritual advisor. The patient should avoid the consumption of raw shellfish.

Sodium restriction will continue for a considerable time, if not permanently. The patient will require written education, reinforcement, and support from the staff as well as family members.

Successful treatment depends on convincing the patient of the need to adhere completely to the therapeutic plan. This includes rest, lifestyle changes, adequate dietary intake, and the elimination of alcohol. The nurse also educates the patient and family about symptoms of impending encephalopathy, possible bleeding tendencies, and susceptibility to infection. Nurses should consider implementing the teach-back method when educating patients and families to insure that they are able to describe what they have been taught in their own words or perform a task as instructed (see Chapter 3 for further discussion of the teach-back method).

Recovery is neither rapid nor easy; there are frequent setbacks and apparent lack of improvement. Many patients find it difficult to refrain from using alcohol for comfort or escape. The nurse has a significant role in offering support and encouragement to the patient and in providing positive feedback when the patient experiences success.

Continuing and Transitional Care

Referral for transitional or home care may assist the patient in dealing with the transition from hospital to home. The use of alcohol may have been an important part of normal home and social life in the past. The nurse assesses the patient's progress at home and the manner in which the patient and family are coping with the elimination of alcohol and the dietary restrictions. The nurse also reinforces previous education and answers questions that may not have occurred to the patient or family until the patient is back home and trying to establish new patterns of eating, drinking, and lifestyle.

CANCER OF THE LIVER

Hepatic tumors may be malignant or benign. Benign liver tumors were uncommon until oral contraceptives were in widespread use in western countries. Now, benign liver tumors such as hepatic adenomas occur most frequently in women in their reproductive years who are taking oral contraceptives, though the incidence has decreased with the development of

modern contraceptives which contain less estrogen. The risk of these tumors is increased in those who are overweight or have obesity. These lesions may be complicated by hemorrhage and conversion to a malignant state (Tsilimigras, Rahnemai-Azar, Ntanasis-Stathopoulos, et al., 2019).

Primary Liver Tumors

Few cancers originate in the liver. Primary liver tumors usually are associated with chronic liver disease, hepatitis B and C infections, and cirrhosis. HCC is the most common type of primary liver cancer, responsible for 75% of all liver cancers, with more than half a million cases diagnosed each year on a worldwide basis. HCC is the second leading cause of cancer-related mortality worldwide. It is rare in the United States and northern Europe, accounting for fewer than 6 cases per 100,000 inhabitants (Akinyemiju, Abera, Ahmed, et al., 2017; Schiff et al., 2018). Other types of primary liver cancer include fibrolamellar carcinoma, angiosarcoma, hepatoblastoma, cholangiocellular carcinoma, and combined hepatocellular and cholangiocellular carcinoma. HCC is usually nonresectable because of rapid growth and metastasis. If found early, resection of primary liver cancer may be possible; however, early detection is not common.

Cirrhosis, chronic infection with HBV and HCV, and exposure to certain chemical toxins (e.g., vinyl chloride, arsenic) have been implicated as causes of HCC. Cigarette smoking has also been identified as a risk factor, especially when combined with alcohol (Petrick, Campbell, Koshiol, et al., 2018). Some evidence suggests that aflatoxin, a metabolite of the fungus *Aspergillus flavus,* may be a risk factor for HCC. This is especially true in areas where HCC is endemic (i.e., Asia, Africa). Aflatoxin and other similar toxic molds can contaminate food such as ground nuts and grains and may act as co-carcinogens with hepatitis B (Friedman & Martin, 2018). The risk of contamination is greatest when these foods are stored unrefrigerated in tropical or subtropical climates.

Liver Metastases

Metastases from other primary sites, particularly the digestive system, breast, and lung, are found in the liver 2.5 times more frequently than tumors due to primary liver cancers (Friedman & Martin, 2018; Goldman & Schafer, 2019). Malignant tumors are likely to reach the liver eventually, by way of the portal system or lymphatic channels, or by direct extension from an abdominal tumor. Moreover, the liver apparently is an ideal place for these malignant cells to thrive. Often, the first evidence of cancer in an abdominal organ is the

appearance of liver metastases; unless exploratory surgery or an autopsy is performed, the primary tumor may never be identified.

Clinical Manifestations

The early manifestations of malignancy of the liver include pain—a continuous dull ache in the right upper quadrant, epigastrium, or back. Weight loss, loss of strength, anorexia, and anemia may also occur. The liver may be enlarged and irregular on palpation. Jaundice is present only if the larger bile ducts are occluded by the pressure of malignant nodules in the hilum of the liver. Ascites develops if such nodules obstruct the portal veins or if tumor tissue is seeded in the peritoneal cavity.

Assessment and Diagnostic Findings

The diagnosis of liver cancer is based on clinical signs and symptoms, the history and physical examination, and the results of laboratory and x-ray studies. Increased serum levels of bilirubin, alkaline phosphatase, AST, GGT, and lactic dehydrogenase may occur. Leukocytosis (increased white blood cells), erythrocytosis (increased red blood cells), hypercalcemia, hypoglycemia, and hypocholesterolemia may also be seen on laboratory assessment.

The serum level of alpha-fetoprotein, which serves as a tumor marker, is elevated in 80% to 90% of patients with HCC, commonly to levels greater than 200 ng/mL (Friedman & Martin, 2018). Patients with small tumors (<5 cm in diameter) have normal or minimally elevated levels of alpha-fetoprotein. The level of carcinoembryonic antigen, a marker of advanced cancer of the digestive tract, may be elevated. These two markers together are useful to distinguish between metastatic liver disease and primary liver cancer.

Many patients have metastases from the primary liver tumor to other sites by the time the diagnosis is made; metastases occur primarily to the lung but may also occur to regional lymph nodes, adrenals, bone, kidneys, heart, pancreas, or stomach.

X-rays, liver scans, CT scans, ultrasound studies, MRI, arteriography, and laparoscopy may be part of the diagnostic workup and may be performed to determine the extent of the cancer. Positron emission tomography (PET) scans are used to evaluate a wide range of metastatic tumors of the liver.

Confirmation of a tumor's histology can be made by biopsy under imaging guidance (CT scan or ultrasound) or laparoscopically. Local or systemic dissemination of the tumor by needle biopsy or fine-needle biopsy can occur. Because of the small but real risks of tumor seeding (0.5% to 2%), hemorrhage, and false-negative results from biopsy, many transplant centers avoid biopsy, particularly in patients who may be candidates for liver resection

or liver transplantation. Assessment of the imaging characteristics for the diagnosis of HCC is preferred in these instances, and a confirmed diagnosis of HCC is made by frozen section at the time of surgery (Goldman & Schafer, 2019).

Medical Management

Although surgical resection of the liver tumor is possible in some patients, the underlying cirrhosis is so prevalent in cancer of the liver that it increases the risks associated with surgery. Radiation therapy and chemotherapy have been used to treat cancer of the liver with varying degrees of success. Although these therapies may prolong survival and improve quality of life by reducing pain and discomfort, their major effect is palliative.

Radiation Therapy

The use of external-beam radiation for the treatment of liver tumors has been limited by the radiosensitivity of normal hepatocytes and the risk of destruction of normal liver parenchyma. More effective methods of delivering radiation to tumors of the liver include IV or transarterial injection of a lipiodol-ethanol (radiopaque agent) mixture (also known as transarterial chemoembolization [TACE]) that specifically attacks tumor-associated antigens, use of drug-eluding beads (DEB-TACE) and percutaneous placement of a high-intensity source for interstitial radiation therapy (delivery of radiation directly to the tumor cells). Internal radiotherapy can result in reduction in tumor size, but its effect on survival is yet to be determined (Friedman & Martin, 2018; Schiff et al., 2018).

Chemotherapy

Typically, studies of patients with advanced cases of liver cancer have shown that the use of systemic chemotherapeutic agents leads to poor outcomes. For patients with stable hepatic function (Child class A), a targeted molecular therapy, sorafenib, has been developed and approved for use and is the standard systemic treatment for patients with advanced HCC. Regorafenib may be used in patients who cease responding to sorafenib (Friedman & Martin, 2018). Systemic chemotherapy may be used to treat metastatic liver lesions. Embolization of tumor vessels with chemotherapy produces anoxic necrosis with high concentrations of trapped chemotherapeutic agents. This therapy has begun to show some promising results. An implantable pump has been used to deliver a high concentration of chemotherapy by constant infusion to the liver through the hepatic artery in cases of metastatic disease. This method has shown a moderate response rate (Friedman & Martin, 2018).

Percutaneous Biliary Drainage

Percutaneous biliary or transhepatic drainage is used to bypass biliary ducts obstructed by liver, pancreatic, or bile duct tumors in patients who have inoperable tumors or are considered poor surgical risks. Under fluoroscopy, a catheter is inserted through the abdominal wall and past the obstruction into the duodenum. Such procedures are used to reestablish biliary drainage, relieve pressure and pain from the buildup of bile behind the obstruction, and decrease pruritus and jaundice. As a result, the patient is made more comfortable, and quality of life and survival are improved.

For several days after its insertion, the catheter is opened to external drainage. The bile is observed closely for amount, color, and presence of blood and debris. Complications of percutaneous biliary drainage include sepsis, leakage of bile, hemorrhage, and reobstruction of the biliary system by debris in the catheter or by encroaching tumor. Therefore, the patient is observed for fever and chills, bile drainage around the catheter, changes in vital signs, and evidence of biliary obstruction, including increased pain or pressure, pruritus, and recurrence of jaundice.

Other Nonsurgical Treatments

Laser hyperthermia has been used to treat hepatic metastases. Heat has been directed to tumors through several methods to cause necrosis of the tumor cells while sparing normal tissue. In radiofrequency thermal ablation, a needle electrode is inserted into the liver tumor under imaging guidance. Radiofrequency energy passes through to the noninsulated needle tip, causing heat and tumor cell death from coagulation necrosis.

Immunotherapy is another treatment modality under investigation. In this therapy, lymphocytes with antitumor reactivity are given to the patient with hepatic cancer. Tumor regression has been demonstrated in patients with metastatic cancer for whom standard treatment has failed.

Transcatheter arterial embolization interrupts the arterial blood flow to small tumors by injecting small particulate embolic or chemotherapeutic agents (as described previously) into the artery supplying the tumor. As a result, ischemia and necrosis of the tumor occur.

For multiple small lesions, ultrasound-guided injection of alcohol promotes dehydration of tumor cells and tumor necrosis (Srinivasan & Friedman, 2018).

Surgical Management

Surgical resection is the treatment of choice when HCC is confined to one lobe of the liver and the function of the remaining liver is considered adequate for postoperative recovery. In the case of metastasis, hepatic resection can be performed if the primary site can be completely excised and the metastasis is limited. However, metastases to the liver are rarely limited or solitary. Capitalizing on the regenerative capacity of the liver cells, some surgeons have

successfully removed 90% of the liver. However, the presence of cirrhosis limits the ability of the liver to regenerate. Laparoscopic liver resection for malignant tumors has also been described. Staging of liver tumors aids in predicting the likelihood of surgical cure (Cameron & Cameron, 2020; Friedman & Martin, 2018; Schiff et al., 2018).

In preparation for surgery, the patient's nutritional, fluid, and general physical status are assessed, and efforts are undertaken to ensure the best physical condition possible. Extensive diagnostic studies may be performed. Specific studies may include liver scan, liver biopsy, cholangiography, selective hepatic angiography, percutaneous needle biopsy, peritoneoscopy, laparoscopy, ultrasound, CT scan, PET scan, MRI, and blood tests, particularly determinations of serum alkaline phosphatase, AST, and GGT and its isoenzymes.

Lobectomy

Removal of a lobe of the liver is the most common surgical procedure for excising a liver tumor. If it is necessary to restrict blood flow from the hepatic artery and portal vein for longer than 15 minutes, it is likely that hypothermia will be used. For a right-liver lobectomy or an extended right lobectomy (including the medial left lobe), a thoracoabdominal incision is used. An extensive abdominal incision is made for a left lobectomy.

Local Ablation

In patients who are not candidates for resection or transplantation, ablation of HCC may be accomplished by chemicals such as ethanol or by physical means such as radiofrequency ablation (most frequently used local ablative therapy) or microwave coagulation. These techniques may be performed under ultrasound or CT guidance laparoscopically or percutaneously. Radiofrequency ablation is becoming a standard mode of treatment; a tumor up to 5 cm in size can be destroyed in one session. The most common complications following ablation are local pain or bleeding. Serious complications are rare (Friedman & Martin, 2018).

Immunotherapy with interferon may be used after surgical resection for HCC to prevent recurrence of the lesion in those patients who have developed the lesion related to hepatitis B or C.

Liver Transplantation

Liver transplantation offers good patient outcomes. Candidates with liver cancer meet stringent selection criteria, including having small, early-stage lesions (Friedman & Martin, 2018; Gerber, Baliga, & Karp, 2018; Yang, Larson, Watt, et al., 2017). The Milan criteria have been developed to limit transplantation to patients who are most likely to have better outcomes. The

Milan criteria include that the patient must have a single tumor measuring less than 5 cm, or have three or fewer lesions with none over 3 cm in size (Friedman & Martin, 2018; Schiff et al., 2018). This treatment involves removing the liver and replacing it with a healthy donor organ. Studies report decreased recurrence rates of the primary liver malignancy after transplantation, with improvement in 4-year survival rates to approximately 85%, which is similar to survival rates seen in patients transplanted for nonmalignant disorders (Friedman & Martin, 2018; Schiff et al., 2018). Metastasis and recurrence may be enhanced by the immunosuppressive therapy that is needed to prevent rejection of the transplanted liver. In patients with small (less than 5 cm), single lesions, liver transplantation has been shown to be beneficial, but its use is limited by organ shortages. The increasing use of living donor transplantation may improve this situation and decrease the waiting time and tumor proliferation that is characteristic of patients with liver cancer (see later discussion).

Nursing Management

For patients with liver cancer anticipating surgery, support, education, and encouragement are provided to help them prepare psychologically for the surgery. After surgery, potential problems related to cardiopulmonary involvement may include vascular complications and respiratory and liver dysfunction. Metabolic abnormalities require careful attention. Because extensive blood loss may occur as well, the patient receives infusions of blood and IV fluids. The patient requires constant, close monitoring and care for the first 2 or 3 days, similar to postsurgical abdominal and thoracic nursing care.

If the patient is to receive chemotherapy or radiation therapy in an effort to relieve symptoms, they may be discharged home while still receiving one or both of these therapies. The patient may also go home with a biliary drainage system or hepatic artery catheter in place. In most cases, the hepatic artery catheter has been inserted surgically and has a prefilled infusion pump implanted subcutaneously that delivers a continuous chemotherapeutic dose until completed (Friedman & Martin, 2018; Schiff et al., 2018). A hepatic artery port may also be inserted to provide access for intermittent chemotherapy infusion. This port dwells under the skin, but because it provides direct arterial access, it is not used for continuous infusion therapy in the home environment; the access line is discontinued once the chemotherapeutic agent has infused. The patient and family require education about care of the biliary catheter and the effects and side effects of hepatic artery chemotherapy. This education is necessary because of participation of the patient and family in patient care in the home setting.

Promoting Home, Community-Based and Transitional Care

Educating Patients About Self-Care

The nurse educates the patient to recognize and report the potential complications and side effects of the chemotherapy and the desirable and undesirable effects of the specific chemotherapy regimen. The nurse also emphasizes the importance of follow-up visits to assess the response to chemotherapy and radiation therapy. In addition, if the patient is receiving chemotherapy on an outpatient basis, the nurse explains the patient's and family's role in managing the chemotherapy infusion and in assessing the infusion or insertion site. The nurse encourages the patient to resume routine activities as soon as possible while cautioning about falls and activities that may damage the infusion pump or site.

Patients at home with a biliary drainage system in place typically fear that the catheter will become dislodged; this fear is often shared by the patient's family. Reassurance and education can help reduce their fear that the catheter will fall out easily. The patient and family also require education on catheter care, including instruction on how to keep the catheter site clean and dry and how to assess the catheter and its insertion site. Irrigation of the catheter with sterile normal saline solution or water may be prescribed to keep the catheter patent and free of debris. The patient and caregivers are taught proper technique to avoid introducing bacteria into the biliary system or catheter during irrigation. They are instructed not to aspirate or draw back on the syringe during irrigation in order to prevent entry of irritating duodenal contents into the biliary tree or catheter. The patient and caregivers are also educated about the signs of complications and are encouraged to notify the nurse or primary provider if problems or questions arise. The nurse should consider using the teach-back method when educating patients and family about these interventions (see Chapter 3 for further discussion of the teach-back method).

Patients with implantable ports are educated about the chemotherapy regimen, types of medications, effects and side effects that may occur, and appropriate management strategies if problems occur. If a hepatic artery port is inserted for intermittent chemotherapy, patients and their families are provided the same educational content. Such a port has an internal one-way valve; therefore, it is not aspirated for a blood return before the infusion is initiated. The patient is instructed to assess the port site between infusions and to note and report any sign of infection or inflammation.

Continuing and Transitional Care

In many cases, referral for transitional or home care enables the patient with liver cancer to be at home in a familiar environment with family and friends. Because of the poor prognosis associated with liver cancer, the nurse serves a

vital role in assisting the patient and family to cope with the symptoms that may occur and the prognosis. The patient's physical and psychological statuses are assessed as well as adequacy of pain relief, nutritional status, and presence of symptoms indicating complications of treatment or progression of disease. During home visits, the nurse assesses the function of the chemotherapy pump, the infusion site, and the biliary drainage system, if indicated. The nurse collaborates with the other members of the health care team, the patient, and the family to ensure effective pain management and to manage potential problems, which include weakness, pruritus, inadequate dietary intake, jaundice, and symptoms associated with metastasis to other sites. The nurse also assists the patient and family in making decisions about hospice care and assists with initiation of referrals. The patient is encouraged to discuss preferences for end-of-life care with family members and health care providers (see Chapter 13).

LIVER TRANSPLANTATION

Liver transplantation is used to treat life-threatening ESLD for which no other form of treatment is available. The transplantation procedure involves total removal of the diseased liver and replacement with a healthy liver from a deceased donor or with the right lobe from a live donor in the same anatomic location, referred to as **orthotopic liver transplantation [OLT]**. Removal of the liver creates a space for the new liver and permits anatomic reconstruction of the hepatic vasculature and biliary tract as close to normal as possible.

The success of liver transplantation depends on successful immunosuppression. Immunosuppressant agents currently used include the calcineurin inhibitors cyclosporine and tacrolimus. Corticosteroids are commonly used for induction immunosuppression. Mycophenolate mofetil blocks lymphocyte proliferation and results in lower dose requirements of calcineurin inhibitors. Target of rapamycin inhibitors sirolimus (formerly known as rapamycin) and everolimus inhibit T- and B-cell proliferation. Antibody therapies such as antithymocyte globulin, basiliximab, and daclizumab deplete lymphocytes and inhibit T-cell proliferation (Friedman & Martin, 2018). There is no one, accepted, optimal immunosuppressive regimen. Most transplant centers have developed their own therapeutic practices, largely based on experience. Multiple immunosuppressive strategies can be used to prevent transplanted organ rejection. Most strategies involve the use of more than one agent, but current recommendations advise the minimization of immunosuppression in order to avoid toxicity (Friedman & Martin, 2018). Using multiple immunosuppressive agents has the effect of blocking multiple targets in the immune response cascade. This allows the use of lower doses of each drug, thus avoiding toxicity associated with high doses of these powerful drugs. Some patients are treated with "triple therapy" using corticosteroids, a calcineurin inhibitor, and either an antiproliferative agent

(mycophenolate mofetil) or a target of rapamycin inhibitor (Friedman & Martin, 2018). Some transplant centers also prescribe steroid-free immunosuppressant regimens after liver transplantation. This regimen has been found to be a safe alternative. Still other transplant centers advocate monotherapy with a calcineurin inhibitor alone to provide long-term immunosuppression (Cameron & Cameron, 2020; Friedman & Martin, 2018). In order to prevent acute rejection in the early, high-risk months after liver transplantation, some centers employ induction therapy, which is the use of prophylactic, perioperative course of immunosuppressant drugs that suppress the body's response to the foreign, transplanted tissue and may improve graft survival by reducing the risk of acute cellular rejection (Friedman & Martin, 2018). Over time, withdrawal of all immunosuppressants is possible but rare; randomized, prospective studies are needed before this clinical practice is accepted.

Despite the success of immunosuppression in reducing the incidence of rejection of transplanted organs, liver transplantation is not routine and may be accompanied by complications related to the lengthy surgical procedure, immunosuppressive therapy, infection, and technical difficulties encountered in reconstructing the blood vessels and biliary tract. Long-standing systemic problems resulting from the primary liver disease may complicate the pre- and postoperative course. Previous surgery of the abdomen, including procedures to treat complications of advanced liver disease (i.e., shunt procedures used to treat portal hypertension, esophageal varices) increase the complexity of the transplantation procedure.

General indications for liver transplantation include irreversible advanced chronic liver disease, ALF, metabolic liver diseases, and some hepatic malignancies. Examples of disorders that are indications for liver transplantation include hepatocellular liver diseases (e.g., viral hepatitis, drug- or alcohol-induced liver disease, Wilson disease) and cholestatic diseases (primary biliary cirrhosis, sclerosing cholangitis, NASH, and biliary atresia).

The patient being considered for liver transplantation frequently has many systemic problems that influence pre- and postoperative care. Because transplantation is more difficult if the patient has developed severe GI bleeding and hepatic coma, efforts are made to perform the procedure before the disease progresses to this stage. The patient must undergo a thorough evaluation of hepatic reserve and general health. Part of this evaluation includes classification of the degree of medical need, an objective determination known as the MELD classification, which stratifies the level of illness of those awaiting a liver transplant. The MELD score is derived from a complex formula incorporating bilirubin levels, PT/INR, creatinine, and the cause of the liver disease (i.e., cholestatic, alcoholic, or other). The MELD score is an indicator of short-term mortality for those with ESLD. Organs are allocated

using the MELD score in an effort to provide transplants to the most severely ill patients (Friedman & Martin, 2018; Schiff et al., 2018).

Liver transplantation is an established therapeutic modality, and the number of liver transplant centers is increasing. Patients requiring transplantation are often referred from distant hospitals to these centers. To prepare the patient and family for liver transplantation, nurses in all settings must understand the processes and procedures of liver transplantation.

Many ethical issues arise concerning liver transplantation, particularly concerning the allocation of organs. The way in which some persons contracted liver disease (e.g., alcohol use, hepatitis) leads others to question allocation of organs to them, and some believe that preference should be given to people who need liver transplants but do not have a history of socially unacceptable behavior. More issues arise when a patient requires a second transplant operation because of a return to alcohol or drug use or failure to follow immunosuppressive regimens. Transplant recipients must go through a rigorous selection and preparation process that includes counseling and education to aid them in making critical choices for their improved health. Nurses and other health care providers need to be aware of and confront their own biases and work toward improved understanding and acceptance.

Surgical Procedure

During the procedure, the donor liver is freed from other structures, the bile is flushed from the gallbladder to prevent damage to the walls of the biliary tract, and the liver is perfused with a preservative and cooled. Before the donor liver is placed in the recipient, it is flushed with cold lactated Ringer solution to remove potassium and air bubbles. The presence of portal hypertension increases the difficulty of the procedure.

Anastomoses (connections) of the blood vessels and bile duct are performed between the donor liver and the recipient liver. There are two types of biliary anastomoses. Biliary reconstruction is performed with an end-to-end anastomosis of the donor and recipient common bile ducts; a stented T-tube may be inserted for external drainage of bile. In patients with biliary disease such as primary sclerosing cholangitis or if the recipient's bile duct is not suitable for anastomosis for other reasons, a biliary-enteric end-to-side anastomosis with a 40- to 50-cm Roux-en-Y loop of jejunum is created for biliary drainage (known as a Roux-en-Y procedure) (see Fig. 43-14A); in this case, bile drainage is internal, and a T-tube is not inserted (Cameron & Cameron, 2020). Figure 43-14B,C illustrates the final appearance of the grafted liver and final closure and one method of drain placement. Some transplant centers may use fewer drains.

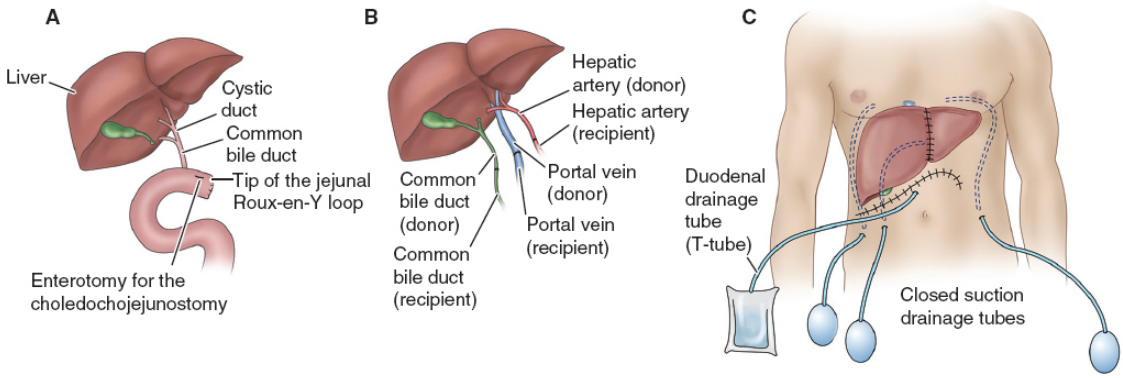

Figure 43-14 • **A.** Some transplant recipients have diseases or conditions that cause their bile ducts to be unusable for anastomosis to the donor liver bile duct. In this case, a loop of jejunum is used as a bridge from the donor liver bile duct to the recipient's small bowel for biliary continuity and drainage. This procedure is termed *Roux-en-Y hepaticojejunostomy.* **B.** Final appearance of implanted liver graft with an end-to-end biliary anastomosis. **C.** Final closure and drain placement after liver transplantation with an end-to-end biliary anastomosis and T-tube placement.

Several additional techniques have been developed to expand the donor pool for liver transplantation. In a split-liver transplant, a single organ is used to provide grafts for two individuals with ESLD, with the smaller patient receiving the smaller left lobe. This procedure has resulted in a higher complication rate and lower survival rate than traditional liver transplantation. Living donor transplantation is being increasingly performed from adult to adult using full right lobes, although it is controversial because it is a major surgical procedure for the donor, and some donor deaths have occurred.

Living donor liver transplantation (LDLT) is considered for patients who have a high potential for mortality while awaiting a deceased liver donor, such as those patients with HCC or those with severe complications of cirrhosis including GI bleeding or hepatic encephalopathy (Cameron & Cameron, 2020). The results thus far have indicated that this procedure is most successful when donor and recipient are appropriately selected using careful screening criteria (Cameron & Cameron, 2020). The option of LDLT decreases the waiting list mortality and produces positive recipient outcomes with a low risk of morbidity and mortality for the donor. The LDLT procedure involves transplantation of the right hepatic lobe from an adult donor to the recipient. Potential donors are evaluated by a donor advocate team. Donors must be completely healthy and have hepatic size and anatomy compatible with right lobe transplantation (Cameron & Cameron, 2020). There is an extensive informed consent process for live liver donors. The donor advocate ensures that the concern for donor safety is paramount, especially in the intra- and

postoperative period when complications can occur. The clear separation of donor and recipient teams ensures that the donor is treated without ulterior motives, which might occur if the same team cared for both the donor and recipient.

In the LDLT procedure, the surgeon performs a formal right hepatic lobectomy. The right lobe is then flushed with preservative solution and vascular reconstruction is completed to prepare for implantation. The recipient operation involves an inferior vena cava–sparing hepatectomy with anastomosis of the donor right-sided vascular and biliary structures to the corresponding recipient structures (Cameron & Cameron, 2020).

Liver transplantation is a long surgical procedure, partly because the patient with liver failure often has portal hypertension, requiring ligation of many venous collateral vessels. Blood loss during the surgical procedure may be extensive. If the patient has adhesions from previous abdominal surgery, lysis of adhesions is often necessary. If a shunt procedure was performed previously, it must be surgically reversed to permit adequate portal venous blood supply to the new liver. During the lengthy surgery, it is important to provide regular updates to the family about the progress of the operation and the patient's status.

Complications

The postoperative complication rate is high, primarily because of technical complications or infection. Immediate postoperative complications may include bleeding, infection, and rejection. Disruption, infection, obstruction of the biliary anastomosis, and impaired biliary drainage may occur. Vascular thrombosis and stenosis are other potential complications. These complications occur in patients receiving either a deceased donor or live donor organ. Despite the development of some complications, the 1-year patient survival rate approaches 90%, and the 5-year patient survival rate is approximately 80% (Cameron & Cameron, 2020; Friedman & Martin, 2018).

Bleeding

Bleeding is common in the postoperative period and may result from coagulopathy, portal hypertension, and fibrinolysis caused by ischemic injury to the donor liver. Hemodynamic instability and transient hypotension may occur in this phase, secondary to blood loss, loss of vasomotor tone, and vasodilatation due to rewarming the hypothermic patient or due to preexisting cardiac conditions such as cardiomyopathy (Goldman & Schafer, 2019). Administration of platelets, fresh-frozen plasma, or other blood products may be necessary. Hypertension may co-occur postoperatively but is more common later in the postoperative phase, although its cause is uncertain. Currently available hypertension guidelines do not have specific recommendations for

management in the liver transplant population. However, calcium channel blockers such as nifedipine or amlodipine are frequently used for their vasodilatory effects and are the agents of choice. These drugs also are preferable due to their low interaction level with the cytochrome P450 enzyme system with resultant minimal risk of disruption of immunosuppressant levels. Angiotensin-converting enzyme (ACE) inhibitors and ARB medications are not first-line drugs for the treatment of hypertension during the first year after transplant due to low levels of renin during this time period. Thiazide diuretics are reserved for patients requiring more than one medication for blood pressure control (Friedman & Martin, 2018). Blood pressure elevation that is significant or sustained is also managed with lifestyle modifications, a low-sodium diet, and an exercise regimen.

Infection

Infection is the leading cause of death after liver transplantation. Pulmonary and fungal infections are common; susceptibility to infection is increased by the immunosuppressive therapy that is needed to prevent rejection (Friedman & Martin, 2018). Therefore, precautions must be taken to prevent health care–associated infections. The nurse uses strict asepsis when manipulating central venous catheters, arterial lines, and urine, bile, and other drainage systems; obtaining specimens; and changing dressings. Meticulous hand hygiene is crucial. In the ICU, the nurse vigilantly monitors for early clinical manifestations of sepsis (see Chapter 11, Chart 11-6) and uses evidence-based practice guidelines (or bundles) developed by the Institute for Healthcare Improvement (IHI) in the care of the postoperative liver transplant patient. Some of these care guidelines include prevention of sepsis through prevention of central line–associated bloodstream infections and its rapid treatment (see Chapter 11, Chart 11-2) and prevention of ventilator-associated pneumonia (VAP) (see Chapter 19, Chart 19-6).

Rejection

Rejection is a major concern. A transplanted liver is perceived by the immune system as a foreign antigen. This triggers an immune response, leading to the activation of T lymphocytes that attack and destroy the transplanted liver. Immunosuppressive agents are used as long-term therapy to prevent this response and rejection of the transplanted liver. These agents inhibit the activation of immunocompetent T lymphocytes to prevent the production of effector T-cells.

Although the 1- and 5-year survival rates have increased dramatically with the use of new immunosuppressive therapies, these advances are not without major side effects. A major side effect of cyclosporine, which has been widely used in transplantation, is nephrotoxicity; this problem seems to be dose

related. Cyclosporine-related side effects have caused many transplant centers to use tacrolimus instead as first-line therapy because of its efficacy and lower side-effect profile.

Corticosteroids, azathioprine, mycophenolate mofetil, sirolimus, antithymocyte globulin, basiliximab, and daclizumab are also used in various regimens of immunosuppression. These agents may be used as the initial therapy to prevent rejection or used later to treat rejection. Liver biopsy and ultrasound may be required to evaluate suspected episodes of rejection.

Retransplantation is usually attempted if the transplanted liver fails, but the success rate of retransplantation does not approach that of initial transplantation. The greater rates of organ dysfunction and loss after a second or third liver transplant are related to technical intraoperative difficulties and higher bleeding risk (Cameron & Cameron, 2020; Friedman & Martin, 2018).

Complications of the LDLT Donor

Improved surgical techniques have made the LDLT procedure an increasingly safe one; however, complications do occur for donors as well. The most frequently occurring complications include pulmonary emboli, portal vein thrombosis, bile duct injury, and liver insufficiency secondary to a resection that is too extensive (Cameron & Cameron, 2020; Friedman & Martin, 2018).

Nursing Management

The patient considering transplantation, together with the family, must make difficult choices about treatment, the use of financial resources, and relocation to another area to be closer to the medical center. They must also be aware of the risks and benefits of the procedure and its consequences. In addition, they must also cope with the patient's long-standing health problems and any social and family problems associated with behaviors that may have caused the patient's liver failure. As a result, considerable emotional stress occurs while the patient and family consider liver transplantation and wait for an available liver. The nurse must be aware of these issues and attuned to the emotional and psychological status of the patient and family. Referral to a psychiatric liaison nurse, psychologist, psychiatrist, or spiritual advisor may help them cope with the stressors associated with ESLD and liver transplantation.

If the patient and family are considering undergoing an LDLT, they are subject to additional stressors. Both the patient and the potential donor must undergo a thorough and exhaustive physical and psychological workup to ensure that all involved parties are physically and emotionally prepared. Often, but not always, the donor is a close family member. Coercion must be excluded as influencing the decision to donate a portion of one's liver to another. The potential donor must be aware of the risks associated with the procedure.

If the patient and family believe that liver transplantation may be appropriate, the nurse, surgeon, hepatologist, and other health care team members provide the patient and family with full explanations about the procedure, the chances of success, and the risks (for the donor—bleeding and venous thromboembolism), including the side effects of long-term immunosuppression and postoperative complications in the recipient as well as bleeding and biliary abnormalities (Cameron & Cameron, 2020; Friedman & Martin, 2018). The need for close follow-up and lifelong adherence to the therapeutic regimen, including immunosuppression, is emphasized to the patient and family.

Preoperative Nursing Interventions

Once the patient has been accepted as a candidate, they are placed on a waiting list at the transplant center, and patient information is entered into the United Network for Organ Sharing (UNOS) computer system. The UNOS system uses the MELD score to determine organ allocation priorities so that the patient with the highest MELD score will receive the first available organ. Candidates may be matched with appropriate organs as they become available. MELD scores provide the necessary information regarding medical need.

Except in the case of LDLT, a liver becomes available for transplantation only with the death of another person, usually someone who had been healthy except for severe brain injury and brain death. Therefore, the patient and family undergo a stressful waiting period, and the nurse is often their major source of support. The patient must be accessible at all times in case an appropriate liver becomes available. During this time, liver function may deteriorate further, and the patient may experience complications from the progressing disease. Because of the shortage of donor organs, many patients die awaiting transplantation.

Malnutrition, massive ascites, and fluid and electrolyte disturbances are treated before surgery to increase the likelihood of a successful outcome. If the patient's liver dysfunction has a very rapid onset, as in ALF, there is little time or opportunity for the patient to consider and weigh options and their consequences; the patient may be in a coma and the decision to proceed with transplantation made by the family.

The nurse coordinator is an integral member of the transplant team and plays an important role in preparing the patient for liver transplantation. The nurse serves as an advocate for the patient and family and assumes the important role of liaison between the patient and the other members of the transplant team. The nurse also serves as a resource to other nurses and health care team members involved in evaluating and caring for the patient.

Postoperative Nursing Interventions

The organ recipient is maintained in an environment as free from bacteria, viruses, and fungi as possible, because immunosuppressive medications reduce the body's natural defenses. In the immediate postoperative period, cardiovascular, pulmonary, renal, neurologic, and metabolic functions are monitored continuously. Mean arterial and pulmonary artery pressures are also monitored continuously. Cardiac output, central venous pressure, pulmonary artery wedge pressure, arterial and mixed venous blood gases, oxygen saturation, oxygen demand and delivery, urine output, heart rate, and blood pressure are used to evaluate the patient's hemodynamic status and intravascular fluid volume. Liver function tests, electrolyte levels, the coagulation profile, chest x-ray, electrocardiogram, and fluid output (including urine, bile from the T-tube, and drainage from Jackson–Pratt tubes) are monitored closely. Because the liver is responsible for the storage of glycogen and the synthesis of protein and clotting factors, these substances need to be monitored and replaced in the immediate postoperative period.

There is a high risk of atelectasis and an altered ventilation–perfusion ratio caused by insult to the diaphragm during the surgical procedure, prolonged anesthesia, immobility, and postoperative pain. The patient may have an endotracheal tube in place and require mechanical ventilation during the initial postoperative period. Suctioning is performed as required, and sterile humidification is provided. Evidence-based practice guidelines are implemented to prevent the development of pneumonia in the postoperative liver transplant recipient (see Chapter 19, Chart 19-6).

As the patient's condition stabilizes, efforts are made to promote recovery from the trauma of this complex surgery. After removal of the endotracheal tube, the nurse encourages the patient to use an incentive spirometer to decrease the risk of atelectasis (see Chapter 19, Chart 19-1 for further details on incentive spirometry). Following extubation, the patient is assisted to get out of bed, to ambulate as tolerated, and to participate in self-care to prevent the complications associated with immobility (Pearson, Mangold, Kosiorek, et al., 2018). Close monitoring for signs and symptoms of liver dysfunction and rejection continue throughout the hospital stay. Plans are made for close follow-up after discharge as well. Education is initiated during the preoperative period and continues after surgery.

The live donor is frequently admitted to an ICU setting along with the recipient. The donor also requires close monitoring for cardiovascular, hemodynamic, and pulmonary stability. The nurse closely assesses the donor for signs of hemorrhage, biliary complication, respiratory decompensation, and infection. The donor is mobilized early in the postoperative phase to prevent the development of complications such as pulmonary embolism. Studies suggest that the donor may experience more pain than the recipient, possibly requiring more analgesia for pain control (Friedman & Martin, 2018). Patient

education focuses on prevention and recognition of complications as well as activity progression and pain management.

Promoting Home, Community-Based and Transitional Care

Educating Patients About Self-Care

Educating the patient, family, and caregivers about long-term measures to promote health is crucial for the success of transplantation and is an important role of the nurse. The patient and family must understand why they need to adhere closely to the therapeutic regimen, with special emphasis on the methods of administration, rationale, and side effects of the prescribed immunosuppressive agents. The nurse provides written and verbal education about how and when to take the medications. To avoid running out of medication or skipping a dose, the patient must make sure that an adequate supply of medication is available. Education is provided about the signs and symptoms that indicate problems necessitating consultation with the transplant team. The patient with a T-tube in place must be educated about how to manage the tube, drainage, and skin care.

Chart 43-11  **NURSING RESEARCH PROFILE**

Psychosocial Adjustments in Patients Undergoing Liver Transplantation

Yıldız, E., & Kılınç, G. (2018). The relationship between anxietydepression status and psychosocial adjustments in the patients undergoing liver transplantation. *Perspectives in Psychiatric Care*, *54*(2), 221–229.

Purpose

The purpose of this study was to determine the relationship between the anxiety-depression status and psychosocial adjustments in patients undergoing liver transplantation.

Design

This was a descriptive correlational study conducted with 90 participants who received a liver transplant in one transplant facility in Turkey. The participants included in the study were administered two questionnaires, the Hospital Anxiety and Depression Scale (HADS) and the Psychosocial Adjustment to Illness Self Report (PAIS).

Findings

The study found that as the anxiety risk of participants increased, their adjustments to their domestic and psychological environments were negatively affected.

In younger participants, the risk of experiencing anxiety increased and psychological adjustment to undergoing liver transplantation decreased. Women had a greater risk of anxiety. Most participants showed low psychosocial adjustment after liver transplantation, but this was most pronounced in those who were single, had a moderate socioeconomic level, and who were employed.

Nursing Implications

A psychiatric assessment is one element of the intensive preoperative evaluation of patients prior to undergoing liver transplantation. Psychiatric nurse practitioners may take part in such evaluations, and this information is important to have not only in the preoperative realm but after surgery should patients experience anxiety. It is important that patients are able to adjust socially and psychologically to their life changes after liver transplantation. Nurses are key participants in identifying methods to alleviate anxiety and improve coping strategies. Nurses provide encouragement for patients to participate in self-care activities that can promote effective psychosocial adjustment. Some of the patient education and support that is carried out preoperatively may facilitate this adjustment postoperatively.

Coordinating an effective plan with the interprofessional team, including psychiatric professionals, is part of the nursing role in caring for recipients of liver transplants and in helping these patients to achieve seamless transitions, less anxiety, and optimum levels of adjustment.

Following liver transplantation, the patient experiences a period of psychosocial adjustment (Ko, Muehrer, & Bratzke, 2018; Yıldız, & Kılınç, 2018). The nurse educates patients and caregivers to be alert for signs and symptoms of anxiety and depression and to report them to the transplant team so that appropriate referrals can be made for treatment as needed. See the Nursing Research Profile in Chart 43-11.

Continuing and Transitional Care

The nurse emphasizes the importance of follow-up laboratory tests and appointments with the transplant team. Trough blood levels of immunosuppressive agents are obtained, along with other blood tests that assess the function of the liver and kidneys. During the first months, the patient is likely to require blood tests two or three times a week. As the patient's condition stabilizes, laboratory studies and visits to the transplant team are less frequent. The importance of routine ophthalmologic examinations is emphasized because of the increased incidence of cataracts and glaucoma associated with the long-term corticosteroid therapy used with transplantation. Regular oral hygiene and follow-up dental care, with administration of prophylactic antibiotics before dental examinations and treatments, are recommended because of the immunosuppression.

The nurse reminds the patient that preventing rejection and infection is essential and increases the chances for survival and a more normal life than before transplantation. Many patients live successful and productive lives after receiving a liver transplant. Pregnancy may be considered after transplantation but it is not without risks. Despite advances in immunosuppressive therapy, increasing experience in the management of pregnancy after liver transplantation and some successful outcomes, these pregnancies are considered high risk for both mother and infant and referral should be made to a high-risk pregnancy center well before conception (Baskiran, Karakas, Ince, et al., 2017). Transplant recipients should be advised about birth control. The waiting period allows time to establish good health, stable liver function, and lower maintenance levels of immunosuppressive therapy (Baskiran et al., 2017).

LIVER ABSCESSES

Two categories of liver abscess have been identified: amebic and pyogenic. Amebic liver abscesses are most commonly caused by *Entamoeba histolytica.* Most amebic liver abscesses occur in the developing countries of the tropics and subtropics because of poor sanitation and hygiene. Pyogenic liver abscesses are much less common, but they are more common in developed countries than the amebic type (Friedman & Martin, 2018).

Pathophysiology

Whenever an infection develops anywhere along the biliary or GI tract, infecting organisms may reach the liver through the biliary system, portal venous system, or hepatic arterial or lymphatic system. Most bacteria are destroyed promptly, but occasionally some gain a foothold. The bacterial toxins destroy the neighboring liver cells, and the resulting necrotic tissue serves as a protective wall for the organisms.

Meanwhile, leukocytes migrate into the infected area. The result is an abscess cavity full of a liquid containing living and dead leukocytes, liquefied liver cells, and bacteria. Pyogenic abscesses of this type may be either single or multiple and small. Examples of causes of pyogenic liver abscess include cholangitis (usually related to benign or malignant obstruction of the biliary tree) and abdominal trauma.

Clinical Manifestations

The clinical picture is one of sepsis with few or no localizing signs. Fever with chills and diaphoresis, malaise, anorexia, nausea, vomiting, and weight loss may occur. The patient may complain of dull abdominal pain and tenderness in the right upper quadrant of the abdomen. Hepatomegaly, jaundice, anemia, and pleural effusion may develop. Sepsis and shock may be severe and life-threatening.

Appropriate diagnosis may be delayed and requires a high degree of clinical suspicion, especially in light of the lack of localizing signs in some patients. The diagnosis is made with the wide availability of various radiologic modalities including ultrasound, CT, and MRI (Goldman & Schaefer, 2019).

Assessment and Diagnostic Findings

Although blood cultures are obtained, the organism may not be identified with this test. Aspiration of the liver abscess, guided by ultrasound, CT, or MRI, may be performed to assist in diagnosis, obtain cultures and identify the organism. Percutaneous drainage of pyogenic abscesses is carried out to evacuate the abscess material and promote healing. A catheter may be left in place for continuous drainage; the patient must be educated about its management. Percutaneous drainage alone without catheter placement has received recent attention with patients followed with close clinical monitoring and serial ultrasounds. Results of this method are promising but controlled clinical trials are necessary to clarify effects and outcomes (Goldman & Schaefer, 2019).

Medical Management

Treatment includes IV antibiotic therapy; the specific antibiotic used in treatment depends on the organism identified. Continuous supportive care is indicated because of the serious condition of the patient. Open surgical drainage may be required if antibiotic therapy and percutaneous drainage are ineffective (Friedman & Martin, 2018; Schiff et al., 2018).

Nursing Management

Although the manifestations of liver abscess vary with the type of abscess, most patients appear acutely ill. Others appear to be chronically ill and debilitated. The nursing management depends on the patient's physical status and the medical management that is indicated. For patients who undergo evacuation and drainage of an abscess, monitoring the drainage and providing skin care are imperative. Strategies must be implemented to contain the drainage and to protect the patient from other sources of infection. Vital signs are monitored to detect changes in the patient's physical status. Deterioration in vital signs or the onset of new symptoms such as increasing pain, which may indicate rupture or extension of the abscess, is reported promptly. The nurse administers IV antibiotic therapy as prescribed. The white blood cell count and other laboratory test results are monitored closely for changes consistent with worsening infection. The nurse prepares the patient for discharge by providing education about symptom management, signs and symptoms that should be reported to the primary provider, management of drainage, and the importance of taking antibiotics as prescribed.

CRITICAL THINKING EXERCISES

1 pq You are the nurse working with a 46-year-old woman who is at high risk for hepatitis B and C due to a history of IV drug abuse. What laboratory testing is likely to be done first for this patient? If laboratory testing is positive for either or both diseases, what invasive and noninvasive testing is warranted next? Describe the education you should provide about these tests. What are the priorities for the treatment plan if testing is positive for the diseases?

2 ipc A 58-year-old man underwent an orthotopic liver transplant for decompensated alcoholic cirrhosis. He is placed on an immunosuppressant regimen including corticosteroids, mycophenolate mofetil, and tacrolimus. On day 9 postoperatively, he develops a fever with an acute change in mental status and confusion. What nursing and interprofessional assessments are indicated for this patient? What interprofessional services should be engaged?

3 ebp A 44-year-old woman with obesity is diagnosed with NAFLD and is symptomatic with jaundice and fatigue. What are the best risk reduction tactics for this patient? How should you prepare and educate the patient to achieve specific evidence-based management goals and potentially control the disease? Should this patient be evaluated for malnutrition and sarcopenia even though she has obesity? If so, why would an evaluation for sarcopenia be important?

44 Management of Patients with Biliary Disorders

LEARNING OUTCOMES

On completion of this chapter, the learner will be able to:

1. Identify the structure and function of the biliary tract and pancreas.
2. Describe the pathophysiology, clinical manifestations, and medical management of cholelithiasis.
3. Differentiate between acute and chronic pancreatitis.
4. Apply the nursing process as a framework for care of the patient with cholelithiasis, undergoing laparoscopic or open cholecystectomy, or with acute pancreatitis.
5. Explain the nutritional and metabolic effects of surgical treatment of tumors of the pancreas.

NURSING CONCEPTS

Comfort
Family
Infection
Inflammation
Metabolism
Nutrition

GLOSSARY

amylase: pancreatic enzyme; aids in the digestion of carbohydrates
cholecystectomy: removal of the gallbladder
cholecystitis: inflammation of the gallbladder which can be acute or chronic
cholecystojejunostomy: anastomosis of the jejunum to the gallbladder to divert bile flow
cholecystokinin (CCK): hormone; major stimulus for digestive enzyme secretion; stimulates contraction of the gallbladder
cholecystostomy: surgical opening and drainage of the gallbladder
choledocholithiasis: stones in the common bile duct
choledochostomy: opening into the common bile duct
cholelithiasis: calculi in the gallbladder
dissolution therapy: the use of medications to break up/dissolve gallstones
endocrine: secreting internally; hormonal secretion of a ductless gland
endoscopic retrograde cholangiopancreatography (ERCP): procedure using fiberoptic technology to visualize the biliary system
endoscopic ultrasound (EUS): invasive procedure using an ultrasound probe at the end of an endoscope to detect cholelithiasis and to decompress the gallbladder in the setting of acute cholecystitis
exocrine: secreting externally; hormonal secretion from excretory ducts
lipase: pancreatic enzyme; aids in the digestion of fats
lithotripsy: disintegration of gallstones by shock waves
pancreatitis: inflammation of the pancreas; may be acute or chronic
secretin: hormone responsible for stimulating bicarbonate secretion from the pancreas; also used as an aid in diagnosing pancreatic exocrine disease
steatorrhea: frothy, foul-smelling stools with a high fat content; results from impaired digestion of proteins and fats due to a lack of pancreatic juice in the intestine
trypsin: pancreatic enzyme; aids in the digestion of proteins
Zollinger-Ellison syndrome: hypersecretion of gastric acid that produces peptic ulcers as a result of a non–beta-cell tumor of the pancreatic islets

Disorders of the biliary tract and pancreas are common and include gallbladder stones and pancreatic dysfunction. An understanding of the structure and function of the biliary tract and pancreas is essential, along with an

understanding of how biliary tract disorders are closely linked with liver disease. Patients with acute or chronic biliary tract or pancreatic disease require care from nurses who are knowledgeable about the diagnostic procedures and interventions that are used in the management of gallbladder and pancreatic disorders.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The Gallbladder

The gallbladder, a pear-shaped, hollow, saclike organ that is 7.5 to 10 cm (3 to 4 inches) long, lies in a shallow depression on the inferior surface of the liver, to which it is attached by loose connective tissue. The capacity of the gallbladder is 30 to 50 mL of bile. Its wall is composed largely of smooth muscle. The gallbladder is connected to the common bile duct (CBD) by the cystic duct (see Fig. 44-1).

The gallbladder functions as a storage depot for bile. Between meals, when the sphincter of Oddi is closed, bile produced by the hepatocytes enters the gallbladder. During storage, a large portion of the water in bile is absorbed through the walls of the gallbladder; thus, bile in the gallbladder is five to 10 times more concentrated than that originally secreted by the liver. When food enters the duodenum, the gallbladder contracts and the sphincter of Oddi (located at the junction of the CBD with the duodenum) relaxes. Relaxation of this sphincter allows the bile to enter the intestine. This response is mediated by secretion of the hormone **cholecystokinin (CCK)** from the intestinal wall (Norris, 2019). CCK is the major stimulus for digestive enzyme secretion and acts by stimulating the gallbladder to contract.

Bile is composed of water and electrolytes (sodium, potassium, calcium, chloride, and bicarbonate) along with significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. The bile salts, together with cholesterol, assist in emulsification of fats in the distal ileum. They are then reabsorbed into the portal blood for return to the liver, after which they are once again excreted into the bile. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the *enterohepatic circulation.* Because of this circulation, only a small fraction of the bile salts that enter the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells.

Approximately half of the bilirubin (a pigment derived from the breakdown of red blood cells) is a component of bile. It is converted by the intestinal flora into urobilinogen, which is a highly soluble substance. Urobilinogen is either excreted in the feces or returned to the portal circulation, where it is re-excreted into the bile. About 5% is normally absorbed into the general circulation and then excreted by the kidneys (Goldman & Schafer, 2019; Norris, 2019).

If the flow of bile is impeded (e.g., by gallstones in the bile ducts), bilirubin does not enter the intestine. As a result, blood levels of bilirubin increase. This causes increased renal excretion of urobilinogen, which results from conversion of bilirubin in the small intestine, and decreased excretion in the stool. These changes produce many of the signs and symptoms seen in gallbladder disorders.

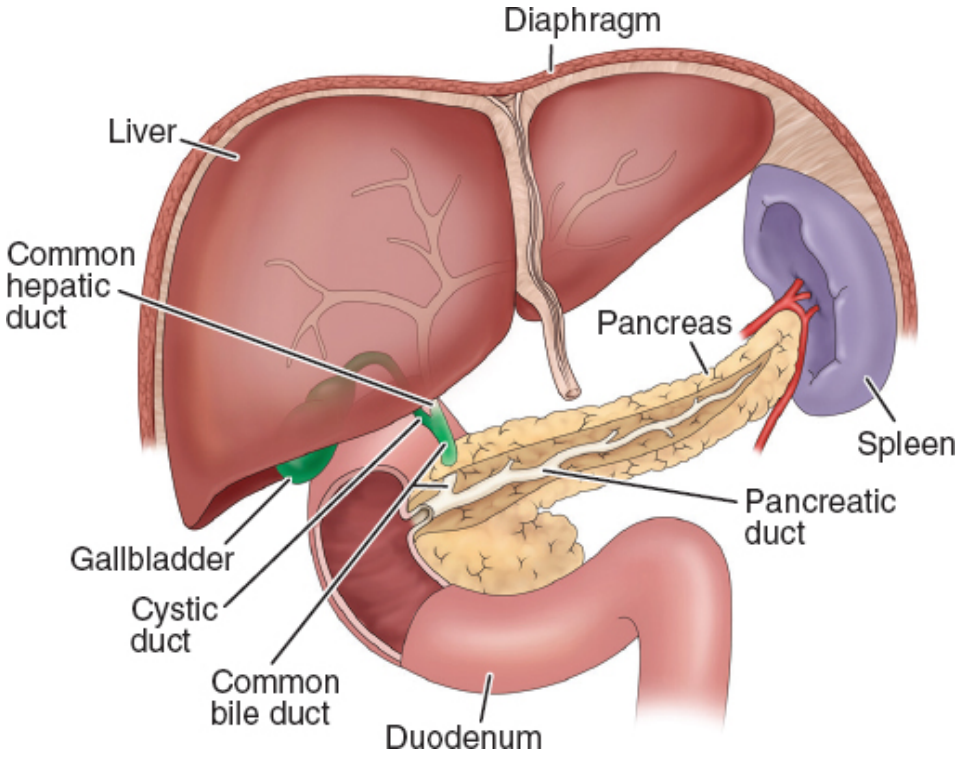

Figure 44-1 • The liver, biliary system, and pancreas.

The Pancreas

The pancreas is located in the upper abdomen (see Fig. 44-1). It has both **exocrine** (secreting externally; hormonal secretion from excretory ducts) and **endocrine** (secreting internally; hormonal secretion of a ductless gland) functions. The exocrine functions include secretion of pancreatic enzymes into the gastrointestinal (GI) tract through the pancreatic duct. The endocrine functions include secretion of insulin, glucagon, and somatostatin directly into the bloodstream.

The Exocrine Pancreas

The secretions of the exocrine portion of the pancreas are collected in the pancreatic duct, which joins the CBD and enters the duodenum at the ampulla of Vater. Surrounding the ampulla is the sphincter of Oddi, which partially

controls the rate at which secretions from the pancreas and the gallbladder enter the duodenum.

The secretions of the exocrine pancreas are digestive enzymes high in protein content and an electrolyte-rich fluid. The secretions, which are very alkaline because of their high concentration of sodium bicarbonate, are capable of neutralizing the highly acidic gastric juice that enters the duodenum. Pancreatic enzymes include **amylase**, which aids in the digestion of carbohydrates; **trypsin**, which aids in the digestion of proteins; and **lipase**, which aids in the digestion of fats. Other enzymes that promote the breakdown of more complex foodstuffs are also secreted.

Hormones originating in the GI tract stimulate the secretion of these exocrine pancreatic juices. The hormone **secretin** is the major stimulus for increased bicarbonate secretion from the pancreas, and the major stimulus for digestive enzyme secretion is the hormone CCK. The vagus nerve also influences exocrine pancreatic secretion.

The Endocrine Pancreas

The islets of Langerhans, the endocrine part of the pancreas, are collections of cells embedded in the pancreatic tissue. They are composed of alpha, beta, and delta cells. The hormone produced by the beta cells is called *insulin,* the alpha cells secrete glucagon, and the delta cells secrete somatostatin.

Insulin

A major action of insulin is to lower blood glucose by permitting entry of glucose into the cells of the liver, muscle, and other tissues, where it is either stored as glycogen or used for energy. Insulin also promotes the storage of fat in adipose tissue and the synthesis of proteins in various body tissues. In the absence of insulin, glucose cannot enter the cells and is excreted in the urine. This condition, called *diabetes,* can be diagnosed by high levels of glucose in the blood. In diabetes, stored fats and protein are used for energy instead of glucose, causing loss of body mass. Diabetes is discussed in detail in Chapter 46. The level of glucose in the blood normally regulates the rate of insulin secretion from the pancreas (Goldman & Schafer, 2019; Norris, 2019).

Glucagon

The effect of glucagon (opposite to that of insulin) is chiefly to raise the blood glucose by converting glycogen to glucose in the liver. Glucagon is secreted by the pancreas in response to a decrease in the level of blood glucose.

Somatostatin

Somatostatin exerts a hypoglycemic effect by interfering with release of growth hormone from the pituitary and glucagon from the pancreas, both of which tend to raise blood glucose levels.

Endocrine Control of Carbohydrate Metabolism

Glucose required for energy is derived by metabolism of ingested carbohydrates and also from proteins by the process of gluconeogenesis. Glucose can be stored temporarily in the form of glycogen in the liver, muscles, and other tissues. The endocrine system controls the level of blood glucose by regulating the rate at which glucose is synthesized, stored, and moved to and from the bloodstream. Through the action of hormones, blood glucose is normally maintained at less than 100 mg/dL (5.6 mmol/L) (Norris, 2019; Papadakis & McPhee, 2020). Insulin is the primary hormone that lowers the blood glucose level. Hormones that raise the blood glucose level are glucagon, epinephrine, adrenocorticosteroids, growth hormone, and thyroid hormone.

The endocrine and exocrine functions of the pancreas are interrelated. The major exocrine function is to facilitate digestion through secretion of enzymes into the proximal duodenum. Secretin and CCK are hormones from the GI tract that aid in the digestion of food substances by controlling the secretions of the pancreas. Neural factors also influence pancreatic enzyme secretion. Considerable dysfunction of the pancreas must occur before enzyme secretion decreases and protein and fat digestion becomes impaired. Pancreatic enzyme secretion is normally 1500 to 3000 mL/day (Norris, 2019; Papadakis & McPhee, 2020).

Gerontologic Considerations

There is little change in the size of the pancreas with age. However, there is an increase in fibrous material and some fatty deposition in the normal pancreas in people older than 70 years. Some localized arteriosclerotic changes occur with age. There is also a decreased rate of pancreatic enzyme secretion (i.e., amylase, lipase, and trypsin) and decreased bicarbonate output in older adults. Some impairment of normal fat absorption occurs with increasing age, possibly because of delayed gastric emptying and pancreatic insufficiency (Eliopoulos, 2018; Norris, 2019; Papadakis & McPhee, 2020). Decreased calcium absorption may also occur. These changes require care in interpreting diagnostic test results in the normal older patient and in providing dietary counseling.

DISORDERS OF THE GALLBLADDER

Several disorders affect the biliary system and interfere with normal drainage of bile into the duodenum. These disorders include inflammation of the biliary system and carcinoma that obstructs the biliary tree. Gallbladder disease with stones is the most common disorder of the biliary system. Not all occurrences of cholecystitis are related to stones (calculi) in the gallbladder (**cholelithiasis**) or stones in the CBD (**choledocholithiasis**). However, most of the 15 million Americans with gallstones have no pain and are unaware of the presence of stones (Cameron & Cameron, 2020; Kellerman & Rakel, 2018).

Cholecystitis

Cholecystitis (inflammation of the gallbladder which can be acute or chronic) causes pain, tenderness, and rigidity of the upper right abdomen that may radiate to the midsternal area or right shoulder and is associated with nausea, vomiting, and the usual signs of an acute inflammation. An empyema of the gallbladder develops if the gallbladder becomes filled with purulent fluid (pus).

Calculous cholecystitis is the cause of more than 90% of cases of acute cholecystitis (Brunicardi, 2019; Cameron & Cameron, 2020). In calculous cholecystitis, a gallbladder stone obstructs bile outflow. Bile remaining in the gallbladder initiates a chemical reaction; autolysis and edema occur; and the blood vessels in the gallbladder are compressed, compromising its vascular supply. Gangrene of the gallbladder with perforation may result. Bacteria play a minor role in acute cholecystitis; however, secondary infection of bile occurs in approximately 50% of cases. The organisms involved are generally enteric (normally live in the GI tract) and include *Escherichia coli, Klebsiella* species, and *Streptococcus*. Bacterial contamination is not believed to stimulate the actual onset of acute cholecystitis (Feldman, Friedman, & Brandt, 2016; Goldman & Schafer, 2019).

Acalculous cholecystitis describes acute gallbladder inflammation in the absence of obstruction by gallstones. Acalculous cholecystitis occurs after major surgical procedures, orthopedic procedures, severe trauma, or burns. Other factors associated with this type of cholecystitis include torsion, cystic duct obstruction, primary bacterial infections of the gallbladder, and multiple blood transfusions. It is speculated that acalculous cholecystitis is caused by alterations in fluids and electrolytes and alterations in regional blood flow in the visceral circulation. Bile stasis (lack of gallbladder contraction) and increased viscosity of the bile are also thought to play a role. The occurrence of acalculous cholecystitis with major surgical procedures or trauma makes its diagnosis difficult (Brunicardi, 2019; Cameron & Cameron, 2020; Hammer & McPhee, 2019).

Cholelithiasis

Calculi, or gallstones, usually form in the gallbladder from the solid constituents of bile; they vary greatly in size, shape, and composition (see Fig. 44-2). They are uncommon in children and young adults but become more prevalent with increasing age. It is estimated that the prevalence of gallstones ranges from 5% to 20% in women between the ages of 20 and 55 years and from 25% to 30% in women older than 50 years. Cholelithiasis affects approximately 50% of women by the age of 70 years (Littlefield & Lenahan, 2019).

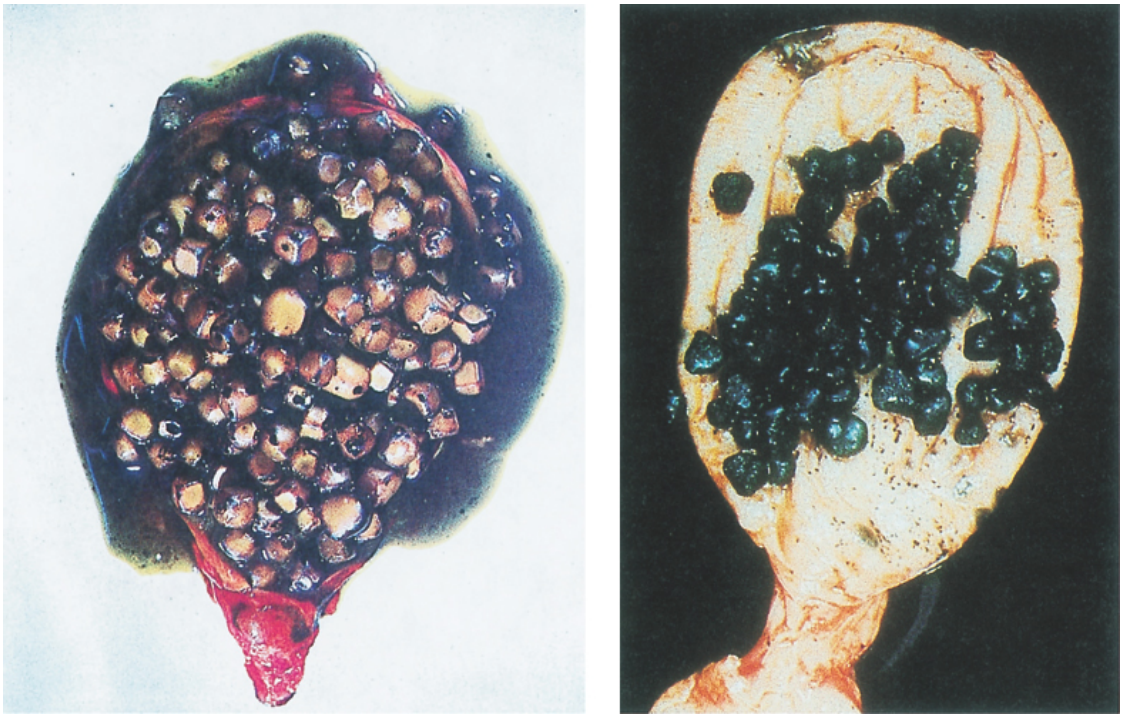

Figure 44-2 • Examples of cholesterol gallstones (**left**) made up of a coalescence of multiple small stones and pigment gallstones (**right**) composed of calcium bilirubinate. Reprinted with permission from Strayer, D. S., & Rubin, E. (2015). *Rubin's pathology: Clinicopathologic foundations of medicine* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Pathophysiology

The pathophysiology of gallstone development is multifactorial. There are two major types of gallstones: those composed predominantly of pigment and those composed primarily of cholesterol. Pigment stones probably form when unconjugated pigments in the bile precipitate to form stones; these stones account for about 10% to 25% of cases in the United States (Hammer & McPhee, 2019). The risk of developing such stones is increased in patients

with cirrhosis, hemolysis, and infections of the biliary tract. Pigment stones cannot be dissolved and must be removed surgically.

Cholesterol stones account for most of the remaining 75% of cases of gallbladder disease in the United States. Cholesterol, which is a normal constituent of bile, is insoluble in water. Its solubility depends on bile acids and lecithin (phospholipids) in bile (Hammer & McPhee, 2019). In gallstone-prone patients, there is decreased bile acid synthesis and increased cholesterol synthesis in the liver, resulting in bile supersaturated with cholesterol, which precipitates out of the bile to form stones (Hammer & McPhee, 2019). The cholesterol-saturated bile predisposes to the formation of gallstones and acts as an irritant that produces inflammatory changes in the mucosa of the gallbladder (Hammer & McPhee, 2019).

Two to three times more women than men develop cholesterol stones and gallbladder disease; affected women are usually older than 40 years, multiparous, and have obesity (Feldman et al., 2016; Goldman & Schafer, 2019; Hammer & McPhee, 2019). Stone formation is more frequent in people who use oral contraceptives, estrogens, or clofibrate; these medications are known to increase biliary cholesterol saturation (Hammer & McPhee, 2019). The incidence of stone formation increases with age as a result of increased hepatic secretion of cholesterol and decreased bile acid synthesis (Hammer & McPhee, 2019). In addition, there is an increased risk because of malabsorption of bile salts in patients with GI disease or T-tube fistula and in those who have undergone ileal resection or bypass. The incidence is also greater in people with diabetes (see Chart 44-1). The role of diet in the causation of cholesterol stones has not been confirmed but is under study. Those at high risk may be encouraged to maintain an optimal body weight and consider reducing modifiable risk factors by avoiding consumption of sugar and sweet foods, low-fiber foods, and fast foods (Di Ciaula, Garruti, Frühbeck, et al., 2019).

Chart 44-1 RISK FACTORS

Cholelithiasis

- Cystic fibrosis
- Diabetes
- Frequent changes in weight
- Ileal resection or disease
- Low-dose estrogen therapy—carries a small increase in the risk of gallstones
- Obesity
- Rapid weight loss (leads to rapid development of gallstones and high risk of symptomatic disease)
- Treatment with high-dose estrogen
- Women, especially those who have had multiple pregnancies or who are of Native American or U.S. southwestern Hispanic ethnicity

Clinical Manifestations

Gallstones may be silent, producing no pain and only mild GI symptoms. Such stones may be detected incidentally during surgery or evaluation for unrelated problems (Hammer & McPhee, 2019; Srinivasan & Friedman, 2018).

The patient with gallbladder disease resulting from gallstones may develop two types of symptoms: those due to disease of the gallbladder itself and those due to obstruction of the bile passages by a gallstone. The symptoms may be acute or chronic. Epigastric distress, such as fullness, abdominal distention, and vague pain in the right upper quadrant of the abdomen, may occur. This distress may follow a meal rich in fried or fatty foods (Brunicardi, 2019; Cameron & Cameron, 2020; Hammer & McPhee, 2019).

Pain and Biliary Colic

If a gallstone obstructs the cystic duct, the gallbladder becomes distended, inflamed, and eventually infected (acute cholecystitis). The patient develops a fever and may have a palpable abdominal mass. The patient may have biliary colic with excruciating upper right abdominal pain that radiates to the back or right shoulder. Biliary colic is usually associated with nausea and vomiting, and it is noticeable several hours after a heavy meal. The patient moves about restlessly, unable to find a comfortable position. In some patients, the pain is constant rather than colicky (Brunicardi, 2019; Cameron & Cameron, 2020).

Such a bout of biliary colic is caused by contraction of the gallbladder, which cannot release bile because of obstruction by the stone. When distended, the fundus of the gallbladder comes in contact with the abdominal wall in the

region of the right ninth and 10th costal cartilages. This produces marked tenderness in the right upper quadrant on deep inspiration and prevents full inspiratory excursion.

The pain of acute cholecystitis may be so severe that analgesic medications are required. The use of morphine has traditionally been avoided because of concern that it could cause spasm of the sphincter of Oddi. This is controversial, because morphine is the preferred analgesic agent for management of acute pain. Furthermore, all opioids stimulate the sphincter of Oddi to some degree (Littlefield & Lenahan, 2019; Papadakis & McPhee, 2020).

If the gallstone is dislodged and no longer obstructs the cystic duct, the gallbladder drains and the inflammatory process subsides after a relatively short time. If the gallstone continues to obstruct the duct, abscess, necrosis, and perforation with generalized peritonitis may result.

Jaundice

Jaundice occurs in a few patients with gallbladder disease, usually with obstruction of the common bile duct. The bile, which is no longer carried to the duodenum, is absorbed by the blood and gives the skin and mucous membranes a yellow color. This is frequently accompanied by marked pruritus (itching) of the skin.

Changes in Urine and Stool Color

The excretion of the bile pigments by the kidneys gives the urine a very dark color. The feces, no longer colored with bile pigments, are grayish (like putty) or clay colored.

Vitamin Deficiency

Obstruction of bile flow interferes with absorption of the fat-soluble vitamins A, D, E, and K. Patients may exhibit deficiencies of these vitamins if biliary obstruction has been prolonged. For example, a patient may have bleeding caused by vitamin K deficiency (vitamin K is necessary for normal blood clotting).

Assessment and Diagnostic Findings

A wide range of diagnostic studies may be performed in patients with biliary disorders. Table 44-1 identifies various procedures and their diagnostic uses. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should note trends in results because they provide information about disease progression as well as the patient's response to therapy.

TABLE 44-1 Studies Used in the Diagnosis of Biliary Tract and Pancreatic Disease

Studies	Diagnostic Uses
Magnetic resonance cholangiopancreatography (MRCP)	Visualizes the biliary tree and capable of detecting biliary tract obstruction
Cholecystogram, cholangiogram	Visualize gallbladder and bile duct
Celiac axis arteriography	Visualizes liver and pancreas
Laparoscopy	Visualizes anterior surface of liver, gallbladder, and mesentery through a trocar
Ultrasonography	Shows size of abdominal organs and presence of masses
Helical computed tomography and magnetic resonance imaging	Detect neoplasms; diagnose cysts, pseudocysts, abscess, and hematomas; determine severity of pancreatitis based on the presence of necrosis or peripancreatic fluid collections
Endoscopic retrograde cholangiopancreatography	Visualizes biliary structures and pancreas via endoscopy
Endoscopic ultrasound (EUS)	Identifies small tumors and other abnormalities and facilitate fine-needle aspiration biopsy of tumors or lymph nodes for diagnosis
Serum alkaline phosphatase	In the absence of bone disease, to measure biliary tract obstruction
Gamma-glutamyl, gamma-glutamyl transpeptidase, lactate dehydrogenase	Markers for biliary stasis; also elevated in alcohol abuse
Cholesterol levels	Elevated in biliary obstruction; decreased in parenchymal liver disease

Adapted from Fischbach, F. T., & Fischbach, M. A. (2018). *Fischbach's manual of laboratory and diagnostic tests* (10th ed.). Philadelphia, PA: Wolters Kluwer.

Abdominal X-Ray

If the patient presents with symptoms of gallbladder disease, an abdominal x-ray may be obtained to exclude other causes of symptoms. However, only 10% to 15% of gallstones are calcified sufficiently to be visible on such x-ray studies (Brunicardi, 2019; Goldman & Shafer, 2019).

Ultrasonography

Ultrasonography is the diagnostic procedure of choice because it is rapid and accurate and can be used in patients with liver dysfunction and jaundice. It does not expose patients to ionizing radiation. The procedure is most accurate if the patient fasts overnight so that the gallbladder is distended.

Ultrasonography can detect calculi in the gallbladder or a dilated CBD with 90% accuracy (Brunicardi, 2019; Goldman & Shafer, 2019; Littlefield & Lenahan, 2019; Mou, Tesfasilassie, Hirji, et al., 2019).

Radionuclide Imaging or Cholescintigraphy

Cholescintigraphy is used successfully in the diagnosis of acute cholecystitis or blockage of a bile duct (Brunicardi, 2019; Goldman & Schafer, 2019; Littlefield & Lenahan, 2019; Mou et al., 2019). During this procedure, a radioactive agent is administered intravenously (IV), which is taken up by the hepatocytes and excreted rapidly through the biliary tract. The biliary tract is then scanned, and images of the gallbladder and biliary tract are obtained. This test is more expensive than ultrasonography, takes longer to perform, and exposes the patient to radiation. It is often used when ultrasonography is not conclusive, such as in acalculous cholecystitis (Brunicardi, 2019; Goldman & Schafer, 2019; Littlefield & Lenahan, 2019; Mou et al., 2019).

Oral Cholecystography

Oral cholecystography is used if ultrasound equipment is not available or if the ultrasound results are inconclusive. This study may be performed to detect gallstones and to assess the ability of the gallbladder to fill, concentrate its contents, contract, and empty. If the patient is not allergic to iodine or seafood, an iodide-containing contrast agent that is excreted by the liver and concentrated in the gallbladder is given 10 to 12 hours before the x-ray study (Brunicardi, 2019; Goldman & Schafer, 2019; Littlefield & Lenahan, 2019; Mou et al., 2019). The normal gallbladder fills with this radiopaque substance. If gallstones are present, they appear as shadows on the x-ray image.

Oral cholecystography may be used as part of the evaluation of patients who have been treated with gallstone **dissolution therapy** (the use of medications to break up/dissolve gallstones) or **lithotripsy** (disintegration of gallstones by shock waves).

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) permits direct visualization of structures that previously could be seen only during laparotomy. This procedure examines the hepatobiliary system via a side-viewing flexible fiberoptic endoscope inserted through the esophagus to the descending duodenum (see Fig. 44-3). Multiple position changes are required to pass the endoscope during the procedure, beginning in the left semiprone position.

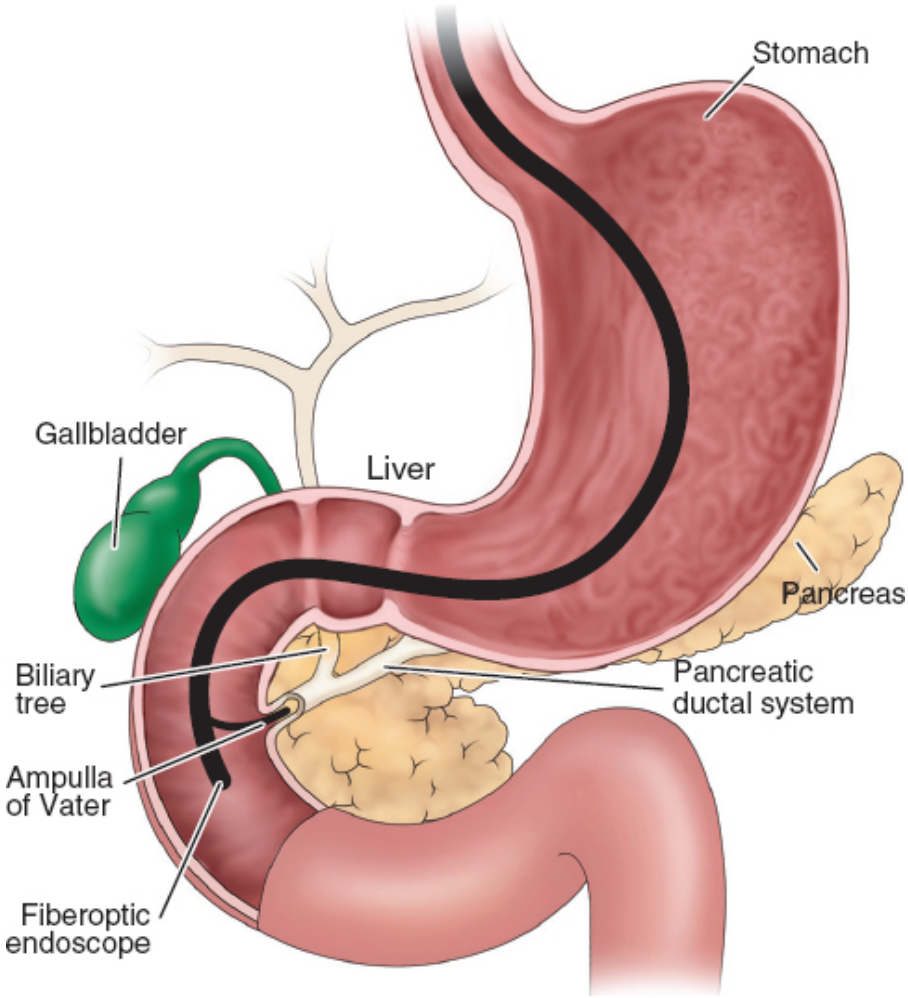

Figure 44-3 • Endoscopic retrograde cholangiopancreatography. A fiberoptic duodenoscope, with side-viewing apparatus, is inserted into the duodenum. The ampulla of Vater is catheterized, and the biliary tree is injected with contrast agent. The pancreatic ductal system is also assessed, if indicated. This procedure is of special value in visualizing neoplasms of the ampulla area and extracting a biopsy specimen.

Fluoroscopy and multiple x-rays are used during ERCP to evaluate the presence and location of ductal stones. Careful insertion of a catheter through the endoscope into the CBD is the most important step in sphincterotomy (division of the muscles of the biliary sphincter) for gallstone extraction via this technique (see later discussion). ERCP is not recommended for the evaluation of suspected CBD stones but can be used to treat confirmed choledocholithiasis before or during laparoscopic cholecystectomy (Brunicardi, 2019; Cameron & Cameron, 2020).

Nursing Implications

Before ERCP, the patient is educated about the procedure and their role in it. This preparation can allay anxiety and facilitate the insertion of the endoscope without damage to the GI tract structures, including the biliary tree. The patient takes nothing by mouth for several hours before the procedure. The procedure requires intravenous (IV) sedation and monitored anesthesia care. In some cases general anesthesia is required, and the sedated patient is monitored closely during and after the procedure (Brunicardi, 2019). It may be necessary to administer medications, such as glucagon or anticholinergic agents, to make cannulation easier by decreasing duodenal peristalsis. The nurse observes closely for signs of respiratory and CNS depression, hypotension, oversedation, and vomiting (if glucagon is given). During ERCP, the nurse monitors IV fluids, administers medications, and positions the patient. After the procedure, the nurse monitors the patient's condition, observing vital signs and assessing for signs of perforation or infection. The nurse also monitors the patient for side effects of any medications received during the procedure.

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (PTC) is rarely used for diagnostic purposes alone due to the multitude of other less invasive and reliable imaging studies. PTC is reserved for those patients in whom an ERCP may be unsafe due to previous surgery involving the biliary tract (Brunicardi, 2019; Cameron & Cameron, 2020; Feldman et al., 2016). The use of PTC has mainly been replaced by ERCP and magnetic resonance cholangiopancreatography (MRCP). PTC involves the injection of dye directly into the biliary tract. Because of the relatively large concentration of dye that is introduced into the biliary system, including the hepatic ducts within the liver, the entire length of the common bile duct, the cystic duct, and the gallbladder is outlined clearly.

This procedure can be carried out in the presence of liver dysfunction and jaundice. It is useful for distinguishing jaundice caused by liver disease (hepatocellular jaundice) from that caused by biliary obstruction, investigating the GI symptoms of a patient whose gallbladder has been removed, locating stones within the bile ducts, and diagnosing cancer involving the biliary system (Brunicardi, 2019; Cameron & Cameron, 2020; Feldman et al., 2016).

This sterile procedure is performed under moderate sedation on a patient who has been fasting; the patient also receives local anesthesia. Coagulation parameters and platelet count should be normal to minimize the risk of bleeding. Broad-spectrum antibiotics are given during the procedure because of the high prevalence of bacterial colonization from obstructed biliary systems (Feldman et al., 2016; Brunicardi, 2019; Cameron & Cameron, 2020). After infiltration with a local anesthetic agent has occurred, a flexible needle is inserted into the liver from the right side in the midclavicular line immediately beneath the right costal margin. Successful entry of a duct is noted when bile is aspirated or on injection of a contrast agent. Ultrasound can be used to guide

puncture of the duct. Bile is aspirated, and samples are sent for bacteriology and cytology (Brunicardi, 2019; Feldman et al., 2016; Kellerman & Rakel, 2018). A water-soluble contrast agent is injected to fill the biliary system. The fluoroscopy table is tilted and the patient is repositioned to allow x-rays to be taken in multiple projections. Delayed x-ray views can identify abnormalities of more distant ducts and determine the length of a stricture or multiple strictures. Before the needle is removed, as much dye and bile as possible are aspirated to forestall subsequent leakage into the needle tract and eventually into the peritoneal cavity, thus minimizing the risk of bile peritonitis.

Nursing Implications

Although the complication rate after this procedure is low, the nurse must closely observe the patient for symptoms of bleeding, peritonitis, and sepsis. The nurse assesses the patient for pain and indications of these complications and reports them promptly to the primary provider, takes measures to reassure the patient, and ensures patient comfort. Antibiotic agents are often prescribed to minimize the risk of sepsis and septic shock.

Medical Management

The major objectives of medical therapy are to reduce the incidence of acute episodes of gallbladder pain and cholecystitis by supportive and dietary management and, if possible, to remove the cause of cholecystitis by pharmacologic therapy, endoscopic procedures, or surgical intervention. Although nonsurgical procedures eliminate risks associated with surgery, these approaches are associated with persistent symptoms or recurrent stone formation. Most of the nonsurgical approaches, including lithotripsy and dissolution of gallstones, provide only temporary solutions to gallstone problems and are infrequently used in the United States. In some instances, other treatment approaches may be indicated; these are described later.

Cholecystectomy (removal of the gallbladder) through traditional surgical approaches has largely been replaced by laparoscopic cholecystectomy (removal of the gallbladder through a small incision through the umbilicus) (see later discussion). As a result, surgical risks have decreased, along with the length of hospital stay and the long recovery period required after standard surgical cholecystectomy. In relatively rare instances, a standard surgical procedure may be necessary.

Nutritional and Supportive Therapy

Approximately 80% of the patients with acute gallbladder inflammation achieve remission with rest, IV fluids, nasogastric suction, analgesia, and antibiotic agents. Unless the patient's condition deteriorates, surgical intervention is delayed just until the acute symptoms subside (usually within a

few days). At this time, the patient undergoes a laparoscopic cholecystectomy (Brunicardi, 2019; Cameron & Cameron, 2020; Goldman & Schafer, 2019).

The diet immediately after an episode is usually low-fat liquids. These can include powdered supplements high in protein and carbohydrate stirred into skim milk. Cooked fruits, rice or tapioca, lean meats, mashed potatoes, non–gas-forming vegetables, bread, coffee, or tea may be added as tolerated. The patient should avoid eggs, cream, pork, fried foods, cheese, rich dressings, gas-forming vegetables, and alcohol. It is important to remind the patient that fatty foods may induce an episode of cholecystitis. Dietary management may be the major mode of therapy in patients who have had only dietary intolerance to fatty foods and vague GI symptoms (Kellerman & Rakel, 2018).

Pharmacologic Therapy

Ursodeoxycholic acid (UDCA) and chenodeoxycholic acid (chenodiol or CDCA) have been used to dissolve small, radiolucent gallstones composed primarily of cholesterol (Goldman & Shafer, 2019). UDCA has fewer side effects than chenodiol and can be given in smaller doses to achieve the same effect. It acts by inhibiting the synthesis and secretion of cholesterol, thereby desaturating bile. Treatment with UDCA can reduce the size of existing stones, dissolve small stones, and prevent new stones from forming. Six to 12 months of therapy is required in many patients to dissolve stones, and monitoring of the patient for recurrence of symptoms or the occurrence of side effects (e.g., GI symptoms, pruritus, headache) is required during this time. The effective dose of medication depends on body weight. This method of treatment is generally indicated for patients who refuse surgery or for whom surgery is contraindicated. The success rate of this therapy is low as the recurrence following it is high (Goldman & Shafer, 2019).

Patients with frequent symptoms, cystic duct occlusion, or pigment stones are not candidates for pharmacologic therapy. Laparoscopic or open cholecystectomy is more appropriate for symptomatic patients with acceptable operative risk (Goldman & Shafer, 2019).

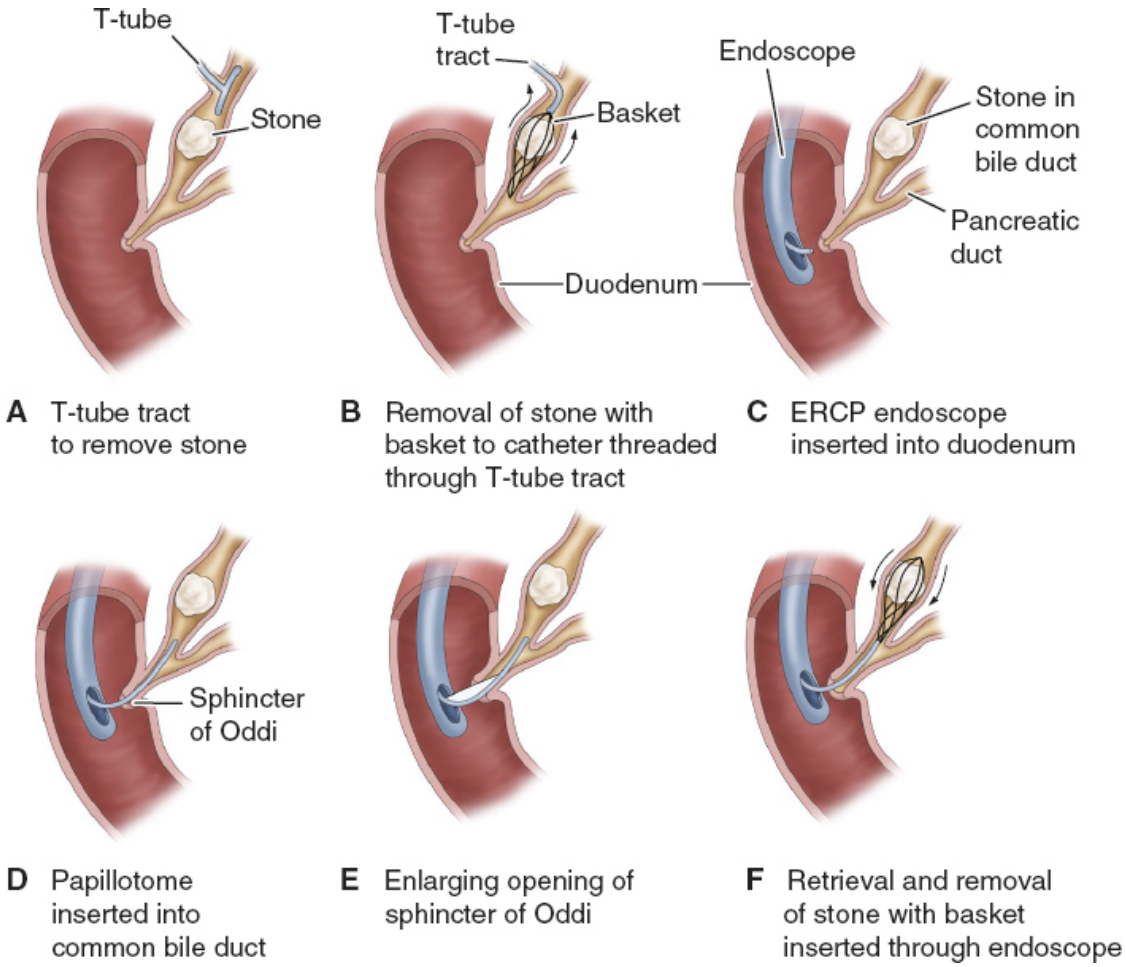

Figure 44-4 • A–F. Procedures for removing gallstones.

Nonsurgical Removal of Gallstones

Dissolving Gallstones

Several methods have been used to dissolve gallstones by infusion of a solvent (mono-octanoin or methyl tertiary butyl ether [MTBE]) into the gallbladder. The solvent can be infused through the following routes: through a tube or catheter inserted percutaneously directly into the gallbladder; through a tube or drain inserted through a T-tube tract to dissolve stones not removed at the time of surgery, endoscopically with ERCP; or via a transnasal biliary catheter, a rarely used procedure due to its lack of success, potential side effects, and recurrence rates of up to 50% (Goldman & Shafer, 2019; Townsend, Beauchamp, Evers, et al., 2016).

Laparoscopic cholecystectomy is the standard for management. Dissolution therapies are used for those patients who may not be candidates for the procedure due to safety concerns regarding general anesthesia (Goldman & Shafer, 2019; Townsend et al., 2016).

Stone Removal by Instrumentation

Several methods are used to remove stones that were not removed at the time of cholecystectomy or have become lodged in the CBD (see Fig. 44-4A,B). A catheter and instrument with a basket attached are threaded through the T-tube tract or fistula formed at the time of T-tube insertion; the basket is used to retrieve and remove the stones lodged in the common bile duct.

A second procedure involves the use of the ERCP endoscope (see Fig. 44-4C). After the endoscope is inserted, a cutting instrument is passed through the endoscope into the ampulla of Vater of the common bile duct. It may be used to cut the submucosal fibers, or papilla, of the sphincter of Oddi, enlarging the opening, which may allow the lodged stones to pass spontaneously into the duodenum. Another instrument with a small basket or balloon at its tip may be inserted through the endoscope to retrieve the stones (see Fig. 44-4D–F). The patient is observed closely for bleeding, perforation, and the development of pancreatitis (see later discussion) or sepsis.

The ERCP procedure is particularly useful in diagnosis and treatment of patients who have symptoms after biliary tract surgery, patients with intact gallbladders, and patients for whom surgery is particularly hazardous.

Intracorporeal Lithotripsy

Stones in the gallbladder or CBD may be fragmented by means of laser pulse technology. A laser pulse is directed under fluoroscopic guidance with the use of devices that can distinguish between stones and tissue. The laser pulse produces rapid expansion and disintegration of plasma on the stone surface, resulting in a mechanical shock wave. Electrohydraulic lithotripsy uses a probe with two electrodes that deliver electric sparks in rapid pulses, creating expansion of the liquid environment surrounding the gallstones. This results in pressure waves that cause stones to fragment. This technique can be used percutaneously with a basket or balloon catheter system or by direct visualization through an endoscope. Repeated procedures may be necessary because of stone size, local anatomy, bleeding, or technical difficulty. A nasobiliary tube can be inserted to allow for biliary decompression and to prevent stone impaction in the common bile duct. This approach allows time for improvement in the patient's clinical condition until gallstones are cleared endoscopically, percutaneously, or surgically.

Extracorporeal Shock Wave Lithotripsy

Extracorporeal shock wave lithotripsy (ESWL) has been used for nonsurgical fragmentation of gallstones. ESWL is a noninvasive procedure that uses repeated shock waves directed at the gallstones in the gallbladder or CBD to fragment the stones. The waves are transmitted to the body through a fluid-filled bag or by immersing the patient in a water bath. After the stones are gradually broken up, the stone fragments can be spontaneously passed from the gallbladder or common bile duct, removed by endoscopy, or dissolved with

oral bile acid or solvents. Because the procedure requires no incision and no hospitalization, patients are usually treated as outpatients, but usually several sessions are necessary. This procedure has largely been replaced by laparoscopic cholecystectomy. ESWL is used in some centers for a small percentage of suitable patients (those with CBD stones who may not be surgical candidates), sometimes in combination with dissolution therapy (Feldman et al., 2016; Kellerman & Rakel, 2018).

Surgical Management

Surgical treatment of gallbladder disease and gallstones is carried out to relieve persistent symptoms, to remove the cause of biliary colic, and to treat acute cholecystitis. Surgery may be delayed until the patient's symptoms have subsided, or it may be performed as an emergency procedure, if necessitated by the patient's condition.

Preoperative Measures

Chest x-ray, electrocardiogram, and liver function tests may be performed in addition to imaging studies of the gallbladder. Vitamin K may be given if the prothrombin level is low. Nutritional requirements are considered, and, if the nutritional status is suboptimal, it may be necessary to provide IV glucose with protein supplements to aid wound healing and help prevent liver damage.

Patient education for gallbladder surgery is similar to that for any upper abdominal laparotomy or laparoscopy. Instructions and explanations are given before surgery about turning and deep breathing. Postoperative pneumonia and atelectasis can be avoided by deep-breathing exercises, frequent turning, and early ambulation. The patient should be informed that drainage tubes and a nasogastric tube and suction might be required during the immediate postoperative period if an open cholecystectomy is performed.

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy (see Fig. 44-5) is the standard of therapy for symptomatic gallstones. Approximately 700,000 patients in the United States require surgery each year for removal of the gallbladder, and 80% to 90% of them are candidates for laparoscopic cholecystectomy (Brunicardi, 2019; Cameron & Cameron, 2020; Feldman et al., 2016; Goldman & Shafer, 2019). If the CBD is thought to be obstructed by a gallstone, an ERCP with sphincterotomy may be performed to explore the duct before laparoscopy (Brunicardi, 2019; Cameron & Cameron, 2020; Goldman & Shafer, 2019; Littlefield & Lenahan, 2019; Mou et al., 2019).

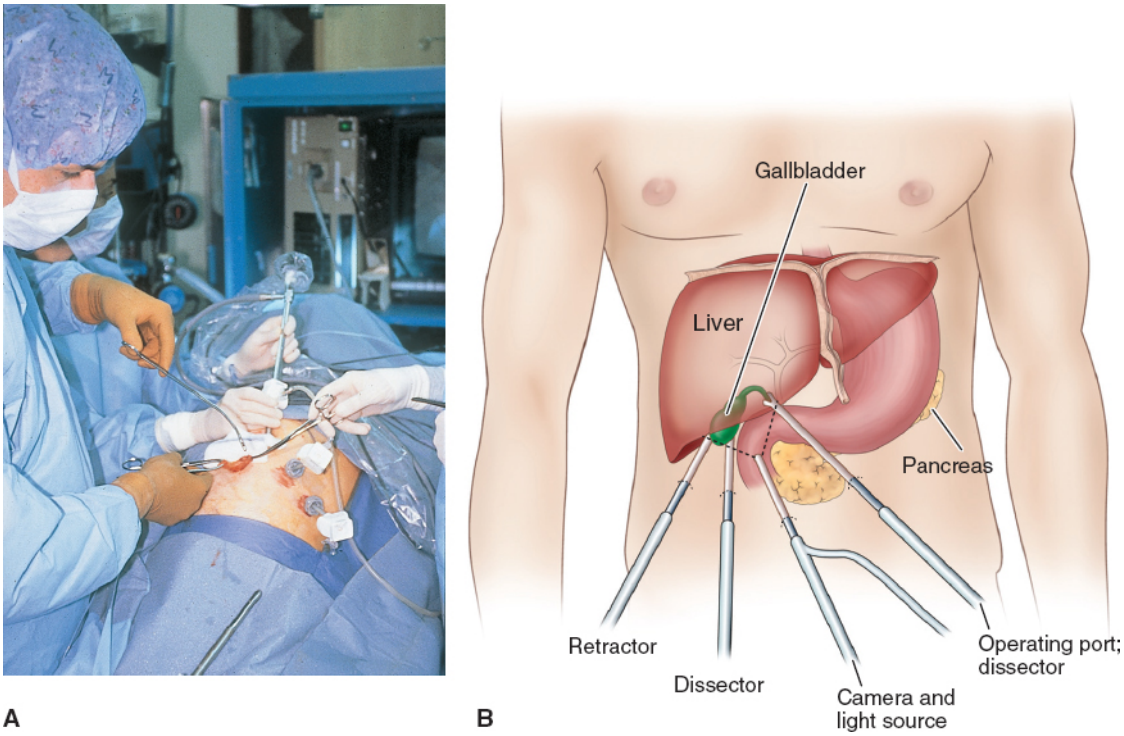

Figure 44-5 • In laparoscopic cholecystectomy (**A**), the surgeon makes four small incisions (less than one half inch each) in the abdomen and inserts a laparoscope with a miniature camera through the umbilical incision (**B**). The camera apparatus displays the gallbladder and adjacent tissues on a screen, allowing the surgeon to visualize the sections of the organ for removal.

Before the procedure, the patient is educated that an open abdominal procedure may be necessary, and general anesthesia is given. Laparoscopic cholecystectomy is performed through a small incision or puncture made through the abdominal wall at the umbilicus. The abdominal cavity is insufflated with carbon dioxide (pneumoperitoneum) to assist in inserting the laparoscope and to aid in visualizing the abdominal structures. The fiberoptic scope is inserted through the small umbilical incision. Several additional punctures or small incisions are made in the abdominal wall to introduce other surgical instruments into the operative field. A camera attached to the laparoscope permits the surgeon to view the intra-abdominal field and biliary system on a television monitor. After the cystic duct is dissected, the CBD can be visualized by ultrasound or cholangiography to evaluate the anatomy and identify stones. The cystic artery is dissected free and clipped. The gallbladder is separated from the hepatic bed and removed from the abdominal cavity after bile and small stones are aspirated. Stone forceps also can be used to remove or crush larger stones.

With the laparoscopic procedure, the patient does not experience the paralytic ileus that occurs with open abdominal surgery and has less postoperative abdominal pain. The patient is often discharged from the hospital

on the same day of surgery or within 1 or 2 days and resumes full activity and employment within 1 week after the procedure.

Conversion to a traditional abdominal surgical procedure occurs in 2.2% of cases in the United States and 3.6% to 8.2% of cases internationally. Conversion to an open procedure occurs if there is inflammation in and around the gallbladder, making safe dissection of the porta hepatis difficult (Brunicardi, 2019; Feldman et al., 2016; Goldman & Shafer, 2019). The porta hepatis is the fissure of the liver where the portal vein and the hepatic artery enter and the hepatic ducts exit the liver.

The most serious complication after laparoscopic cholecystectomy is a bile duct injury, which may be identified and corrected at the time of the procedure. Patients with a postoperative bile leak may not develop symptoms until several days after the procedure, and some have an even more prolonged period before injury to the bile duct becomes apparent (Brunicardi, 2019; Cameron & Cameron, 2020). A bile leak may result in fluid collections, which can usually be managed by endoscopic stent placement. Bile peritonitis, a rare complication, may result in serious illness or death.

Because of the short length of hospital stay with uncomplicated laparoscopic cholecystectomies, it is important to provide patient education about managing postoperative pain and reporting signs and symptoms of intra-abdominal complications, including loss of appetite, vomiting, pain, distention of the abdomen, and temperature elevation. Although recovery from laparoscopic cholecystectomy is rapid, patients are drowsy afterward. The patient must have assistance at home during the first 24 to 48 hours. If pain occurs in the right shoulder or scapular area (from migration of the carbon dioxide used to insufflate the abdominal cavity during the procedure), the nurse may recommend a heating pad for 15 to 20 minutes hourly.

Cholecystectomy

In cholecystectomy, the gallbladder is removed through an abdominal incision (usually right subcostal) after the cystic duct and artery are ligated. The procedure is performed for acute and chronic cholecystitis. In some patients, a drain is placed close to the gallbladder bed and brought out through a puncture wound if there is a bile leak. The drain type is chosen based on the surgeon's preference. A small leak should close spontaneously in a few days, with the drain preventing accumulation of bile. Usually, only a small amount of serosanguineous fluid drains in the initial 24 hours after surgery; afterward, the drain is removed. The drain is typically maintained if there is excess oozing or bile leakage. Insertion of a T-tube (named for its shape) into the CBD during the open procedure is now uncommon; it is used only in the setting of a complication (i.e., retained CBD stone). A T-tube is inserted into the CBD at the time of surgical exploration. It allows external drainage of bile into a collection bag, allowing the surgical site to heal.

Bile duct injury is a serious complication of cholecystectomy, but it occurs less frequently than with the laparoscopic approach, which has largely replaced traditional surgical cholecystectomy.

Small-Incision Cholecystectomy
